Background and aims: BIL, a novel, long-acting basal insulin analog, has previously been shown to demonstrate hepato-preferential action in healthy subjects. This analysis evaluated the effects of therapeutic concentrations of BIL and GL and suprathreshold concentrations of BIL on liver (endogenous glucose production [EGP]) and peripheral tissues (glucose disposal rate [GDR] and lipolysis) in patients with T1DM.

Materials and methods: This was a randomised, open-label, 4-period, crossover study in patients with T1DM (n=14; 22 - 48 years). Each patient had 4 euglycaemic clamp assessments of 8-10 hours duration with primed, continuous infusions of BIL (15.3 and 74.1 mU/min) and GL (10 and 20 mU/m²/min). D-[3-³H]-glucose infusion was administered to assess EGP and GDR. To correct for differences in insulin receptor binding, equivalent human insulin concentrations (EHIC) were calculated by dividing each insulin concentration by its K_i (binding constant) and multiplying by the K_i of human insulin.

Results: At both low and high doses, BIL showed similar effects on EGP suppression (endpoint EGP) compared to GL, but had an attenuated effect on GDR (endpoint GDR) (Table). Lipolysis, assessed by serum concentrations of free fatty acids (FFA) and glycerol, was suppressed at low and high GL doses but only at the high BIL dose (Table).

Conclusion: BIL has similar hepatic activity (EGP suppression) but less peripheral activity (GDR stimulation, lipolysis suppression) at clinically relevant concentrations compared to GL, confirming hepato-preferential action.

Reduced intra-subject variability of Basal Insulin peglispro (BIL) compared to insulin Glargine (GL) in patients with type 1 diabetes mellitus

E. Lam¹, P. Garhyan², H. Linnebjerg², S. Choi¹, M.P. Knadler², V.P. Sinha³, B.M. Sassenfeld⁴, L. Nosek⁴, T. Heise⁴;

¹Lilly-NUS Centre for Clinical Pharmacology Pte Ltd, Singapore, ²Eli Lilly and Company, Indianapolis, USA, ³Food and Drug Administration, Silver Spring, USA, ⁴Profil, Neuss, Germany.

Background and aims: BIL is a novel PEGylated basal insulin that has a flat pharmacokinetic (PK) and glucodynamic (GD) profile which has a hepato-preferential action resulting from reduced peripheral effects. This study compared the variability in the PK and GD of BIL and GL at steady state.

Materials and methods: In this randomised, open-label, parallel study, 75 patients received either 0.5 U/kg BIL or GL subcutaneously once daily after a transition from pre-study basal insulin. On Days 8, 11 and 14, serial blood samples were collected to assess PK and 24-hour automated euglycaemic clamps were performed to assess GD. Intra-subject variability, expressed as CV, was estimated using a linear mixed model on log-

transformed PK and GD parameters and compared using an F-test at 10% significance level.

Results: BIL showed a flatter time-action profile than GL (figure) with a more even distribution of the GD effect over the 1st and 2nd 12 hours of the clamp (total amount of glucose infused [G_{tot}] during the 1st 12 hours/ G_{tot} during the 2nd 12 hours, expressed as percentage of G_{tot} during the whole clamp: 47%/53% for BIL, 61%/39% for GL at Day 8; 55%/45% for BIL, 61%/39% for GL at Day 11; and 57%/43% for BIL, 63%/37% for GL at Day 14). Intra-subject CV was statistically significantly lower by 41% (11% vs 19%), 55% (13% vs 28%) and 35% (41% vs 64%) with BIL vs GL for PK and GD parameters $AUC_{0-24,ss}$, $C_{max,ss}$ and G_{tot} , respectively.

Conclusion: BIL has both a flatter and more predictable time-action profile with less day-to-day intra-subject PK and GD variability compared to GL. This may result in improved glycaemic control and reduced hypoglycaemia.

Clinical Trial Registration Number: NCT01784211

Greater HbA_{1c} reduction with basal insulin peglispro (BIL) vs insulin glargine (GL) in an open-label, randomised study in type 1 diabetic patients: IMAGINE 1

S. Garg¹, H. Jinnouchi², M. Dreyer³, J. Mou⁴, M.L. Hartman⁴, M. Rosilio⁵, E.J. Bastyr III⁴, for the IMAGINE 1 Study Group;

¹Barbara Davis Center for Childhood Diabetes, University of Colorado Denver, Aurora, USA, ²Diabetes Care Center, Jinnouchi Hospital, Kumamoto, Japan, ³Zentrum für Innere Medizin, Hamburg, Germany, ⁴Eli Lilly and Company, Indianapolis, USA, ⁵Lilly France, Neuilly sur Seine, France.

Background and aims: Basal insulin peglispro (BIL) is a novel basal insulin with a flat pharmacokinetic profile which has a hepato-preferential action resulting from reduced peripheral effects.

Materials and methods: We compared BIL with GL in a Phase 3, 78-week study (primary endpoint 26 weeks) in 455 patients (51% female) with T1D (HbA_{1c} <12% [<108 mmol/mol]). Patients were randomised to bedtime BIL (N=295) or GL (N=160) with prandial insulin lispro. An electronic diary was used for data capture and insulin dosing decisions.

Results: At Week 26, HbA_{1c} reduction was greater with BIL compared with GL (baseline: 7.8% [62 mmol/mol]; treatment difference -0.37% [-4.0 mmol/mol]; 95% CI: -0.50%, -0.23% [-5.5, -2.5 mmol/mol]). More patients taking BIL reached HbA_{1c} targets. Glucose variability was reduced in the BIL group, and nocturnal hypoglycaemia rate was 36% lower. Total hypoglycaemia rate was 29% higher with BIL, and severe hypoglycaemia rate was also higher. Basal insulin dose was higher, but bolus and total insulin dosages were lower in the BIL group. Patients on BIL had a significant weight loss. Triglycerides (TG) increased from

baseline with BIL; no treatment differences were seen in LDL-C or HDL-C. In the BIL group, ALT increased from baseline. More patients taking BIL had ALT $\geq 3 \times$ ULN (4.5% vs 0.7%, $p=0.041$) elevations, with no cases of Hy's law. Liver fat content (LFC), assessed by MRI in a subset of T1D patients in 2 studies of BIL vs GL, also increased with BIL. More patients taking BIL had injection site reactions (25% vs 0%, $p<0.001$).

Conclusion: Treatment with BIL compared with GL resulted in lower HbA_{1c}, reduced nocturnal hypoglycaemia, and weight loss, with higher levels of TG, ALT, and LFC, and injection site reactions in patients with T1D.

Sustained glycaemic control and less nocturnal hypoglycaemia with new insulin glargine 300 U/ml versus glargine 100 U/ml over 1 year in Japanese people with type 1 diabetes mellitus (EDITION JP 1)

M. Matsuhisa¹, M. Koyama², X. Cheng³, M. Sumi², T. Hirose⁴, on behalf of the EDITION JP 1 Study Group;

¹Tokushima University, Tokushima, ²Sanofi, Tokyo, Japan, ³Sanofi, Beijing, China, ⁴Toho University School of Medicine, Tokyo, Japan.

Background and aims: In EDITION JP 1, Japanese people with T1DM receiving new insulin glargine 300 U/ml (Gla-300, n=122) showed comparable glycaemic control and less hypoglycaemia over 6 months compared with glargine 100 U/ml (Gla-100, n=121).

Materials and methods: Participants continued to receive Gla-300 or Gla-100 for an additional 6 months.

Results: The 12-month study period was completed by 228 participants; 114 (93.4%) receiving Gla-300 and 114 (94.2%) receiving Gla-100. HbA_{1c} and FPG levels decreased from baseline to month 12 with Gla-300 (mean [SD] change -0.20 [0.80] % and -0.8 [4.8] mmol/l) and Gla-100 (mean [SD] change -0.25 [0.72] % and -0.4 [5.2] mmol/l). At month 12, mean daily Gla-300 dose was 24 U/day (0.36 U/kg/day) and Gla-100 dose was 18 U/day (0.28 U/kg/day), with little change in dose observed between months 6 and 12. Daily mealtime insulin doses were comparable in the Gla-300 (29 U/day [0.45 U/kg/day]) and Gla-100 (29 U/day [0.47 U/kg/day]) groups at the end of the study period. Over 12 months, rates (events per participant-year) and percentage of participants experiencing ≥ 1 nocturnal confirmed (≤ 3.9 mmol/l [≤ 70 mg/dl]) or severe hypoglycaemic event were comparable between groups. At the lower (<3.0 mmol/l [<54 mg/dl]) threshold, a reduction in event rate was observed with Gla-300 compared with Gla-100 during the night (2.39 vs 3.85; rate ratio 0.62; 95% CI: 0.39 to 0.97). Consistently, the percentage of participants experiencing ≥ 1 nocturnal event at this threshold was also reduced with Gla-300 compared with Gla-100 (52.5 vs 66.1; relative risk 0.79; 95% CI: 0.64 to 0.98). Severe hypoglycaemia occurred in 12 and 11 participants receiving Gla-300 and Gla-100, respectively. Similar numbers of adverse events were reported for each treatment group.

Conclusion: Japanese people with T1DM achieved sustained glycaemic control with less nocturnal confirmed (<3.0 mmol/l [<54 mg/dl]) or severe hypoglycaemia over 12 months with Gla-300 vs Gla-100. Gla-300 was well tolerated over the 12-month study period.

Switching basal insulin treatment to insulin degludec in patients with type 1 diabetes having an unsatisfactory HbA_{1c}: a clinical follow-up L. Landstedt-Hallin;

Karolinska Institutet (KI DS), Stockholm, Sweden.

Background and aims: Insulin degludec, a basal insulin, with an ultra-long duration of action became available in Sweden from July 2013. The diabetes team at Danderyd Hospital decided to conduct a simple, prospective, clinical follow-up of patients with type 1 diabetes who switched basal insulin to degludec. Since this evaluation was a part of the quality assurance regarding routine patient care, permission from the ethics committee was not necessary and no written consent was obtained but all patients were informed about the follow-up and agreed to be part of it.

Materials and methods: From August 2013 all consecutive patients with type 1 diabetes, who switched to insulin degludec, were registered in a simple form which included data on (1) most recent HbA_{1c}, (2) type of insulins before switching, (3) insulin doses, (4) self-reported hypoglycaemias - defined as hypoglycaemic symptoms ameliorated by carbohydrate treatment or a self-measured plasma glucose <3.5 mmol/L - during the previous four weeks and (5) the reason/indications for switching. Four major indications were predefined: (i) currently administering basal insulin twice daily; (ii) having unacceptable HbA_{1c} (in relation to the patient's individual goal); (iii) experiencing repeated hypoglycaemic events and/or unstable glucose; and (iv) having an irregular daily schedule making fixed-time administration difficult. For an individual patient one or more of these indications could be present. The switch was decided in conjunction with professional judgment by the healthcare professional. After 4–6 months data on HbA_{1c}, insulin doses and self-reported hypoglycaemias were collected again. Around one year after the change in basal treatment a second HbA_{1c} was retrieved from medical records in order to assess the long-term effect of the switch on glycaemic control as it was recognized that an initial improvement in HbA_{1c} could be due to factors such as patients increasing their self-monitoring of blood glucose when switching to a novel insulin and/or being more conscientious about their diabetes management. In 60% of all patients who switched basal insulin to insulin degludec an unacceptable HbA_{1c} was given as one of the indications for changing treatment. Data from the follow-up in this subgroup are presented here.

Results: At the end of March 2015 we had follow-up data on 239 patients in this poorly controlled subgroup. Median time to follow-up was 21 weeks [IQR 18 to 24] and mean [SD] HbA_{1c} decreased from 78.0 [13.3] to 72.2 [13.7] mmol/mol, $p<0.0001$. In 138 patients a second HbA_{1c} had been retrieved after median 50 weeks [IQR 44 to 54] showing a sustained improvement in HbA_{1c}. This was achieved using lower doses of insulin, median reduction of basal dose was 13% (IQR -22% to -0%) while total dose (basal + prandial) was reduced by 11% (IQR -19% to -1%). The total number of self-reported hypoglycaemic events was unchanged but there was a reduction in nocturnal events, from 1.3 [2.3] at baseline to 0.6 [2.0] at follow-up, $p<0.0001$. No validated measurement of patient satisfaction was used. However, spontaneous comments made by patients suggested that they felt as though blood glucose was much more stable with insulin degludec but also that their prandial insulin seemed to have a better effect.

Conclusion: Due to the improvement in glycaemic control, reduction of insulin dose and less nocturnal hypoglycaemias, we concluded that insulin degludec was clinically useful for our patients with type 1 diabetes.

6

BIOD-531 demonstrates superior prandial glucose control, post-meal dosing flexibility, and less insulin "stacking" compared to marketed prandial/basal insulins

L. Morrow¹, L. Canney², P. Pichotta², A. Krasner², M. Hompesch¹, E. De Souza²;

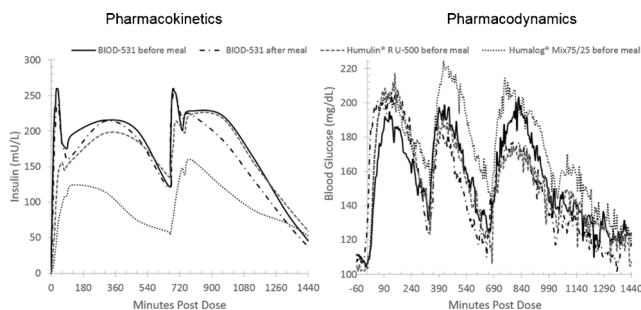

¹Profil Institute for Clinical Research, Chula Vista, ²Biodel, Danbury, USA.

Background and aims: Subcutaneous (SC) injection of BIOD-531, a 400 U/ml formulation of human insulin, EDTA, citrate and magnesium sulfate is associated with ultra-rapid absorption and a basal duration of glucose lowering action. This study was designed to assess the pharmacokinetic (PK) and postprandial glycemia (PD) profiles associated with breakfast and dinner time doses of BIOD-531 vs. marketed comparators in patients with insulin resistant diabetes.

Materials and methods: Twelve patients with type 1 or type 2 diabetes who use insulin at doses of ≥ 150 U/day or ≥ 100 U/injection were randomized into this 4-period crossover trial. Each subject underwent in random order one of the following treatments on separate days: (a) BIOD-531 immediately before meals (pre-meal); (b) Humalog[®] Mix 75/25 (HMix) pre-meal; (c) Humulin[®] R U-500 (U-500) pre-meal; and (d) BIOD-531, 20 min after the start of the meals (post-meal). After baseline glucose normalization, test insulins (1.2 U/kg) were administered by SC injection with a standardized breakfast (921 kcal) followed by a second dose (0.8 U/kg) 11 hours later with a standardized dinner (963 kcal). Subjects also received a standardized lunch (669 kcal) 5.5 hours after breakfast without additional insulin. The primary endpoint was average glucose concentration in the breakfast to lunch interval.

Results: Mean baseline characteristics for the patients evaluated were as follows: insulin dose 205 U/day, 55.4 years old, 117 kg, 25% female. The Figure shows PK and PD profiles. The absorptive phase of BIOD-531 was significantly more rapid than either HMix or U-500 (time to half-maximal insulin concentrations (11.7 ± 1.2 , 42.2 ± 2.6 , and 41.7 ± 9.8 min, respectively, $p<0.001$ for both comparisons). Peak insulin levels after BIOD-531 injections were similar after breakfast and dinner. The post-dinner:post-breakfast peak insulin concentration ratio was significantly higher for HMix (1.21) and U-500 (1.19) compared to BIOD-531 (0.97, $p<0.05$ for both comparisons). Pre-meal BIOD-531 resulted in mean post-breakfast period glucose concentration (mg/dl) of 164.6 ± 11.8 compared to 179.9 ± 10.0 with HMix ($p=0.009$) and 178.0 ± 7.3 with U-500 ($p=0.019$). Over the entire 24 hours of observation, pre- and post-meal BIOD-531 resulted in lower glucose concentrations compared to pre-meal HMix and comparable to pre-meal U-500. The frequency of adverse events was similar between treatments.

Conclusion: Ultra-rapid absorption of BIOD-531 was associated with superior prandial control compared to HMix and U-500 in insulin-resistant diabetes patients. Post-meal dosing of BIOD-531 resulted in superior or comparable overall glycaemic control compared to pre-meal treatment with HMix and U-500. The duration of exposure of BIOD-531 is suitable for twice-daily dosing with evidence for less insulin "stacking" after a second dose.

Diabetes and cause-specific mortality: evidence from 55 000 deaths in 700 000 adults in 44 studies from the Prospective Studies Collaboration

L. Gnatiuc, J. Halsey, J. Emberson, S. Lewington, The Prospective Studies Collaboration;
CTSU, Oxford University, UK.

Background and aims: While the association of diabetes with macrovascular mortality has been well-studied, evidence for the effect of diabetes on mortality from other causes is more equivocal.

Materials and methods: Information from 44 prospective studies was obtained on 54,855 deaths among 690,700 adults with no previous vascular or other chronic disease recorded at baseline. We assessed the associations of DM with cause-specific mortality using Cox proportional-hazards models adjusted for age at risk, gender, smoking, body mass index and cohort.

Results: During 13 million person-years of follow-up there were 21 762 ischaemic, 5 386 non-ischaemic vascular, 18 658 neoplastic and 9 048 other deaths between ages 35–89. Diabetes was associated with about a 2.5-fold increased risk of death from ischaemic heart disease (HR 2.37; 95%CI 2.23–2.52), ischaemic stroke (2.75; 2.29–3.31) and cardiac arrhythmia (2.47; 1.80–3.38), but was more weakly associated with non-ischaemic vascular mortality (1.57; 1.34–1.85). There was about a 2-fold increased risk of renal (1.90; 1.40–2.58) and hepatic (1.75; 1.36–2.26) mortality among people with diabetes, while the increased risk for mortality from any cancer was small (1.13; 1.06–1.21), and was largely driven by cancer of the mouth (1.81; 1.17–2.81), liver (1.80; 1.26–2.58) and pancreas (1.57; 1.21–2.03).

Conclusion: Diabetes was associated with a substantial increased risk of mortality from selected ischaemic and non-ischaemic diseases. Understanding these associations should help reduce the excess mortality among people with diabetes.

8

Causal effects of cardiometabolic traits on cardiovascular and total mortality: a Mendelian randomisation study

G. Rukh, G. Hindy, P. Almgren, C.-A. Schulz, U. Ericson, O. Melander, M. Orho-Melander;
Department of Clinical Sciences in Malmö, Lund University, Malmö, Sweden.

Background and aims: Epidemiological studies have shown associations between cardio-metabolic traits and increased risk of mortality, yet the underlying causal relationships remain unclear. We aimed to understand the causal nature of the associations of common cardio-metabolic traits with cardiovascular (CVD) mortality and/or all-cause total mortality using Mendelian randomization analyses.

Materials and methods: Our study included 28589 participants from the population based Malmö Diet and Cancer study with a mean follow-up period of 15.4 years. We conducted Mendelian randomization analyses by using trait specific weighted genetic risk scores (GRS) for BMI (comprising of 31 SNPs), systolic blood pressure (SBP; 29 SNPs), HDL-cholesterol (HDL-C; 41 SNPs), LDL-cholesterol (LDL-C; 32 SNPs), triglycerides (TG; 26 SNPs) and fasting plasma glucose (FPG; 15 SNPs) as instrumental variables to investigate the causal role of these traits in CVD-mortality (1913 deaths) and total mortality (5708 deaths). We performed a 2-stage regression instrumental variable analysis. First, each

cardio-metabolic trait was regressed on its respective GRS creating instrumental variables and second, the instrumental variables were used as predictor variables for CVD- and total mortality in Cox proportional hazards models. The analyses were adjusted for age and sex. Lipid-lowering and antihypertensive medications were added to the model when lipid traits or SBP were used as outcome or predictor variables, respectively. Finally, we performed multivariable Mendelian randomization analyses using the effect estimates of each SNP first on all cardio-metabolic traits and second, on CVD-mortality and total mortality to adjust for potential pleiotropic effects of the SNPs.

Results: Higher baseline levels of SBP and FPG, and lower levels of HDL-C associated with increased risk of both CVD- and total mortality while higher BMI and TG associated only with increased risk of CVD-mortality. The variances explained by GRSs for BMI, SBP, LDL-C, HDL-C, TG and FPG were 0.8, 0.5, 7.2, 5.7, 4.3 and 2.2%, respectively, in association with their respective traits ($P < 10^{-15}$ for all). The instrumental variable analyses indicated that a one standard deviation (1SD) of genetically elevated BMI (HR: 1.82, 95% CI: 1.09–3.03; $P = 0.02$), LDL-C (1.20, 1.02–1.42; 0.03) and TG (1.28, 1.05–1.57; 0.02) associated with increased risk of CVD-mortality and a 1SD of genetically elevated HDL-C (0.78, 0.65–0.93; 0.006) associated with decreased risk of CVD-mortality. Additionally, a 1SD of genetically elevated TG associated with increased risk of total mortality (1.18, 1.05–1.33, 0.005) and 1SD of genetically elevated HDL-C associated with decreased risk of total mortality (0.89, 0.80–0.99; 0.03). Adjusting for pleiotropic effects in the multivariable Mendelian randomization analyses proposed a direct causal association of TG ($P = 0.02$) and an inverse association of HDL-C ($P = 0.035$) with CVD-mortality.

Conclusion: While randomized clinical trials and Mendelian randomization studies have only provided evidence for causality of higher LDL-C and TG but not of lower HDL-C in coronary disease development, our results suggest a causal role of HDL-C in addition to TG in CVD-mortality. However, whether other cardiometabolic traits causally impact mortality requires further evidence.

Value of genetic risk score in personalised risk prediction of type 2 diabetes: analysis of 10273 individuals of the Estonian Biobank Cohort

K. Fischer¹, K. Läll^{1,2}, R. Mägi¹, A. Metspalu¹;

¹Estonian Genome Center, University of Tartu, ²Institute of Mathematical Statistics, University of Tartu, Estonia.

Background and aims: Large-scale genome-wide association studies (GWAS) have revealed more than 80 genic loci associated with prevalent Type 2 Diabetes (T2D), improving the understanding of molecular pathways leading to the disease. However, practical usefulness of such results in T2D prevention is still heavily disputed. Our aim is to assess the association of the genetic risk score (GRS) for T2D with both prevalent and incident T2D and cardiovascular mortality in a large population-based cohort of European Origin.

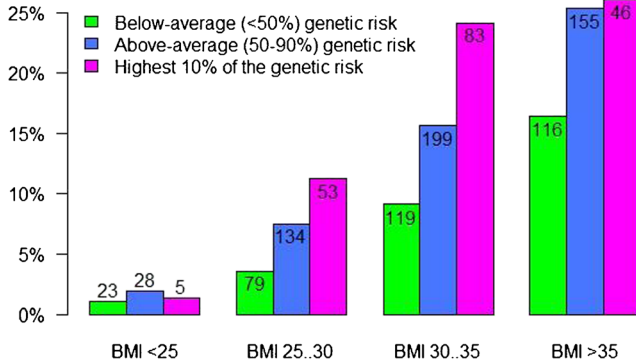

Materials and methods: The GRS is computed as a weighted sum of allele counts of 7500 markers identified by genome-wide genotyping of the cohort. The selection of markers and their weights is based on a large-scale GWAS meta-analysis (Morris et al, 2012). Predictive ability of the GRS is validated in 10,273 individuals of the Estonian Biobank cohort (1181 prevalent and 386 incident T2D cases, median follow-up time 5.5 years).

Results: The odds for T2D prevalence are 2.20 times higher (95% CI 1.82–2.65) in the highest GRS quintile compared to the rest of the cohort and 3.66 times higher (95% CI 2.72–4.91) compared to the lowest GRS quintile. For individuals in the highest GRS quintile, the estimated hazard of developing T2D during the follow-up is 1.78 times higher (95% CI 1.41–2.24) compared to the rest of the cohort and 2.72 times higher

(95%CI 1.94-3.81) compared to the lowest GRS quintile. From the available risk factors, GRS was the second strongest predictor for T2D (after BMI), increasing the area under the receiver operator characteristic curve for overweight individuals from 0.706 to 0.756 ($p=5.4 \times 10^{-13}$). In addition, we detected that individuals in the highest GRS quintile for T2D have significantly higher risk for cardiovascular mortality (adjusted hazard ratio=1.25, 95%CI 1.06-1.48, $p=0.009$).

Conclusion: Our results indicate that implementation of genetic testing in routine risk assessment could greatly improve the accuracy of T2D risk assessment in general population.

T2D prevalence in individuals aged 45-80

10

Glycaemic control and incidence of dementia in 363,573 patients with type 2 diabetes: an observational study

A. Rawshani, A. Rawshani, A.-M. Svensson, S. Gudbjörnsdóttir; Clinical and Molecular Medicine, Inst of Medicine, Gothenburg, Sweden.

Background and aims: A growing body of evidence indicates that diabetes increases the risk of cognitive impairment. This has prompted interest in delineating predictors of cognitive decline and dementia in diabetes. Cohort studies relating glycated haemoglobin (HbA1c) to risk of dementia are lacking. We evaluated extensive clinical data to explore the association between HbA1c and the risk of hospitalization for dementia among persons with type 2 diabetes.

Materials and methods: We identified all patients with type 2 diabetes and no known hospitalization for dementia who were registered in the Swedish National Diabetes Registry between January, 2004, and December, 2012. These patients were followed up until hospital admission for dementia, death, or end of follow-up on Dec 31, 2012. We used Cox regression to assess the association between patients' characteristics, including HbA1c, and dementia. All covariates were modelled as time-dependent predictors.

Results: In a cohort of 395,173 patients (contributing 2,981,247 registrations) with mean age of 64.6 years (SD 12.5) at baseline, 9,175 patients (2.3%) were admitted to hospital with a primary or secondary diagnosis of dementia during a mean (SD) follow-up of 4.6 (2.5) years. In a Cox regression analysis - with adjustment for age, sex, duration of diabetes, marital status, income, education, smoking status, systolic blood pressure, body mass index, estimated glomerular filtration rate, statins, albuminuria, type of glucose lowering treatment, atrial fibrillation, stroke and antihypertensive medications - the hazard ratio for hospitalization for dementia was 2.36 (95% CI 2.00-2.78) in patients with HbA1c of 10.5% or higher, compared with a reference group of patients with HbA1c of less than 6.5%. Statins and antihypertensive medications appeared to be protective from hospitalization for dementia. Stroke was associated with a hazard ratio of 7.69 (95% CI 7.22-8.18) for developing dementia. Albuminuria was also associated with increased risk of dementia. Refer to Figure 1.

Conclusion: The positive association between HbA1c and risk of dementia in fairly young patients with type 2 diabetes indicates a potential for prevention of dementia with improved glycaemic control.

Predictors of Hospitalization for Dementia in Type 2 Diabetes

11

The risk of developing diabetes and other diseases 10-17 years after pregnancy

U. Moll¹, H. Olsson², M. Landin-Olsson¹; ¹Department of Endocrinology, ²Department of Oncology, Lund, Sweden.

Background and aims: A high pre pregnancy BMI and excessive maternal weight gain has negative implications for pregnancy and delivery but has also negative long term effects since these conditions have been acknowledged as risk factors for post gestational weight retention and obesity later in life. The aim of this study was to analyze if a high maternal BMI at start of pregnancy and a high or low maternal weight gain during pregnancy were associated with diseases later in life.

Materials and methods: We used a population based cohort of 23,524 women from southern Sweden. Data regarding these women were merged with the Swedish Medical Birth Register (SMBR). 15014 of these women were found to have at least one registered delivery at least 10 years before answering a health questionnaire. The women were divided into groups based on their BMI (≤ 25 and > 25 ; $n=2415$ and 347) and weight gain (≤ 15 and > 15 kg; $n=2228$ and 1302).

Results: The mean pre pregnancy BMI was 21.84 ± 2.9 kg/m² and the mean weight gain was 14.5 ± 4.6 kg. There was a positive association between BMI > 25 and the risk of developing obesity, diabetes, cardiac disease, endocrine diseases and overall/other morbidity (OR 21.9, 6.1, 2.6, 2.1, 1.2; p -value < 0.001 , < 0.001 , 0.001 , < 0.001 , 0.012 respectively). There was a positive correlation between low maternal weight gain and the risk of developing psychiatric diseases (OR 1.6; $p < 0.001$). There was however no significant association between a high weight gain and the risk of developing diabetes, cardiac or endocrine diseases 10-17 years after delivery.

Conclusion: A high pre pregnancy BMI significantly increases the risk of several diseases later in life, including diabetes and cardiac disease. A high weight gain during pregnancy did not have any implications on metabolic diseases within ten years in our study.

12

Use of antibiotics and risk of type 2 diabetes: a population-based case control study

K.H. Mikkelsen¹, M.F. Nielsen^{2,3}, F.K. Knop⁴, J. Hallas⁵, A. Pottegård⁵; ¹Center for Diabetes Research, Department Medicine, Copenhagen University Hospital Gentofte, Hellerup, ²Department of Medicine, Kolding Hospital, Kolding, ³Endocrine Research Unit, University of Southern Denmark, Odense, ⁴Center for Diabetes Research, Department of Medicine, Copenhagen University Hospital Gentofte, Hellerup, ⁵Clinical Pharmacology, Department of Public Health University of Southern Denmark, Odense, Denmark.

Background and aims: There is accumulating evidence that bacteria in the human gut may influence nutrient metabolism. In rodent models, it is possible to manipulate insulin sensitivity, glucose tolerance and nutrient deposition through antibiotics-induced alterations in the gut microbiota. Further, associations between use of antibiotics and obesity have been reported in recent observational studies. We investigated whether use of antibiotics influences the risk of developing type 2 diabetes, and if so, if the effect can be attributed to specific types of antibiotics.

Materials and methods: The analysis was conducted as a population-based case-control study of incident type 2 diabetes cases in Denmark (population 5.5 million) during the period January 1st 2000 to December 31st 2012. Data from the Danish National Registry of Patients, the Danish National Prescription Registry and the Danish Person Registry were combined. The crude and adjusted odds ratios for the association between antibiotic exposure and risk of developing type 2 diabetes were estimated using conditional logistic regression, controlling for potential confounders.

Results: The study included 170,504 patients with type 2 diabetes and 1,364,008 matched controls. An increased odds ratio for risk of type 2 diabetes was seen with increasing exposure to antibiotics of any type with an odds ratio of 1.53 (95% CI 1.50-1.55) with redemption of 5+ vs 0-1 prescriptions. While no individual group of antibiotics was specifically associated with type 2 diabetes risk, slightly higher odds ratios for type 2 diabetes were seen with narrow-spectrum and bactericidal antibiotics compared to broad-spectrum and bacteriostatic types of antibiotics. The increased use of antibiotics in patients with type 2 diabetes was found up till 15 years before diagnosis of type 2 diabetes, as well as after the diagnosis.

Conclusion: These findings may represent an increased demand for antibiotics due to increased risk of infections in patients with yet undiagnosed diabetes, pre-diabetes or manifest type 2 diabetes. However, the possibility that antibiotics exposure increases diabetes risk cannot be excluded.

OP 03 Incretin-based therapy: on and off conventional targets

Treatment with liraglutide leads to an important reduction in liver fat content, assessed by magnetic resonance spectroscopy, in people with type 2 diabetes

B. Vergès^{1,2}, B. Bouillet¹, B. Guiu¹, P. Buffier¹, S. Baillot-rudoni¹, M.-C. Brindisi¹, E. Crevisy¹, C. Fourmont¹, J.-P. Cercueil¹, J. Petit^{1,2}; ¹Hôpital du Bocage, ²INSERM CRI866, Dijon, France.

Background and aims: Most studies found that 60-75% of patients with type 2 diabetes have Non-Alcoholic Fatty Liver Disease. Unfortunately, there is no treatment of NAFLD in people with diabetes besides weight loss and increased physical activity. Some animal studies have shown that GLP-1 receptor agonists may reduce liver lipogenesis. The effect of the GLP-1 receptor agonist, liraglutide on liver fat remain unknown in patients with type 2 diabetes. This prompted us to perform a prospective study on the effect of liraglutide on liver fat content, in type 2 diabetes.

Materials and methods: A total of 43 patients with type 2 diabetes mellitus were included in this study. Liver fat was measured by 1H-magnetic resonance spectroscopy (gold-standard method for liver fat measurement) before and after 6 months of liraglutide therapy (1.2 mg/j).

Results: Thirty-five (81.3%) patients had steatosis at baseline (hepatic triglyceride content greater than 5.5%). At inclusion, liver fat content was correlated with fasting serum triglycerides ($r=0.33$; $p=0.02$) and alanine aminotransferase (ALAT) ($r=0.46$; $p=0.002$). Treatment with liraglutide was associated with a mean weight loss of 4.4 kg ($p<0.001$), a mean HbA1c reduction of 2.6% ($p<0.001$) and an important reduction in liver fat content (from 19.1% to 12.7%, $p<0.001$) corresponding to a relative decrease of 33.3%. Reduction in liver fat was correlated with weight reduction ($r=0.49$, $p=0.001$), ALAT reduction ($r=0.49$, $p=0.001$), baseline liver fat content ($r=0.33$, $p=0.031$) and borderline significant with HbA1c reduction ($r=0.29$, $p=0.057$). In multivariate analysis, reduction in liver fat was independently associated with weight reduction ($p<0.0001$) and baseline liver fat ($p<0.0001$) ($r^2=0.62$). In the subgroup of patient who showed a relative weight reduction below the median value (3.3%), a significant 19.6% decrease was observed ($p=0.029$) whereas the mean body weight remained unchanged.

Conclusion: Our data indicate that liraglutide is an effective treatment to decrease liver fat content, in patients with type 2 diabetes. Although weight reduction induced by liraglutide appears to be an important factor promoting reduction in liver fat content, we cannot exclude a direct action of liraglutide on lipogenesis since a significant decrease in liver fat was observed in patients without significant weight reduction. Further studies are needed to explore the mechanisms involved in liver fat content reduction linked with liraglutide treatment.

Adipose tissue response to GLP-1 analogue-induced weight loss

K. Kos¹, L.J. McCulloch¹, R. Ward¹, S. Joshi¹, K. Sjöholm², A. Pitt³, K.M. Gooding⁴, A.C. Shore⁴, L.M.S. Carlsson²;

¹Diabetes and Obesity Research, University of Exeter Medical School, Exeter, UK, ²Molecular and Clinical Medicine, University of Gothenburg, Sweden, ³NIHR Exeter Clinical Research Facility, University of Exeter Medical School, ⁴Diabetes and Vascular Research Group, University of Exeter Medical School, Exeter, UK.

Background and aims: Glucagon like peptide-1 (GLP-1) analogues in the treatment of Type 2 diabetes are used for the control of HbA1c and

have the additional benefit of weight loss. Weight loss is considered to reduce obesity-associated adipose tissue inflammation, however, little is known about the effect of GLP-1 on adipose tissue, which is known to express GLP-1 receptors. The aim of the study was to assess the effect of weight loss on adipose tissue inflammatory and fibrotic responses achieved either by 1) treatment with the GLP-1 analogue Liraglutide 2) sustainable calorie reduction and 3) very low calorie dieting.

Materials and methods: Age and BMI matched subjects with well controlled Type 2 diabetes were randomised to Liraglutide (at a dose of 0.6 mg for the first 4 weeks and if tolerated continued at 1.2 mg), or to dietetic counselling and follow up to allow for similar weight loss. Independently, subjects with and without insulin resistance underwent a very low calorie diet (VLCD) of 450 kcal/day to achieve best possible non-surgical weight loss. Assessments included a subcutaneous abdominal adipose tissue biopsy at baseline and after 4 months. Fat samples were analysed for inflammatory and profibrotic markers by microarray and Taqman low density array based analysis. For statistical comparison Wilcoxon Signed Rank Test for paired analysis was used.

Results: Subjects who completed 4 months treatment with Liraglutide lost 3.2 ± 1.08 kg (mean \pm SD, age: 61.4 ± 5.48 years, baseline HbA1c: 59.6 ± 5.28 mmol/mol, BMI: 30.06 ± 4.85 kg/m², n=9) and lost 5.84 ± 3.27 kg in the diet arm (age: 57.0 ± 9.6 years, baseline HbA1c: 56.4 ± 6.54 mmol/mol; BMI: 32.4 ± 3.67 kg/m², n=6). The mean weight loss after VLCD was 28 ± 3.7 kg (baseline HOMA-IR: 4.4 ± 2.7 , baseline BMI: 37.6 ± 4.9 kg/m², BMI at 4 months: 28.6 ± 4.1 kg/m², n=24). After Liraglutide treatment, adipose tissue expression increased for the chemoattractant monocyte chemoattractant protein-1 (1.01 ± 0.13 AU (mean \pm SE) versus 1.54 ± 0.24 AU, $p < 0.05$), the inflammatory adipokine tumor necrosis factor alpha (1.05 ± 0.16 AU versus 1.63 ± 0.21 AU, $p = 0.01$) and the fibrotic cytokine transforming growth factor (TGF) beta-1 (0.91 ± 0.07 AU versus 1.25 ± 0.11 AU, $p < 0.05$); whereas expression of these genes did not change in the diet arm. In contrast, we observed a trend in lower macrophage marker CD14 expression with a diet only induced weight loss of 5.84 ± 3.27 kg (1.1 ± 0.18 AU versus 0.67 ± 0.11 AU, $p = 0.08$). Unlike with Liraglutide treatment and similar to sustained dieting we observed no change in TGFbeta-1 expression with VLCD, whereas there was a tendency for increased expression 2 weeks after refeeding (0.83 ± 0.04 AU versus 0.86 ± 0.05 AU at 4 months and 0.97 ± 0.07 AU with refeeding $p = 0.1$).

Conclusion: Unlike with calorie induced dieting, Liraglutide treatment appears to induce an inflammatory and fibrotic response in adipose tissue with increased expression of inflammatory markers and fibrotic factors not otherwise found with dieting and typical of overfeeding. It remains to be shown whether Liraglutide treatment could accelerate adipose tissue dysfunction in the long term.

Upper and/or lower GI adverse events with long- vs short-acting GLP-1 receptor agonists: incidence, co-incidence, effects on HbA_{1c} and weight

M. Horowitz¹, V. Aroda², J. Han³, E. Hardy⁴, C. Rayner¹;

¹University of Adelaide, Australia, ²MedStar Health Research Institute, Hyattsville, ³Pharmapace, San Diego, ⁴AstraZeneca, Gaithersburg, USA.

Background and aims: In direct comparative clinical trials, long- and short-acting glucagon-like peptide-1 receptor agonists (GLP-1RA) for T2DM appeared to have different efficacy and tolerability profiles. Early transient gastrointestinal adverse events (GI AE) are characteristic of GLP-1RA, but may differ in type and frequency for long- vs short-acting GLP-1RA. Our objective was to evaluate differences in GI

tolerability with long- versus short-acting GLP-1 RA (specifically exenatide once weekly [ExQW], exenatide twice daily [ExBID] or liraglutide once daily [LiraQD]) according to location (upper, lower) and co-incidence. We also investigated whether GI AE were associated with differences in HbA_{1c} or weight reductions.

Materials and methods: Intent to treat analyses of patient-level data from direct comparative trials of 2 GLP-1RA were conducted. Data from 3 studies of ExQW vs ExBID were pooled. Data comparing ExQW with LiraQD (DURATION-6) were analysed separately. GI events were identified according to MedDRA terminology and classified as upper or lower GI. Incidences of upper GI AE, lower GI AE, and combinations of upper and lower GI AE were determined for individual GLP-1RA. Changes in HbA_{1c} and body weight from baseline at study endpoint were assessed according to occurrence of GI AE.

Results: The most common upper GI AE were nausea or vomiting; the most common lower GI AE were diarrhoea or constipation. Incidences of upper GI AE appeared less for ExQW than short-acting GLP-1RA (Table), while lower GI AE appeared comparable across GLP-1RA. Diarrhoea was found to be accompanied by upper GI AE, and mainly occurred within 10 days of an upper GI AE for all GLP-1RA. Although 55% of patients overall were male in both analyses, the majority with upper GI AE were female (57–58%). Few patients discontinued GLP-1RA due to GI AE, but discontinuation was more frequent with short-acting GLP-1 RA than ExQW (Table). Reductions from baseline in HbA_{1c} were similar for patients with no GI AE and those with upper, lower, or combined GI AE for short or long-acting GLP-1RA. Reductions in body weight from baseline were observed in patients without GI AE (-2.0 , -2.0 kg for ExQW, ExBID; -2.4 , -3.5 kg for ExQW, LiraQD) but reductions were greater for those with upper + lower GI AE compared with no GI AE (-3.5 vs -2.0 kg) for ExBID, and for upper GI AE compared with no GI AE for ExQW (-3.9 vs -2.4 kg) in DURATION-6.

Conclusion: Pooled patient-level data from direct comparative trials indicate that upper GI AE occur more frequently with short- vs long-acting GLP-1RA. Lower GI AE are less common and do not differ between GLP-1 RA. Upper GI AE and diarrhoea were often reported by the same patients, suggesting some may be susceptible to upper and lower GI AE with GLP-1 RA. Presence or absence of GI AE did not affect HbA_{1c} reductions but may influence weight reductions in some patients.

Table

	Pooled Data		DURATION-6	
	ExQW	ExBID	ExQW	LiraQD
Patient population (N)	617	606	461	450
Any upper GI (%)	24	36	16	31
Upper GI only (%)	15	27	11	19
Upper + Lower GI (%)	10	11	7	14
Upper GI + diarrhoea (%)	6	5	3	10
Upper GI + constipation (%)	3	4	2	2

Differential effects of GLP-1 receptor agonists on 24-hour averaged heart rate in healthy volunteers and patients with type 2 diabetes

M. Lorenz¹, D. Owens², D. Raccah³, C. Roy-Duval⁴, F. Lawson⁵, A. Lehmann⁶, R. Perfetti⁷, L. Blonde⁸;

¹R&D Diabetes Division, Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, ²Institute of Life Sciences College of Medicine, Swansea University, Swansea, UK, ³University Hospital Sainte-Marguerite, Marseille, ⁴Sanofi R&D, Chilly-Mazarin, France, ⁵R&D Global Diabetes Division, Sanofi US, Bridgewater, USA, ⁶R&D Clinical Sciences & Operations, Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, ⁷Global Medical Affairs, Sanofi, Paris France, ⁸Department of Endocrinology, Ochsner Medical Center, New Orleans, USA.

Background and aims: Heart rate (HR) increases have been reported in studies of glucagon-like peptide-1 receptor agonists (GLP-1 RAs). The present analysis compares data from 24 h time-averaged HR monitoring with GLP-1 RAs.

Materials and methods: A review of studies that report 24 h time-averaged HR monitoring with GLP-1 RAs, including an unpublished QT/QTc study of lixisenatide in healthy subjects, published data for lixisenatide, exenatide, liraglutide, albiglutide and dulaglutide, and a head-to-head comparison of lixisenatide and liraglutide.

Results: Shorter-acting GLP-1 RAs, such as exenatide BID and lixisenatide QD, are associated with a smaller and shorter increase in HR (1-3 bpm, 1-12 h) compared with longer-acting GLP-1 RAs, such as liraglutide, albiglutide and exenatide QW, which induce a greater and more prolonged diurnal and nocturnal effect (6-9 bpm). The HR increase with dulaglutide is relatively small but persists at night (Table). In the head-to-head comparison, smaller LS mean HR increases from baseline were observed with shorter-acting lixisenatide versus longer-acting liraglutide, and the treatment difference was significantly more pronounced at night (Table).

Conclusion: Shorter-acting GLP-1 RAs induce a smaller and transient HR increase; most longer-acting GLP-1 RAs are associated with a more pronounced diurnal and nocturnal HR increase. The clinical consequences of these differential effects are not known.

Drug	Population; study duration	Regimen	Mean heart rate increase from baseline to study end	Source

Risk of pancreatic cancer associated with use of incretin-based therapy and other glucose-lowering agents: a nationwide case-control study in Denmark

R.W. Thomsen¹, D.H. Christensen², J. Kahlert¹, S.T. Knudsen³, L. Pedersen¹, H. Nørrelund¹, O.M. Dekkers⁴, I. Douglas⁵, G. Marchesini⁶, L. Smeeth⁵, N. Møller³, H. Beck-Nielsen⁷, J.O. Jørgensen³, H.T. Sørensen¹;

¹Department of Clinical Epidemiology, Aarhus University Hospital, ²Department of Clinical Epidemiology and Medical Department M (Endocrinology & Diabetes), Aarhus University Hospital, ³Medical Department M (Endocrinology & Diabetes), Aarhus University Hospital, Aarhus, Denmark, ⁴Leiden University Medical Center, Leiden, Netherlands, ⁵London School of Hygiene and Tropical Medicine & University College London, UK, ⁶Alma Mater Studiorum University of Bologna & Bologna University Hospital, Italy, ⁷Danish Centre for Strategic Research in T2D (DD2), Dept. of Endocrinology, Diabetes Research Centre, Odense University Hospital, Denmark.

Background and aims: Incretin-based drugs (glucagon-like peptide 1 (GLP-1) mimetics and dipeptidyl peptidase 4 (DPP-4) inhibitors) have been suspected to increase risk of pancreatic cancer. We examined if use of incretin-based drugs was associated with risk of pancreatic cancer and compared with other glucose-lowering agents.

Materials and methods: Using population-based medical databases this analysis was carried out as an age-, gender- and residence-matched (1:10) case-control study from 2005 to 2012 (6,036 pancreatic cancer cases and 60,360 controls). Odds ratios (ORs) for pancreatic cancer associated with use of incretin-based drugs and other glucose-lowering agents were computed, using conditional logistic regression, and we adjusted for other pancreatic cancer risk factors.

Results: A total of 122 incident pancreatic cancer patients (2.0%) vs. 400 controls (0.7%) had used incretin-based drugs at least once, whereas 20.8% cases vs. 8.6% controls had used any glucose-lowering agent. Patients with pancreatic cancer more often than controls had a hospital

history of chronic pancreatitis (3.6% vs. 0.3%), gallstone (10.7% vs. 5.3%), obesity (4.0% vs. 2.9%), alcoholism (6.5% vs. 3.9%), and chronic pulmonary disease (21.2% vs. 17.9%). Compared with non-users of any glucose-lowering agents, the adjusted risk of pancreatic cancer was increased for DPP-4 inhibitor users (adjusted OR=3.87, 95% CI 3.06–4.89) and GLP-1 mimetic users (adjusted OR=2.70, 95% CI 1.82–4.00), and furthermore for ever users of metformin (adjusted OR=2.65, 95% CI 2.44–2.88), sulfonylureas 2.65 (2.41–2.91) and insulin (adjusted OR=3.61, 95% CI 3.24–4.03). The highest cancer ORs were observed among new initiators of each glucose-lowering agent and in those with fewer than 3 prescriptions filled, suggesting a non-causal or reverse causal association.

Conclusion: The risk of pancreatic cancer was increased to similar levels for all glucose-lowering agents. This suggests that diabetes is a risk factor for pancreatic cancer independent of a specific drug effect, yet warrants further investigation.

DPP4 inhibitor can protect TZD induced bone loss via sclerostin expression in obese diabetic rat

B.-J. Kim, A.-R. Gwon, K. Kwak, Y. Eom, K. Lee, S. Yu, S. Lee, Y. Kim, I. Park, K.-W. Kim;

Endocrinology and Metabolism, Gachon University, School of Medicine, Incheon, Republic of Korea.

Background and aims: Thiazolidinediones (TZDs) are widely prescribed drugs in T2DM. However, recent studies, including large-scale randomized controlled trials and observational studies, suggests that long-term use of thiazolidinediones is associated with bone loss and an increased risk of fractures in women with Type 2 diabetes. Incretin based drugs (glucagon-like-peptide-1 agonist and dipeptidylpeptidase-4 inhibitor) have been added to a new treatment option for glucose control in T2DM and many beneficial effects on beta cell including insulin secretion and beta cell mass. Beyond pancreas, Incretins affect bone mass through stimulating bone remodeling. We already reported exendin-4 might increase BMD by decreasing the expression of SOST/sclerostin in osteocytes in T2DM animal model. This experiment, we evaluate protective effects of DPP-4 inhibitor on TZD induced bone loss in T2DM animal model.

Materials and methods: 12 week old male Zucker Diabetic Fatty (ZDF) rats were randomized with control, vildagliptin, pioglitazone, vildagliptin and pioglitazone treated group and treated for 5 weeks. We performed IPGTT, ITT before and after treatment and measure bone mineral density (BMD) by DEXA and trabecular volume by micro CT at the end of treatment. Also, we assayed circulating levels of GLP-1, GIP, sclerostin, osteocalcin, and tartrate-resistant alkaline phosphatase (TRAP) 5b by ELISA.

Results: Pioglitazone treated group decreased blood glucose and increased body weight. Also, this group decreased BMD in DEXA and decreased trabecular bone volume and thickness in micro CT. Vildagliptin, DPP4 inhibitor, treatment increased BMD and trabecular bone volume and thickness compared with control. Also, combination treated group showed significant increase in BMD and trabecular thickness compared to pioglitazone group. Pioglitazone treatment increased sclerostin, but add vildagliptin to pioglitazone suppressed sclerostin.

Conclusion: Vildagliptin, DPP4 inhibitor, increased bone mass in type 2 diabetes animal model. Also, Vildagliptin can protect bone loss in TZD treated Type 2 diabetes through reducing sclerostin from osteocyte at least in T2DM animal model.

Postprandial brown adipose tissue fatty acid metabolism in lean and obese subjects

T. Saari, J. Raiko, N. Savisto, M. Haaparanta-Solin, P. Nuutila, K.A. Virtanen;
University of Turku, Finland.

Background and aims: Brown adipose tissue (BAT) is activated by cold exposure, increasing its glucose uptake, blood flow and fatty acid uptake (FAU). In animals BAT has thermogenic activity also in pursuance of eating (meal-induced thermogenesis) but this is poorly studied in humans. As fatty acids are the main fuel source for BAT we aimed to quantify FAU in lean and obese subjects during cold exposure and after eating, in postprandial state.

Materials and methods: FAU was quantified in lean ($n=11$, 8 F/3 M, age 33.4 ± 11.8 years, BMI 25.2 ± 1.5 kg/m²) and obese subjects ($n=6$, 5 F/1 M, age: 41.5 ± 11.0 years, BMI 31.5 ± 2.7 kg/m²) using ¹⁸F-FTHA, a palmitate analog and PET/CT. Tissue specific perfusion was measured with ¹⁵O-H₂O-PET/CT. Each subject was imaged twice, once during cold exposure in fasting conditions and once in ambient temperature postprandially. Tissue specific NEFA uptake and perfusion was calculated for supraclavicular adipose deposits, deltoid muscles and subcutaneous white adipose tissue (WAT).

Results: In lean subjects cold-induced FAU in BAT was 3-fold higher than postprandial FAU (2.05 ± 1.66 vs. 0.66 ± 0.64 $\mu\text{mol}/100$ g/min, $P=0.004$). Cold stimulated FAU also in WAT 2-fold (0.42 ± 0.12 vs. 0.19 ± 0.13 $\mu\text{mol}/100$ g/min, $P=0.003$) and in muscle 3-fold (1.06 ± 0.40 vs. 0.32 ± 0.20 , $P=0.0005$) when compared to postprandial FAU, however, these FAU rates were clearly lower than in BAT. In obese subjects, both cold-stimulated and postprandial FAU rates were lower than in lean subjects but FAU was higher in cold than after meal (1.19 ± 0.60 vs. 0.38 ± 0.40 $\mu\text{mol}/100$ g/min, $P=0.001$, cold vs postprandial). Muscle FAU rate was similar in obese and lean subjects being 2-fold higher in cold than postprandial state (0.98 ± 0.25 vs. 0.38 ± 0.31 $\mu\text{mol}/100$ g/min, $P=0.02$) in obese subjects. Postprandial BAT perfusion was higher in lean than in obese subjects (20.00 ± 16.74 vs. 4.85 ± 1.63 ml/100 g/min, $P=0.03$). BAT FAU in cold correlated with postprandial BAT FAU ($r=0.84$, $P=0.00002$) but in WAT or muscle no such correlation was found. Serum FFA levels were similar in lean and obese subjects during cold exposure (0.89 ± 0.18 vs 0.89 ± 0.15 mmol/L) and after meal (0.29 ± 0.22 vs 0.43 ± 0.37 mmol/L).

Conclusion: Fatty acid uptake rate after meal in BAT is lower than during cold stimulus both in lean and obese subjects. However, obesity seems to be related with lowered FAU and perfusion in BAT. This data suggest that in addition to blunted cold-induced FAU obese subjects have impaired postprandial lipid metabolism in the supraclavicular area.

Cold increases brown fat temperature and decreases fat content: measured using MRS in humans

K. Koskensalo¹, J. Raiko¹, T. Saari¹, V. Saunavaara¹, O. Eskola¹, P. Nuutila^{1,2}, R. Parkkola³, K.A. Virtanen¹;

¹Turku PET Center, ²Department of Endocrinology, Turku University Hospital, ³Department of Radiology, Turku University Hospital, Finland.

Background and aims: The role of brown adipose tissue (BAT) is to dissipate stored energy as heat. The aim of this study was to investigate whether the temperature and the proportion of fat (expressed as the proton density fat fraction (PDFF)) of brown and white adipose tissue (WAT) is related to BAT metabolic activity.

Materials and methods: Magnetic resonance spectroscopy (MRS) and ¹⁸F-FDG PET in BAT and subcutaneous WAT were performed for 9 healthy subjects (4 F/5 M, ages 26 - 44 years, BMI 24.6 ± 2.2 kg/m²) using Philips Ingenuity 3 T PET/MR. MRS was obtained with PRESS sequence (TR/TE=2000/35 ms, NSA=72, voxel volume: 1.0 cm³). The voxel was placed in the supraclavicular and subcutaneous adipose tissue. The measurements were obtained during 2-hour non-shivering cold exposure and in ambient room temperature (RT). The chemical shift difference between the CH₂ peak of the lipid chain and H₂O peak was determined with iNMR software (Mestrelab Research, 2014) and converted to temperature. The proton density fat fraction (PDFF) was calculated by dividing the sum of all LCModel fitted fat peaks by the sum of both water and fat peaks. Fat and water were corrected for T₂ and T₁ relaxation effects. The dynamic ¹⁸F-FDG PET data was analyzed using graphical analyses with Carimas 2.8.

Results: All study subjects had functionally active BAT based on cold-induced glucose uptake (17.7 ± 8.4 $\mu\text{mol}/100$ g/min). The PDFF of BAT in cold and RT were $68\pm 12\%$ and $80\pm 14\%$ ($P=0.03$), respectively, and in WAT $76\pm 18\%$ and $86\pm 6\%$ (NS). The temperature of BAT was higher during cold exposure ($34.1\pm 3.0^\circ\text{C}$ in cold and $32.6\pm 4.7^\circ\text{C}$ in RT, $P=0.03$) while in WAT there was no difference in temperature between cold and RT ($31.1\pm 3.8^\circ\text{C}$ and $29.8\pm 2.8^\circ\text{C}$, NS). All subjects had normal plasma lipid profiles (HDL 1.94 ± 0.50 , and LDL 2.23 ± 0.66 mmol/l) and whole-body insulin sensitivity (M-value 44.4 ± 10.5 $\mu\text{mol}/\text{kg}/\text{min}$). BAT temperature in RT correlated strongly with M-value ($r=0.86$, $p=0.0027$) and in cold BAT temperature was associated with BAT glucose uptake ($r=0.69$, $p=0.041$). In cold, PDFF of BAT correlated significantly with plasma LDL ($r=0.76$, $p=0.016$) and inversely with plasma HDL ($r=-0.69$, $p=0.040$).

Conclusion: The increment of BAT temperature during cold exposure can be measured with MRS during cold exposure in humans. BAT temperature in room temperature associates with M-value. Further, MRI-derived PDFF during cold associates with plasma lipid values. Our findings suggest that BAT has an important role in whole-body insulin sensitivity and lipid metabolism.

Impact of caloric restriction on initial age-associated metabolic alterations and browning effect in mice

P. Corrales-Cordon¹, Y. Vivas¹, D. Horrillo¹, A. Izquierdo¹, P. Seoane², C. Martinez-Garcia¹, M. Lopez², M. Ros¹, M. Obregon³, G. Medina-Gomez¹;

¹Universidad Rey Juan Carlos, Madrid, ²Universidade Santiago de Compostela, ³Instituto de Investigaciones Biomédicas Alberto Sols/CSIC-UAM, Madrid, Spain.

Background and aims: Changes in the distribution and function of different deposits of white adipose tissue (WAT) and brown adipose tissue (BAT) occur during ageing. These changes are usually associated to metabolic alterations like Insulin Resistance (IR) and Metabolic Syndrome. It is also known that caloric restriction (CR) reduces the metabolic changes associated with age. Nevertheless, it is difficult to establish when age-associated alterations start. Similarly, the severity and the time-extent to CR are variables under debate. The aim of this work is to investigate the impact of the CR initiated since 3 months of age and maintained until 12 months of age, in the development of IR and other metabolic disorders.

Materials and methods: 3 and 12-month-old male mice fed ad libitum and 12-month-old mice under CR (20%) from 3 months of age were used ($n=10-12$ animals/group). For in vivo studies, we performed glucose (1 g/kg body weight) and insulin (0.75 U/kg body weight) tolerance test in mice. Serum concentration values of glucose, insulin and different cytokines were quantified by Bio-plex ProTM Diabetes Assays. Gen expression involved in lipid metabolism was measured in BAT and

epididimal (eWAT) and subcutaneous (scWAT) WAT. Immunohistochemistry and mRNA expression of UCP-1 was also detected. Total triiodothyronine (T3) and thyroxine (T4) concentrations were determined by radioimmunoassay (RIA) in serum and BAT. Protein levels of lipogenic enzymes in the Central Nervous System (CNS) were also measured.

Results: Our data showed age-associated IR significantly ($p < 0.05$; t-Student) appeared at maturity and is prevented with CR (AUC mean \pm SE: 1536.64 \pm 115.94 in 12-month old mice compared to 1587 \pm 151.23 in animals fed with CR). These findings were in agreement with serum concentration values quantified. Cytokines serum levels were measured. Adiponectin level significantly ($p < 0.05$) decreased with ageing (5.57 \pm 0.47 μ g/ml) and increased with CR (13.62 \pm 2.53 μ g/ml), while the leptin serum levels significantly ($p < 0.05$) increased with ageing (10.5 \pm 3.095 ng/ml) but decreased with CR (2.61 \pm 0.74 ng/ml). Furthermore, CR restored initial age-associated alterations in lipid metabolism and markers of macrophage infiltration, such as MCP-1 (2.00 \pm 0.38 with ageing; 1.32 \pm 0.16 with CR), only in scWAT. Remarkably, brown like adipocytes or browning effect was detected in scWAT in old animals subject to CR. The lower browning process associated to ageing was accompanied by a significant ($p < 0.05$) decrease in the expression of some brown fat-selective genes (such as UCP-1, PRDM16, FGF21), but restored with CR. T3 and T4 levels in BAT were significantly ($p < 0.05$) decreased with ageing but restored by CR. In addition, serum T3 levels were significantly ($p < 0.05$) decreased with ageing. Finally, we also found significantly ($p < 0.05$) changes in lipogenic enzymes such as ACC and AMPK in the hypothalamic AMPK pathway during the first stages of ageing.

Conclusion: Long-term CR prevents the morphological and initial aged-related metabolic changes in WAT and BAT. The browning effect observed in scWAT and the activation of BAT could be explained by improved thyroid hormones status and function of CNS.

Identification of compounds inducing UCP1 in differentiating human white preadipocytes

J. Boucher, S. Eng, E. Carlsson, B. Magnusson, A. Sabirsh, S. Bartesaghi, M. Andersson, A. Hogner, A. Forslöw, O. Engkvist, A. Paunovic, G. O'Mahony, X.-R. Peng, S. Hallen; AstraZeneca, Mölndal, Sweden.

Background and aims: While white adipose tissue is the major energy storage tissue in the body, brown adipose tissue dissipates energy in the form of heat, due to the unique presence of the mitochondrial uncoupler protein UCP1. Converting white into brown-like adipocytes, expressing high levels of UCP1 with increased oxidative and energy wasting capacity, is a promising therapeutic strategy to counter insulin resistance and type 2 diabetes. Our goal is to identify small molecules that increase UCP1 expression and function, and induce the “browning” of white fat.

Materials and methods: We developed a screening strategy using human adipose derived stem cells (hASCs) isolated from subcutaneous fat. hASCs were differentiated for up to 15 days in the presence or absence of compounds and UCP1 mRNA levels were measured. UCP1 qPCR assay was run in a 384 well format, and compounds were tested at 0.5 and 10 μ M. We tested ~3000 small molecules covering more than a thousand targets.

Results: We identified small molecule compounds that robustly induce UCP1 mRNA in hASCs (3% hit rate). Top UCP1 inducers were confirmed by measuring both UCP1 protein and β -adrenergic/free fatty acid stimulated uncoupled respiration using the Seahorse XF Analyzer. High content imaging demonstrated that UCP1 protein is evenly distributed in the lipid droplet-containing adipocytes and co-localizes with

mitochondria. In addition to UCP1, other brown fat genes such as Dio2, PGC1 α and PRDM16 or beige fat markers (TMEM26), were also increased in treated cells, while white fat markers leptin and Hoxc8 were decreased, confirming the switch of white adipocytes to a brown-like phenotype. PPAR γ agonists, such as rosiglitazone, are currently among the most potent inducers of a brown-like phenotype in cultured primary adipocytes. The metabolic modulators described here were increasing UCP1 protein levels to a greater extent than rosiglitazone and other PPAR agonists.

Conclusion: We have identified novel and potent UCP1 inducers using a qPCR based screening assay in human preadipocytes. The UCP1 increase was confirmed at the protein level, and drives uncoupled respiration after activation. Hence, the observed step jump in UCP1 expression level induced by these novel small molecules opens the prospect of bringing white precursor cells one step closer to the true brown adipocyte phenotype.

23

The β 3-adrenoceptor agonist CL316,243 increases in vivo free fatty acid uptake and utilisation in interscapular and perirenal brown fat but not inguinal fat in high-fat fed rats

A. Warner¹, A. Kjellstedt¹, A. Carreras², P. Seale³, N. Oakes¹, D. Lindén¹;

¹CVMD iMed, AstraZeneca AB, ²Discovery Sciences, Transgenics, AstraZeneca AB, Mölndal, Sweden, ³University of Pennsylvania, Philadelphia, USA.

Background and aims: Activation of brown adipose tissue (BAT) and browning of white adipose tissue present potential new therapies for metabolic diseases such as Type 2 diabetes and obesity. Through the partitioning of substrates for mitochondrial uncoupling, energy is used for the production of heat rather than ATP. Here we investigate the effects of β 3-adrenergic stimulation on glucose tolerance and whole-body metabolic parameters, and for the first time determine tissue-specific uptake and storage of free fatty acids (FFA) and its implications for whole-body FFA metabolism using a multi-radiotracer technique.

Materials and methods: For whole-body energy metabolism, male C57BL/6 mice were fed 60% (kcal) high fat diet for a total of 20 weeks and during the last 4 weeks administered β 3-agonist CL316,243 (1 mg/kg/day) or saline via osmotic minipumps. After 14 days an oral glucose tolerance test was performed. After 21 days the mice were recorded in metabolic cages for 24 hours at ambient room temperature (22 \pm 0.2°C), and 24 hours at thermoneutrality (30 \pm 0.2°C). For the study of tissue-specific FFA metabolism, male Wistar rats were fed 45% (kcal) high fat diet for 12 weeks in total and during the last 3 weeks administered β 3-agonist CL316,243 (1 mg/kg/day) or saline via osmotic minipumps. At the end of the study, the rats were fasted and acutely infused with a tracer mixture (¹⁴C-palmitate and the partially-metabolised ³H-R-bromopalmitate) under anaesthesia.

Results: In mice, CL316,243 (CL) infusion decreased body weight (BW change, CL = -1.80 \pm 0.63 g vs. saline 1.27 \pm 0.45 g, $p < 0.01$, t-test), improved glucose tolerance (glucose AUC CL = 1110.0 \pm 100.1 vs. saline 1459.0 \pm 106.9, $p < 0.05$; insulin AUC CL = 427.4 \pm 46.1 vs. saline = 762.5 \pm 78.0, $p < 0.01$, t-tests), and attenuated the reduction of oxygen consumption seen in the transition of environmental temperature from 22 to 30°C (thermoneutrality) seen in saline controls ($p < 0.0001$ for infusion, two-way ANOVA). In the rats, CL infusion decreased body weight and fasting plasma glucose levels (BW change CL = 17.3 \pm 7.3 vs. saline = 34.9 \pm 4.3 g, $p < 0.05$, t-test; glucose CL = 4.53 \pm 0.09 vs. saline = 5.13 \pm 0.20 mM, $p < 0.05$), while there was no effect on food intake. Using infrared thermo-imaging, an increase in tail heat dissipation was seen in the CL-infused rats (CL = 33.6 \pm 0.6 vs. saline = 29.8 \pm 0.3°C, $p < 0.01$, t-test). Whole-body FFA clearance and appearance were unchanged while CL administration markedly increased both FFA storage ($p < 0.0001$, t-

test) and utilisation ($p < 0.0001$, t-test) in the interscapular and perirenal BAT. Surprisingly, CL did not influence FFA uptake or utilisation in the inguinal fat depot.

Conclusion: In summary, β_3 -agonism improved glucose tolerance and increased oxygen consumption in mice. In rats, β_3 -agonism robustly increased FFA flux to BAT coupled with an enhanced utilisation, which was not the case in inguinal fat. Enhanced BAT activation was most likely driving the increased heat dissipation through the tail in order to maintain thermostasis. Our results emphasise the quantitative role of brown fat as the functional target of β_3 -agonism.

24

Effect of metformin on glucose and fatty acid utilisation in brown adipose tissue

J. Trnovska, V. Skop, H. Malinska, L. Kazdova;

Center for Experimental Medicine, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Metformin is the first-line drug for the treatment of type 2 diabetes. Its main action is the inhibition of glucose synthesis and gluconeogenesis in the liver. In addition to its antihyperglycemic properties, growing evidence indicates that metformin also affects lipid metabolism and reduces body weight and abdominal fat mass. However, the mechanisms are still unclear. These effects might be mediated by lowered production of VLDL-TG in the liver or by increase in VLDL-TG clearance in peripheral tissues. Recently, brown adipose tissue (BAT) was identified as an important organ involved in clearing plasmatic VLDL-TG for thermoregulation and thus could prevent obesity, ectopic fat accumulation and associated metabolic disturbances. The aim of this study was to investigate if metformin increases glucose and fatty acid utilization in BAT, and ameliorate related parameters of metabolic syndrome.

Materials and methods: Male Wistar rats (age: 8 months) were fed a standard diet (SD) or SD enriched by metformin in the following dose: 300 mg/kg b.wt./day for 4 weeks. Plasma levels of selected parameters were measured using commercially available kits: triglycerides, insulin, high molecular weight (HMW) adiponectin and C-reactive protein (CRP). BAT activity was determined *ex vivo* by oxidation of ^{14}C -U-palmitic acid and ^{14}C -U-glucose into CO_2 in BAT and incorporation of ^{14}C -U-palmitic acid and ^{14}C -U-glucose into BAT lipids after 2-hour incubation at 37°C .

Results: Metformin treatment significantly decreased body weight from 527 ± 20 g at the beginning to 431 ± 16 g at the end of treatment ($p < 0.001$), whereas body weight of controls was not significantly affected (559 ± 16 vs. 575 ± 22 g; N.S.). Compared to controls, metformin decreased the weight of visceral adipose tissue: epididymal adipose tissue (0.422 ± 0.025 vs. 1.087 ± 0.078 g/100 g b.wt; $p < 0.002$) and perirenal adipose tissue (0.073 ± 0.009 vs. 0.616 ± 0.092 g/100 g b.wt; $p < 0.01$). Plasma levels of triglycerides were decreased by metformin treatment (0.560 ± 0.060 vs. 1.360 ± 0.180 mmol/l; $p < 0.01$). Metformin also reduced ectopic fat accumulation in selected tissues: the liver (2.718 ± 0.201 vs. 9.594 ± 1.564 $\mu\text{mol/g}$; $p < 0.02$), heart (0.989 ± 0.276 vs. 2.880 ± 0.533 $\mu\text{mol/g}$; $p < 0.03$), aorta (4.482 ± 0.866 vs. 8.659 ± 0.434 $\mu\text{mol/g}$; $p < 0.01$) and diaphragm (3.551 ± 1.100 vs. 17.360 ± 2.769 $\mu\text{mol/g}$; $p < 0.01$). Metformin increased palmitic acid oxidation in BAT (106 ± 15 vs. 58 ± 10 nmol palm./g/2 h; $p < 0.03$) and palmitic acid incorporation into BAT lipids (2443 ± 129 vs. 1797 ± 111 nmol palm./g/2 h; $p < 0.01$). Glucose incorporation into BAT lipids were higher after metformin treatment (basal: 1141 ± 117 vs. 448 ± 61 nmol gl./g/2 h; $p < 0.01$ and insulin-stimulated: 4876 ± 345 vs. 1945 ± 583 nmol gl./g/2 h; $p < 0.01$), whereas basal and insulin-stimulated glucose oxidation were not influenced. In addition, metformin also reduced plasma insulin levels (0.182 ± 0.008 vs. 0.469 ± 0.003 nmol/l; $p < 0.001$), increased HMW adiponectin plasma levels (1.365 ± 0.105 vs. 0.952 ± 127 $\mu\text{g/ml}$; $p < 0.04$) and decreased CRP plasma concentration (238 ± 33 vs. 502 ± 127 $\mu\text{g/ml}$; $p < 0.015$).

Conclusion: Results indicate that metformin-induced increase of lipid and glucose utilization in BAT may participate in the mechanism of improving metabolic syndrome and related disorders.

The peripherally restricted CB1 receptor antagonist AM6545 reverts experimental diabetic nephropathy

F. Barutta, S. Grimaldi, G. Gruden;

Medical Sciences, University of Turin, Italy.

Background and aims: Diabetic nephropathy (DN) is characterised by increased glomerular permeability to proteins and excessive extracellular matrix accumulation in the mesangium. The endocannabinoid system has been implicated in the pathogenesis of DN as the cannabinoid receptor of type 1 (CB1R) is overexpressed by podocytes and CB1R blockade with AM6545 prevents the onset of both albuminuria and renal structural abnormalities in an animal model of streptozotocin-induced diabetes. AM6545, a peripherally restricted CB1R antagonist, is devoid of behavioural side effects as it does not cross the blood-brain barrier and may thus represent a novel tool for DN treatment. Our aim was to perform a reversal study to establish if AM6545, either alone or in combination with a ACE-inhibitor, reverts characteristic features of DN in diabetic mice with established proteinuria.

Materials and methods: Male C57Bl6 mice were made diabetic by intraperitoneal (i.p.) injection of streptozotocin (55 mg/kg in citrate buffer delivered in 5 consecutive days). Control mice (ND) were injected with citrate buffer alone. Eight weeks after diabetes onset, diabetic mice (DM) were further randomised to receive treatment with either vehicle (n=4), AM6545 (DM-A: 10 mg/kg i.p. daily; n=4), enalapril (DM-E: 2 mg/kg gavage daily; n=4) or both (DM-A+E, n=4). After six weeks of treatment, mice were individually placed in metabolic cages for urine collections and blood samples taken for blood glucose and glycated haemoglobin measurements. Then, mice were sacrificed, kidneys removed, weighed, and analysed. Urinary albumin excretion was measured by enzyme-linked immunosorbent assay. Expression of slit-diaphragm proteins (nephrin and podocin) was assessed by immunofluorescence. Markers of fibrosis (fibronectin, collagen I) were assessed by immunofluorescence and/or real-time PCR on total renal cortex.

Results: Diabetes was associated with reduced body weight and an increase in both blood glucose and glycated haemoglobin levels. Systolic blood pressure was unaltered by AM6545, but reduced by enalapril. Albuminuria was significantly ($p < 0.001$) increased in the diabetic [DM:429.9 (382.7-513.7) $\mu\text{g}/18$ hrs, geometric mean (25th-75th percentile)] as compared to ND mice [ND:118.4 (110.7-124.6)] and ameliorated by treatment with either AM6545 [DM-A:242.6 (213.2-297.9); $p < 0.05$ DM-AM6545 vs DM] or enalapril [DM-E: 235.1 (217.4-267.9); $p < 0.05$ vs DM]. Combination therapy with AM6545 and enalapril further reduced albuminuria and the difference as compared to ND mice was no longer statistically significant [DM-A+E: 144.8 (112.3-204.5); $p < 0.05$ DM-A+E vs DM-A and DM-E]. In DM mice the increase in albuminuria was paralleled a significant reduction in both podocin and nephrin expression. This was significantly reduced by treatment with either AM6545 or enalapril and completely prevented by the combination therapy. Diabetes-induced overexpression of fibronectin and collagen was abolished by single therapy and hence administration of both compounds did not result in further benefit.

Conclusion: Treatment with AM6545 ameliorated experimental DN and combination therapy with AM6545 and enalapril abolished diabetes-induced both albuminuria and slit diaphragm protein loss.

Background and aims: Increased levels of reactive oxygen species (ROS) greatly contribute to the development of diabetic complications such as nephropathy. They induce carbonylation of proteins, which in high amounts impedes normal cell function. However, physiological amounts of ROS might have protective effects as they are involved in cellular signaling pathways. This study aims to analyze the influence of age-dependent protein carbonylation on the expression and activity of the cytosolic anti-oxidative selenoenzyme GPx in the context of diabetic nephropathy in mice.

Materials and methods: In addition to standard methods, dinitrophenylhydrazine (DNPH) derivatization has been used to detect carbonylated proteins in kidney homogenates and tissue sections of diabetic Ins2Akita mice of different ages and 18 week old db/db mice. GPx activity was determined using a luminescent activity assay.

Results: Protein carbonylation was found to be increased in the kidneys of both db/db and Ins2Akita mice compared to non-diabetic control mice. Carbonylation increased with age in Ins2Akita mice and carbonylated proteins co-localized with podocytes and mesangial cells in glomeruli. In line, GPx1 and GPx4 expression were found to be increased in those cell types in diabetic Ins2Akita mice compared to non-diabetic animals. In addition, GPx activity was augmented in kidneys of Ins2Akita mice, especially in young (1 month) diabetic animals that did not show a simultaneous upregulation of GPx on the protein level. In these young animals, immunoprecipitated GPx1 was found to be carbonylated. Using a recombinant GPx1 protein, an increased activity after mild in vitro carbonylation could be proved. In podocytes cultured under high glucose conditions (25 mM for 7 days), GPx protein expression was increased as well, whereas its activity was found to be decreased.

Conclusion: GPx carbonylation in the kidney is associated with an increase in its activity at early stages of diabetes whereas this effect was absent in animals with end-stage disease and cultured podocytes demonstrating the role of protein carbonylation in the mechanism of ROS signaling. These results indicate that there might be a threshold for beneficial carbonylation-dependent redox signaling during the progression of diabetic nephropathy.

Loss of ALCAM/CD166 partially protects against diabetic nephropathy

A. Sulaj¹, R. von Bauer², S. Kopf¹, E. Gröne³, H.-J. Gröne³, S. Hoffmann⁴, E. Schleicher⁵, H.-U. Häring⁵, V. Schwenger⁶, S. Herzig⁷, P.P. Nawroth¹, T. Fleming¹;

¹Department of Internal Medicine I and Clinical Chemistry, University of Heidelberg, ²Department of Internal Medicine, SRH Klinikum Karlsbad-Langensteinbach, Karlsbad, ³Division of Cellular and Molecular Pathology, German Cancer Research Center, Heidelberg, ⁴Medical Research Center, Medical Faculty Mannheim, University of Heidelberg, Mannheim, ⁵Department of Internal Medicine, University of Tübingen, ⁶Department of Nephrology, University of Heidelberg, ⁷Joint Research Division, Molecular Metabolic Control, German Cancer Research Center DKFZ, Network Aging Research, ZMBH, Heidelberg, Germany.

Background and aims: Activated leukocyte cell adhesion molecule (ALCAM/CD166) has been shown to function as a pattern recognition receptor, analogue to the receptor of advanced glycation endproducts, and has been implicated in the development and progression of diabetic nephropathy (DN). In this study the role of ALCAM in DN was investigated in patients with type 2 diabetes, suffering from DN, and further investigated in vitro and in vivo using homozygous knock-out mice for ALCAM (ALCAM^{-/-}).

Materials and methods: Serum concentration of soluble ALCAM (sALCAM) and the expression of ALCAM and its ligand S100B in the kidney of patients with type 2 diabetes were determined by ELISA and histology, respectively. In vivo, diabetes was induced by low-dose streptozotocin in wild-type and ALCAM^{-/-} mice. Diabetes was maintained for six months, after which time, the mice were assessed for symptoms of DN, as well expression of ALCAM. In vitro isolated tubular epithelial cells from wild-type and ALCAM^{-/-} mice were studied.

Results: Serum concentration of sALCAM was significantly increased in patients with type 2 diabetes (59.85±14.99 ng/ml vs. 126.88±66.45 ng/ml, P<0.0001), and correlated positively with HbA1c (R=0.45, P<0.001), as well as the extent of chronic kidney disease but negatively correlated with estimated GFR (R=-0.3, P<0.01). In the kidneys of patients with type 2 diabetes, the expression of ALCAM was significantly up-regulated in both the glomeruli and proximal and distal tubules. In contrast, the expression of S100B was significantly increased in the glomeruli, especially in the podocytes, but not in the tubules. In mice, the expression of ALCAM was also localized to the glomeruli and tubules. However, expression of S100B was only localized to the tubules. It was found that diabetic ALCAM^{-/-} mice had no increase in albuminuria as well as no changes in either creatinine/body weight ratio or kidney-to-body weight ratio. Furthermore, glomerular and tubular damage were significantly lower than in the wild-type diabetic mice. In vitro it was found that S100B-induced expression of TGF-beta was dependent on ALCAM under diabetes conditions.

Conclusion: This study identifies ALCAM as a novel mediator in the late complications of diabetes in the kidney.

Soluble Nogo-B ameliorate angiogenesis in vitro in an experimental model of diabetic nephropathy

J. Pan¹, J. Karalliedde¹, N. Fountoulakis¹, A.E. Hayward¹, L. Ashraf¹, A. Kahlon¹, K.E. White², D.A. Long³, L. Gnudi¹;

¹Cardiovascular Division, King's College London, ²Electron Microscopy Research Services, University of Newcastle, ³Developmental Biology and Cancer, University College London, UK.

Background and aims: We recently explored the role of neurite outgrowth inhibitor (Nogo)-B, in the pathophysiology of diabetic

nephropathy (DN). Nogo-B and its soluble form (sNogo-B) have been implicated in the regulation of cell survival, cell migration and vascular remodelling - known to be altered in diabetic glomerulopathy. Both Nogo-B (at the cellular level) and sNogo-B (systemically) bind to NgBR (expressed mainly in endothelial cells), and promote vascular remodelling. In earlier work we have demonstrated that Nogo-B and NgBR are expressed in glomeruli and that Nogo-B is downregulated in glomeruli of experimental animal model of diabetes. The role of Nogo-B and sNogo-B in diabetic glomerulopathy is unknown, therefore our aims were to investigate: i) the role of high glucose and VEGF-A on Nogo-B and sNogo-B expression in human glomerular endothelial cells (GECs) in vitro; ii) in vitro, whether sera obtained from patients with type-1 diabetes and DN (T1DM/DN+) is paralleled by altered angiogenesis when compared to sera from T1DM without DN (T1DM/DN-); iii) whether overexpression of sNogo-B could modulate angiogenesis.

Materials and methods: Conditionally immortalised GECs were incubated with high (HG: 25 mM) or normal (NG: 5 mM+20 mM mannitol) glucose, with or without VEGF-A (50 ng/ml), for 72 h. Serum was obtained from patients with T1DM/DN+ (n=18) or T1DM/DN- (n=17); the two groups had similar age, sex, HbA1c, duration of diabetes, BP, lipid profile, renal function, urine albumin/creatinine ratio, sNogo-B serum levels and only differed in that the DN+ had history of albuminuria and were all treated with inhibitors of the renin-angiotensin-system. Angiogenesis assay with human umbilical vein endothelial cells (HUVEC) was conducted in the presence of the patient sera (4%vol/vol) on Matrigel and tube formation assessed after 24 h under light microscopy and quantified with image analysis. sNogo-B overexpression was achieved by transfection with adenoviral vector. ELISA was utilised to quantify sNogo-B levels in cell supernatant and patients' sera.

Results: HG and VEGF-A resulted in Nogo-B downregulation in GEC (p<0.05), no additive effect was seen with their combination. The downregulation of full length Nogo-B was always paralleled by an increase of sNogo-B in the cells supernatant (p<0.05). HUVEC cultured in T1DM/DN+ sera displayed a 50% reduction in tube formation (total loop number), when compared to cells cultured in T1DM/DN- sera (p<0.05). HUVEC transfection with sNogo-B vector achieved a 4-5 folds increase in sNogo-B in the cell supernatant when compared to control vector (p<0.001). Overexpression of sNogo-B improved the impaired tube formation observed in cells incubated with T1DM/DN+ sera (p<0.05). No significant effect of the overexpression was seen within the group incubated with T1DM/DN- sera.

Conclusion: High glucose and VEGF-A downregulate Nogo-B, an event paralleled by upregulation of sNogo-B. Overexpression of sNogo-B improves the impaired angiogenesis seen in cells incubated with sera from patients with T1DM/DN+. Circulating sNogo levels may influence the progression of kidney disease in diabetes and future work will address this question in experimental model of diabetes and in the clinical setting. The renal protective effects of induction of heme oxygenase-1 combined with increased adiponectin on the glomerular VEGF-NO axis in obese rats

F. Han¹, X. Liu², N. Hou², X. Sun²;

¹Department of Pathology, Affiliated Hospital of Weifang Medical University, ²Department of Endocrinology, Affiliated Hospital of Weifang Medical University, China.

Background and aims: The uncoupling of glomerular vascular endothelial growth factor (VEGF) - nitric oxide (NO) axis is an important mechanism of obesity-related nephropathy. The beneficial effects of heme oxygenase-1(HO-1) induction in metabolic disease are mediated via its effects on adiponectin-dependent pathways, which is called the HO-1/adiponectin axis This study aimed to investigate whether induction of

heme oxygenase-1 (HO-1) can reduce microalbuminuria and provide renal protective effects by improving endothelial dysfunction and uncoupling of glomerular VEGF-NO axis through increasing the adiponectin levels in obese rats.

Materials and methods: Rats received high-fat diets and were injected with either cobalt protoporphyrin (CoPP) to induce HO-1, or stannous protoporphyrin to inhibit HO-1. Blood and urine samples were collected. Endothelial function was determined by measuring endothelium-dependent vasodilatation of the aorta. Renal tissues were collected for CD34 immunohistochemistry. Glomerular NO levels were measured by the Griess reaction. Glomerular AMPK, Akt and eNOS protein were measured by western blot.

Results: Obese rats exhibited a significant increase in body weight, visceral fat, albumin-to-creatinine, plasma FFA levels, and serum levels of triglyceride, hs-CRP, TNF- α and malondialdehyde when compared with the control rats ($P < 0.01$). Induction of HO-1 by CoPP resulted in a significant decrease in the above index in obese rats when compared with untreated obese rats (body weight, 579.7 ± 66.5 g vs 702.3 ± 94.4 g; visceral fat, 24.8 ± 10.3 g vs 54.90 ± 14.18 g; albumin-to-creatinine, 49.25 ± 14.93 mg/g vs 94.1 ± 16.27 mg/g; FFA, 0.74 ± 0.31 mmol/L vs 1.29 ± 0.36 mmol/L; hs-CRP, 1.04 ± 0.41 mg/L vs 2.28 ± 0.61 mg/L; TNF- α , 56.8 ± 8.9 pg/ml vs 92.5 ± 0.2 pg/ml; malondialdehyde, 2.28 ± 0.51 μ mol/L vs 3.92 ± 0.51 μ mol/L, $P < 0.01$). Serum adiponectin levels were reduced in obese rats compared with control rats (12.77 ± 2.77 mg/g vs 20.34 ± 2.76 mg/g, $P < 0.01$), which increased after induction of HO-1 (19.35 ± 2.67 mg/g vs 12.77 ± 2.77 mg/g, $P < 0.01$). Severe endothelium-dependent vasodilatation impairment was observed in the obese rats, which was partially improved by HO-1 induction. CD34 expression in the glomeruli was also enhanced in obese rats, indicating increased proliferation of glomerular endothelial cells [mean optical density (IOD/area): 0.123 ± 0.015 vs. 0.094 ± 0.010 , $P < 0.05$]. However, induction of HO-1 improved the increased proliferation of endothelial cells in glomeruli in obese rats (IOD/area: 0.101 ± 0.009 vs. 0.123 ± 0.015 , $P < 0.05$). Obese rats showed increased glomerular VEGF expression and reduced NO levels ($P < 0.05$). This uncoupling of the VEGF-NO axis was partially improved by induction of HO-1, with enhancement of phosphorylation of glomerular AMPK, AKT and eNOS in obese rats ($P < 0.05$).

Conclusion: Induction of HO-1 with CoPP, paralleled by an increase in serum adiponectin levels, reduces the degree of microalbuminuria and has renal protective effects by improving endothelial dysfunction and regulating the uncoupled glomerular VEGF-NO axis in diet-induced obese rats. The mechanism may be related to increased activation of the HO-1/adiponectin axis.

Cellular hypoxia and mitochondrial reactive oxygen species may promote hyperglycaemic damage in a coordinated manner

S. Kiminori¹, T. Nishikawa², D. Kukidome¹, N. Kajiwara¹, H. Motoshima¹, T. Matsumura¹, E. Araki¹;

¹Metabolic Medicine, Kumamoto University, ²Molecular Diabetology, Kumamoto University, Japan.

Background and aims: We previously proposed that hyperglycemia-induced mitochondrial reactive oxygen species (mtROS) production is a key event in the development of diabetic complications. However, “legacy effect” and “metabolic memory”, which are reported in DCCT/EDIC and UKPDS, respectively, cannot be explained by the theory. Interestingly, there are some common points between hyperglycemia and hypoxia-induced phenomena such as apoptosis and fibronectin production. Therefore, we suspect that hyperglycemia may induce cellular hypoxia, which can produce mtROS without hyperglycemia.

Materials and methods: Bovine aortic endothelial cells (BAEC), C57BL6 mice, and eMnSOD-Tg mice (which express manganese

superoxide dismutase (MnSOD) specifically in vascular endothelial cells) were used for analysis. Cellular hypoxia was evaluated by hypoxia-sensing probes, pimonitazol and LOX-1. mtROS was measured by the reduced MitoTracker Red probe. Apoptosis was evaluated by TUNEL assay. Fibronectin mRNA was measured by quantitative RT-PCR.

Results: 1) In BAEC, cellular hypoxia evaluated by pimonitazol and LOX-1 increased 1.9 and 2.0 times, respectively, after 3 hours incubation with hyperglycemic condition (25 mM glucose) compared to that with normoglycemic condition (5.5 mM glucose), and this phenomenon was also observed after 24, 72 or 168 hours incubation with hyperglycemic condition. Hypoxia was also observed in the glomeruli of STZ-induced diabetic mice compared to those of control non-diabetic mice. 2) In BAEC, mtROS production was increased in both hyperglycemic and hypoxic condition (1, 3, 5 or 10% oxygen). The hypoxia-induced mtROS production was reduced by Bis-2-(5-phenylacetamido-1, 3, 4-thiadiazol-2-yl) ethyl sulfide (BPTES), which can inhibit glutamine incorporation into mitochondria, whereas hyperglycemia-induced mtROS production was not reduced by BPTES. 3) Rotenone and antimycin, both of which can reduce oxygen consumption in mitochondria, ameliorated hyperglycemia-induced cellular hypoxia. Interestingly, the hyperglycemia-induced cellular hypoxia was also reduced by the overexpression of MnSOD in BAEC and in eMnSOD-Tg mice. 4) The overexpression of aquaporin-1, which is a water and gas channel, ameliorated hyperglycemia-induced cellular hypoxia, apoptosis and fibronectin mRNA induction in BAEC.

Conclusion: The findings of this study demonstrate that hyperglycemia can induce cellular hypoxia, and the hypoxia can increase mtROS production without hyperglycemia. In addition, increased oxygen consumption and overproduction of mtROS are involved in hyperglycemia-induced cellular hypoxia. Ameliorating cellular hypoxia by the overexpression of aquaporin-1 can inhibit apoptosis and fibronectin production by hyperglycemia. Therefore, hyperglycemia-induced mtROS production and cellular hypoxia may develop diabetic complications in a coordinated manner, and these phenomena may be one of the mechanisms of “legacy effect” and “metabolic memory”.

Weight loss improves impaired muscle capillary recruitment in overweight/obese men: effects on metabolic insulin resistance

Y.H.A. Kusters^{1,2}, C.G. Schalkwijk^{1,2}, A.J.H. Houben¹, J. Op 't Roodt^{1,2}, P.J. Joris^{3,2}, R.P. Mensink^{3,2}, E.J. Barrett⁴, C.D.A. Stehouwer¹; ¹Department of Internal Medicine, MUMC, Maastricht, ²Top Institute Food and Nutrition, Wageningen, ³Department of Human Biology, MUMC, Maastricht, Netherlands, ⁴Department of Medicine, Endocrinology and Metabolism, University of Virginia, Charlottesville, USA.

Background and aims: Overweight and obesity are associated with metabolic insulin resistance, and an increased risk of type 2 diabetes (T2DM) and cardiovascular diseases (CVD). In skeletal muscle, insulin normally increases the number of perfused capillaries, enhancing its own delivery and that of glucose to myocytes. Impairments in insulin-induced muscle capillary recruitment may be responsible for the metabolic insulin resistance in obese individuals. It is, however, unknown whether weight loss can restore capillary recruitment and whether this improves metabolic insulin sensitivity. Therefore, we compared healthy lean men to overweight/obese men and subsequently studied the effect of weight loss in the latter.

Materials and methods: In a randomized controlled trial with blinded analyses, 53 non-smoking, overweight/obese men (waist circumference 102–110 cm; aged 18–65; no CVD or T2DM) underwent either an 8-week weight loss program (6 weeks low calorie diet (LCD), 2 weeks weight stable) or maintained their usual diet for 8 weeks and were compared to 25 lean men (waist circumference <94 cm). During a 1 mU/kg/min euglycaemic insulin clamp, we estimated metabolic insulin sensitivity from the glucose infusion rate (GIR) and forearm muscle capillary recruitment as the change in microvascular blood volume (Δ MBV) using contrast-enhanced ultrasound. Overweight/obese men were studied at baseline and after completion of their 8-week program, whereas lean men were studied at baseline only.

Results: All 25 lean men and 50 overweight/obese men completed the study. Baseline BMI was 23.3 ± 1.8 kg/m² in lean men, 29.9 ± 2.5 kg/m² in the usual-diet group, and 30.0 ± 1.7 kg/m² in the LCD group. LCD reduced BMI by 3.0 ± 0.8 kg/m² ($p < 0.001$), whereas BMI in the usual-diet group did not change ($+0.1 \pm 0.4$ kg/m²). Insulin-induced Δ MBV at baseline was $44.4 \pm 41.2\%$ in lean men; in both the usual-diet ($0.7 \pm 27.6\%$) and the LCD group ($-5.6 \pm 26.2\%$) capillary recruitment was blunted ($p < 0.001$). LCD was able to restore part of this response, to $33.4 \pm 39.6\%$ ($p < 0.001$), whereas Δ MBV remained unchanged in the usual-diet group ($0.4 \pm 25.4\%$). Baseline metabolic insulin sensitivity was 6.76 ± 1.79 mg/kg/min in lean men, 4.03 ± 1.39 mg/kg/min in the usual-diet group, and 4.06 ± 1.28 mg/kg/min in the LCD group. LCD increased insulin sensitivity by 1.31 ± 1.19 mg/kg/min ($p < 0.001$), whereas insulin sensitivity remained unaltered in the usual-diet group. At baseline, Δ MBV was associated with both BMI ($r = -0.414$; $p < 0.001$) and GIR ($r = 0.577$; $p < 0.001$). Moreover, changes in Δ MBV were accompanied by changes in GIR ($r = 0.499$; $p < 0.001$).

Conclusion: We conclude that both insulin-induced muscle capillary recruitment and metabolic insulin sensitivity are impaired in overweight/obese men. LCD-induced weight loss was associated with improved insulin-induced muscle capillary recruitment and insulin sensitivity. Furthermore, these changes were related to one another. These findings support the hypotheses that impaired vascular actions of insulin contribute to metabolic insulin resistance in overweight/obese individuals and that weight loss improves both.

Impaired metabolism and transcriptional profile in cultured muscle stem cells from individuals born with low birth weight

N.S. Hansen¹, L. Hjort¹, C. Broholm¹, L. Gillberg¹, M. Schrölkamp¹, B. Mortensen², S.W. Jørgensen³, M. Friedrichsen⁴, J.F.P. Wojtaszewski⁴, B.K. Pedersen⁵, A. Vaag¹;

¹Department of Endocrinology, Rigshospitalet, Copenhagen, ²Center for Diabetes Research, Gentofte Hospital, ³Steno Diabetes Center A/S, Gentofte, ⁴Department of Nutrition, Exercise and Sports, University of Copenhagen, The August Centre, Copenhagen, ⁵Centre of Inflammation and Metabolism, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Individuals born with low birth weight (LBW) have an increased risk of developing type 2 diabetes (T2D) later in life. We hypothesized that immature muscle stem cell functions including abnormal differentiation potential and metabolic function could link LBW with risk of developing T2D.

Materials and methods: We recruited 23 young men with LBW (mean birth weight 2.7 ± 0.2 kg) and 16 age-matched control subjects (mean birth weight 3.7 ± 0.2 kg) with normal birth weight. Biopsies were obtained from vastus lateralis and muscle stem cells were isolated and cultured into fully differentiated myotubes. We studied glucose uptake, insulin signaling, myokine secretion, selected site specific DNA methylation and key transcriptional markers of cell maturity as well as mitochondrial gene expression throughout cell differentiation.

Results: In the cultured LBW cells, we found significantly reduced glucose uptake, decreased glucose transporter-4 gene expression and decreased levels of Akt substrate of 160 kDa compared to NBW cells. Additionally, interleukine-6 release was increased during myoblast differentiation and the expression levels of a selected set of mitochondrial OXPHOS genes including the peroxisome proliferator-activated receptor- γ coactivator-1 α (PGC-1 α), as well as the sarcomere gene myosin heavy chain 2, were down regulated in LBW cells. Decreased gene expression was not explained by changes in DNA methylation levels in gene promoter regions.

Conclusion: Our findings of transcriptional and metabolic changes in cultured muscle stem cells from LBW subjects support the idea of altered muscle stem cells function potentially contributing to increased risk of developing T2D in these subjects.

Maternal obesity and telomere length associate with skeletal muscle insulin resistance which is reversed by exercise training in elderly women

M. Bucci¹, V. Huovinen^{1,2}, M.A. Guzzardi³, S. Koskinen¹, J. Raiko¹, H. Lipponen¹, R.M. Badeau¹, N. Sarja¹, M. Salonen⁴, J. Andersson⁵, J. Kullberg⁵, S. Sandbøge⁴, P. Iozzo³, J.G. Eriksson^{4,6}, P. Nuutila^{1,7};

¹Turku Pet Centre, ²Department of Radiology, Medical Imaging Centre of Southwest Finland, Turku University and Turku University Hospital, Finland, ³PET Centre, Institute of Clinical Physiology, National Research Council, Pisa, Italy, ⁴Folkhälsan Research Centre, Helsinki, Finland, ⁵Department of Radiology, Uppsala University, Sweden, ⁶University of Helsinki, ⁷Department of Medicine, University of Turku and Turku University Hospital, Finland.

Background and aims: Maternal obesity during pregnancy predisposes for subsequent morbidities in the offspring, including type 2 diabetes. T2DM and insulin resistance have been associated with shortening of leucocyte telomere length (LTL). Effects of resistance training (RT) on whole body and skeletal muscle glucose disposal are not known in elderly. The aims of this study were to test insulin sensitivity in elderly frail

women with maternal obesity and test the effects of RT on muscle insulin sensitivity and masses.

Materials and methods: We recruited 48 women with the mean age of 72 years, of which 11 were non-frail controls (CTR), 20 frail offspring of lean/normal weight mothers (OLM) ($\text{BMI} \leq 26.3 \text{ kg/m}^2$) and 17 frail offspring of obese mothers (OOM) ($\text{BMI} \geq 28.1 \text{ kg/m}^2$). The frail women were studied before and after a 4 mo RT intervention, and controls once using FDG-PET during hyperinsulinemic euglycaemic clamp and MRI for the measurement of skeletal muscle mass. Glucose uptake (GU/kg) and accounting for masses (GU(depot)) were calculated for the skeletal muscles of the thigh. LTL was assessed from peripheral blood mononuclear cells.

Results: The OOM group had a lower thigh muscle insulin sensitivity compared to the OLM group ($p=0.048$). Significant positive correlations were found in the OOM group between LTL and thigh muscle GU/(kg and depot) ($R \geq 0.53$, $p \leq 0.05$). Training increased whole body ($p=0.004$) and skeletal muscle insulin sensitivity both per volume and per total muscle mass ($p=0.013$ and $p=0.004$, respectively). Quadriceps muscle mass increased by intervention in both groups ($p=0.008$ and $p=0.001$, OLM and OOM respectively).

Conclusion: Maternal obesity during pregnancy and telomere length are associated with insulin resistance in the adult offspring. RT helps to reverse the insulin resistance in elderly women with maternal obesity. RT is equally effective in increasing muscle mass in elderly women regardless of their maternal BMI.

Impaired PI 3-kinase signalling in a mouse model of SHORT syndrome

M.H. Solheim^{1,2}, J.N. Winnay¹, A. Molven^{2,3}, P.R. Njølstad^{2,4}, C.R. Kahn¹;

¹Joslin Diabetes Center, Harvard Medical School, Boston, USA, ²KG Jebsen Center for Diabetes Research, Dept of Clinical Science, University of Bergen, ³Gade Laboratory for Pathology, Dept of Clinical Science, University of Bergen, ⁴Dept of Pediatrics, Haukeland University Hospital, Bergen, Norway.

Background and aims: The phosphatidylinositol 3-kinase (PI3K) pathway regulates a range of cellular functions involving glucose metabolism, cell growth, differentiation and apoptosis. A key factor regulating this pathway is the p85 α regulatory subunit of PI3K, encoded by the PIK3R1 gene. We recently identified a heterozygous missense mutation in PIK3R1 resulting in an Arg649Trp substitution in patients with SHORT syndrome, characterized by short stature, partial lipodystrophy and insulin resistance. To investigate whether the Arg649Trp mutation alone is sufficient to replicate characteristic features of SHORT syndrome in vivo and to explore the function of the mutant protein at a mechanistic level, we generated knock-in mice harboring this mutation.

Materials and methods: Body weight was assessed longitudinally at the indicated time-points. Body composition, length, blood glucose, serum insulin and glucose tolerance tests were performed on animals at the indicated ages. Insulin signaling was assessed in adipose tissue, liver and skeletal muscle, snap frozen ten minutes following intra venous administration of vehicle or insulin. Western blotting was performed on whole cell lysates isolated from brown preadipocyte cell lines or primary hepatocytes.

Results: Heterozygous knock-in mice demonstrated multiple features of SHORT syndrome including a reduction in body weight and length, a Rieger like abnormality in the iris and a reduction in subcutaneous adipose tissue. By 8 weeks, knock-in mice were hyperglycemic in the fed state compared to controls (17.7 ± 1.4 vs. $11.8 \pm 0.9 \text{ mmol/l}$). An assessment of insulin levels at the same age revealed marked hyperinsulinemia in mutant animals (fed insulin 107.9 ± 12.9 vs. $8.9 \pm 1.2 \text{ pmol/l}$). Mutant mice also demonstrated a clear impairment in glucose tolerance and a

reduced response to exogenous insulin. At a molecular level, this was caused by reduced activation of the PI 3-kinase pathway in adipose tissue and liver in response to insulin assessed by the phosphorylation of AKT. Brown preadipocyte cell lines and primary hepatocytes from control and heterozygous mutant mice showed a distinct reduction in insulin-dependent phosphorylation of AKT. Primary hepatocytes demonstrated a reduction in phosphorylation of AKT upon stimulation with additional growth factors including IGF-1 and EGF, suggesting resistance to multiple growth factors. The reduced capacity of the mutant protein to link the upstream activation of the insulin signaling pathway with the downstream activation of AKT is due to a failure of the mutant protein to bind to IRS-1 following insulin stimulation.

Conclusion: Mice heterozygous for the Arg649Trp mutant allele phenocopy multiple aspects of the human SHORT syndrome, including a reduction in weight and length, partial lipodystrophy associated with a selective reduction in subcutaneous adipose tissue and insulin resistance. At a mechanistic level, we have demonstrated that the mutant protein fails to interact with IRS-1 in response to insulin, leading to impaired activation of AKT.

HIF-1 α transcription factor: a molecular link between exercise and insulin action

S.W. Görgens¹, K. Eckardt¹, M. Hjorth², F. Norheim², T. Holen², S. Lee², T.M. Langlete², K.I. Birkeland², H.L. Gulseth², C.A. Drevon², J. Eckel¹;

¹German Diabetes Center, Düsseldorf, Germany, ²Department of Nutrition, University of Oslo, Oslo, Norway.

Background and aims: Skeletal muscle insulin resistance is the hallmark of type 2 diabetes, and develops long before the onset of the disease. It is well accepted that regular physical activity improves glycemic control but the knowledge on underlying mechanisms mediating the protective effects remains incomplete. Exercise is accompanied by a reduction in intra-muscular oxygen tension resulting in enhanced HIF-1 α protein expression. HIF-1 α is a master regulator of gene expression and might play an important role in skeletal muscle function and metabolism. Thus, we examined the role of oxygen tension in insulin- and contraction-stimulated glucose metabolism in primary human skeletal muscle cells (HskMC). Furthermore, we analyzed the impact of acute and long-term exercise on skeletal muscle HIF-1 α expression in healthy control and dysglycemic subjects.

Materials and methods: HskMC were in vitro differentiated and electrical pulse stimulation (EPS) was applied at different oxygen tensions. Insulin action was measured by the phosphorylation of kinases of the insulin signaling pathway and glucose uptake. Sedentary individuals for the human study were divided in two groups; controls ($n=13$) with normal glucose metabolism and dysglycemic subjects (pT2D; $n=11$). All participants were subjected to a training program for 12 weeks. An acute exercise session was performed before and after the 12 weeks of training intervention. Muscle biopsies were taken before, directly after, and 2 h after the acute exercise before as well as after 12 weeks of training. Whole body insulin sensitivity was assessed by euglycemic-hyperinsulinemic clamp.

Results: Reduced O₂ tension in combination with EPS strongly enhanced the insulin action at the level of Akt and AS160 phosphorylation as well as glucose uptake. Furthermore, the combination of 7% O₂ and EPS resulted in an enhanced IL-6 production and secretion as well as HIF-1 α and GLUT4 protein expression. In contrast, knockdown of HIF-1 α totally inhibits the insulin- and contraction-induced glucose uptake as well as insulin-stimulated signaling. Furthermore, GLUT4 and GLUT1 protein expression were decreased. In addition, human skeletal muscle HIF-1 α mRNA expression was enhanced after acute and long-term exercise, and positively correlated with glucose infusion rate ($p=$

0.03; $r=0.47$) and negatively with fasting glucose ($p=0.02$; $r=-0.49$). Interestingly, the induction of exercise-mediated HIF-1 α mRNA expression was reduced in the pT2D group.

Conclusion: We have demonstrated that the reduction of oxygen to 7% and the combination with muscle contraction improved insulin action in primary human skeletal muscle cells. Furthermore, we showed that HIF-1 α is an important determinant in insulin- and contraction-induced glucose uptake. Muscle HIF-1 α mRNA expression was up-regulated by acute and long-term exercise, and positively correlated with whole body insulin sensitivity in subjects with normal glucose metabolism. Thus, we suggest that muscle HIF-1 α is a key regulator of insulin- and exercise-stimulated glucose metabolism in human skeletal muscle.

The influence of hyperinsulinaemia and circulating NEFA elevation on sirtuin 1 expression in human skeletal muscle

M. Stefanowicz^{1,2}, N. Matulewicz^{1,2}, A. Nikolajuk², M. Strączkowski^{1,2}, M. Karczewska-Kupczewska^{1,2};

¹Department of Metabolic Diseases, Medical University of Białystok,

²Department of Prophylaxis of Metabolic Diseases, Polish Academy of Sciences, Olsztyn, Poland.

Background and aims: Sirtuin 1 (SIRT1), belonging to the family of sirtuins (Sir2, silent information regulator 2 protein) is involved in the regulation of glucose and lipid metabolism. SIRT1 has been proposed to be an important regulator of insulin sensitivity. SIRT1 stimulates a glucose-dependent insulin secretion from pancreatic β cells and may influence directly or indirectly on insulin signaling pathway in insulin sensitive cells. Furthermore, SIRT1 in interaction with PGC1 α could increase fatty acid oxidation and glucose uptake in muscle, which also can prevent insulin resistance. The aim of our study was to estimate the relationship between muscle SIRT1 and insulin signaling and the effects of hyperinsulinemia and NEFA elevation on skeletal muscle SIRT1 expression in humans.

Materials and methods: We examined 108 apparently healthy men with normal glucose tolerance (age: 23.30 ± 2.7 years; BMI: 25.7 ± 4.0 kg/m²). In all subjects insulin sensitivity was evaluated by the 2 h euglycemic-hyperinsulinemic clamp. Additionally, in 20 subjects, clamp was prolonged to 6 hours. After one week, another 6 h clamp combined with Intralipid/heparin infusion was performed in 20 volunteers. In all subjects before the clamp muscle biopsy was performed. In 20 individuals with prolonged clamps, muscle biopsy were taken before and after 6 h clamp with and without Intralipid/heparin infusion. Tissue mRNA expression of SIRT1 and IRS1, IRS2, PIK3R1, PIK3CA, Akt2, SLC2A4, PGC1 α was analyzed with Real Time PCR.

Results: Intralipid/heparin infusion caused 4-fold concentration NEFA in serum ($p<0.001$). Insulin sensitivity was decreased by about 40% after 6 h Intralipid/heparin infusion ($p<0.001$). Hyperinsulinemia increased muscle SIRT1 expression ($p=0.016$), whereas in the presence of Intralipid/heparin infusion this stimulatory effect of hyperinsulinemia was abolished. Hyperinsulinemia resulted in a significant increase in the expression of PIK3R1 ($p<0.001$), Akt2 ($p=0.007$), SLC2A4 ($p=0.02$) and PGC1 α ($p<0.001$). Intralipid/heparin infusion abolished most of these changes. We observed a positive correlation between the expression of SIRT1 and expression of IRS2 ($r=0.31$, $p<0.001$), PIK3R1 ($r=0.26$, $p=0.007$), PIK3CA ($r=0.26$, $p=0.008$), Akt2 ($r=0.45$, $p<0.001$), SLC2A4 ($r=0.24$; $p=0.011$) and PGC1 α ($r=0.21$; $p=0.03$) in the baseline state. Increase in muscle SIRT1 expression in response to hyperinsulinemia was related to the concurrent change in PGC1 α ($r=0.46$, $p=0.049$) and SLC2A4 ($r=0.52$, $p=0.02$).

Conclusion: Our results indicate that insulin increases muscle SIRT1 expression and this effect is abolished by circulating NEFA elevation. Thus, muscle SIRT1 may be involved in lipid- induced insulin resistance. Supported by: UDA-POIG.01.03.01-00-128/08-00

OP 07 A glimpse at future diabetes therapy

Pharmacokinetics, pharmacodynamics and tolerability of a novel glucokinase activator TMG-123, after single oral ascending doses in Japanese healthy subjects

T. Kimura, K. Sakurai, K. Morino, M. Shimizu, T. Ishikawa, K. Shiobara, S. Suzuki, M. Taneda, M. Yamamoto; Teijin Pharma Limited, Tokyo, Japan.

Background and aims: TMG-123 is a novel glucokinase activator with a postulated liver dominant mechanism of action and with the potential to deliver effective glucose-lowering in Type 2 diabetes mellitus. Two Phase I studies were conducted to evaluate the pharmacokinetics (PK), pharmacodynamics (PD) and tolerability of TMG-123 in Japanese healthy male subjects after single oral ascending doses.

Materials and methods: Two, double-blinded, randomized, placebo-controlled studies were conducted. Gradually increasing single oral doses of 1 mg up to 160 mg TMG-123 or placebo were administered during fasting conditions. Each subject participated once, either on TMG-123 or on placebo, with the exception of one dose group in the second study. Subjects in this group participated on 2 occasions, once on TMG-123 / placebo given in fasting conditions and once on TMG-123 / placebo given in combination with a standardized breakfast. Eight dose levels were evaluated in the first study and four in the second study. The PK and PD variables were calculated by non-compartmental analyses.

Results: In total, 96 Japanese healthy male volunteers aged from 20 to 34 years were participated, and from 1 mg to 160 mg of TMG-123 or placebo were administered. TMG-123 was well tolerated up to 160 mg dose without serious adverse event or hypoglycemia, and most adverse events were mild. No clinically significant changes in ECG, vital signs, or safety laboratory assessments were observed. Following TMG-123 dosing in fasting conditions, TMG-123 was rapidly absorbed at all dose levels studied. The maximum concentration of TMG-123 in plasma (C_{max}) was generally reached within 1 hour after dosing. In the first study, C_{max} and AUC were increasing in dose up to 40 mg, whereas C_{max} / AUC were increasing in dose up to 80 / 160 mg in the second study. TMG-123 dosing in 30 minutes after the standardized breakfast had no effect on C_{max} , while AUC was slightly increased and the time reached C_{max} was delayed compared to fasting conditions. The plasma TMG-123 concentration dependent serum glucose decrease was observed up to around 200 ng/mL of plasma TMG-123 level, whereas plasma TMG-123 level was reached around 500 ng/mL in the studies. A serum glucose lowering effect was maintained during a fasting period. A serum insulin level was transiently increased at 0.5 hours post-dose to around 15 μ U/mL over 80 mg dosing. No dose dependent serum glucagon changes were observed.

Conclusion: TMG-123 was well tolerated in single doses up to 160 mg, and no safety concerns were raised. TMG-123 was rapidly absorbed in fasting conditions and no significant food effect on C_{max} and AUC were observed. The PK / PD result suggests a liver dominant glucokinase activation of TMG-123 in humans.

ISIS PTP-1BRx, a novel PTP-1B antisense inhibitor, improves HbA_{1c} and body weight in patients with type 2 diabetes on metformin±sulphonylurea

A. Digenio, L. Watts, B. Jung, R. Geary, S. Bhanot; Clinical Development, Isis Pharmaceuticals, Inc., Carlsbad, USA.

Background and aims: Protein-tyrosine phosphatase 1B (PTP-1B) is a negative modulator of insulin and leptin signaling. Inhibition of PTP-1B

action could address both diabetes and obesity, making it an attractive target for drug development. This study evaluated the safety, tolerability and efficacy of 6-month treatment with a PTP-1B antisense inhibitor (ISIS PTP-1B_{Rx}) in a double-blind placebo-controlled, Phase 2 study in overweight patients with Type 2 diabetes inadequately controlled on metformin with or without sulphonylurea (SU).

Materials and methods: Patients, mean age 57, 63% female, 53% Black, with a hemoglobin A1c $\geq 7.5\%$ and a mean BMI of 34 kg/m² were randomized to ISIS PTP-1B_{Rx} 200 mg or placebo administered as once weekly subcutaneous injections for 26 weeks. Patients had to be on a stable dose of metformin (≥ 1000 mg/day) alone or in combination with SU (≥ 10 mg/day). Seventy-five patients completed treatment and 69 were evaluated for the primary endpoint based on protocol specified criteria.

Results: Data are Mean \pm SD; #Mean Change (Δ) from Baseline to Week 36 ISIS-PTP-1B_{Rx} was well-tolerated and did not cause severe hypoglycemia, gastrointestinal side effects or clinically significant changes in hepatic or renal function.

Conclusion: In this study, ISIS PTP-1B_{Rx} treatment was generally safe and well tolerated and resulted in significant reductions in HbA1c and body weight that continued after cessation of treatment. ISIS PTP-1B_{Rx} showed an attractive profile that includes improved glycaemic control without severe hypoglycemia and with the additive benefit of weight loss, supporting future development in patients with Type 2 diabetes.

Improved postprandial glycaemic control with faster-acting insulin aspart in individuals with type 1 diabetes using CSII

B.W. Bode¹, L. Hyveled², S.C. Tamer², P. Ybanez¹, M. Demissie²;

¹Atlanta Diabetes Associates, Atlanta, USA, ²Novo Nordisk A/S, Søborg, Denmark.

Background and aims: This double-blind, randomised, crossover, active-controlled trial compared 14 days of continuous subcutaneous insulin infusion (CSII) of two formulations of faster-acting insulin aspart (faster aspart) with CSII of insulin aspart (IAsp) in 43 adults with type 1 diabetes. Only data for the faster aspart formulation undergoing further development are presented.

Materials and methods: The primary endpoint was the mean change in postprandial glucose response 2 h after a standardised meal test (individualised insulin dosing by bolus calculator), as evaluated by mean change in plasma glucose (Δ PG_{av,0-2h}). Subjects had blinded continuous glucose monitoring (CGM) during the trial.

Results: Faster aspart provided statistically significant lower Δ PG_{av,0-2h}, compared with IAsp (3.03 vs 4.02 mmol/L; mean difference [95% CI]: -0.99 [-1.95; -0.03]; Table). The greater glucose-lowering effect demonstrated at meals with faster aspart vs IAsp was confirmed by interstitial glucose (IG) profiles, with the largest differences at breakfast (Table). The duration of low IG (≤ 3.9 mmol/L per 24 h) was significantly longer for IAsp (2.45 h) than faster aspart (2.03 h; mean difference [95% CI]: -0.42 [-0.72; -0.11]). No new safety findings were observed with faster aspart compared with IAsp.

Conclusion: In summary, faster aspart had significantly greater glucose-lowering effect than IAsp after a standardised meal, with findings confirmed by CGM for all meals, and less time spent with low glucose levels, as measured by IG.

Table: Glucose-lowering effect of faster aspart vs IAsp

Basal insulin peglispro is superior to insulin glargine in reducing HbA1c in insulin-naïve patients with type 2 diabetes treated with oral antihyperglycaemic drugs: IMAGINE 2

M.J. Davies¹, D. Russell-Jones², J.-L. Selam³, T.S. Bailey⁴, Z. Kerényi⁵, J. Luo⁶, J. Bue-Valleskey⁶, T. Iványi⁷, M.L. Hartman⁶, J.G. Jacobson⁶, S.J. Jacober⁶;

¹University of Leicester Diabetes Research Centre, Leicester, ²Royal Surrey County Hospital, Guildford, UK, ³Diabetes Research Center, Tustin, ⁴AMCR Institute, Inc., Escondido, USA, ⁵Csepe Health Service, Budapest, Hungary, ⁶Eli Lilly and Company, Indianapolis, USA, ⁷Eli Lilly and Company, Budapest, Hungary.

Background and aims: Basal insulin peglispro (BIL) is a novel basal insulin with a flat activity profile which has a hepato-preferential action resulting from reduced peripheral effects. The primary objective of this Phase 3, double-blind, treat-to-target study was to assess whether BIL was non-inferior (margin=.4%) to insulin glargine (GL) at 52 weeks in reducing HbA1c when added to prestudy oral antihyperglycaemic medications in patients with type 2 diabetes.

Materials and methods: Patients were randomised to evening dosing of BIL (N=1003) or GL (N=535); 168 patients underwent magnetic resonance imaging to assess liver fat content. Testing of the primary objective for superiority was pre-specified with adjustment for multiplicity.

Results: BIL-treated patients had statistically superior HbA1c change at week 52 compared to GL-treated patients (-1.6 vs -1.3%; Δ = -.3% [95% CI: -.40, -.19]), with lower HbA1c (6.9 vs 7.2%, $p < .001$) and more at goal (HbA1c $\leq 6.5\%$: 36 vs 24%, $p < .001$; HbA1c $< 7.0\%$: 58 vs 43%, $p < .001$). Within-day glycaemic variability using standard deviation (SD) of SMBG profiles was lower for BIL (1.7 \pm .03 vs 1.9 \pm .04 mmol/L [31 \pm 5 vs 34 \pm 7 mg/dL], $p = .003$), as was between-day fasting glycaemic variability (SD of the prior 7 days) (.9 \pm .02 vs 1.0 \pm .03 mmol/L [16 \pm 4 vs 17 \pm 5 mg/dL], $p = .02$). Total hypoglycaemia rates were similar (BIL vs GL: 1.16 \pm .06 vs 1.21 \pm .07 events/patient/30 days) as was incidence of severe hypoglycaemia (.4 vs .6%). Nocturnal hypoglycaemia rates were lower with BIL (.30 \pm .02 vs .40 \pm .03 events/patient/30 days, $p < .001$). More patients had HbA1c $< 7\%$ without nocturnal hypoglycaemia

(LOCF) with BIL (26%) than with GL (15%), $p < .001$. At week 52, weight gain was less with BIL (2.1 ± 2 vs 2.6 ± 2 kg, $p = .046$), but insulin dose was higher ($.45 \pm .01$ vs $.42 \pm .01$ U/kg, $p = .022$). Thus BIL was titrated to a higher dose than GL with similar total hypoglycaemia, lower HbA1c, and less weight gain. At week 52, triglycerides increased with BIL and decreased with GL ($.12 \pm .03$ mmol/L [11 ± 2 mg/dL] vs $-.08 \pm .04$ mmol/L [-7 ± 3 mg/dL], $p < .001$). HDL- and LDL-cholesterol did not differ between groups. Adjudicated cardiovascular events were similar between BIL and GL. ALT increased 4.1 IU/L with BIL and decreased 2.0 IU/L with GL ($p < .001$). More BIL patients had ALT ≥ 3 X ULN (2.3% vs .6%, $p = .012$) but none met Hy's law criteria for acute, severe drug-induced liver injury. Liver fat content was unchanged with BIL ($-.6 \pm .5\%$, $p = .232$) but decreased $3.1 \pm .7\%$ with GL ($p < .001$; BIL vs GL, $p = .002$). Injection site reactions were more common with BIL (3.5% vs .6%, $p < .001$) and the majority of these were lipohypertrophy (2.1 vs .4%, $p = .007$).

Conclusion: At 52 weeks in this double-blind, treat-to-target study of insulin-naïve patients with type 2 diabetes, BIL provided greater reduction in HbA1c, less nocturnal hypoglycaemia, less weight gain, and higher triglycerides compared to GL, consistent with reduced peripheral insulin action and a hepato-preferential effect of BIL. Liver fat content was unchanged from baseline with BIL but decreased with GL.

Unique profile of the weekly insulin HM12470: very slow onset of action, rapid off-rate similar to insulin, and absence of insulin receptor downregulation

N. Wronkowitz¹, T. Hartmann¹, S.W. Görgens¹, D. Dietze-Schröder¹, I. Choi², S. Park², Y. Lee², S. Kwon², Y. Kang³, M. Hompesch³, J. Eckel¹; ¹Paul-Langerhans Group for Integrative Physiology, German Diabetes Center, Düsseldorf, Germany, ²Hanmi Pharmaceuticals Inc., Seoul, Republic of Korea, ³Profil Institute for Clinical Research, Chula Vista, USA.

Background and aims: The novel long-acting basal insulin HM12470 consists of an insulin analog (Insulin 115) conjugated to the non-glycosylated FC region of a human immunoglobulin fragment via non-peptidyl linker and is developed for once-weekly administration. Previously, extended pharmacokinetics and prolonged glucose lowering efficiency of HM12470 have been shown in rodents. The aim of the present study was to characterize the early steps of HM12470 signaling at the receptor and post-receptor level and to assess the metabolic and mitogenic potency of this analog in vitro.

Materials and methods: The off-rate of HM12470 was measured in H9C2-E2 cells by a competition binding assay with 125I-labelled regular insulin. The impact of HM12470, Insulin 115, AspB10 and regular insulin on the insulin signaling cascade was assessed in H9C2-E2, primary human vascular smooth muscle cells (hVSMC) and primary human skeletal muscle cells (hSkMC) by Western Blot analysis. To address functional endpoints, we analysed proliferation in hVSMC by BrdU incorporation and glucose uptake in hSkMC using 14C-labelled 2-deoxy-glucose.

Results: In H9C2-E2 cells overexpressing the human insulin receptor, we observed an off-rate for HM12470 very similar to regular insulin. At the receptor level, HM12470 and Insulin 115 showed no differences in the phosphorylation pattern of tyrosine 1146, 1150/1151 and 972 in comparison to insulin. HM12470 did not acutely activate Akt or MAPK signaling pathways in human skeletal (hSkMC) and human vascular smooth muscle cells (hVSMC). However, upon long-term stimulation we could detect a significant Akt phosphorylation after 24 or 48 h exposure to HM12470 in hSkMC and hVSMC, respectively. Remarkably, in the chronic treatment HM12470 did not induce downregulation of the insulin receptor in both hVSMC and hSkMC. Under these conditions, both regular insulin and AspB10 insulin completely abrogated the insulin receptor. At 100 nM, HM12470 did not induce proliferation of hVSMC in

sharp contrast to AspB10 insulin (2-3 fold stimulation). Acute stimulation of glucose uptake in hSkMC was obtained at EC50 values of 36.1 nM and 154.9 nM for regular insulin and HM12470, respectively. However, after 24 h exposure the HM12470-induced glucose uptake was similar to insulin.

Conclusion: In conclusion, the long-acting basal insulin HM12470 shows a flat profile of action without increased mitogenic potency and downregulation of the insulin receptor in vitro. Thus, HM12470 appears safe and it does not desensitize target cells under conditions of chronic exposure and therefore represents an excellent candidate for a weekly basal insulin.

Glucagon nasal powder: an effective alternative to intramuscular glucagon in youth with type 1 diabetes

J.L. Sherr¹, K.J. Ruedy², N.C. Foster², C. Piché³, H. Dulude³, M.R. Rickels⁴, W.V. Tamborlane¹, K.E. Bethin⁵, L.A. DiMeglio⁶, L.A. Fox⁷, R. Wadwa⁸, D.A. Schatz⁹, B.M. Nathan¹⁰, S.M. Marcovina¹¹, R.W. Beck²;

¹Yale School of Medicine, New Haven, ²Jaeb Center for Health Research, Tampa, USA, ³Loceemia Solutions ULC, Montreal, Canada, ⁴University of Pennsylvania Perelman School of Medicine, Philadelphia, ⁵School of Medicine and Biomedical Sciences at the University of Buffalo, The State University of New York, Buffalo, ⁶Indiana University School of Medicine, Indianapolis, ⁷Nemours Children's Clinic, Jacksonville, ⁸Barbara Davis Center for Childhood Diabetes, Aurora, ⁹University of Florida, Gainesville, ¹⁰University of Minnesota, Minneapolis, ¹¹Northwest Lipid Metabolism and Diabetes Research Laboratories, Seattle, USA.

Background and aims: Intramuscular glucagon (IM), in weight adjusted 0.5 and 1.0 mg doses, is the only currently available pharmacologic treatment for severe hypoglycemia in children and adolescents outside of the hospital setting. Unlike current IM emergency kits, needle-free dry-powder intranasal glucagon (IN) does not require reconstitution prior to administration. Having demonstrated that a 3 mg IN dose of glucagon effectively reverses hypoglycemia in adults with T1D, this study examined the dose response relationships of 2 mg and 3 mg IN glucagon in youth 4- <17 years of age.

Materials and methods: 45 youth with T1D were studied at 7 centers participating in the T1D Exchange. The two youngest cohorts (4- <8; 8- <12 yrs) were randomized to receive either IN administrations, of 2 mg and 3 mg IN on two separate days in double blind, random order or a single weight based-dose of IM glucagon. Subjects 12- <17 yrs received in random order, 1 mg IM at one session and 3 mg IN at another session. Glucagon was given after blood glucose was lowered to <80 mg/dL and the primary outcome was a ≥ 25 mg/dL rise in plasma glucose from nadir.

Results: The primary efficacy outcome was met after all IM and IN doses of glucagon within 10-20 minutes (Table) with one exception- a 6 yo who immediately blew his nose following a 2-mg dosage. Lack of absorption of the intranasal dose is supported by his low peak glucagon (324 pg/mL). Time to peak and peak glucagon levels were similar in both IM and IN conditions. Transient nausea (with or without vomiting) occurred with 67% of IM sessions vs. 42% of IN sessions ($P = 0.06$).

Conclusion: These data support the efficacy of a novel glucagon nasal powder delivery system for treatment of hypoglycemia in youth with T1D. Given the transient nature of adverse effects when they occur, we conclude that a single 3 mg IN dose can be safely used across the 4- <17-year range of pediatric patients.

Longitudinal trajectories of insulin sensitivity and beta cell function before the development of type 2 diabetes in Japanese individuals

Y. Heianza¹, Y. Arase², S. Kodama¹, H. Tsuji², S. Tanaka³, T. Kobayashi², S. Hara², H. Sone¹;

¹Department of Internal Medicine, Niigata University Faculty of Medicine, ²Health Management Center, Toranomon Hospital, Tokyo, ³Department of Pharmacoepidemiology, Graduate School of Medicine and Public Health, Kyoto University, Niigata, Japan.

Background and aims: Evidence is limited about long-term trajectories revealed through detailed assessments of insulin and glucose concentrations before the development of type 2 diabetes (T2D). We aimed to clarify the time point of deteriorating insulin sensitivity and beta-cell function that could be observed during the development of T2D among Japanese individuals.

Materials and methods: We investigated data on 474 Japanese individuals without T2D (T2D indicated by a self-report of clinician-diagnosed diabetes, fasting glucose concentrations of ≥7.0 mmol/L, HbA1c ≥6.5% or 2-h glucose concentrations of ≥11.1 mmol/L) who had available data on glucose and insulin concentrations. We assessed glucose and insulin concentrations during a 75-g oral glucose tolerance test over a 10-y follow-up. The homeostasis model assessment of insulin resistance (HOMA-IR), insulinogenic index (IGI) and the Matsuda index of whole body insulin sensitivity were calculated. The insulin secretion/insulin resistance index (disposition index, DI) was calculated as the product of the Matsuda index and IGI. Stumvoll first-phase and second-phase insulin release during OGTT were also evaluated.

Results: Individuals who did not develop T2D (n=420) had consistently low mean fasting values (<5.3 mmol/L) and postprandial glucose concentrations at 30 min (<8.6 mmol/L), 60 min (<8.4 mmol/L), 90 min (<7.3 mmol/L) and 120 min (<6.7 mmol/L) over 10 y. Those who later developed T2D (n=54) had higher glucose concentrations at 0 to 120 min even 10 y before diagnosis than those who did not develop T2D; incident cases of T2D also experienced a sharp increase in these glucose measures 3 y before diagnosis. A large difference between cases and non-cases was observed for glucose measurements at 60 min over the total observational period while glucose concentrations at 180 min specifically deteriorated only 1-2 y before diagnosis. Glucose concentrations at 60 min was significantly predictive of future T2D independently of glucose concentrations at 0 min and at 120 min. Interestingly, those who later developed T2D had constantly reduced IGI values, reduced Stumvoll insulin release levels and reduced DI values. These values remained low and did not markedly increase in the late stage before diagnosis. A sharp increase in the HOMA-IR in the late stage before diagnosis predicted T2D. Stumvoll insulin sensitivity index levels were also deteriorated in the late stage of the disease course.

Conclusion: Japanese individuals who later developed T2D had clearly elevated glucose concentrations at 60 min rather than other glucose measurements even 10 y before diagnosis. Those who developed T2D also had consistently reduced beta-cell function over 10 y before diagnosis, values similar to those observed at diagnosis.

Factors affecting the risk for the first appearance of an islet autoantibody in The Environmental Determinants of Diabetes in the Young (TEDDY) study

A. Lernmark¹, H. Elding Larsson², H.-S. Lee³, J. Krischer³, K. Vehik³, K.F. Lynch³, M. Haller⁴, W.A. Hagopian⁵, M.J. Rewers⁶, J.-X. She⁷, O.G. Simell⁸, J. Toppari⁸, A.-G. Ziegler⁹, B. Akolkar¹⁰, TEDDY Study Group;

¹University Hospital MAS, Lund University, ²University Hospital SUS, Lund University, Malmö, Sweden, ³Department of Pediatrics, University of South Florida, Tampa, ⁴Department of Pediatrics, University of Gainesville, ⁵Pacific Northwest Diabetes Research Institute, Seattle, ⁶University of Colorado, Aurora, ⁷Center for Biotechnology and Genomic Medicine, Georgia Regents University, Augusta, USA, ⁸Department of Pediatrics, Turku University Hospital, Finland, ⁹Forschergruppe Diabetes e.V., Institute of Diabetes Research, Helmholtz Zentrum München, and Klinikum rechts der Isar, Neuherberg, Germany, ¹⁰University Hospital MAS, National Institute of Diabetes & Digestive & Kidney Diseases, Bethesda, USA.

Background and aims: Autoantibodies against Insulin (IAA), GAD65 (GADA) and IA-2 (IA-2A) are detectable for a variable period of time prior to diabetes onset. In the TEDDY study the incidence of IAA only peaked within the first year of life and declined over the following 5 years. GADA only increased till the second year and remained relatively constant. IA-2A only was rare. GADA only were more common than IAA only among HLA-DQ2/2 but less common among HLA-DQ4/8 children. The aim was to study prenatal factors that may affect the risk for HLA-dependent autoantibody appearance.

Materials and methods: Children (n=8676) with HLA-DQ high risk genotypes (DQ2/8, DQ8/8, DQ4/8 and DQ2/2) were enrolled at 3–4.5 months of age and followed with standardized autoantibody assessments quarterly through the first 4 years of life and then semiannually thereafter. Non-diabetic mothers of singleton infants (n=6,947) filled out a questionnaire 3–4.5 months after pregnancy. Lower birth weight was defined as the lower 25% of the TEDDY children's birth weights.

Results: The risk for IAA only (n=197) was increased in Finland and Sweden but not in Germany compared to the US but not for GADA only (n=192). The risk for both autoantibodies was increased among first degree relatives and IAA only among boys. Maternal smoking was associated with country (Europe), maternal BMI, drinking during the 3rd trimester (>2 drinks/month), and maternal infections (lower respiratory tract infection, skin infection or rash, genital infection). After adjusting for country, type 1 diabetes in a first degree relative, HLA genotypes and gender, none of these maternal factors were associated with an islet autoantibody. However, lower birth weight, but not maternal smoking, was independently associated with a decreased risk for GADA only but not for IAA only.

Conclusion: Prenatal factors may affect the risk for HLA-associated first appearance of either IAA or GADA.

Using genomic information to differentiate diabetes aetiology in young-adult onset diabetes

F.K. Kavvoura^{1,2}, L. Moutsianas³, A. Bennett¹, A. Mahajan³, N. Robertson³, N.W. Rayner^{3,4}, C.J. Groves¹, K.R. Owen^{1,2}, M.I. McCarthy^{1,2}; ¹Oxford Centre for Diabetes, Endocrinology & Metabolism (OCDEM), ²Oxford National Institute for Health Research (NIHR) Biomedical Centre, ³Wellcome Trust Centre for Human Genetics, Oxford, ⁴Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Background and aims: Establishing the aetiology in young adult-onset diabetes can be challenging, in view of the overlapping features between common diabetes types. Current tools include clinical parameters and

laboratory tests but are often inadequate to allow firm clinical decisions to be made. The recent discovery of a large number of variants associated with increased risk both for type 1 (T1D) and type 2 diabetes (T2D), offers a potential adjunct in the differential diagnosis of common diabetes types. We assessed whether individual genetic risks using known T1D and T2D risk variants offer useful diagnostic discrimination between T1D and T2D diagnosed in early adulthood.

Materials and methods: North European subjects (n=715) with diabetes onset <45 years were provisionally classified as T1D (n=293), T2D (n=370) and LADA (n=52), based on the presence of pancreatic antibodies, time to insulin use from diagnosis, and c-peptide level. We used common risk variants for T1D (47 variants) and T2D (65 variants), plus high risk and protective variants for T1D in the Major Histocompatibility Complex (23 variants) to calculate weighted Genetic Risk Scores (GRS) for T1D (T1DGRS) and T2D (T2DGRS). Differences in GRS between clinical parameters, diabetes subtypes and progression to insulin were estimated with parametric and non-parametric tests. The area under the receiver operator curve (AUC) was calculated for discriminating T1D and T2D using the T1DGRS and T2DGRS.

Results: Higher T1DGRS was associated with diagnosis <18 years ($p=2 \times 10^{-13}$), undetectable c-peptide ($p=2 \times 10^{-9}$) and insulin vs. tablets as initial or current treatment (both $p < 10^{-22}$), features consistent with T1D. Higher T2DGRS was observed with diet ($p=0.002$) or tablet use ($p=0.04$) vs. insulin therapy at diagnosis and with current oral therapy ($p=0.0002$), characteristics suggestive of T2D. The difference in T1DGRS and T2DGRS between clinically defined T1D vs. T2D cases was highly significant (both $p < 10^{-22}$), as was the difference between T2D vs. LADA labelled subjects ($p < 10^{-22}$ and $p=0.0001$ respectively). Non-T1D cases starting insulin within 1 year from diabetes diagnosis had higher T1DGRS compared to the remainder ($p=0.0004$), therefore estimating T1DGRS at diagnosis could aid in tailoring management. The AUC for clinically defined T1D and T2D patients using the T1DGRS and T2DGRS were 80% and 64%, respectively, indicating that T1DGRS on its own can contribute to the discrimination between clinically labelled T1D and T2D.

Conclusion: Genetic Risk Scores correlate well with traditional diabetes classification parameters and the clinically defined diabetes diagnosis. T1DGRS may also predict early progression to insulin in non-T1D individuals. In summary, genomic information could be a useful adjunct in the differential diagnosis and management of young adult onset diabetes from diagnosis.

A signal near TMEM170A is associated with coronary artery disease and SNPs near IL15RA/IL2RA and THY1 may interact with diabetes status to modify the risk of CAD

N.R. van Zuydam¹, B. Voight², C. Ladenvall³, R. Strawbridge⁴, S. Willems⁵, E. van Iperen⁶, J. Hartiala⁷, E. Vlachopoulou⁸, E. Mihailov⁹, L. Kwee¹⁰, C. Nelson¹¹, M. Kleber¹², L. Qu², A. Goel¹, S. Kanoni¹³; ¹University of Oxford, UK, ²University of Pennsylvania, Philadelphia, USA, ³Lund University, Malmö, ⁴Karolinska Institute, Stockholm, Sweden, ⁵Erasmus University, Rotterdam, ⁶Academic Medical Center, Amsterdam, Netherlands, ⁷University of Southern California, Los Angeles, USA, ⁸University of Helsinki, Finland, ⁹University of Tartu, Estonia, ¹⁰DUKE University, Durham, USA, ¹¹University of Leicester, UK, ¹²LURIC study, Freiburg im Breisgau, Germany, ¹³Wellcome Trust Sanger Institute, Cambridge, UK.

Background and aims: Subjects with type 2 diabetes (T2D) are three or four times more likely to suffer from coronary artery disease (CAD) than non-diabetic individuals. Subjects with T2D have accelerated and a larger burden of atherosclerosis compared to non-diabetic individuals. We hypothesise that there may be different genetic factors that contribute towards these differences.

Materials and methods: We combined summary statistics from 1000G imputed, HapMap 2 imputed and CardioMetaboChip genotypes from 24,257 subjects with T2D (10,012 CAD cases and 14,245 CAD free controls) and 42,384 non-diabetic individuals (17,694 CAD cases and 24,690 CAD free controls) in a fixed effects variant weighted meta-analysis and performed a test for interaction with diabetes status. Six hundred and eighty six independent SNPs ($\text{distance} > 100\text{Kb}/R^2 < 0.3$) analyses based on p value of association $< 1E-4$ for replication from the diabetes stratified and interaction analysis. These associations were replicated in 11,537 patients with T2D (3,706 CAD cases and 7,831 CAD free controls) and 106,250 non-diabetic individuals (12,988 CAD cases and 93,262 CAD free controls).

Results: A known CAD SNP, rs4977574 in the 9p21.3 region, was the top signal for CAD in non-diabetic individuals ($P=7.7E-41$) and was also genome-wide significant for CAD in subjects with T2D ($P=3.9E-9$). Rs11072811, a known CAD SNP near *ADAMTS7*, was the top signal for CAD in subjects with T2D (OR (95%CI)=1.05 (1.02-1.09), EAF=0.52, $P=9.7E-11$) but was not genome wide significant for CAD in non-diabetic individuals (OR (95%CI)=1.02 (0.99-1.05), EAF=0.52, $P=2.8E-3$). There was some evidence for interaction ($P=4.5E-3$) that was not significant after correction for multiple testing. We identified a genome wide significant hit near *TMEM170A* that had been previously reported (not at genome wide significance) for CAD and carotid intima thickness (cIMT). Rs6564261 (R^2 with rs4888378 > 0.8) was associated with CAD in non-diabetic individuals (OR (95%CI)=1.04 (1.01-1.07), EAF=0.62, $P=2E-10$) with no evidence of interaction with diabetes status ($P=8E-2$). Two SNPs did show evidence for interaction with diabetes status, with the same direction of effect in the discovery and replication analyses and an interaction $p < 0.05$ in the replication. Rs79705396, near *IL15RA* and *IL2RA* ($P=5.2E-6$), and rs7952366, near *THY1* ($P=1.6E-5$).

Conclusion: We reported a locus for CAD near *TMEM170A* at genome wide significance that has been associated with cIMT, and two SNPs that may interact with diabetes status to modify the risk of CAD near genes that may have a biological role in the atherosclerosis.

Serum lipidome as an independent predictor of progression to type 2 diabetes: the METSIM study

M. Oresic¹, I. Bondia Pons¹, H. Cederberg², A. Stančáková², T. Suvitaival¹, J. Kuusisto², J. Nolan¹, T. Hyötyläinen¹, M. Laakso²,
¹Steno Diabetes Center A/S, Gentofte, Denmark, ²Institute of Clinical Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

Background and aims: There is a need for early markers to track progression from a state of normal glucose tolerance through pre-diabetes (impaired fasting glucose and/or impaired glucose tolerance) to type 2 diabetes (T2D). Several diabetes risk models and scores have been developed as prognostic tools. However, these are mainly based on established risk factors of T2D and they lack the specificity required for clinical practice.

Materials and methods: We applied global lipid profiling based on ultra-high performance liquid chromatography (UHPLC) coupled to quadrupole time-of-flight (QTOF) mass spectrometry (MS) at baseline and at 5-year follow-up plasma samples of well phenotyped male participants (107 T2D progressors, 216 matched normoglycemic controls; dataset 1) from the longitudinal study METSIM (METabolic Syndrome In Men) to identify lipidomic profiles of progression to T2D, and to develop a lipid-based predictive model for T2D. The selection of progressors was based on fastest progression to T2D and greater glucose AUC at follow-up. Age-matched controls were selected as non-progressors. In addition, we performed global lipidomic profiling at baseline of a larger subset of the previous cohort (dataset 2), which was characterized by a wide distribution in terms of

glucose tolerance ($n=640$), including non-progressors with a high percentage of subjects with impaired fasting glucose (IFG; 60%), subjects with HbA1C between 5.7-6.4% (11%), subjects with impaired glucose tolerance (IGT; 2%), both IFG+IGT (6%), and subjects with normal glucose tolerance (21%). 20 subjects in dataset 2 progressed to T2D during the follow-up.

Results: A total of 280 lipids were analyzed. The global lipidome was first surveyed by clustering the baseline data from dataset 1 using Bayesian model-based clustering. By applying linear mixed models to the resulting 13 clusters, eight of them showed significant differences in their lipid mean levels between progressors and non-progressors at baseline, after adjusting for BMI. Four clusters consisting only of triglyceride species (grouped by different carbon chain lengths and number of double bonds in their structures) and a cluster consisting mainly of phospholipids were upregulated in T2D progressors (adjusted p-value < 0.05). Two clusters containing sphingomyelins and ether phospholipids were downregulated. A similar pattern was observed when dataset 2 was surveyed. Those non-progressors classified as subjects with IFG at baseline showed similar yet less pronounced lipid changes at the cluster level as progressors to T2D. Selected lipids were then considered to build a lipid-based predictive model of T2D with the dataset 1, by using stepwise logistic regression. We compared the candidate models with the Finnish Diabetes Risk Score (FINDRISC) based-model applied to our data. The candidate lipid marker was an independent predictor of T2D and improved the predictive model based on FINDRISC.

Conclusion: Our study indicates that a lipid molecular signature predictive of diabetes is present already years before the diagnosis of diabetes, independent of other risk factors

Non-coding RNA biomarkers of diabetes complications

M.V. Joglekar¹, A.A. Hardikar¹, R.J. Farr¹, A. Januszewski¹, T. Evans², S. Satoor¹, W. Wong¹, J.D. Best², C.S. Yajnik³, S. Blankenberg², R. Scott², A. Jenkins¹, A.C. Keech¹, on behalf of the FIELD investigators; ¹NHMRC Clinical Trials Centre, University of Sydney, ²C/O NHMRC Clinical Trials Centre, University of Sydney, Australia, ³Diabetes Unit KEM Hospital, Pune, India.

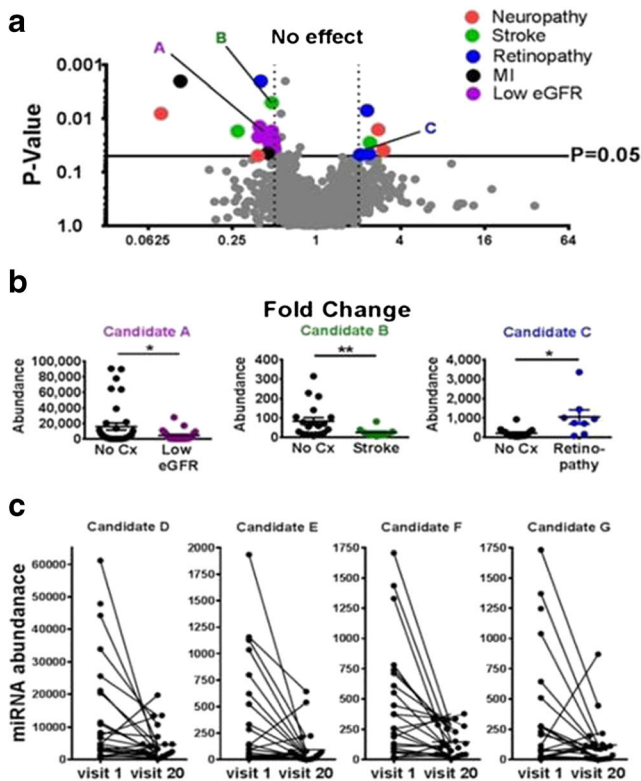

Background and aims: Type 2 Diabetes (T2D) increases the risk of cardiovascular disease (CVD), and other vascular complications including retinopathy and neuropathy and is now well-accepted to be an outcome of intra-uterine programming and exposure to environmental (lifestyle) factors during post-natal life. It is essential and timely to identify early biomarkers of T2D and its complications. In recent years microRNAs (miRNAs), a subset of small non-coding (nc) RNAs, have been detected in circulation and demonstrated as promising biomarkers, mostly in cancer research. We aim to validate circulating ncRNA and DNA methylation signatures for T2D and its vascular complications using two unique longitudinal cohorts i) the Pune Maternal Nutrition study (PMNS) comprising of 18 year follow up study of undernourished children and their parents from preconception period, 20% of whom have now developed insulin resistance at 18 years of age ii) the FIELD study, which demonstrated that, relative to placebo, long-term fenofibrate improved some CVD and all microvascular complications with 9,795 subjects enrolled in study and analysed at baseline, 1 and 5 years and in 1,744 of these individuals at 12 years. We present epigenetic (DNA methylation) and ncRNA signatures for T2D and its complications over lifetime and response to therapy, enabling early management of at-risk individuals and facilitating development of novel therapeutics.

Materials and methods: Circulating miRNAs in plasma were assessed from i) PMNS study subjects at 18, 12 and 6 years as well as at their birth and from their parents (at conception) and ii) T2D subjects in the FIELD cohort (Fenofibrate Intervention and Event Lowering in Diabetes) with retinopathy, neuropathy, low eGFR,

ACR, non-fatal stroke or non-fatal myocardial infarction and were compared to individuals without complications using ultra-high throughput qPCR profiling. DNA methylation in both study cohorts was assessed on Illumina 450 K DNA methylation arrays.

Results: We observed that circulating miRNAs in five T2D complication groups Vs no complications were differentially expressed as seen in volcano plot (Figure 1A). Some of the miRNAs identified in the initial high throughput analysis (\pm 2-fold change and $P < 0.05$) were also found to be significantly different in multiple samples when validated using low-throughput high sensitivity quantitative (q)PCR. We also found serum levels of four candidate microRNAs related to vascular health to be lower in FIELD T2D subjects at visit 20 (5 years) Vs visit 1 (baseline).

Conclusion: miRNAs are found to be differentially expressed in individuals with diabetic complications, which could allow early identification of at risk individuals, thereby providing a vital opportunity to improve health prior to clinical onset.

OP 09 The price of diabetes care

49

The economic consequences of clinical inertia in treatment intensification for type 2 diabetes mellitus in the UK

M. Willis¹, C. Neslusan², P. Johansen¹, A. Nilsson¹, C. Asseburg¹;

¹The Swedish Institute for Health Economics, Lund, Sweden, ²Janssen Global Services, LLC, Raritan, USA.

Background and aims: Chronic hyperglycemia may lead to severe and debilitating micro- and macrovascular complications and an elevated risk of premature mortality. While there is no cure for T2DM, current treatment recommendations suggest treating patients with agents to maintain near normal HbA1c levels. Despite many available treatments, T2DM gradually worsens over time and treatment intensification is required to meet HbA1c goals. Recent evidence confirms clinical inertia in treatment intensification in everyday UK practice; patients taking 1 or 2 oral antihyperglycemic drugs (OADs) waited a median of 1.5 and 7.2 years, respectively, after exceeding a treatment goal of HbA1c <7.5% before being prescribed rescue therapy. Reducing clinical inertia is expected to lead to better health outcomes, but these benefits occur over long time horizons. This analysis used modeling techniques to estimate the potential magnitude of the health benefits associated with reducing clinical inertia in terms of treatment intensification for patients with T2DM receiving mono- or dual therapy in the UK.

Materials and methods: The Economic and Health Outcomes Model of T2DM (ECHO-T2DM), a validated, long-term stochastic microsimulation model, was used to estimate the potential health benefits over 30 years of reducing clinical inertia in the treatment of T2DM for patients taking 1 OAD (monotherapy) and for those taking 2 OADs (dual therapy) in the UK. For the monotherapy simulation, patients were assigned metformin (MET) at baseline and sulphonylurea (SU) was added as the 2nd line treatment. For 3rd line, SU was discontinued and basal insulin was added. Prandial insulin was specified as the add-on in 4th line. For the dual therapy simulation, patients in both arms were assigned MET plus SU at baseline; the same insulin rescue sequence with basal and then prandial was used. In each of these simulations, patients were separated into 2 arms based on assumptions about the delay in treatment intensification. In the “No Delay” arm, treatment intensification was triggered immediately when HbA1c >7.5% (in line with UK norms). In the “Delay” arm, intensification at each step was postponed based on mean values derived from the recent UK real world evidence study; add-on with SU was delayed by 2.16 years and add-on with basal insulin by 10.63 years. Baseline patient characteristics were sourced from The Health Improvement Network (THIN) database in the UK, separately for patients starting on mono- and dual therapy. Treatment effects for the OADs were obtained from published clinical trials.

Results: With mono- and dual therapy, discounted life-years (LYs) were 0.123 and 0.180 larger over 30 years, respectively, in the No Delay arm compared with the Delay arm, in line with modest relative risk reductions (RRRs) in the occurrence of myocardial infarctions and stroke (4.7% and 4.6% for monotherapy and 6.3% and 5.7% for dual therapy, respectively). There were sizable RRRs in the occurrence of retinopathy and neuropathy outcomes. For example, RRRs for proliferative diabetic retinopathy and severe vision loss were ~50% for monotherapy and more than 55% for dual therapy; the RRRs for lower extremity amputation were 10.6% for monotherapy and 14.0% for dual therapy.

Conclusion: These simulation results suggest that reducing clinical inertia in the UK, and likely elsewhere, has the potential to improve long-run patient outcomes.

50

A regimen-based measure of adherence and its association with healthcare costs in patients with type 2 diabetes and patients with both cardiovascular disease and type 2 diabetes mellitusG.S. Carls¹, R.-D. Tan¹, C. Frois², E. Tuttle¹;¹Analysis Group, Menlo Park, ²Analysis Group, Boston, USA.

Background and aims: In order to achieve recommended HbA1c targets, many patients require multidrug regimens, but these regimens present increased hurdles to patient adherence. Adherence may be particularly important for T2DM patients with cardiovascular disease (CVD) due to increased risks associated with poor HbA1c control for these patients. A common measure of adherence, proportion of days covered (PDC) $\geq 80\%$ by any diabetes medication, may overestimate adherence to multidrug regimens if patients fill each drug inconsistently but have some drugs on hand most of the time. This study develops a refined regimen-based measure of adherence that accounts for drug regimen changes for patients with T2DM and a subset of patients with both T2DM and cardiovascular disease.

Materials and methods: A retrospective cross-sectional study was conducted using data from Optum-Humedia for adult patients with T2DM that included person-linked claims, electronic medical records (EMR), and vital records for the period 1/2007–3/2014. PDC and health care costs (medical, pharmacy, and total) were assessed over the most recent one year period with continuous enrollment and at least 1 diabetes drug fill. Patients were also required to be continuously enrolled for at least 3 months prior so that drugs on hand at the start of the year could be accurately assessed. Patients with both T2DM and CVD were identified based on diagnosis codes. Adherence was measured based on regimen-based PDC $\geq 80\%$ accounting for initiation, switching, discontinuation, and stockpiling at the class level and compared with the standard adherence measure based on the percent of days with any diabetes drugs on hand. Healthcare costs were estimated using data on estimated allowed amount for each claim. Generalized linear models (log link and Poisson distribution) were used to estimate excess costs related to non-adherence after adjusting for demographic and health plan characteristics.

Results: 26,063 patients met study criteria and had a mean age of 61 years, 52% male, mean HbA1c of 7.3% and mean healthcare cost of \$18,047. 26% of patients (N=6,652) had CVD. Non-adherent patients were younger (mean age 59 vs. 64, $p < 0.001$) and had higher mean HbA1c (7.5% vs. 7.1%, $p < 0.001$). Non-adherent patients (N=13,666, 52%) cost 29% more than adherent patients (\$20,297 vs. \$15,761, $p < 0.001$) using the regimen-based measure. Among patients with CVD and T2DM, non-adherent patients cost 35% more than adherent patients (\$40,413 vs. \$29,859 $p < 0.001$) and nearly twice the cost vs. all patients with T2DM. 52% of all patients filled multiple drug classes. The fraction of multidrug patients classified as non-adherent increased to 57% (regimen-based) from 36% (standard). The excess healthcare cost of non-adherent multidrug patients was 20% higher compared to adherent patients (\$4,508 [regimen-based] vs. \$3,750 [standard] $p < 0.001$). A parsimonious model with only age categories as control variables yielded similar results.

Conclusion: A measure of PDC which more closely approximates T2DM medication regimen shows that standard measures have misclassified non-adherent multidrug patients and consequently underestimated the burden of non-adherence. Estimates of medication adherence in T2DM should be based on the patient's regimen and not simply any diabetes medication on hand. Among T2DM patients with CVD, the economic burden of non-adherence is higher than in other T2DM patients.

Post-prandial hyperglycaemia (PPH): missed work time and reduced productivity among people with type 1 and type 2 diabetes in the US, UK and GermanyA. Nikolajsen¹, M. Brod², J. Weatherall³, K.M. Pfeiffer²;¹Novo Nordisk A/S, Søborg, Denmark, ²The Brod Group, Mill Valley,³Novo Nordisk, Inc., Plainsboro, USA.

Background and aims: Post-prandial hyperglycaemia (PPH) is a persistent challenge for diabetes management. Unfortunately, the impact of PPH episodes on work absenteeism and functioning while at work among people with diabetes is not well understood. The purpose of this study was to investigate the impact of PPH episodes on missed work time and work productivity among people with type 1 (T1DM) and type 2 (T2DM) diabetes in the US, UK, and Germany.

Materials and methods: Data were collected in a web survey of 906 adults diagnosed with T1DM (39%) or T2DM (61%) and treated with self-administered bolus insulin in the US (40%), UK (26%), and Germany (34%). Experience of PPH and missed work time/work productivity issues due to PPH were respondent-reported.

Results: A total of 519 respondents (57%) reported working for pay, working an average of 35.2 hours per week. Inadequate post-prandial glucose (PPG) control among both working and non-working respondents was common. Among respondents who worked for pay, 68% experienced difficulty getting their blood glucose (BG) stable after eating during the past week, and 27% experienced PPH episodes 3 or more times in the past week. Among working respondents, 27% reported missing at least some work the last time they experienced a PPH episode. A total of 10% of working respondents indicated that they missed a full day of work the last time they experienced a PPH episode, while 14% reported being late to work and/or 19% left work early. On average, respondents reported missing 168 minutes of work time in the previous week due to their BG being out of range after eating. Furthermore, 71% of working respondents indicated that they had work productivity issues the last time they experienced a PPH episode; 54% of respondents reported that they experienced difficulty focusing at work, 45% indicated that they were less productive at work, 44% reported needing to take a break at work, 28% indicated making more mistakes at work, 11% had to cancel or reschedule a work meeting/appointment, and 10% missed meetings at work. There were no significant differences in missed work time due to PPH by diabetes type or by country. Compared to those with T1DM, respondents with T2DM were significantly more likely to report experiencing any work productivity issues due to PPH (77.0% vs. 62.6%, $p < .05$), finding it difficult to focus at work due to PPH (62.8% vs. 43.5%, $p < .01$), and being less productive at work due to PPH (50.0% vs. 37.4%, $p < .05$). The association between PPH and work productivity also differed somewhat by country. German respondents were significantly more likely than those in the US and UK to report any work productivity issues due to PPH (Germany, 83.5%; US, 64.5%; UK, 61.6%, $p < .01$), making more mistakes at work due to PPH (Germany, 37.1%; US, 24.7%; UK, 19.2%, $p < .05$), and finding it difficult to focus due to PPH (Germany, 64.9%; US, 46.2%; UK, 50.7%, $p < .05$).

Conclusion: The results indicate that the experience of PPH episodes among people with T1DM and T2DM treated with bolus insulin is common and significantly associated with missed work time and reduced work productivity. The findings highlight the need for better clinical management of PPH, particularly for people with T1DM or T2DM treated with self-administered bolus insulin and engaged in the workforce. The results also suggest that PPH may be associated with economic costs related to missed work time and reduced work productivity.

The importance of appropriately incorporating the effects of hypoglycaemia within a health economic model when hypoglycaemia rates are high

E. Lovato¹, M. Warburton¹, P. McEwan², M. Lamotte³, V. Foos⁴;

¹IMS Health, London, ²Health Economics & Outcomes Research Ltd, Cardiff, UK, ³IMS Health, Vilvoorde, Belgium, ⁴IMS Health, Basel, Switzerland.

Background and aims: Hypoglycaemia is an important determinant of health utility and thus the cost-effectiveness of blood glucose lowering therapies in people with diabetes. Standard health economic evaluations typically attribute a per-event disutility (PED) to clinical outcomes including hypoglycaemia. Increasingly in diabetes sources of real-world data are being used to conduct health economic evaluations in which patients may have very high rates of hypoglycaemia. Importantly, there is growing evidence of the diminishing marginal effects (DME) of hypoglycaemia on health utility as frequency increases. The objective of this study was to compare PED versus DME on predicted quality adjusted life expectancy (QALE) using an established diabetes model.

Materials and methods: This study used the CORE Diabetes Model (CDM) and published real-world audit data for patients with type 1 diabetes switching to insulin degludec (ID) from either insulin glargine or detemir (IGD). Mean (\pm SD) baseline profiles were age 35.0 years (\pm 11.4); diabetes duration 18.2 years (\pm 7.5); HbA1c 9.4% (\pm 0.8); weight 77.0 kg (\pm 10.7) and 3.9 hypoglycaemia (severe and non-severe) events per week (\pm 0.9). Mean change in clinical variables was HbA1c -0.5% (\pm 0.3); weight +0.8 g (\pm 1.6) and hypoglycaemia events/week -3.6 (\pm 0.9). A baseline cohort was projected over a lifetime using the CDM using published PED disutility (-0.0052) and published DME disutility (0.0141*[number of events]^{0.3393}) with and without treatment effects applied to calculate life expectancy (LE) and QALE associated with the pre and post-switch profiles. Results were discounted at 3.5%.

Results: Overall discounted LE was 18.8 years and 19.06 years for IGD and ID profiles respectively and discounted QALE (ignoring the impact of hypoglycaemia) was 12.13 and 12.4 for IGD and ID respectively. Discounted QALE was reduced by 1.85 (IGD) and 0.849 (ID) using the DME approach applied to hypoglycaemia rates of 3.9 and 0.4 events/week respectively. Using the PED approach discounted QALE was reduced by 22.96 (IGD) and 2.355 (ID). The PED approach resulted in a QALE prediction less than zero for IGD.

Conclusion: Failure to adequately accommodate the relationship between hypoglycaemia frequency and quality of life within health economic evaluations may lead to misleading predictions and estimates of QALE that lack face validity; this is particularly so when hypoglycaemia event rates are high.

53

A first evaluation of the cost-effectiveness of CSII versus MDI in type 2 patients: projection of clinical and economic benefits in the Netherlands

S. Roze¹, S. de Portu², Y. Reznik³, B.F.E. de Brouwer⁴, H.W. de Valk⁵;

¹HEVA HEOR, Lyon, France, ²Medtronic International, Tolochenaz, Switzerland, ³Department of Endocrinology, University of Caen Côte de Nacre Regional Hospital Center, Caen, France, ⁴Medtronic NL, Heerlen, ⁵Dept. Internal Medicine, University Medical Centre Heidelberglaan, Utrecht, Netherlands.

Background and aims: Literature in type 1 patients demonstrated that CSII was often cost-effective over MDI in uncontrolled patients and in various countries. However, this question remained unaddressed so far for type 2 patients. The present study is the first investigating and reporting health economic outcomes for CSII versus MDI in type 2 patients based

on improvements in glycaemic control since new clinical data were published in type 2 patients in 2014.

Materials and methods: We published the results of the OpT2mise randomized controlled trial, during which they followed 331 people with type 2 diabetes who were on MDI with at least 3 injections per day and uncontrolled HbA1c. Mean HbA1c at baseline was 9% with average age of 56 years. At 6 months, mean HbA1c had decreased by 1.1% in the CSII group and by 0.4% in the MDI group. The CORE Diabetes Model (CDM) was used in order to project the long-term clinical and economic benefits of these interventions in type 2 patients. The CDM has been widely published and validated. For type 2 patients, it is based on the published UKPDS risk equations amongst others published sources. The CDM uses the baseline risk factors combined with the impact of CSII and MDI to assess annually the risk of developing complications and mortality. Unit costs are attached to each individual diabetes-related complication. Dutch costs (complications and interventions) come from various published and official sources. To reflect the decrement in quality of life due to diabetes, a specific utility value was also associated to each complication. These utilities are taken from a published systematic literature review. Costs and clinical outcomes were discounted at 4% and 1.5% p.a. respectively. The health economic analysis has been conducted from a Dutch third party payer perspective. Sensitivity analyses were also conducted to test the robustness of the results.

Results: Undiscounted life expectancies were improved for CSII versus MDI by 0.785 years. Total QALYs were 9.38 and 8.95 respectively for CSII and MDI. The breakdown of costs indicated that around 50% of these costs were attributable to diabetes related complications. Extra acquisition costs of CSII versus MDI were partially offset by the reduction in complications. The ICER has been estimated (in EUR/QALY) at 62,895 and at 60,474 when indirect costs were included.

Conclusion: These results indicate that accordingly to commonly accepted threshold CSII could be considered a cost-effective intervention compared to MDI in uncontrolled type 2 patients in the Netherlands. CSII also increased the life expectancy of uncontrolled patients as well as reduced morbidity and improved their quality of life.

54

Weight change over time and its link to healthcare costs among newly-diagnosed type 2 diabetes patients in Sweden

U. Sabale¹, J. Bodegard¹, J. Sundström², B. Svennblad², C. Östgren³, P.M. Nilsson⁴, G. Johansson², M. Ekman¹;

¹AstraZeneca, Södertälje, ²Uppsala University, Uppsala, ³Linköping University, Linköping, ⁴Lund University, Malmö, Sweden.

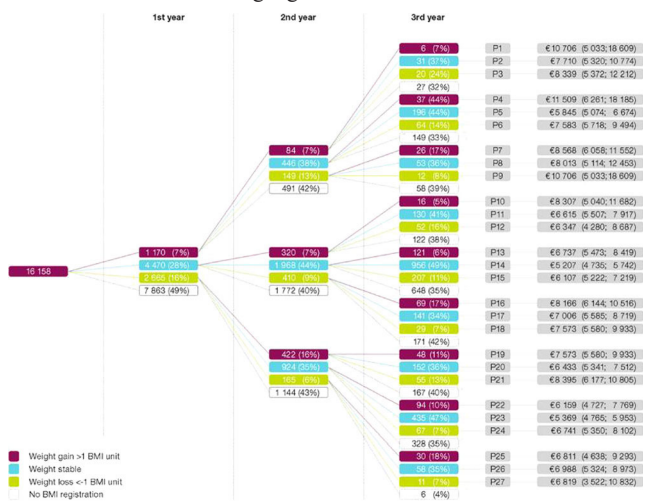

Background and aims: Weight control is an important parameter in management of patients with type 2 diabetes (T2DM), however actual knowledge on the impact of weight changes in relation to health care resource use is scarce. The aim was to comprehensively describe relative weight (body mass index, BMI) change pathways by using repeated BMI measurements in newly diagnosed type T2DM patients and link that to healthcare resource utilization costs from primary and hospital care.

Materials and methods: Between 1999-2009, all newly diagnosed T2DM patients in 84 primary care centers (almost 10% of all primary care centers in Sweden) were extracted. Patients eligible for the study had BMI measurement at diagnosis and subsequent BMI measurements at 12, 24, and 36 months were identified. Patients with BMI<18, cancer and heart failure at T2DM diagnosis were excluded from the analysis due to the risk of unintentional weight loss. Three BMI change categories were defined based on BMI change over a period of one year: weight gain (\geq 1 BMI unit increase), weight stable (<1 BMI unit change), and weight loss (\geq 1 BMI unit decrease). Based on the observed individual BMI change sequence over three consecutive years, patients were assigned to one of totally 27 possible BMI change pathways (P1-P27, Figure). The most common pathways were identified by estimating a conditional probability of a patient moving between BMI categories over a period of one year.

Mean three year healthcare costs for each pathway were estimated by applying Swedish unit costs to the healthcare resource data extracted from electronic patient journals and the Swedish National Patient register.

Results: Of the 16,158 newly diagnosed T2DM patients, 8,295 had a BMI measurement at baseline and year 1; 4,888 at year 1 and 2; and 3,116 at all three years. Patients eligible for BMI change calculations in the 1st year were 44% women, mean age 61 years, had mean HbA1c 6.8% and BMI 30.8 kg/m². The most frequently observed BMI change pathway was associated with weight stability over 3 years (P14, €5,207). The second and third most common pathways were associated with weight loss or gain in year 1 and weight stability in subsequent years (P23, €5,369 and P5, €5,845, respectively). Over 3 years, the highest healthcare costs were observed among individuals with weight gain in year 1 (€8,335, average costs of P1-P9) whereas patients whose remained weight stable or had weight loss in year 1 on average incurred €6,907 (average costs of P7-18) and € 6,810 (average costs of P19-P27), respectively.

Conclusion: In newly diagnosed diabetes, an initial moderate weight gain leads to increased healthcare costs. Costs of interventions that maintain weight in patients with diabetes should be considered in the context of costs associated with weight gain.

OP 10 Incretins: that gut feeling

55

Impaired sensitivity to incretins and adaptation of the incretin response in type 2 diabetes

A. Mari¹, A. Tura¹, J.I. Bagger², E. Ferrannini^{3,4}, J.J. Holst⁵, F.K. Knop^{2,5}, T. Vilsbøll²;

¹CNR Institute of Neuroscience, Padova, Italy, ²Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Hellerup, Denmark, ³Department of Internal Medicine, University of Pisa School of Medicine, ⁴CNR Institute of Clinical Physiology, Pisa, Italy, ⁵The NNF Center for Basic Metabolic Research and Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Denmark.

Background and aims: In type 2 diabetes (T2D), the sensitivity to incretin hormones, determined by exogenous hormone infusion, is reduced. Whether this holds true under more physiological conditions, e.g. during an OGTT, has not been determined. In addition, the relationship between sensitivity to incretins and the incretin response has not been explored.

Materials and methods: We used 25, 75, and 125 g OGTT and isoglycaemic glucose infusions in patients with T2D (n=8) and matched (n=8) normal glucose tolerant (NGT) subjects (3 males; age: 57±1 (mean ± SE) years; BMI: 29±0.3 kg/m²), and a beta cell mathematical model to assess the time course of incretin potentiation (Pincr) of insulin secretion. Total glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) were also measured, thus allowing evaluation of the relationships between the time course of incretin hormones and Pincr.

Results: Pincr increased dose-dependently during the OGTTs and then returned to baseline. As expected, the Pincr increase was markedly blunted in T2D. Across all glucose doses Pincr was linearly correlated in every subject with GLP-1 and GIP concentrations; the correlation was stronger in NGT (average r=0.64 and 0.61, for GLP-1 and GIP) than in T2D (r=0.46 and 0.47), due to the flatter Pincr response in T2D. The slope of the individual relationships was used as an index of beta cell sensitivity to GLP-1 and GIP. Of note, this assessment of incretin sensitivity is not intrinsically related to the magnitude of the incretin response. The sensitivities to GLP-1 and GIP were correlated (r=0.66, p<0.006). GLP-1 sensitivity was impaired in T2D (0.008±0.002 l/pmol) vs. NGT (0.020±0.006 l/pmol, p<0.027). However, there was a wide overlapping between the two groups (range: 0.007-0.045 l/pmol in NGT vs. 0.002-0.015 l/pmol in T2D). Using all OGTT data, the GLP-1 AUC was inversely related to GLP-1 sensitivity, with the glucose dose as a factor increasing AUC, and a steeper slope in NGT vs. T2D (r=0.81, p<0.0001). Similar results were obtained for GIP (GIP sensitivity: 0.003±0.001 and 0.013±0.006 l/pmol in T2D and NGT, respectively, p<0.030). This relationship suggests the existence of a compensation mechanism that upregulates incretin secretion in presence of decreased sensitivity to incretins; this compensation is impaired in T2D.

Conclusion: This analysis indicates that relative incretin insensitivity is partly compensated for by higher incretin secretion, both in NGT and T2D. In T2D we found both a moderate impairment in incretin sensitivity and a defective compensation of the incretin secretion.

Clinical Trial Registration Number: NCT00529048

56

HNF-4 gamma and HNF-4 alpha have opposite effects on diet-induced diabetes

S. Ayari^{1,2}, F. Baraille^{1,2}, V. Carrière^{1,2}, C. Osinski^{1,2}, A. Leturque^{1,2}, P. Serradas^{1,2}, A. Ribeiro^{1,2};

¹Inserm UMR-S 1138, Centre de Recherche des Cordeliers, Sorbonne Universités, UPMC Univ Paris 06, Université Paris Descartes, Sorbonne Paris Cité, ²Institut de Cardiométabolisme et Nutrition ICAN, Hôpital Pitié-Salpêtrière, Université Pierre et Marie Curie, Paris, France.

Background and aims: Transcription factors, HNF-4 α and HNF-4 γ belong to nuclear receptor superfamily whose ligands are fatty acids. HNF-4 α plays pleiotropic roles in liver functions. In Human, heterozygous mutations in HNF4A gene lead to Maturity Onset Diabetes of the Young Type I (MODY I). In intestine, our team showed that HNF-4 α controls epithelium homeostasis and HNF-4 γ impacts the glucose homeostasis through a decreased incretin effect. Furthermore, HNF-4 α and HNF-4 γ have opposite effect on abundance and differentiation of enteroendocrine cells producing incretin hormones. We test thus the hypothesis that HNF-4 α and HNF-4 γ have opposite effects in susceptibility to diet induced type 2 diabetes (T2D).

Materials and methods: We used 2 mouse models: 1- a constitutive and total Hnf4g gene inactivation and 2-an inducible and intestine specific Hnf4a gene inactivation, fed high-fat/high-fructose diet for 4 weeks. We performed oral and intraperitoneal glucose tolerance tests and measured insulin and enterohormone plasma concentrations to evaluate the T2D susceptibility. GLP-1-positive cell number was measured by immunohistology. The expression of transcription factors involved in the differentiation of enteroendocrine cells (Ngn3, NeuroD1, PAX6 and PAX4, ISL1, FOXA1 and FOXA2, NKX2.2, ARX, PDX1) and of some enterohormones (CCK, PYY, GIP and GCG) was studied by RT-qPCR.

Results: We show that the inactivation of Hnf4g gene protects mice from weight gain and glucose intolerance, induced by 4 weeks of diet rich in lipids and fructose, that is observed in control mice. Contrary to intestinal HNF-4a inactivation, Hnf4g inactivation improves oral glucose tolerance but not intraperitoneal glucose tolerance. The high-fat/high-fructose diet does not further modify the impact of Hnf4g inactivation on the abundance of GLP-1 cell number and the transcription factor expression involved in enteroendocrine lineage.

Conclusion: We demonstrate for the first time that HNF-4 γ increases the susceptibility to diet induced T2D. This occurred in part through intestine action: a decrease of incretin hormone secretion mediated by lower enteroendocrine cell differentiation. Targeting the enteroendocrine cell differentiation through nuclear receptors HNF-4 might be a new therapeutic approach in DT2.

Differentiation and abundance of enteroendocrine cells are impaired in obese and diabetic obese subjects

A. Ribeiro^{1,2}, E.L. Hubert^{1,2}, C. Osinski^{1,2}, J. deToro Martin^{1,2}, V. Moreira^{1,2}, L. Hedjazi^{3,2}, D.A. Tregouët^{3,2}, K. Clement^{3,2}, C. Poitou^{3,4}, E. Brot-Laroche^{1,2}, A. Leturque^{1,2}, P. Serradas^{1,2};

¹UMRS 1138, Paris, ²Institut de Cardiométabolisme et Nutrition ICAN, Paris, ³UMRS ICAN 1166, Paris, ⁴Nutrition and Endocrinology Department and CRNH-Ile de France, Assistance Publique-Hôpitaux de Paris, France.

Background and aims: A worldwide obesity and diabetes epidemic is spreading in humans since two decades. Gastric bypass, the most effective treatment for morbid obesity, is leading to diabetes improvement or resolution. This occurs partly through changes in gut hormone secretions, which can rely on differentiation, number and function of enteroendocrine (EE) cells. However, it is not known if an alteration of EE cell differentiation

could explain the lower level of enterohormone in obese subjects. This study evaluates the impact of obesity and type 2 diabetes (T2D) on the expression of genes coding for enterohormones and for transcription factors responsible for the commitment of EE cell subtypes in obese and obese-diabetic subjects.

Materials and methods: Jejunum samples were obtained from gastric bypass of obese (n=37) and obese-diabetic subjects (n=21) or from a set of non-diabetic normal weight individuals (lean) obtained through collaboration with surgeons (n=22). We used an integrated strategy combining immunohistological phenotyping of EE cell types and gene expression studies on isolated jejunal epithelial cells by RT-qPCR using Taqman® Arrays Cards. Expression of transcription factors involved in the differentiation of EE cells (*Ngn3*, *NeuroD1*, *PAX6* and *PAX4*, *ISL1*, *FOXA1* and *FOXA2*, *NKX2.2*, *ARX*, *PDX1*) and of some enterohormones (*CCK*, *PYY*, *GIP* and *GCG*) were studied. The statistic tests were a non-parametric Kruskal-Wallis test (lean/obese status) or an ANOVA test (lean/obese/obese-diabetic status).

Results: We have shown that the number of EE L-cells (GLP-1), K-cells (GIP) and I-cells (CCK) in the jejunum of obese subjects is lower than in lean control subjects (50%, 30%, and 30% respectively, p<0.05), in accordance with reported low levels of plasma hormones. We then evaluated EE cell differentiation by low density arrays according to the obese/lean status. We showed that *PAX6* gene expression was significantly decreased (p<0.001) between obese and lean subjects. Moreover, *PAX6*, *NKX2*, *ARX*, *CCK*, *GCG* genes were found to be differentially expressed (p<0.001) between the three groups of subjects, obese, obese-diabetic and lean subjects. We showed that obesity impacted significantly the EE GLP-1 cell lineage whereas T2D in obesity impacted preferentially on CCK cell lineage.

Conclusion: Our study highlights differences on gene expression profile according to the metabolic status of individuals. Obesity and T2D modulate the EE lineage in humans by limiting the abundance of EE cell type in the absorptive segment of the intestine. Deregulation of the EE differentiation could cause alterations in enterohormone secretions observed in obese and obese diabetic subjects.

Neuromedin U is a mammalian dectretin hormone suppressing insulin secretion through NmuR1

C.F. Jacovetti, S. Park, R.W. Alfa, H. Peiris, Y. Liu, X. Gu, G.H. Diaz, S.K. Kim;

Developmental Biology, Howard Hughes Medical Institute, Stanford University, Palo Alto, USA.

Background and aims: Delectretins are enteroendocrine hormones postulated from classical studies of starvation in humans and other mammals to suppress insulin secretion and provoke 'starvation diabetes'. We recently identified a delectretin in *Drosophila* called Limostatin (Lst) that is induced by carbohydrate restriction and suppresses insulin output by signaling through the G-protein coupled Limostatin Receptor (LstR). Our work on isolated human islets suggested that the hormone Neuromedin U (Nmu) and its islet β -cell receptor NmuR1 might be mammalian orthologues of Lst/LstR. To test this hypothesis, we investigated in vivo Nmu signaling in mice.

Materials and methods: We used mice homozygous for a null NmuR1 allele and Nmu-eGFP transgenic mice to investigate Nmu regulation and signaling in vivo. We also generated novel sensitive enzyme linked immunosorption assays (ELISA) to measure Nmu in mouse and human serum.

Results: Nmu mRNA and protein were produced abundantly in mouse stomach and intestinal enteroendocrine cells. We detected a two-fold increase of serum Nmu levels in mice after 72 hours fasting, accompanied by increased Nmu mRNA expression in Nmu-eGFP+ cells. In this setting, oral glucose challenge evoked hyperglycemia accompanied by

relative hypoinsulinemia, effects not observed after overnight fasting or in mice lacking NmuR1. Glucose-stimulated insulin secretion by isolated mouse islets revealed that Nmu inhibits insulin release, an effect abolished in NmuR1 mutant islets. Unexpectedly, we discovered that during the latter phases of standard oral glucose tolerance testing after overnight fasting, serum Nmu concentration increased as insulin levels declined in control mice. By contrast, insulin levels at this stage remained elevated in NmuR1 mutant mice, revealing that Nmu may suppress insulin secretion in physiological states distinct from starvation. Consistent with this view, in mice fasted 24 hours we found Nmu injection that increased serum Nmu levels two-fold led to reduced insulin levels, increased glucagon levels, and hyperglycemia. Nmu administered in this way during oral glucose challenge was also sufficient to impair glucose-stimulated insulin secretion and glucose tolerance. Thus, a small increase of serum Nmu levels in physiological settings had a marked impact on the output of insulin and glucagon, and metabolic homeostasis.

Conclusion: Here we show that, in pathological settings like prolonged fasting, Nmu functions as a incretin to suppress insulin output through NmuR1 and provokes starvation diabetes. Our studies also unexpectedly revealed how inter-organ Nmu signaling between the gastrointestinal tract and endocrine pancreas may be regulated to coordinate changes in secretion of insulin and other hormones during physiological feeding. This previously unidentified function of Nmu suggests that drugs modulating this entero-insular axis may be useful in physiological and disease states, including diabetes mellitus.

Incretin effects of branched-chain amino acids

J. Gojda, R. Strakova, A. Havlova, J. Potockova, P. Tuma, M. Andel; Centre for Diabetes, Metabolism and Nutrition, 3rd Faculty of Medicine, Prague, Czech Republic.

Background and aims: Incretin effect described first in 1986 by Nauck describes different insulin response to glucose load after oral vs. intravenous administration. Intestinal hormones incretins, namely GLP-1 and GIP, are responsible for this augmented insulin secretion after oral administration. Other nutrients than glucose are capable of stimulating insulin secretion in the same glucose-independent incretin way. Branched chain amino acids (BCAA) are known to exert insulinogenic effect. Whether this effect is also mediated by incretins has not been well addressed in literature. The aim of this study is to show that oral administration of BCAA elicits higher insulin and incretin response when compared to intravenous route of the same dose of BCAA.

Materials and methods: Twenty four healthy, male Caucasian subjects were recruited, mean age was 25.5 years, and mean weight was 76.2 kg. Two tests were performed on a different day after an over-night fast. First test (IV test) comprised of intravenous application of BCAA solution (Nutramin VLI, Fresenius Kabi) in total dose of 0.4 g/kg in a 2 hours infusion (mean total dose of BCAA 30.5 g). Second test (PO test) comprised of oral ingestion of BCAA capsules (BCAA Nutrend) in a single dose of 0.4 g/kg. Plasma levels of glucose, insulin, GLP-1 and GIP were measured at time intervals for up to 240 minutes. Insulin secretion response was assessed as incremental area under the curve (iAUC) and was calculated using the trapezoid model.

Results: Oral administration of BCAA induced higher insulin response than intravenous (iAUC 0-240 min PO 22.48±29.3 vs. IV 7.91±21.8 mIU/L, $p < 0.05$). The peak plasma insulin concentration were observed at 60 minute in PO test (PO 4.85±3.88 vs. IV 1.92±2.92 mIU/L, $p < 0.05$) and at 90 minutes in IV test respectively (PO 4.49±4.37 vs. IV 2.65±3.48 mIU/L, $p = 0.14$). PO test induced considerably higher GLP-1 (iAUC 0-90 min PO 9.03±5.7 vs. IV 0.97±3.45 pmol/l, $p < 0.001$) and GIP response (iAUC 0-90 min PO 36.72±52.59 vs. IV -16.27±56.18 pg/ml, $p < 0.005$). The plasma GLP-1 peak was at 60 minute (GLP-1 max 2.94±

2.25 pmol/l) and GIP peak at 30 minute (GIP max 13.79±18.03 pg/ml) in PO test. Plasma glucose levels declined in the same pattern during both tests (iAUC 0-240 min PO -8.94 mmol/L, IV -8.49 mmol/L) reaching its minimum at 210 minute in PO test (3.86±0.24 mmol/L) and 120 minute in IV test respectively (3.78±0.24 mmol/L).

Conclusion: We found that oral administration of BCAA elicits significantly higher insulin and incretin response when compared to intravenous application. We conclude therefore that BCAA effect on insulin secretion is at least partially incretin dependent.

NHE3 blockade ameliorates glucose intolerance via its inhibitory action on SGLT1-mediated intestinal glucose absorption in diabetes

L. Chan¹, T. Wong¹, E. Ng², P. Leung¹;

¹School of Biomedical Sciences, Faculty of Medicine, The Chinese University of Hong Kong, ²Department of Surgery, Prince of Wales Hospital, Hong Kong.

Background and aims: Na⁺-glucose cotransporter 1 (SGLT1) plays a pivotal role in regulating intestinal glucose uptake and has a profound impact on glucose homeostasis and type 1 and 2 diabetic states. Interestingly, we have previously shown that angiotensin II (AngII), via its receptor AT1R, has an inhibitory action on SGLT1 function. In light of these findings, investigation is warranted to identify additional modulators of SGLT1. Therefore, the present study aimed to unravel a previously unknown role of sodium-hydrogen exchanger 3 (NHE3), a critical transporter for sodium homeostasis, in the regulation of SGLT1-mediated intestinal glucose absorption, and to elucidate its downstream signaling cascades, as well as further exploring a potential interaction of the “AT1R-NHE3-SGLT1” signaling axis in the control of intestinal glucose uptake and glucose homeostasis, and thus its consequence on diabetes.

Materials and methods: ¹⁴C-glucose absorption in human and mouse (*m+/db* & *db/db*) jejunums, and human Caco2 cells after incubation with EIPA (NHE3 blocker) was measured by liquid scintillation counting. Changes in plasma levels of fasting blood glucose of mice after gastric gavage with EIPA were studied by OGTT. NHE3 was also downregulated by siRNA-mediated transient knockdown and overexpressed in Caco2 cells. Intracellular pH (pH_i) and its recovery rate after incubation with AngII, L162313 (non-peptide AT1R agonist), losartan (AT1R blocker) and KT5823 (PKG blocker) were measured using the fluorescent dye, BCECF-AM.

Results: NHE3 blockade inhibited SGLT1-mediated glucose uptake in a GLUT2-independent manner across the 3 study models consistently, i.e. human jejunum (1.0 mM EIPA: -41.6%, $p < 0.0001$), human Caco2 cells (1.0 mM EIPA: -40.5%, $p < 0.0001$), and mouse jejunum (1.0 mM EIPA: *m+/db*, -76.1%, $p < 0.0001$; *db/db*, -44.1%, $p < 0.0001$). In parallel, knockdown of NHE3 in Caco2 cells significantly reduced SGLT1-mediated glucose uptake (-29.1%, $p < 0.0001$) and mRNA levels of SGK1 (-34.5%, $p < 0.001$) and SGLT1 (-63.0%, $p < 0.0001$); whereas overexpression of NHE3 reversely upregulated SGLT1 mediated glucose uptake (+52.1%, $p < 0.001$) and mRNA levels of SGK1 (+161.3%, $p < 0.001$) and SGLT1 (+89.8%, $p < 0.001$). For the effect on glucose metabolism, NHE3 blockade did not significantly alter the blood glucose levels in *m+/db* mice (0.5 mM EIPA: -9.2%, $p > 0.05$) but remarkably reduced those of *db/db* mice (0.5 mM EIPA: -33.7%, $p < 0.0001$), as shown by OGTT. For the study of AT1R, AngII inhibited NHE3-mediated pH_i recovery (1 μM: -34.6%, $p < 0.01$), of which its effect was abolished by blockade of AT1R (1 μM losartan: -3.93%, $p > 0.05$) and PKG (1 μM KT5823: -4.61%, $p > 0.05$). Activation of AT1R attenuated protein expressions of NHE3, as revealed by Western blot (10 μM L162313: -51%, $p < 0.0001$).

Conclusion: Collectively, our data reveal for the first time that NHE3 blockade reduces glucose intolerance in diabetes by inhibiting SGLT1-mediated intestinal glucose absorption, probably via SGK1 mediation. Such an interaction may be modulated by an upstream inhibitory action of AT1R-PKG activation on NHE3. Our study provides a perspective of counteracting hyperglycemia by targeting intestinal glucose uptake, and opens an avenue for the potentially clinical use of NHE3 blockade in the regulation of post-prandial hyperglycemia for diabetic patients.

Incidence and predictors of ulceration and amputation in a Dutch type 2 diabetes mellitus population

A.A.W. van der Heijden, T.E. Crezee, B.C. van der Zwaard, P. Elders, G. Nijpels;

The EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: Ulceration and amputation are burdensome complications of type 2 diabetes (T2DM). A reliable method that predicts these outcomes would help in the identification of patients at risk of ulceration and amputation. We therefore aimed to identify predictors of ulceration and amputation.

Materials and methods: This study was conducted in 5,466 patients who were treated by the Diabetes Care System (DCS) in the West-Friesland region of the Netherlands between 2011 and 2013. In these patients, a general foot inspection was performed, in line with the SIMM's classification, to check for foot deformities or local pressure points. Patients were examined to obtain information on peripheral neuropathy, vibration sensation, peripheral arterial disease and limited joint mobility. Diabetic foot ulceration was defined as a skin lesion distal to the ankle. Information of foot ulceration and amputation in the last year, was obtained by self-report during the annual screening. According to this examination, patients were categorized according to the SIMM's risk classification. The primary outcome of this study was the incidence of ulceration or amputation (SIMM's category 3). Potential predictors of ulceration and amputation, other than SIMM's category 1 and 2 were also determined during the annual screening including age, sex, diabetes duration, smoking status, BMI, blood pressure, HbA1c, lipid levels. The prevalence of the different SIMM's risk categories and the 2-year incidence ulceration and amputation was determined. Predictors for ulceration and amputation were identified out of easily available clinical measurements performed at baseline, using backward logistic regression analyses using the Akaike information criterion, with a significance level of 15.7% ($p < 0.157$).

Results: Two-year incidence of ulceration and amputation was 1.9%. SIMM's risk classification 1 (OR 4.03 (95% CI 2.34–6.92)) and 2 (OR 3.92 (95% CI 2.50–6.15)) Current smoking (OR 1.81 (95% CI 1.14–2.88)), BMI (OR 1.03 (95% CI 1.00–1.07)) and HbA1c (OR 1.02 (95% CI 1.00–1.03)) were identified as predictors for ulceration and amputation (Table).

Conclusion: This study identified risk factors for the prediction of ulceration and amputation. The predictors are factors routinely measured during usual diabetes care, which will allow for a translation to clinical care. Using this classification system, it provides a method to select patients at higher risk for ulceration and amputation and distribute medical care to those at most need.

62

Magnetic resonance imaging shows wide-spread bone marrow oedema in the acute Charcot foot and this can be quantitated by a novel scoring system

N.L. Petrova¹, A.N. Donaldson¹, L. Meacock², A. Isaac², D. Elias², M.E. Edmonds¹;

¹Diabetic Foot Clinic, King's College Hospital, ²Department of Radiology, King's College Hospital, London, UK.

Background and aims: Magnetic resonance imaging (MRI) is an established modality in the diagnosis of acute Charcot foot. It shows the extent of bone and joint damage not only in areas presenting with radiological changes but also in areas which appear "normal" on standard foot

and ankle radiographs. We devised a novel semi-quantitative bone marrow oedema (BMO) score that can be used on foot and ankle MRI scans in patients with acute Charcot foot. The aim of this study was to investigate the extent of BMO on MRI scans in patients with acute Charcot foot and to determine the inter- and intra-observer reliability of the BMO score.

Materials and methods: We studied 45 patients presenting to a single centre with a recent onset of acute Charcot foot. All bones (proximal phalanges, medial and lateral sesamoids, metatarsals, tarsals, distal tibial plafond, medial and lateral malleoli) were scored individually by three observers for the extent of oedema (BMO score: 0- no oedema; 1-oedema 50% on two planes) on a non-contrast MRI scan (Siemens Avanto 1.5 T, dedicated foot and ankle coil). Zones of involvement were assessed using Sanders and Frykberg's classification (pattern I - metatarsal-phalangeal joints; pattern II - metatarsal-tarsal joint; pattern III - tarsal joints; pattern IV - ankle joint and pattern V - calcaneum). The inter-observer and intra-observer reliability for assessing the total BMO score and identifying the zones of involvement were also determined.

Results: The MRIs showed extensive bone marrow oedema throughout the foot involving several combinations of patterns and only 2 cases presented with a classical single pattern of involvement - pattern II (1 case, 2.2%) and pattern IV (1 case, 2.2%). The two most common presentations were the combination of patterns I+ II+III, which was observed in 13 cases (28.9%) and the combination of patterns II +III, which was observed in 12 cases (26.7%). Five cases presented with a combination of patterns I+II (11.1%) and further 5 cases presented with a combination of patterns I+II+III+IV (11.1%). Less frequent presentations included a combination of patterns II+III+IV noted in 3 cases (6.7%) and patterns I+II+IV noted in 2 cases (4.4%). The remaining presentations were noted only in single cases. These included a combination of patterns I+III (1 case, 2.2%), patterns I+II+IV (1 case, 2.2%), patterns I+II+III+IV+V (1 case, 2.2%). The total BMO score showed no significant difference between the three observers (Interclass Correlation Coefficient 78% (95%CI 60% to 95%), $p=0.47$) and there was good intra-observer reliability (2 replications of 10 scans - mean difference -0.179 (95%CI -2.031 to 1.674), $p=0.21$). There was very good intra-observer reliability for the identification of patterns I, II and III (Kappa coefficients 75%, 100%, 79% respectively) and moderate for patterns IV and V (Kappa coefficients 43% and 47%, respectively).

Conclusion: We report an extensive distribution of BMO on foot and ankle MRI scans in diabetic patients with acute Charcot foot, which has not been previously noted. The total BMO score has very good intra- and inter-observer reliability. MRI imaging of the whole foot should be considered when Charcot foot is suspected to allow full appreciation of the extent of bone and joint damage. The proposed semi-quantitative BMO score can become a novel tool in the assessment of the acute Charcot foot. Supported by: Diabetes UK

Improved 6-year survival in patients with chronic diabetic foot ulcers after hyperbaric oxygen therapy: outcome from a randomised double-blind study

M. Löndahl¹, K. Fagher¹, A.L. Nilsson², P. Katzman¹;

¹Endocrinology, Clinical Sciences, Lund, Sweden, ²Internal Medicine, Angelholm Hospital, Angelholm, Sweden.

Background and aims: Presence of a chronic diabetic foot ulcer (DFU) is associated with increased mortality. Hyperbaric Oxygen Therapy (HBO), a medical treatment for chronic DFU in selected patients, increases tissue oxygenation, stimulates angiogenesis and restores stem cell mobilization from bone marrow. We have previously shown, beside improved healing rates, an increased 3-year survival in DFU patients receiving HBO compared to placebo (89.5 vs. 70.3%, $p=0.04$). The aim of this study was to evaluate whether this plausible effect persists in a 6-year perspective.

Materials and methods: Patients with chronic DFU were included in a prospective randomized double-blind placebo-controlled study evaluating the effect of 40 treatment sessions with HBO (2.5 ATA, 90 minutes) compared to hyperbaric air (placebo). Patients receiving >35 treatment sessions (per-protocol requirement) were included in the analysis. Mortality data were received from the Swedish National Death Registry. Non-parametric statistics were used to assess differences between groups. Survival was estimated with Kaplan-Meier curves and Log-rank test. Data are given as median and percentages. A two-tailed p -value <0.05 was taken as statistically significant.

Results: 75 patients (38 HBO and 37 placebo) with a median age of 67 and 71 years (HBO and placebo, respectively, n.s) and a diabetes duration of 22 and 21 years (n.s) were included in the analysis. Baseline comorbidities were similar between groups, as were prescription patterns of antidiabetic and cardiovascular protective drugs. Baseline QTc time on ECG were similar between groups. The 6-year survival rate was higher in HBO compared to placebo treated patients (63.2 vs. 40.5%, $p<0.05$). The deceased patients were 68.2 years old at baseline in the HBO group compared to 73.3 years in placebo group ($p=0.18$). Since age could be a plausible confounding factor, a subgroup analysis excluding patients <50 years, was performed (Figure). In this analysis of 69 patients (33 HBO and 36 placebo) aged 71.2 and 71.0 years respectively (n.s.), the difference in 6-year survival persisted (63.2% in HBO vs. 40.5% in placebo, $p<0.05$) and no difference in baseline age of non-survivors was found (71.9 vs. 73.3 years). QTc time between survivors and non-survivors at time of inclusion, did not differ in the HBO-group (425 vs. 432 ms, $p=0.85$), whereas a difference was seen in the placebo group (419 vs. 434 ms, $p=0.02$), with a longer QTc time among non-survivors. Similar outcome was found in the subgroup analysis excluding patients <50 years of age.

Conclusion: Our study indicates that HBO may improve 6-year survival in patients with chronic diabetic foot ulcers. Whether this finding is due to improved healing rates and thus less co-morbidity or whether the effect might be mediated by an improved cardiac microcirculation and perhaps a protective effect against further QTc prolongation needs to be further evaluated.

Capsaicin 8% patch in painful diabetic peripheral neuropathy: a randomised, double-blind, placebo-controlled study

M. Stoker¹, N. Katz^{2,3}, J. Van⁴, R. Snijder¹, H. Jacobs¹, S. Long¹, D. Schregardus¹, B. Lambourg⁵, J. Robinson-Papp⁶, D. Simpson⁶;

¹Astellas Pharma Europe B. V., Leiden, Netherlands, ²Analgesic Solutions, Natick, ³Tufts University School of Medicine, Boston, ⁴Diabetes Research Center, Tustin, ⁵Helix Biomedics, Boynton Beach, ⁶Icahn School of Medicine at Mount Sinai, New York, USA.

Background and aims: The capsaicin 8% patch has demonstrated analgesic efficacy over 12 weeks in patients with post-herpetic neuralgia and HIV-associated distal sensory polyneuropathy, as well as non-inferior efficacy to pregabalin in peripheral neuropathic pain, with a faster onset of action, fewer systemic side effects and greater treatment satisfaction. STEP evaluated the efficacy and safety of the capsaicin 8% patch versus placebo in patients with painful diabetic peripheral neuropathy (PDPN).

Materials and methods: STEP was a Phase III, multicentre, double-blind, placebo-controlled, 12-week study. Patients with painful, distal, symmetrical, sensorimotor diabetic polyneuropathy of at least 1 year's duration, glycosylated haemoglobin $\leq 11\%$ and average daily pain score ≥ 4 (question 5 of Brief Pain Inventory-Diabetic Neuropathy [BPI-DN]), were randomised (1:1) to either capsaicin 8% patch or placebo patch to painful areas of the feet for 30 minutes. The primary endpoint was percentage change in average daily pain score from baseline to between Weeks 2-8. Secondary endpoints included weekly average daily pain, 30% responder rates, BPI-DN sleep interference score and weekly sleep interference score.

Results: Overall, 369 patients with mean [SD] duration of PDPN 5.8 [4.0] years, glycosylated haemoglobin 7.3% [1.3] and average daily pain 6.5 [1.4], were randomised to capsaicin 8% patch (n=186) or placebo patch (n=183). In the primary analysis, a statistically significant greater mean reduction in average daily pain score was observed for capsaicin 8% patch versus placebo from baseline to between Weeks 2-8 (-27.4% versus -20.9%; $p=0.025$). Greater reductions in weekly average daily pain score were observed from Week 3 onwards with capsaicin versus placebo ($p<0.05$ each week, except at Week 6). A greater proportion of the capsaicin versus placebo group achieved at least a 30% reduction in average daily pain score from baseline to between Weeks 2-8 (39.8% versus 32.8%; $p=0.108$), and also Weeks 2-12 (40.9% versus 31.7%; $p=0.05$). Greater improvements in sleep interference score were observed with capsaicin versus placebo from baseline to between Weeks 2-8 ($p=0.030$), and also Weeks 2-12 ($p=0.020$). In addition, greater improvements in weekly sleep interference score were observed with capsaicin versus placebo from Week 6 onwards ($p<0.05$ each week, except at Week 10). Apart from transient application site reactions, treatment-emergent adverse events (TEAEs) in the capsaicin and placebo arms were very similar, and no discontinuations due to drug-related TEAEs occurred in either arm.

Conclusion: The capsaicin 8% patch provided statistically significant improvements in pain relief and sleep quality compared with placebo in patients with PDPN, with no new safety issues. The STEP study extends the range of peripheral neuropathic pain aetiologies for which the capsaicin 8% patch has demonstrated efficacy and safety.

Impact of chronic renal failure on the clinical outcome of stem cell therapy in diabetic patients with critical limb ischaemia

M. Dubský¹, A. Jirkovská¹, R. Bem¹, A. Nemcová¹, V. Fejfarová¹, L. Pagacová², K. Navrátil³, E. Syková⁴;

¹Diabetes Centre, Institute for Clinical and Experimental Medicine, ²Autotransfusion Unit, Institute for Clinical and Experimental Medicine, ³Clinic of Transplant Surgery, Institute for Clinical and Experimental Medicine, ⁴Institute for Experimental Medicine, Czech Academy of Sciences, Prague, Czech Republic.

Background and aims: Therapeutic vasculogenesis by autologous stem cell therapy is a new treatment method for diabetic patients with critical limb ischemia (CLI). Chronic renal failure (CRF) can be one of the main factors that influence the prognosis and amputation rates in patients with diabetic foot disease, especially with CLI. The aim of our study was to assess the impact of CRF on the outcomes of stem cell therapy in diabetic patients with CLI.

Materials and methods: Sixty-two patients with CLI persisting after unsuccessful standard revascularization, treated by autologous stem cells in our foot clinic from January 2008 to October 2014 were included in the study. Patients were divided in a CRF group (17 patients) and a non-CRF group (42 patients). Patients with the same inclusion criteria treated conservatively in the same period and diagnosed to have CRF formed a control group (21 patients). CRF was defined as chronic kidney disease stages 4-5 (glomerular filtration rate < 29 ml/min/1.73 m²). Mean follow-up was 17.9 \pm 13.1 months. Death and major amputation were assessed during the follow-up; the changes in transcutaneous oxygen pressure (TcPO₂) were evaluated at 6 months after cell treatment.

Results: The increase of TcPO₂ after 6 months was significantly higher in the non-CRF group (25.7 \pm 12.5 mm Hg) in comparison with the CRF group (16.1 \pm 11.3 mm Hg, $p=0.032$) and control group (9.2 \pm 5.4 mm Hg, $p=0.002$). TcPO₂ was significantly increased in both cell therapy groups after 6 months compared to baseline ($p=0.0008$, $p=0.0002$), we observed no change in control group. No significant difference in mortality rates during the follow-up between CRF and control groups was observed (5/17 vs. 6/21, NS), non-CRF group revealed significantly lower mortality (6/42, $p=0.039$); all deaths were without a causal link to cell treatment. The major amputation rate in surviving patients was significantly lower in the non-CRF group compared to the control group (10/36 vs 8/15, $p=0.0034$), comparison of CRF and control groups revealed no difference (5/12 vs 8/15, NS).

Conclusion: Our study showed that stem cell therapy of patients with CLI and chronic renal failure significantly improved ischemia in comparison with chronic renal patients treated conservatively, but did not influence the mortality and rates of major amputation. Patients with normal renal function treated by stem cells had significantly lower mortality, amputation rate and higher improvement of ischemia. The therapeutic vasculogenesis by autologous stem cells should always be considered in patients on hemodialysis.

Local application of human stem cells accelerated wound healing in diabetic rat model

R. Bem¹, M. Dubský¹, J. Kříž¹, Z. Kočí^{2,3}, K. Turnovcová^{2,3}, A. Němcová¹, Š. Kubínová², V. Fejfarová¹, J. Skibová¹, E. Syková^{2,3}, A. Jirkovská¹;

¹Diabetes Centre, Institute for Clinical and Experimental Medicine, ²Department of Neuroscience, Institute of Experimental Medicine, ³Department of Neuroscience, 2nd Faculty of Medicine, Prague, Czech Republic.

Background and aims: Wounds associated with diabetes are recalcitrant to healing due to many cellular and molecular aberrations as a result of diabetic complications such as neuropathy, immune impairment and

ischemia. There is increasing evidence that bone marrow mononuclear cells (BM-MNC), their subpopulation - mesenchymal stem cells (BM-MSc) and adipose tissue derived mesenchymal stem cells (AT-MSc) can differentiate into haematopoietic and non-haematopoietic cells, that can be related to wound healing. The aim of our study was to compare the process of wound healing in diabetic rats treated with the various types of stem cell suspensions of human BM-MNC, BM-MSc and AT-MSc obtained from diabetic and nondiabetic donors.

Materials and methods: Human BM-MNC, BM-MSc and AT-MSc were isolated from diabetic and nondiabetic donors by standard methods. BM-MNC concentrate, BM-MSc and AT-MSc in the 2nd passage were divided in aliquots and cryopreserved till application to rats. Diabetes in 56 Wistar rats was induced by a single intraperitoneal injection of streptozotocin 64 mg/kg bw and confirmed 48 h later by a blood glucose level higher than 15 mmol/l. 14 days later, the animals were divided into 7 groups of 8 rats. In each animal, one full thickness skin wound 0.8 cm in diameter was created by a punch biopsy device in the area of the back. The cell suspension from diabetic or non-diabetic donors was injected into the base of the wound, and its close surroundings: 1) 0.5 ml of BM-MNC concentrate; 2) 1 million of BM-MSc in a volume of 0.5 ml or 3) 1 million of AT-MSc in volume of 0.5 ml. The seventh group (Controls) of 8 rats undergone all the procedures except the application of cell suspension. All animals had a wound covered with silicon dressing and also were treated daily with subcutaneous long acting insulin and immunosuppression. Photographs and measurements of the wound has been taken for the assessment of the effect of cell therapy on wound healing after 3, 7 and 14 days of the appropriate therapy.

Results: The sizes of the wounds before treatment were comparable in all groups. After 3, 7 and 14 days, there was a significant reduction of wound size in all groups, including controls ($p < 0.05$). After 7 days, a significant acceleration of healing in all BM-MNC and BM-MSc groups in comparison with the controls (all $p < 0.05$) was seen, but acceleration in both AT-MSc groups was not significant. After 14 days, there was a significant acceleration of wound healing in all cells groups in comparison with controls, the average area reduction was 99.2% and 94.4% in diabetic and nondiabetic BM-MNC groups; analogous 97.8% and 98.6% in BM-MSc; 96.6% and 95% in AT-MSc; but only 83.8% in controls (all $p < 0.05$).

Conclusion: In our experiment, the local application of human stem cells derived from bone marrow and adipose tissue accelerated wound healing in diabetic rats compared with controls receiving only standard therapy; a significant difference between the diabetic and nondiabetic cell suspensions was not found. AT-MSc were slower to improve healing after 7 days, but after 14 days, there were not significant differences between the types of used stem cells. Topical treatment of wounds by stem cells could be a promising therapy for patients with diabetes.

Dipeptidyl peptidase-4 inhibitor anagliptin alleviates lipotoxicity-induced hepatic insulin resistance and steatohepatitis in mice

Y. Sakai, M. Nagashimada, N. Nagata, Y. Ni, S. Kaneko, T. Ota; Brain/Liver Interface Medicine Research Center, Kanazawa University, Kanazawa, Japan.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) is a form of a lipotoxic liver injury that can impair systemic insulin resistance and progress to nonalcoholic steatohepatitis (NASH). We previously demonstrated that excessive hepatic lipid accumulation promotes the activation of macrophages/Kupffer cells, resulting in exacerbated insulin resistance and hepatic inflammation. However, there are few promising treatments targeting lipotoxicity-mediated hepatic activation/polarization of macrophages in NASH. Dipeptidyl peptidase-4 (DPP-4) is widely expressed, including in immune cells such as monocytes/macrophages. In this study, to test the hypothesis that DPP-4 plays a role in immune cell-mediated insulin resistance and NAFLD progression to NASH, we examined the effect of anagliptin, a DPP-4 inhibitor, on diet-induced NAFLD.

Materials and methods: Eight-week-old C57BL/6 mice were fed a high-cholesterol/high-fat (CL) diet with or without 0.3% anagliptin (CL + Ana) for 14 weeks. The liver histology, insulin sensitivity, and DPP-4 activity were examined. Next, we quantified intrahepatic immune cells using a fluorescence-activated cell sorter (FACS).

Results: After 14 weeks of feeding, histological examination revealed hepatic steatosis and inflammation in mice fed the CL diet. The mice exhibited hyperinsulinemia and glucose intolerance, indicating that mice fed the CL diet developed NASH associated with insulin resistance. Anagliptin administration improved the hepatic steatosis by decreasing TG and FFA levels by 23% and 50%, respectively. Anagliptin also inhibited the development of hepatic inflammation and fibrosis, lowering F4/80+ macrophage/Kupffer cell infiltration and the hydroxyproline content in the liver. Importantly, hepatic DPP-4 protein expression was increased in mice fed the CL diet compared with mice fed normal chow (NC), while anagliptin significantly suppressed DPP-4 expression. Moreover, in the CL group, the DPP-4 activity increased 2.2-fold and 1.4-fold in the plasma and liver, respectively, compared with the NC group, whereas anagliptin markedly reduced the DPP-4 activity in both plasma and liver by 88% and 65%, respectively ($p < 0.01$). Anagliptin administration in mice fed the CL diet led to improved glucose intolerance and hyperinsulinemia and enhanced insulin signal assessed by IR β and Akt phosphorylation in the liver. These findings were associated with endoplasmic reticulum stress reduction (GRP78/CHOP and phospho-eIF2 α) and MAPK (JNK/p38MAPK) and NF κ B attenuation in the liver. To assess the effect of anagliptin on hepatic inflammation further, intrahepatic leukocytes were quantified using FACS. Hepatic macrophages identified as CD45+CD11b+F4/80+ cells were decreased in the CL + Ana group by 26% compared with mice fed the CL diet. In addition to a slight reduction of the total macrophage content in the liver, mice fed CL + Ana had 38% fewer CD11c+CD206- (M1)-type macrophages, but 24% more CD11c-CD206+ (M2)-type macrophages than mice fed the CL diet, resulting in a predominance of M2 over the M1 macrophage population.

Conclusion: DPP-4 activity in both liver and plasma is increased significantly in the dietary model of NAFLD associated with insulin resistance. Anagliptin suppresses lipotoxicity-induced aberrant activation of DPP-4 and attenuates hepatic insulin resistance and steatohepatitis by regulating M1/M2 status in hepatic macrophages.

68

Dipeptidyl peptidase-4 inhibitor suppresses inflammation in U937 monocytes by inhibiting phosphorylation of caveolin-1 through CD26

M. Hiromura¹, K. Nohtomi¹, M. Terasaki¹, Y. Mori¹, H. Kuwata², T. Hirano¹;

¹Diabetes, Metabolism, and Endocrinology, Showa University School of Medicine, ²Oral Microbiology and Immunology, Showa University School of Dentistry, Tokyo, Japan.

Background and aims: We reported that dipeptidyl peptidase-4 inhibitors (DPP-4i) confer an anti-atherosclerotic effect in apolipoprotein-E null mice by incretin-dependent and -independent manner. To elucidate the molecular mechanisms, we focused on the effect of DPP-4i on expression of proinflammatory cytokines in monocytes.

Materials and methods: Cultured U937 human monocytes were treated with or without 10 µg/ml of Lipopolysaccharide (LPS) and teneligliptin (1–10 nM). Treated cells lysates, and RNA were collected for Western blotting and real-time reverse transcription polymerase chain reaction. Some cells were treated with teneligliptin (5 and 10 nM) or vehicle with LPS, and RNA was subjected to microarray analysis.

Results: Teneligliptin (1–10 nM) widely suppressed the expression of inflammatory molecules, such as IL-1β, IL-6, TNF-α, NF-κB, TLR-4, MCP-1, CCR2, IL-8, IP-10, and RANTES induced by LPS without affecting cell proliferation. Treatments with antibody (Ab) or small interfering (si) RNA against CD26 mimicked anti-inflammatory effect of teneligliptin. Microarray analysis failed to detect a specific molecule to explain anti-inflammatory action of teneligliptin, suggesting posttranslational mechanisms. We nominated caveolin (Cav)-1, a signaling protein associated with caveolae, as a candidate molecule because it has been reported that Cav-1 binds to CD26 via DPP-4 catalytic site, which mediates inflammatory signals. Anti-Cav-1 polyclonal antibody [H97] recognizing 82–178 amino acids of Cav-1 significantly suppressed IL-1β, IL-6, TNF-α, and NF-κB mRNAs, whereas anti-Cav-1 monoclonal antibody [7c8] reacts epitope between residue 32 and the C-terminus of Cav-1 did not. Cav-1 gene expression was not altered by LPS or teneligliptin, however, Cav-1 was phosphorylated by LPS and teneligliptin attenuated LPS-induced p-Cav-1 generation. Likewise, anti-CD26Ab suppressed p-Cav-1 generation. Anti-Cav-1Ab [7c8] suppressed slightly but anti-Cav-1Ab [H97] strongly suppressed p-Cav-1 generation by LPS. Induction of siRNAs into CD26 and Cav-1 genes successfully suppressed gene expression of CD26 and Cav-1, which resulted in significantly suppression of LPS-induced expression of IL-1β, IL-6, TNF-α, and NF-κB mRNAs. CD26siRNA and Cav-1siRNA tended to suppress CD86 mRNA, a downstream of NF-κB signal. ERK1/2 was phosphorylated by LPS, and teneligliptin, Anti-CD26Ab and anti-Cav-1Ab [H97] all suppressed p-ERK1/2 generation. Likewise CD26siRNA and Cav-1siRNA suppressed p-ERK1/2 generation. IRAK-4, a master molecule of downstream of TLR-4 signaling, was phosphorylated by LPS. Teneligliptin significantly suppressed LPS-induced p-IRAK-4 generation. Anti-CD26Ab and anti-Cav-1Ab [H97] tended to suppress p-IRAK-4 expression.

Conclusion: The present study suggests that a DPP-4i suppresses LPS-induced inflammation in human monocytes by inhibiting interaction of CD26 and Cav-1, which resulted in suppressed TLR4/IRAK-4 mediated NF-κB and MAPK pathways.

69

Dipeptidyl peptidase 4 inhibition by gemigliptin prevent abnormal vascular remodelling mediated by Nrf2 activation

A. Khang¹, S. Choi², S. Park³, Y.-K. Choi¹, J.-H. Jeon¹, K.-H. Bae¹, G.-S. Jung¹, M.-K. Kim⁴, E.-H. Kim⁵, K.-G. Park¹, I.-K. Lee¹;

¹Kyungpook National University School of Medicine, ²Department of Biomedical Science, Kyungpook National University School of Medicine, ³Leading-edge Research Center for Drug Discovery and Development for Diabetes and Metabolic Disease, Kyungpook National University School of Medicine, ⁴Department of Internal Medicine, Keimyung University School of Medicine, ⁵Department of Internal Medicine, Daegu Fatima Hospital, Daegu, Republic of Korea.

Background and aims: Dipeptidyl peptidase-4 (DPP-4) inhibitors exert a potent anti-hyperglycemic effect and reduce cardiovascular risk in type 2 diabetic patients. Several experimental studies have shown that in addition to glucagon-like peptide-1 augmentation, DPP-4 inhibitors including sitagliptin and anagliptin have a beneficial effect in cardiovascular diseases such as atherosclerosis and cardiac infarction that involves reactive oxygen species. Here, we show that gemigliptin, a new DPP-4 inhibitor, can directly attenuate the abnormal proliferation and migration of vascular smooth muscle cells (VSMCs) via enhanced NF-E2-related factor 2 (Nrf2) activity.

Materials and methods: The carotid artery ligation model was performed for the assessment of neointimal hyperplasia in male C57BL/6 N mice treated with different concentrations of gemigliptin in a normal chow diet (0, 0.04, 0.09, and 0.27% in diet). VSMCs were isolated from the thoracic aortas of four-week-old SD rats and the cells from the third to fifth passages were used for *in vitro* experiments: WST-1 assay, FACS analysis, RT-PCR and Western blotting, and wound healing assay. The expression of DPP-4 in VSMCs was knockdown by small interfering RNA (siRNA) using Lipofectamine® RNAiMAX.

Results: Gemigliptin significantly prevented the neointimal hyperplasia induced by ligation injury in mouse carotid arteries, *in vivo*. Likewise, the proliferation of rat primary VSMCs stimulated by 20% FBS was significantly attenuated by gemigliptin in a dose dependent manner, confirmed by the decreased phospho-Rb leading to G1 cycle cell arrest, consequently. We found that gemigliptin enhanced Nrf2 activity by not only its mRNA expression but also increased Keap1 proteasomal degradation by p62, resulting in the induction of Nrf2 target genes such as NAD(P)H quinone oxidoreductase 1 and heme oxygenase 1. The anti-proliferative role of gemigliptin disappeared in VSMCs with DPP4 siRNA knockdown, indicating that the endogenous DPP4 in VSMCs mediated the effect of gemigliptin. Besides, gemigliptin diminished TNF-α-mediated cell adhesion molecules such as MCP-1, VCAM-1 and MMP2 activity in VSMCs.

Conclusion: Taken together, our data indicate that gemigliptin exerts a prohibitory effect on the proliferation and migration of VSMCs via Nrf2 activity for the prevention of cardiovascular diseases.

70

Effects of DPP-4 inhibition on glomerular and tubular function in a rat model of ischaemia-reperfusion injury

C. Reichetzer¹, K. von Websky¹, O. Tsuprykov¹, V. Antonenko¹, A. Mohagheghi Samarin^{1,2}, B. Hoher¹;

¹University of Potsdam, Germany, ²University of South Bohemia, České Budějovice, Czech Republic.

Background and aims: Dipeptidyl peptidase (DPP)-4 inhibitors have protective effects in ischaemia-reperfusion injury (IRI) of the heart and lung. DPP-4 shows strong renal expression and its substrates are present in the kidney. Therefore, we studied the effects of the DPP-4 inhibitors linagliptin, vildagliptin and sitagliptin on the outcome of IRI-induced acute kidney injury in uninephrectomised rats.

Materials and methods: Male Wistar rats obtained from Charles River (Germany) weighing 150–170 g were subjected to uninephrectomy. Two weeks later, the remaining kidney was exposed to IRI by clamping the renal artery for 30 min; sham surgery was performed without clamping. The rats ($n=10\text{--}14/\text{group}$) received DPP-4 inhibitor treatment once-daily with either linagliptin (1.5 mg/kg/day), vildagliptin (8 mg/kg/day), sitagliptin (30 mg/kg/day) or vehicle via gavage on the 3 consecutive days prior to IRI. An additional group was treated with sitagliptin until study end in order to inhibit DPP-4 activity during the entire experiment. This group was initially treated with sitagliptin 30 mg/kg/day; after induction of IRI, the dose was adjusted to 15 mg/kg/day because of renal failure.

Results: Levels of active glucagon-like peptide-1 increased 3–4 fold in all DPP-4 inhibitor treatment groups versus placebo up to 24 h after clamping ($p<0.05$ for all comparisons). Plasma cystatin C, a marker of glomerular filtration rate, peaked 48 h after clamping and increased from 1454 ± 320 ng/ml in the sham-operated group to 1728 ± 323 ng/ml in the placebo-treated group ($p=0.059$). However, this increase was unaffected by treatment with either linagliptin, vildagliptin, or sitagliptin. In contrast, DPP-4 inhibitor treatment elicited beneficial effects on tubular regeneration. The tubular dilatation score, assessed 1 week after induction of IRI, was significantly reduced in all treatment groups compared with placebo.

Conclusion: In rats with acute IRI of the kidney, DPP-4 inhibition does not alter glomerular function but may enhance tubular regeneration.

The neuroprotective efficacy of the DPP-4 inhibitor linagliptin against stroke is not mediated by GLP-1 receptor activation

V. Darsalia¹, M. Larsson¹, D. Nathanson¹, D.J. Drucker², T. Nyström¹, T. Klein³, C. Patrone¹;

¹Karolinska Institutet, Department of Clinical Science and Education, Södersjukhuset, Internal Medicine, Stockholm, Sweden, ²Department of Medicine, Mount Sinai Hospital and the Lunenfeld-Tanenbaum Research Institute, University of Toronto, Canada, ³Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

Background and aims: Diabetes and obesity are strong risk factors for premature and severe stroke. Inhibition of dipeptidyl peptidase (DPP)-4 is a treatment for type 2 diabetes that prevents the inactivation of glucagon-like peptide (GLP)-1 and therefore increases levels of active GLP-1. In addition to their glycaemic actions, DPP-4 inhibitors have been shown to have neuroprotective effects in several experimental models. Specifically, our research group has shown that the DPP-4 inhibitor linagliptin is efficacious against stroke in normal and type 2 diabetic and obese mice. However, the mechanism of action of DPP-4 inhibitor-mediated neuroprotection remains largely unknown. The aim of this study was to determine whether the efficacy of linagliptin against stroke is mediated by GLP-1 receptor (GLP-1R) activation by performing stroke efficacy studies in normal versus knockout mice lacking the GLP-1R (Glp1r^{-/-} mice).

Materials and methods: Adult male mice with or without functional disruption of GLP-1R were treated orally with linagliptin 10 mg/kg/day or vehicle for 7 weeks. There were 4 experimental groups: Glp1r^{-/-} plus linagliptin, $n=9$; Glp1r^{-/-} plus vehicle, $n=8$; wild type plus linagliptin, $n=9$; wild type plus vehicle, $n=9$. After 4 weeks of treatment, the mice were subjected to 30 min of transient middle cerebral artery occlusion to induce ischaemic stroke. Drug treatment was continued for 3 additional weeks until sacrifice. The severity of the ischaemic damage was measured by evaluating the stroke volume and by stereological counting of NeuN-positive surviving neurons in the striatum and cortex.

Results: Linagliptin treatment resulted in a strong trend, albeit not statistically significant, towards a reduction of ischaemic volume in wild type mice (mean linagliptin= 6.5 mm³ vs mean vehicle= 11.8 mm³). In the Glp1r^{-/-} mice, the effect of linagliptin on the reduction of ischaemic volume reached significance (mean linagliptin= 18.8 mm³ vs mean

vehicle= 7.9 mm³; $p<0.001$). The results also showed that linagliptin treatment resulted in a significant reduction of stroke damage in both wild type (mean linagliptin= 2.27×10^6 vs mean vehicle= 1.62×10^6 ; $p<0.05$) and Glp1r^{-/-} mice (mean linagliptin= 2.07×10^6 vs mean vehicle= 1.18×10^6 ; $p<0.0005$) as measured by the number of surviving neurons in the striatum and cerebral cortex.

Conclusion: These results indicate that linagliptin-induced neuroprotection is mediated by a GLP-1R-independent mechanism. Because DPP-4 inhibitors can also increase the levels of other DPP-4 substrates that may have beneficial effects in the brain, our results should provide a strong rationale for identifying these factors.

Amelioration of hyperglycaemia with SGLT2i prevents atherosclerosis through suppression of macrophage foam cell formation in diabetic mice independent of insulin action

M. Terasaki^{1,2}, M. Hiromura¹, K. Kohashi¹, H. Kushima¹, M. Nagashima¹, Y. Mori¹, T. Hirano¹;

¹Department of Medicine, Showa University School of Medicine, ²Ebara Hospital, Tokyo, Japan.

Background and aims: Although diabetes is one of the leading causes of atherosclerosis, it is poorly understood the direct association between hyperglycaemia and atherosclerosis independent of insulin action. A SGLT2i is a recently developed oral anti-diabetic agent, which reduces plasma glucose levels by increasing urinary glucose excretion without affecting insulin secretion and action. We investigated how amelioration of glycaemia by SGLT2i is associated with macrophage-driven atherosclerosis in mouse models of type 1 and type 2 diabetes.

Materials and methods: Male *ApoE*^{-/-} mice receiving injection of streptozotocin (50 mg/kg i.p x 5 days, $n=34$) or saline ($n=31$) were randomly assigned to SGLT2i treatment (dapagliflozin, 1.0 mg/kg/day) or vehicle. Male *db/db* diabetic mice were maintained on the food containing SGLT2i (ipragliflozin, 1.0 mg/kg/day, $n=14$) or none ($n=30$). After 4 weeks, the peritoneal macrophages (M ϕ) migrated by an i.p. injection of thioglycolate were collected to evaluate foam cell formation measured by incorporation of [³H]-oleate into [³H]-cholesteryl-oleate in the presence of ox-LDL. In the *ApoE*^{-/-} mice, The atherosclerosis was assessed as en face atherosclerotic plaque area determined by oil red O staining. In the diabetic mice, gene expressions related to foam cell formation in M ϕ were examined by RT-PCR.

Results: In the type 1 diabetic *ApoE*^{-/-} mice, the SGLT2i decreased the fasting blood glucose (FBG), HbA1c, and glucose-AUC after oral glucose tolerance test (OGTT) compared to vehicle. The body weight, daily food intake, systolic blood pressure, or insulin and lipids were not changed by treatment with the SGLT2i in the diabetic and non-diabetic mice. In the diabetic *ApoE*^{-/-} mice, the atherosclerotic lesions and foam cell formation were accelerated compared to the non-diabetic counterparts (2-3 folds, $p<0.01$), and significantly suppressed by the SGLT2i administration (33-34%, $p<0.01$). The atherosclerotic lesions was highly correlated to the degree of foam cell formation ($r=0.95$, $p<0.01$, $n=15$) and the HbA1c levels ($r=0.86$, $p<0.01$, $n=15$), but insignificantly to the cholesterol levels ($r=0.31$, $p=0.12$). In the *db/db* type 2 diabetic mice with hyperinsulinemia, the SGLT2i decreased the body weight, levels of plasma triglycerides, FBG, and HbA1c, and the glucose AUC with increased water intake by 3 times and doubled urine volume. Foam cell formation was suppressed by the SGLT2i (34%, $p<0.01$), which correlated to the HbA1c levels ($r=0.88$, $p<0.01$, $n=36$), but insignificantly to lipid levels ($r=-0.46$, $p=0.06$) or insulin ($r=-0.15$, $p=0.56$). Gene expressions of scavenger receptors, CD36 and Lox-1, and ACAT-1, a rate limiting enzyme for cholesterol esterification were up-regulated, while ABCA1, a key molecule for cholesterol efflux was down-regulated in

M ϕ obtained from both diabetic mice. The SGLT2i decreased expressions of scavenger receptors and ACAT-1 by approximately 30 to 40% and increased ABCA1 by 42%.

Conclusion: The SGLT2is exert anti-atherogenic effects by normalization of blood glucose levels in both type1 and type2 diabetic mice through preventing foam cell formation of M ϕ , which is independent of insulin action. Our results suggest that the foam cell formation regulated by scavenger receptors, ACAT-1, and cholesterol efflux is highly sensitive to glycaemia *ex vivo*.

Endogenous GLP-1 and treatment with liraglutide affect activation in reward and satiety related brain areas in response to palatable food

J.S. ten Kulve¹, D.J. Veltman², L. van Bloemendaal³, P.F.C. Groot⁴, H.G. Ruhé⁵, F. Barkhof⁶, M. Diamant³, R.G. IJzerman³;

¹Diabetes Centre / Internal Medicine, VU University Medical Centre, ²Psychiatry, VU University Medical Centre, ³Diabetes Centre / Internal Medicine, VU University Medical Centre, ⁴Radiology, Academic Medical Center, Amsterdam, ⁵Psychiatry, University of Groningen, University Medical Centre Groningen (UMCG), Groningen, ⁶Radiology & Nuclear Medicine, VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: Central nervous system (CNS) activation in response to food cues may play an important role in the regulation of food intake. Obesity is associated with a deficit in responsiveness to palatable food in reward areas of the CNS, which may lead to an increase in food intake, as a means to compensate for understimulation of the CNS reward system. It is suggested that alterations in these CNS responses may contribute to the development of obesity and type 2 diabetes (T2DM). The gut-derived hormone glucagon-like peptide-1 (GLP-1) and GLP-1 receptor agonists (GLP-1RA) reduce appetite and body weight. It has been suggested that these effects are, at least to some extent, mediated by effects on the CNS. We hypothesized that, in humans, endogenous GLP-1 and treatment with a GLP-1RA influence activation in reward and satiety related areas in the CNS in response to intake of palatable food.

Materials and methods: Using functional magnetic resonance imaging (fMRI), we determined the effects of endogenous GLP-1 and treatment with the GLP-1 analogue liraglutide on acute CNS activation to the receipt of chocolate milk. In the first study, infusion of the GLP-1 receptor antagonist exendin 9-39, was used to block endogenous GLP-1 effects in healthy lean individuals (n=20, mean \pm SD age 56.3 \pm 6.2 yrs, BMI 22.5 \pm 1.7 kg/m², 10 males) and obese patients with T2DM (n=20, mean \pm SD age 59.3 \pm 4.1 yrs, BMI 32.0 \pm 4.7 kg/m², 11 males). Infusion with exendin 9-39 was compared to placebo infusion, which were performed on two separate test visits. In the second study, in a cross-over design with only the T2DM patients, we compared CNS activation between treatment with liraglutide 1.8 mg and insulin glargine at two time points, i.e. after 10 days and 12 weeks of treatment.

Results: Reduced activation in response to the receipt of chocolate milk was observed in T2DM patients, compared to lean individuals, in right insula (p=0.04). Blockade of endogenous GLP-1 effects blunted the activation to chocolate milk receipt in healthy lean individuals in bilateral insula (right p=0.01, left p=0.03). Increased activations in response to chocolate milk were observed after 10 days of treatment with liraglutide, compared to insulin, in right insula (p=0.03) and right caudate nucleus (p=0.01), but these effect ceased to be significant after 12 weeks of treatment.

Conclusion: We found effects of GLP-1 and liraglutide in the insula and caudate nucleus, areas implicated in CNS reward and the central regulation of food intake. Our results indicate that endogenous GLP-1 contributes to the central regulation of feeding. Furthermore, compared to insulin, short-term treatment with the GLP-1 analogue liraglutide may improve the observed deficit in the responsiveness of the CNS to palatable food in obese T2DM patients, which may contribute to the induction of weight loss observed during this treatment. However, there were no long-term effects of liraglutide on CNS activation. This may explain why weight loss does not proceed after the initial treatment period with liraglutide 1.8 mg.

A randomised double-blind trial of liraglutide to control HbA_{1c} in subjects with type 2 diabetes treated with multiple daily insulin injections (MDI/Liraglutide trial)

M. Lind^{1,2}, I. Hirsch³, J. Tuomilehto⁴, S. Dahlqvist¹, B. Ahrén⁵, O. Torffvit⁵, S. Attvall², M. Ekelund⁵, K. Filipsson⁵, B.-O. Tengmark⁶, S. Sjöberg⁷, N.-G. Pehrsson⁸;

¹NU Hospital Group, Uddevalla, ²University of Gothenburg, Sweden, ³University of Washington, Seattle, USA, ⁴Helsinki University, Helsinki, Finland, ⁵Lund University, Lund, ⁶Citydiabetes, Stockholm, ⁷Karolinska Institutet, Stockholm, ⁸Statistiska Konsultgruppen, Gothenburg, Sweden.

Background and aims: Multiple daily insulin injections (MDI) are generally a final treatment option in subjects with type 2 diabetes (T2D) and poor glycaemic control, but are often associated with weight gain and increased risk of hypoglycaemia. Many individuals also have significantly reduced insulin production and do not reach glycaemic targets. Randomized controlled trial data are lacking on whether adjunctive glucose lowering agents can improve glycaemic control in these individuals.

Materials and methods: In total, 124 subjects with T2D treated with MDI at 14 hospitals in Sweden were randomized to liraglutide (L) or placebo (P) for 24 weeks. The primary endpoint was change in HbA_{1c} from baseline to week 24 estimated by ANCOVA, adjusted for baseline HbA_{1c}.

Results: Mean age at baseline was 63.8 and 63.6 years, HbA_{1c} 74.6 mmol/mol (9.0%) and 74.4 mmol/mol (9.0%), BMI 33.7 and 33.5 kg/m² and total insulin dose 105.3 and 105.6 units in the L and P groups, respectively. In the Intention to Treat Analysis, HbA_{1c} was reduced by 16.9 mmol/mol (1.5%) in the L group, compared to 4.6 mmol/mol (0.4%) in the P group, difference -12.3 mmol/mol (-1.1%, $p < 0.0001$). There were more in the L group (42.9%) than in the P group (5.1%), who reached HbA_{1c} < 53 mmol/mol = 7.0% ($p < 0.0001$). Body weight was reduced by 3.8 kg in L but not P subjects, +0.0 kg, difference -3.8 kg ($p < 0.0001$). Total insulin dose was reduced by 18.1 U with L and 2.3 U with P, difference -15.8 U ($p < 0.0001$). Fasting and postprandial glucose levels were lower in the L than P group, difference -1.5 and -2.0 mmol/l, respectively ($p < 0.01$ for both). The mean glucose levels ($p < 0.001$) and standard deviation of glucose levels ($p = 0.001$) estimated by masked continuous glucose monitoring were significantly lower in the L than P group, -1.9 and -0.5 mmol/l, respectively. There were no severe hypoglycaemia in either group. No significant difference existed in symptomatic or asymptomatic non-severe hypoglycaemias with values < 4.0 or < 3.0 mmol/l between the L and P groups. The most common type of hypoglycaemia was non-severe symptomatic hypoglycaemia < 4.0 mmol/l, mean number during follow-up 1.29 and 1.24 in the L and P Groups respectively ($p = 0.96$).

Conclusion: Adding liraglutide to individuals with T2D treated with MDI improves glycaemic control without increased risks of hypoglycaemia, reduces weight and patients can lower their insulin doses. *Clinical Trial Registration Number: NCT02113332*

Once-daily liraglutide vs lixisenatide as add-on to metformin in type 2 diabetes: a 26-week randomised controlled clinical trial

M.A. Nauck¹, M. Rizzo², V. Pirags³, H. Bosch-Traberg⁴, J. Madsen⁴, B. Cariou⁵;

¹Division of Diabetology, St. Josef Hospital, Ruhr University Bochum, Germany, ²University of Palermo, Italy, ³Pauls Stradins Clinical University Hospital, University of Latvia, Riga, Latvia, ⁴Novo Nordisk, Søborg, Denmark, ⁵Hôpital Nord-Laënnec, Saint Herblain, France.

Background and aims: Liraglutide (lira) and lixisenatide (lix) are GLP-1 receptor agonists for the treatment of type 2 diabetes mellitus (T2DM), both to be injected once daily. The aim of the trial was to compare the efficacy

and safety of lira vs lixi, as add-on to metformin (MET) in patients with T2DM not achieving adequate glycaemic control on MET alone.

Materials and methods: This was a 26-week, randomised, parallel group, open label trial. Patients (age ≥ 18 years, HbA_{1c} 7.5–10.5% [58–91 mmol/mol], BMI ≥ 20 kg/m²) with T2DM were randomised 1:1 to lira 1.8 mg or lixi 20 μ g as add-on to MET (maximum tolerated dose, 1000–3000 mg daily). Dose escalation and administration of lira and lixi were according to the approved label for both drugs at the time of the trial. Lira was administered once daily at any time of the day irrespective of meals. Lixi was administered once daily, within an hour prior to the morning or evening meal.

Results: 404 patients (mean age 56 years, male/female 60%/40%, BMI 35 kg/m², HbA_{1c} 8.4% [68 mmol/mol], T2DM duration 6.4 years) were randomised. At Week 26, lira reduced mean HbA_{1c} significantly more than lixi did (estimated treatment difference: -0.62%, 95% CI: -0.80 to -0.44; $p < 0.0001$), with more patients reaching HbA_{1c} goals of $< 7\%$ and $\leq 6.5\%$, compared to lixi (Table). Lira was associated with greater improvement in the HOMA-B index. As HOMA-B was measured in the fasting state, the improvement was possibly determined by differences in drug exposure due to different half-lives of lira and lixi. Lira reduced fasting plasma glucose more than lixi. Greater reduction in mean 9-point self-measured plasma glucose was seen with lira. However, lixi had smaller post-prandial increments for the meal following injection compared to lira. Both drugs promoted similar body weight decrease (-4.3 kg for lira and -3.7 kg for lixi; $p = ns$). Systolic and diastolic blood pressure similarly decreased in both groups. The safety profile was overall similar between the two groups. The most common adverse events were gastrointestinal disorders (nausea: 21.8% for lira and lixi; diarrhoea: 12.4% for lira and 9.9% for lixi). Confirmed hypoglycaemic episodes (severe hypoglycaemia or PG < 3.1 mmol/L) were rare (4 events in 3 patients for lira, and 8 events in 5 patients for lixi, $p = ns$), with no severe hypoglycaemic episodes.

Conclusion: Liraglutide was more efficacious than lixisenatide as add-on to MET in achieving glycaemic control, and may be associated with greater improvement in beta-cell function in patients with T2DM. Body weight and blood pressure reductions were similar, and both treatments were well-tolerated with low risk of hypoglycaemia and similar gastrointestinal adverse events profiles.

Table. Effect of liraglutide vs lixisenatide in patients with T2DM after 26 weeks of treatment

	Lira (n=202)		Lixi (n=202)		P-value*
	Estimated change from baseline*	Estimated change from baseline*	Estimated difference*	95% CI	
HbA _{1c} (%)	-1.83	-1.21	-0.62	[0.80; 0.44]	<0.0001

Continuous glucose monitoring in type 2 diabetes patients treated with once weekly dulaglutide or once daily glargine, both combined with insulin lispro (AWARD-4 substudy)

J. Jendle¹, M. Testa², S. Martin³, H. Jiang³, Z. Milicevic⁴;

¹Endocrine and Diabetes Center, Örebro University, Örebro, Sweden, ²Harvard T.H. Chan School of Public Health, Boston, ³Eli Lilly and Company, Indianapolis, USA, ⁴Eli Lilly and Company Regional Operations, Vienna, Austria.

Background and aims: Since higher glycaemic variability may predict potentially greater risk for both hypo- and hyperglycaemia, we compared continuous glucose monitoring (CGM) metrics during treatment with 1.5 mg and 0.75 mg doses of once weekly GLP-1 receptor agonist dulaglutide (DU) vs daily glargine (GLA), both with prandial lispro (\pm metformin), in a subset of patients with type 2 diabetes (T2D) enrolled in the AWARD-4 trial.

Materials and methods: The study population comprised patients with T2D uncontrolled on conventional insulin regimens. Participants (n=144) had mean baseline age of 59.9 y, HbA1c of 8.57% [70.2 mmol/mol], and a BMI of 32.9 kg/m². A CGMS[®] iPro[™] was used for 3 days, at baseline and 26 (primary endpoint) and 52 weeks after randomisation, to estimate between-group differences in 24 h glycaemic ranges, thresholds, and variability. Study participants also performed 8-point self-monitored blood glucose (SMBG).

Results: The mean decreases from baseline to 26 weeks in CGM glucose (see Table) were similar to those from 8-point SMBG (LSM \pm SE; DU 1.5 mg -3.3 \pm 0.4 mmol/L; DU 0.75 mg -3.1 \pm 0.3 mmol/L; GLA -2.8 \pm 0.3 mmol/L), with no significant differences between treatments. These results were similar at 52 weeks. Increases in % time within the 3.9–7.8 mmol/L range were not different between treatments; however, DU 1.5 mg increased % time within the 3.9–10.0 mmol/L range significantly more than GLA at 26 weeks. Treatment effect on % time <3.9 mmol/L at 26 weeks were not different, but at 52 weeks treatment with GLA significantly increased % time <3.9 mmol/L versus both DU doses. DU 1.5 mg had a greater reduction in glycaemic variability as measured by within-patient standard deviation at 26 weeks versus GLA with no significant differences between treatments at 52 weeks. Total mean amplitude of glucose excursions (MAGE) was not different between treatments.

Conclusion: At primary endpoint, after 26 weeks, DU 1.5 mg compared to GLA resulted in greater increase in % time with CGM glucose in the 3.9–10.0 mmol/L range and with lower glycaemic variability. Both dulaglutide doses were associated with smaller increase in % time <3.9 mmol/L at final endpoint (52 weeks). These results are consistent with reported lower risk of clinical hypoglycaemia with DU 1.5 mg versus GLA in the overall AWARD-4 but further investigations are need to evaluate potential causal relationship between the observed changes in glucose variability and episodes of hypoglycaemia.

Once weekly dulaglutide does not increase the risk for cardiovascular (CV) events in type 2 diabetes: a prespecified meta-analysis of prospectively adjudicated CV events

K.C. Ferdinand¹, P. Sager², C.M. Atisso³, F.T. Botros⁴;

¹Tulane University SOM, New Orleans, ²Sager Consulting, San Francisco, ³Statistics, Eli Lilly and Company, ⁴Diabetes Development, Eli Lilly and Company, Indianapolis, USA.

Background and aims: Patients with type 2 diabetes have a 2- to 4-fold greater risk for cardiovascular disease than those without diabetes. Dulaglutide is a once weekly glucagon-like peptide-1 receptor agonist recently approved for treatment of type 2 diabetes. This meta-analysis evaluates the cardiovascular risk in type 2 diabetes patients treated with dulaglutide in 9 randomised safety and efficacy trials (mean [median] treatment duration was 333 [358] days).

Materials and methods: Reported cardiovascular events were independently adjudicated by a blinded clinical endpoint committee. The primary endpoint was a composite of death due to cardiovascular causes, nonfatal MI, nonfatal stroke, or hospitalisation for unstable angina (4-component major adverse cardiovascular event or MACE). Additional prespecified endpoints, composite and individual, included adjudicated coronary revascularisations, hospitalisation for heart failure, or all-cause mortality. Cox proportional hazards regression model stratified by study was used to estimate the hazard ratio (HR) and confidence interval (CI); the model included treatment as a fixed effect with 2 levels for the factor (dulaglutide or control).

Results: The analysis included 6010 randomised patients (dulaglutide: 3885; all comparators [active or placebo]: 2125); cumulative exposure to dulaglutide or control was 3941 and 2223 patient-years, respectively. The demographic and baseline cardiovascular disease characteristics were well-balanced across groups. Twenty-six (0.67%) patients in the dulaglutide group vs 25 (1.18%) in the all comparators group experienced a primary MACE-4 event. Treatment with dulaglutide was not associated with an increase in the risk of experiencing a MACE-4 endpoint compared with control therapies (HR: 0.57; multiplicity-adjusted (98.02%) CI: 0.30, 1.10) (Table). Results for the 3- and 6-component MACE, and all-cause mortality were consistent with the primary analysis (HR <1.0 for

all). In the dulaglutide group, 23 (0.59%) patients experienced a 3-component MACE event (composite of death from CV causes, nonfatal MI, or nonfatal stroke) compared to 21 (0.99%) in the all comparators group (HR: 0.60; 95% CI: 0.33, 1.08).

Conclusion: These results suggest that dulaglutide does not increase the risk of MACE events in type 2 diabetes patients. The ongoing cardiovascular outcomes study, REWIND, will further assess cardiovascular safety of dulaglutide.

Table. Summary of 4-component MACE analysis

Endpoint Component	All Dulaglutide (N=3885) n (%)	All Comparators (N=2125) n (%)	Hazard Ratio ^a Estimate (adj. 98.02% CI)	Treatment Comparison p value ^b
Primary 4-Component MACE Endpoint	26 (0.67)	25 (1.18)	0.57 (0.30, 1.10)	.046
- Death from CV Causes ^b	3 (0.08)	5 (0.24)	0.35 (0.07, 1.87)	.119
- Nonfatal MI	9 (0.23)	14 (0.66)	0.35 (0.13, 0.95)	.014
- Nonfatal Stroke	12 (0.31)	4 (0.19)	1.61 (0.42, 6.20)	.411
- Hospitalization for Unstable Angina	3 (0.08)	6 (0.28)	0.28 (0.05, 1.46)	.054

^a Calculated from a stratified Cox Proportional Hazards regression model; the p-values should be compared to the significance level of 0.0198 that resulted from adjusting for a second possible meta-analysis
^b Death from CV causes was defined as a death resulting from an acute MI, sudden cardiac death, death due to heart failure, death due to stroke, and death due to other CV causes.

Advancing basal insulin glargine with prandial lixisenatide QD vs insulin glulisine QD or TID in type 2 diabetes: the GetGoal-Duo2 evidence-based trial

C. Roy-Duval¹, M. Hanefeld², S. Gentile³, R. Aronson⁴, F.J. Tinahones^{5,6}, B. Guerci^{7,8}, E. Souhami¹, M. Wardecki⁹, J. Ye¹⁰, S. Heller¹¹, J. Rosenstock¹², on behalf of the GetGoal-Duo2 study investigators; ¹Sanofi, Paris, France, ²GWT-TUD, Study Centre Prof. Hanefeld, Dresden Technical University, Dresden, Germany, ³Department of Clinical and Experimental Medicine, Second University of Naples, Italy, ⁴LMC Diabetes & Endocrinology, Toronto, Canada, ⁵CIBER de Fisiopatología de la Obesidad y Nutrición (CIBEROBN), Instituto de Salud Carlos III, ⁶Hospital Virgen de la Victoria, Malaga, Spain, ⁷University of Lorraine, ⁸Department of Diabetology, Metabolic Diseases and Nutrition, Brabois Adult Hospital, Vandoeuvre Lès Nancy, France, ⁹Sanofi, Warsaw, Poland, ¹⁰Sanofi, Bridgewater, USA, ¹¹Department of Human Metabolism, University of Sheffield, UK, ¹²Dallas Diabetes and Endocrine Center, Dallas, USA.

Background and aims: To provide evidence on how to advance basal insulin (BI).

Materials and methods: We explored treatment options in poorly controlled, BI-treated (≥6 mo±1-3 OADs), predominantly obese adults with type 2 diabetes mellitus (T2DM) randomized to lixisenatide 20 µg QD (LIXI), insulin glulisine QD (GLU-1) or GLU TID (GLU-3), all added to insulin glargine (IG)±metformin, if HbA_{1c} remained ≥7-≤9% after a 12-week IG optimization run-in period after stopping other OADs. Co-primary endpoints at 26 weeks were (1) non-inferiority (95% CI upper bound <0.4%) in HbA_{1c} reduction with LIXI vs GLU-1 and (2) for LIXI vs GLU-3, either non-inferiority in HbA_{1c} reduction (2a) OR superiority (one-sided α=0.025) in body weight change (2b). FPG, PPG, IG dose, AEs and hypoglycaemia were assessed. Each arm randomized 298 pts (T2DM duration 12 yrs, BI duration 3 yrs, weight 89 kg).

Results: All co-primary endpoints were met as LIXI was non-inferior to GLU-1 and GLU-3 for HbA_{1c} reductions and statistically superior to both for body weight loss (Table). Documented hypoglycaemia was numerically and significantly lower with LIXI than with GLU-1 and GLU-3, respectively.

Conclusion: BI plus LIXI may become a preferred option to advance BI, attaining meaningful glycaemic targets with less hypoglycaemia and without negative impact on weight vs prandial insulin as Basal Plus or Basal Bolus for uncontrolled, BI-treated T2DM.

OP 14 The interplay between liver fat and insulin action

79

Adverse impact of visceral fat on lipid and metabolic profile in fatty liver disease

C. Saponaro¹, M. Gaggini¹, C. Rosso², E. Buzzigoli¹, F. Carli¹, D. Ciociaro¹, L. Mezzabotta², E. Vanni², F. Saba², M. Abate², A. Smedile², M. Rizzetto², E. Bugianesi², A. Gastaldelli¹;

¹Institute of Clinical Physiology, CNR, Pisa, ²Division of Gastroenterology and Hepatology and Lab. of Diabetology, Dept. of Medical Sciences, University of Turin, Italy.

Background and aims: Abdominal/visceral (VF) adiposity is a major risk factor for metabolic syndrome and type 2 diabetes and could be implicated in onset and development of non alcoholic fatty liver disease (NAFLD). However, the relative role in the progression of liver damage and dysfunction is still unknown. Insulin resistance, lipotoxicity and inflammation are the main events that occur in FLD. The aim of this work was to evaluate the impact of visceral fat on histological liver damage, lipid profile and metabolic alterations in patients with proven NAFLD.

Materials and methods: In 34 non diabetic subjects with biopsy proven non alcoholic FLD and 8 controls (CT) we measured visceral, subcutaneous and hepatic fat by MRI, plasma concentrations of triglycerides (TG), total cholesterol, free fatty acids (FFA), and GGT. Gas chromatography mass spectrometry was used to assess FFAs composition. From plasma FFA we calculated the de novo lipogenesis index (DNL = palmitic/linoleic acid) and unsaturated to saturated fat ratio (PUFA/SFA). By use of tracers we evaluated lipolysis and endogenous glucose production (EGP) and calculated adipose tissue insulin resistance (Adipo-IR = Lipolysis x Insulin) and hepatic insulin resistance (Hep-IR = EGP x Insulin). Histology was scored according to Kleiner.

Results: Of the 34 recruited patients 10 were without fibrosis (F0), 24 with fibrosis score 1 to 4 (F1-4). Fibrosis was associated with a worse metabolic profile, with increased both adipo-IR (8.3 ± 4.3 vs 7.4 ± 6.0 vs 3.6 ± 1.4) and HOMA index (3.2 ± 1.9 vs 2.6 ± 1.2 vs 1.3 ± 0.4) in F1-4 vs F0 vs CT (all $p < 0.05$ for F1-4 vs CT). In addition patients with F1-4, compared to F0 and CT, had higher VF (2.9 ± 1.1 vs 2.1 ± 0.6 vs 0.7 ± 0.4 kg, $p < 0.03$). VF and hepatic fat correlated with Adipo-IR ($r = 0.42$, $r = 0.64$) and HOMA index ($r = 0.42$, $r = 0.52$) and with increased plasma levels of TG ($r = 0.53$, $r = 0.52$) and DNL ($r = 0.46$, $r = 0.52$) all $p < 0.05$. Also alterations in FFA composition, in particular reduced PUFA/SFA ratio, were associated with higher VF ($r = -0.41$) and hepatic fat ($r = -0.57$ $p < 0.005$). Moreover, VF and hepatic fat correlated positively with MCP-1 ($r = 0.52$, $r = 0.55$) and oxLDL ($r = 0.37$, $r = 0.25$) and negatively with adiponectin ($r = -0.49$, $r = -0.53$), all $p < 0.05$, documenting a pro-inflammatory profile.

Conclusion: In patients with NAFLD, hepatic fat is associated with metabolic derangements and HOMA, but Adipo-IR and visceral fat accumulation appear to provide a major contribution to liver damage and is associated with an adverse lipid and inflammatory profile.

In massively obese patients with a metabolically healthy phenotype the prevalence of non alcoholic fatty liver disease is high and associated with sympathetic overactivity

S. Chiheb, N. Helmy, B. Merioud, A. Rezki, M. Ziou, C. Barrat, C. Vons, P. Valensi;

Jean Verdier Hospital, Bondy, France.

Background and aims: Metabolically healthy obese (MHO) individuals are relatively insulin sensitive, normotensive and have favourable glucose

and lipid profiles. Obesity and metabolic syndrome (MS) were reported to be associated with sympathetic nervous system overactivity. Non alcoholic fatty liver disease (NAFLD) is considered as the hepatic component of MS. The role of inflammation in the development of steatohepatitis (NASH) and the relation with sympathetic activity and metabolic disorders has been suggested. This study aimed to determine whether in massively obese patients with MHO phenotype inflammatory markers, insulin resistance, cortisol and sympathetic activity are associated with NAFLD.

Materials and methods: In a prospective study of patients undergoing bariatric surgery, liver biopsies were obtained peroperatively. We included 66 patients (54 women) aged 36.4 ± 9.6 years, body mass index 44.7 ± 0.9 kg/m². All of them were free of other liver disease. Liver changes were classified by histological analysis into 3 groups: normal liver, simple steatosis and steatohepatitis (NASH). MHO phenotype was defined as no or only one feature of the metabolic syndrome (IDF criteria). Biological measurements included plasma liver enzymes, lipids, glucose, cortisol, inflammatory markers (C-reactive protein (CRP), fibrinogen) and HOMA-IR. Sympathetic activity was assessed by plasma epinephrine and norepinephrine at fasting and 2 hours after an oral glucose challenge.

Results: Among the 66 patients 34 had steatosis and 16 NASH. Twenty-two patients had definite MHO status, including 8 with histologically normal liver, 11 with steatosis and 3 NASH. Among MHO patients, those with steatosis or NASH had higher post-glucose norepinephrine, afternoon cortisol levels and CRP levels ($p = 0.04$, 0.01 , 0.05 respectively). No other significant difference was detected between these patients and those with normal liver.

Conclusion: The prevalence of liver disease is high in massively obese patients with MHO phenotype. Those with NAFLD exhibit a more marked cluster of inflammation, hypercortisolism and sympathetic activity.

81

The link between obesity and insulin resistance by hepassocin

C.-J. Chang¹, H.-T. Wu^{1,2}, H.-Y. Ou³, F.-H. Lu¹, H.-C. Hung³, Y.-C. Yang¹, J.-S. Wu¹;

¹Department of Family Medicine, College of Medicine, National Cheng Kung University and Hospital, ²Research Center of Herbal Medicine, New Drugs, and Nutritional Supplements, National Cheng Kung University, ³Department of Internal Medicine, College of Medicine, National Cheng Kung University and Hospital, Tainan, Taiwan.

Background and aims: The prevalence of obesity has increased in most of the world over the past few decades, and the excess of body fat is associated with adverse health consequences. Numerous studies indicated that inflammation-mediated adipokines or hepatokines release led to the development of insulin resistance, the relationship among these factors was still obscure. Hepassocin was previously discovered as a hepatokine that exerted a lipogenic activity and led to insulin resistance. A recent study indicated that hepassocin also expressed in the adipose tissue. However, the role of hepassocin between obesity and insulin resistance is still obscure

Materials and methods: A total of 150 subjects with normal weight, overweight, and obesity ($n = 50$ for each group) were enrolled. Serum hepassocin concentrations were measured by enzyme-linked immunosorbent assay. Overexpression or knockdown of hepassocin in the adipose tissue of high fat diet-fed mice was achieved by lenti-viral vector transfection to evaluate the effects of hepassocin in fat pad. In addition, 3 T3-L1 adipocytes were used to investigate the possible mechanisms in hepassocin-induced lipogenesis, and to clarify the role of hepassocin in obesity. Moreover, HepG2 cells were treated with hepassocin recombinant protein to evaluate the effect of hepassocin on hepatic insulin sensitivity.

Results: The serum concentrations of hepassocin were significantly increased in subjects with overweight, or obesity as compared with normal

weight group (P for trend <0.01). The expression of hepassocin was detected in the epididymal fat, and the epididymal hepassocin expression was increased in high fat fed mice, as compared with chow group. Interleukin-6 treatment induced the expression of hepassocin in 3 T3-L1 adipocytes. In addition, treatment with hepassocin in 3 T3-L1 adipocytes significantly increased the lipogenesis through an ERK1/2-dependent pathway. Overexpression of hepassocin in epididymal adipose tissue significantly increased the size of the fat pad in mice. Furthermore, hepassocin disrupted insulin signaling to increase glucose production in HepG2 hepatocytes.

Conclusion: Inflammation in adipose tissue increased the expression of hepassocin and the elevated hepassocin in circulation further led to the insulin resistance in liver, and affected hepatic glucose production. In addition, hepassocin increased lipogenesis in adipocytes to induce obesity. Thus, we provided a novel mechanism of obesity-induced insulin resistance by hepassocin.

82

Glucagon-Like Peptide-1 (GLP-1) and its receptor agonist, exendin-4, affect cholesterol metabolism by regulating SREBP2 in hepatocyte Y. Hasegawa^{1,2}, M. Hori², T. Nakagami¹, M.H. Shiba², Y. Uchigata¹; ¹Diabetes Center, Tokyo Women's Medical University School of Medicine, Tokyo, ²Department of Molecular Innovation in Lipidology, National Cerebral and Cardiovascular Center Research Institute, Osaka, Japan.

Background and aims: Type2 diabetes mellitus (T2DM) causes dyslipidemia characterized by enhance of production of very low-density lipoprotein (VLDL) and LDL, and decrease of high-density lipoprotein (HDL). Glucagon-like peptide-1 (GLP-1) has been implicated in decreasing postprandial Apo-B48, chylomicron, triacylglycerol in animal models and patients with T2DM, by reducing intestinal lipoprotein production. To date, GLP-1 has some effects on cholesterol metabolism, but it remains to be completely elucidated. In this study, we investigated the effect of GLP-1 on cholesterol metabolism in liver of mice and Huh7 hepatocytes.

Materials and methods: (1) *in vivo* study, ten-weeks-old male C57BL/6J mice ($n=16$) were treated with the agonist of GLP-1 receptor, exendin-4 (ex-4, 10 nmol/kg body weight) or saline (control) by intraperitoneal injection for 5 days. Serum biological analysis was performed. Hepatic cholesterol contents were determined by Folch method. Protein levels and mRNA expressions involved with cholesterol metabolism in mice liver and small intestine were analyzed by western blotting and quantitative real-time PCR, respectively. (2) *In vitro* study, cultured Huh7 hepatocytes were treated with 0, 100, or 500 nM GLP-1(7-36) amide and LDL (100 $\mu\text{g}/\text{mL}$) in medium containing 10% lipoprotein derived serum (LPDS). Cellular protein and mRNA levels were analyzed described above.

Results: (1) The change in body weights did not differ between ex-4 treated mice and control mice. Serum VLDL- and LDL-cholesterol levels were significantly decreased in ex-4 treated mice than control mice (9.2 ± 1.4 vs. 6.3 ± 1.8 mg/dL, 11.6 ± 2.3 vs. 8.8 ± 2.0 mg/dL, $p < 0.05$). Hepatic protein levels of sterol regulatory element-binding protein (SREBP2) and LDL receptor (LDLR) were significantly increased by ex-4 treatment. Ex-4 increased hepatic mRNA expression levels of hydroxymethylglutaryl-CoA synthase and reductase, which are related to cholesterol synthesis, by 2.0- ($p=0.03$) and 1.5-folds ($p=0.005$), respectively. It decreased those of ATP-binding cassette transporters-G5/8 (ABCG5/8), which are related to cholesterol excretion, by 0.6- ($p=0.02$) and 0.7-folds ($p=0.01$), respectively. Ex-4 did not change hepatic cholesterol contents and the mRNA expression levels of cholesterol metabolism-related genes in small intestine. (2) In Huh7 cells, 500 nM GLP-1 increased the protein levels of SREBP2 and LDLR. 100 nM GLP-1 significantly increased mRNA expression of SREBP2 and LDLR by 1.5- ($p=0.01$) and 2.5- ($p=0.01$) folds while it significantly decreased those of ABCG5/8 by 0.3- ($p=0.02$) and 0.5- folds

($p=0.04$), respectively. 100 or 500 nM GLP-1 enhanced phosphorylated Erk1/2 associated with activation of insulin signal pathway.

Conclusion: Ex-4 decreased serum levels of VLDL- and LDL-cholesterol by increasing the hepatic expression of SREBP2 and LDLR in C57BL/6J mice. In culture hepatocytes, GLP-1 also increased the SREBP and LDLR expression, suggesting that ex-4/GLP-1 increases the uptake of VLDL and LDL in liver and reduce serum cholesterol independent of insulin.

83

Hepatic FGF21 protects mice against diet-induced lipid dysregulation and insulin resistance

Z. Huang, T.-H. Lee, C.-M. Wong, K.-L. Lam, A. Xu; Medicine, The University of Hong Kong, Hong Kong.

Background and aims: Fibroblast growth factor 21 (FGF21) is a potent metabolic hormone produced by a number of organs. It has been shown to confer multiple metabolic benefits on obesity and diabetes. Therapeutic administration of FGF21 or its analog protects against diet-induced obesity and hyperglycemia in both rodents and humans. However, the physiological roles of FGF21 remain ambiguous. Since the liver is the major site of production for circulating FGF21, we propose that the endocrine actions of FGF21 derived from the liver may account for its metabolic effects on lipid metabolism.

Materials and methods: We therefore generated the liver-specific FGF21 KO (LiverKO) mouse strain by crossbreeding transgenic mice bearing a conditional FGF21 allele with the exons 2 and 3 flanked by LoxP sites with mice expressing Cre under the control of the albumin promoter. LiverKO mice and their age-matched wild-type (WT) littermates were fed a high fat diet (HFD) for 20 weeks and assessed for the metabolic phenotypes.

Results: Circulating FGF21 was significantly elevated in WT mice during fasting or HFD feeding. However, this elevation of circulating FGF21 level was completely abolished in LiverKO mice, suggesting the liver is the major source of circulating FGF21. LiverKO mice treated with HFD showed a significant reduction in body fat mass when compared to WT mice, as revealed by NMR body composition analyzer suggesting resistance to obesity was mainly attributed to the loss of hepatic FGF21. Interestingly, although LiverKO mice had lean phenotype, they developed more severe glucose intolerance and insulin resistance after HFD feeding as shown by GTT and ITT, respectively. In addition, LiverKO mice had higher serum triglyceride and free fatty acid (FFA) levels suggesting that lipid homeostasis is impaired. It is possible that hepatic FGF21 inhibits lipolysis while promotes lipid uptake in adipocytes.

Conclusion: These data collectively suggest that circulating FGF21 is mainly derived from the liver. Hepatic FGF21 regulates lipid metabolism in adipocytes, and therefore protects mice against diet-induced hyperglycemia and insulin resistance possibly via reducing ectopic lipid accumulation in non-adipose tissues such as the liver and skeletal muscles.

Monounsaturated fatty acid enriched high fat diets attenuate obesity induced hyperinsulinaemia concurrent with an altered hepatic lipidome

A.M. Murphy¹, M. Morine², O. Finucane¹, C. Reynolds¹, C. Lyons¹, N. Healy¹, L. Brennan³, F. McGillicuddy¹, H. Roche¹;

¹UCD Conway Institute for Biomolecular and Biomedical Science, University College Dublin, Ireland, ²The Microsoft Research, University of Trento Centre for Computational and Systems Biology Rovereto, Italy, ³UCD Institute of Food and Health, University College Dublin, Ireland.

Background and aims: Altered lipid metabolism underlies many metabolic disorders such as obesity and Type 2 Diabetes Mellitus (T2DM).

Excess lipids and their metabolites act as metabolic stressors to induce inflammation and promote insulin resistance (IR). Lipidomics represents a novel tool to identify lipid biomarkers of disease. A lipidomic approach sought to investigate the differential effect of saturated fatty acid (SFA) versus monounsaturated fatty acid (MUFA) high-fat diet (HFD) challenges on the hepatic lipidome and an IR profile.

Materials and methods: C57BL/6 mice were fed SFA-HFD (45% palm oil), MUFA-HFD (45% olive oil) or chow diet for 24 weeks. GTT, ITT and an insulin secretory response determined insulin sensitivity. The hepatic lipidome of 36 mice was quantified by Biocrates Austria. Electrospray ionization-MS/MS screened glycerophospholipids and sphingolipids. The lipidomic database was combined with phenotypic data. Multivariate principle component analysis (PCA) and regression analysis were performed using SPSS. A novel visualization approach, manually superimposed liver lipidomic data onto the online LipidMaps sphingolipid biosynthesis pathway using a BioPAX level 3 format to differentiate the synthesis of these lipids between diets.

Results: MUFA-fed mice had reduced hyperinsulinaemia compared to SFA-fed mice despite equivalent obesity. PCA combined with regression analysis highlighted that a high-SFA/high-ceramide/low-PE cluster was predictive of an IR phenotype. Hepatic sphingolipid synthesis was down-regulated following a MUFA-HFD compared to chow and SFA-HFD.

Conclusion: Dietary intake of MUFA, can attenuate obesity-induced hyperinsulinaemia concurrent with an altered hepatic lipidome. A novel visualization of LipidMaps illustrated that MUFA-HFD prevented sphingomyelin or ceramide synthesis, which were associated with IR. Further work is required to determine the mechanistic basis of the altered hepatic lipidome, wherein to what extent can replacement of dietary SFA with MUFA, prevent IR by modifying hepatic lipid biology.

Pancreatic beta cell function, insulin sensitivity and metabolic phenotypes in type 2 diabetes at the time of diagnosis. The Verona newly diagnosed type 2 diabetes study

M. Dauriz¹, R.C. Bonadonna², M. Trombetta¹, L. Boselli¹, L. Santi¹, C. Brangani¹, I. Pichiri¹, C. Bianchi³, R. Miccoli³, S. Del Prato³, E. Bonora¹; ¹Department of Medicine, Division of Endocrinology, Diabetes and Metabolism, University of Verona School of Medicine and AOUI Verona, ²Division of Endocrinology, Department of Clinical and Experimental Medicine, University of Parma School of Medicine and Azienda Ospedaliera Universitaria of Parma, ³Department of Endocrinology and Metabolism, Section of Diabetology and Metabolic Disease, University of Pisa School of Medicine, Pisa, Italy.

Background and aims: Presence and frequency of beta cell (BC) dysfunction (BCD) and insulin resistance (IR) in patients with newly diagnosed type 2 diabetes mellitus (NDT2D) are imperfectly known, because previous studies used small cohorts and/or only surrogate indexes of BC function and IR. We sought to assess BC function and IR with state-of-art methods in the VNDS.

Materials and methods: In 712 GADA-negative, drug naïve, consecutive Italian NDT2D patients we assessed: 1. standard parameters; 2. insulin sensitivity (IS) by the euglycaemic insulin clamp; 3. BC function by state-of-art modeling of prolonged (5 hours) OGTT-derived glucose/C-peptide curves. Thresholds for BCD and IR were the 25th percentiles of BC function and IS assessed with the same methods of the VNDS in Italian subjects with normal glucose regulation of the GENFIEV (n=340) and GISIR (n=386) studies, respectively.

Results: In the VNDS, 89.8% [95% C.I.: 87.6 - 92.0%] and 87.8% [85.4 - 90.2] patients had BCD and IR, respectively. Patients with only one defect were 19.7% [16.8 - 22.6]. Isolated BCD and isolated IR were present in 10.9% [8.6 - 13.2] and 8.9% [6.8 - 11.0] patients, respectively. Coexistence of BCD and IR was observed in 78.9% [75.9 - 81.9] of the patients. 1.4% [0.5 - 2.3] of the patients had no detectable alterations in BC function and IS. Patients (19.7%) with only one metabolic defect had lower BMI, fasting glucose, HbA1c, triglycerides and BC function, and higher HDL-cholesterol and IS than patients with both BCD and IR (p<0.01 or less after Bonferroni's correction).

Conclusion: In conclusion, in NDT2DM patients: 1. at least 75.9% have both BCD and IR; 2. At least 87.6% and 85.4% have BCD and IR, respectively; 3. At least 16.8% have only one defect and a significantly different (milder) metabolic phenotype compared to patients with both defects. These findings may be relevant to therapeutic strategies centered on the metabolic phenotype of the patient.

Cardio-vascular changes associated with impaired as compared with normal glucose tolerance in obese patients. Role of sympathetic activity

A. Rezki, M. Fysekidis, B. Merioud, S. Chiheb, I. Banu, E. Cosson, P. Valensi;

Department of Endocrinology-Diabetology-Nutrition, CRNH-IdF, CINFO, AP-HP, Jean Verdier Hospital, Bondy, France.

Background and aims: An increase in cardiac output and alterations in cardio-vascular autonomic activity are clearly demonstrated in obese patients. Glucose intolerance is associated with more marked alterations of

cardiac autonomic function. This study aimed to compare cardio-vascular autonomic activity and hemodynamic parameters in obese patients with normal (NGT) or impaired glucose tolerance (IGT).

Materials and methods: Sixty-six obese patients were included and classified according to OGTT as NGT (n=38) or IGT (n=28). NGT and IGT patients were similar for sex ratio, age and BMI (38.4±4.1 and 37.4±4.3 kg/m², respectively). All were normotensive or had well-controlled hypertension and were free of cardio-vascular history. Arterial stiffness (carotid-to-femoral pulse wave velocity), central and peripheral blood pressure and left ventricular ejection time (LVET) were assessed by applanation tonometry (SphygmoCor®). Cardiac sympathetic activity (LF-HR) and sympatho-vagal balance (LF/HF-HR) were determined by spectral analysis of heart rate variations (Task Force Monitor® digital plethysmography). Cardiac output, stroke volume (SV), cardiac index (CI) and thoracic fluid content (TFC) were measured by thoracic impedance. The stroke volume to pulse pressure ratio (SV/PP, an index of total arterial compliance) was calculated from SphygmoCor® aortic and peripheral blood pressure measurements.

Results: Blood pressures and pulse wave velocity were similar in both groups. Compared with NGT, IGT patients had higher CI (2.3±0.5 vs 1.8±0.7 l/min*m²), SV (68±19 vs 55±17 ml) and TFC and longer LVET (317±25 vs 304±25 ms), and lower total peripheral resistance index (p<0.04 to p<0.002). The SV/PP ratio derived from aortic (1.1±0.4 vs 2.2±0.8) and peripheral (0.8±0.2 vs 1.7±0.5) pulse pressure were significantly higher in IGT patients (p=0.002, p<0.0001). In the overall population, plasma glucose at fasting and 2 hours after the oral glucose challenge correlated with LF/HF-HR (r=0.27, p=0.02; r=0.26, p=0.03), even after adjusting for age and BMI.

Conclusion: In obese patients, IGT is accompanied by an increase in left ventricular output and ejection duration and hypervolemia, all probably favoured by higher sympathetic activity. IGT patients also have a better total arterial compliance, in line with lower peripheral resistance.

87

Influence of replacement therapy on metabolic profile in male patients with type 2 diabetes mellitus and androgen deficiency

M. Rabijewski, P. Piątkiewicz;

Department of Internal Medicine, Diabetology and Endocrinology, Warsaw Medical University, Warsaw, Poland.

Background and aims: Low testosterone levels are observed in about 40% of men with diabetes mellitus type 2 and are associated with metabolic disorders, abnormalities of body composition and glycemic control. The aim of our study was to investigate the influence of testosterone replacement therapy on lipids, anthropometric parameters and HbA1c level in patients with diabetes mellitus type 2 and testosterone deficiency.

Materials and methods: We investigated 102 male patients with diabetes mellitus type 2, aged 53 to 68 years, with BMI from 27.5 to 38.5 kg/m². We assessed total (TT) and free testosterone (fT) levels, lipids, HbA1c, body mass index (BMI), waist-to-hip ratio (WHR) and waist circumferences (WC). Patients were divided into two groups: 1) treatment group, where we used diet, antidiabetic therapy and testosterone replacement therapy during 12 months; 2) control group where we used diet and antidiabetic therapy. In treatment group PSA and prostate volume were controlled.

Results: In treatment group baseline mean TT and fT levels were 8.24 nmol/l and 0.256 nmol/l, respectively and in control group 8.45 nmol/l and 0.265 nmol/l respectively, and did not differ significantly between groups. During testosterone replacement therapy mean TT and fT levels increased to 16.45 nmol/l and 0.567 nmol/l, respectively. After 12 months of treatment we observed significant improvement of lipids profile in both groups (decreasing of total cholesterol from mean 256.4 mg/dl to 221.8 mg/dl in treatment group and from 249.4 mg/dl to 238.2 mg/dl in control group and decreasing of LDL-cholesterol from 179.3 mg/dl to 147.4 mg/dl in treatment group and from 175.5 mg/dl to

163.3 mg/dl in control group) but changes in testosterone group were higher (p<0.05 and p<0.02, respectively). We observed also decreasing of HbA1c levels in testosterone group (8.3 vs. 7.2%; p<0.001) and in control group (8.4 vs. 7.6%; p<0.001) but there were also significant differences between both groups (p<0.02). BMI values decreased but changes between groups did not differ significantly. WHR and WC values also decreased in both groups (p<0.002 and p<0.01; respectively), but changes in testosterone group were higher (p<0.02 and p<0.05; respectively). The method of antidiabetic therapy (oral or insulin) had not significant impact on changes of lipids, HbA1c and anthropometric indexes during study. PSA and prostate volume did not change significantly during treatment.

Conclusion: Testosterone replacement therapy in men with diabetes mellitus type 2 and androgen deficiency testosterone influenced positively on lipids, body composition and HbA1c. This treatment is safe and routine testosterone measurement should be taken under consideration in diabetic men with testosterone deficiency.

88

The impact of TSH increment on incident type 2 diabetes mellitus in euthyroid subjects

J. Jun, Y.-B. Lee, S.-E. Lee, W. Hong, Y. Hong, S.-M. Jin, M.-K. Lee, J. Kim;

Samsung Medical Center, Seoul, Republic of Korea.

Background and aims: It is widely known that thyroid function influences glucose metabolism. However, there have been no longitudinal studies to determine the association between thyroid function and diabetes. Therefore, the objective of this study was to investigate the incidence of type 2 diabetes mellitus (T2DM) according to the change of TSH level.

Materials and methods: A total of 23,063 participants had taken thyroid function tests (thyroid-stimulating hormone [TSH], total or free thyroxine [T4] and triiodothyronine [T3]) between 2006 and 2012 through a yearly health check-up program. Among them, 16,921 euthyroid subjects without diagnosed T2DM were enrolled in the study. Euthyroid was defined as having normal total T4 (4.7 to 12.5 ng/dL) or free T4 (0.78 to 1.85 ng/dL) and normal total T3 (76 to 190 ng/dL) with normal TSH level (0.4 to 4.2 μIU/L). TSH changes were calculated from TSH ratio as dividing TSH level at the end of follow-up or until a year before the last date of diabetes diagnosis into baseline TSH level.

Results: During 86,010 person-years of follow-up, there were 726 incident cases of T2DM. In cox proportional hazards models, the higher TSH ratio was significantly associated with the increased risk of incident T2DM (HR=1.10, 95% CI : 1.02-1.18, p=0.011) after adjusting baseline HbA1c, fasting glucose, age, sex, BMI, TG, HDL and LDL. In comparison with subjects in the lowest tertile (0.6±0.2), the subjects in the highest tertile of TSH ratio (1.9±1.0) also had a greater risk of incident T2DM (HR=1.39, 95% CI : 1.16-1.66, p for trend<0.001). Most of the subjects (4814, 83.0%) in the highest tertile of TSH ratio maintained an euthyroid status. However, either baseline TSH level or tertiles were not associated with the risk of incident T2DM.

Conclusion: This study demonstrated that TSH increment, rather than baseline TSH level itself, can be an additional risk factor of incident T2DM even in the subjects with preserving euthyroidism.

89

Apelin administration improves insulin sensitivity: proof of concept study in overweight healthy men

P. Gourdy¹, L. Cazals², C. Thalamas³, E. Lami², A. Sommet⁴, F. Calvas³, M. Galitzky³, I. Castan-Laurell⁵, P. Valet⁵;

¹Diabetology Department, Toulouse University Hospital and INSERM U1048/I2MC, ²Diabetology Department, Toulouse University Hospital, ³Clinical Investigation Center, Toulouse University Hospital, ⁴Department of Clinical Pharmacology, Toulouse University Hospital, ⁵Team 3, INSERM U1048/I2MC, Toulouse, France.

Background and aims: Apelin is a recently identified adipokine that influences various biological systems through the activation of its G protein-coupled receptor (APJ). This adipokine is thought to exert beneficial actions on glucose metabolism since apelin administration has been demonstrated to improve glucose tolerance in various murine models by enhancing insulin sensitivity in peripheral tissues such as skeletal muscles and white adipose tissues. The aim of the present “APELINS” proof of concept study was to determine the influence of apelin administration on insulin sensitivity in humans.

Materials and methods: We designed a Phase I, double-blind, placebo-controlled, cross-over study which included non diabetic overweight male volunteers to successively assess the efficacy and the tolerance of two doses of (pyr1)-Apelin-13 versus placebo. A first group of subjects received 9 nmol/kg (n=8), and, after safety data review by an independent expert committee, a second group received 30 nmol/kg (n=8). Each volunteer participated in two hyperinsulinemic (1 mU.Kg⁻¹.min⁻¹) euglycemic clamps spaced from 7 to 21 days. The primary endpoint (Δ GIR) was the difference between the glucose infusion rate (GIR) measured during the steady state ending the “investigational product” perfusion (GIRperfusion 210th-240th min) and the GIR measured during the first steady state ending the “basal” phase (GIRbasal 90th -120th min).

Results: Main clinical characteristics of male volunteers were as follows: 32.8±6.8 yr, BMI: 27.6±1.4 kg/m², waist circumference: 99.3±4.7, fasting plasma glucose: 94±8 mg/dl, A1c: 5.4±0.3%. Mean concentrations of total plasma apelin were similar and stable in the different groups during the “basal” phase and placebo administration (from 277±106 to 305±59 pg/ml), but raised to 1332±1525 pg/ml and 4815±1874 respectively during the steady states ending the perfusion of low dose and high dose apelin. At low dose (9 nmol/kg), apelin administration induced a non significant increase in Δ GIR versus placebo (+2.21±0.54 vs +1.57±0.53 mg/kg/min, p=0.06). A significant improvement in insulin sensitivity was observed with the dose of 30 nmol/kg (Δ GIR: + 1.72±0.47 mg/kg/min with apelin administration versus + 0.89±0.62 mg/kg/min with placebo, p=0.03). Cardiovascular monitoring and safety reports did not reveal any specific side effect of apelin administration.

Conclusion: The present data provide the first demonstration of the insulin sensitizing action of apelin in humans, as recently suggested by animal studies, and thus open new therapeutic perspectives. The apelin/APJ pathway should now be considered for the development of alternative strategies aiming to fight against insulin resistance in type 2 diabetic subjects.

Insulin sensitivity to glucose uptake is similarly changed across insulin sensitive tissues: evidence from a positron emission tomography study

M.-J. Honka¹, M. Bucci¹, J.C. Hannukainen¹, K.K. Kalliokoski¹, K.A. Virtanen¹, P. Nuutila^{1,2}, M. Laakso³;

¹Turku PET Centre, University of Turku, ²Department of Endocrinology, Turku University Hospital, Turku, ³Institute of Clinical Medicine, Internal Medicine, University of Eastern Finland, Kuopio, Finland.

Background and aims: Insulin resistance is the major pathophysiological feature of type 2 diabetes. Skeletal muscle, liver, and adipose tissue are the key insulin sensitive tissues in humans. Impaired effect of insulin is reflected by reduced glucose uptake (GU) into these tissues. No previous study has investigated whether insulin sensitivity to GU differs across the insulin sensitive tissues in the same individual. To investigate this question, we measured GU in skeletal muscle, liver, and adipose tissue in a single session using positron emission tomography (PET) and euglycemic-hyperinsulinemic clamp.

Materials and methods: The study population consisted of 141 subjects without type 2 diabetes, who had previously participated in PET studies. PET-studies included the measurement of GU in the liver, quadriceps femoris muscle, and intra-abdominal and abdominal subcutaneous adipose tissue during the euglycemic-hyperinsulinemic clamp using fluorine-18 labelled deoxyglucose and PET. Principal component analysis (PCA) was used to analyze the rates of GU across the different tissues. Eigenvalue 1 was used as a threshold for component extraction.

Results: In PCA analysis, skeletal muscle, intraperitoneal adipose tissue and liver GU loaded on one single principal component indicating that the rates of GU were similarly changed across the tissues. The model explained 53% of the variance of GU. When intraperitoneal adipose tissue was substituted by abdominal subcutaneous adipose tissue the results remained almost unchanged, and the model explained 55% of the variance of GU. PCA resulted in one principal component even after the inclusion of BMI and age into the model.

Conclusion: PCA analysis showed that over half of the variance in the insulin stimulated GU in skeletal muscle, liver, and adipose tissue was explained by a single principal component. Our results indicate that the insulin sensitivity to GU is similarly changed across the insulin-sensitive tissues, independently of obesity and age.

OP 16 The stressed beta cell

91

TYK2, a candidate gene for type 1 diabetes, modulates apoptosis and the innate immune response in human pancreatic beta cells

L. Marroqui¹, R.S. Dos Santos¹, T. Fløyel², I. Santin^{3,4}, A. Op de beeck¹, L. Marselli⁵, P. Marchetti⁵, F. Pociot², D.L. Eizirik¹;

¹ULB Center for Diabetes Research, Brussels, Belgium, ²Department of Pediatrics, Herlev University Hospital, Herlev, Denmark, ³Endocrinology and Diabetes Research Group, BioCruces Health Research Institute, Barakaldo, Spain, ⁴Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders (CIBERDEM), Spain, ⁵Department of Clinical and Experimental Medicine, Pancreatic Islet Laboratory, University of Pisa, Pisa, Italy.

Background and aims: Type 1 diabetes (T1D) is a chronic autoimmune disease characterized by the specific destruction of pancreatic β -cells. Linkage and genome-wide association studies have identified >50 loci across the human genome associated with risk of T1D, including two SNPs in the TYK2 gene. These SNPs are predicted to decrease TYK2 function and are associated with a decreased risk to develop T1D. TYK2 is a member of the JAK family of tyrosine kinases that play a critical role in the interferons (IFN) signaling via phosphorylation and activation of STAT proteins. We presently evaluated whether TYK2 plays a role in human pancreatic β -cell apoptosis and production of pro-inflammatory mediators.

Materials and methods: Human β -cell line EndoC- β H1 cells and dispersed human islets were transfected with small interfering (si)RNA targeting TYK2 (inhibition of >50%) and subsequently exposed to intracellular polyinosinic-polycitidilic acid (PIC; a synthetic viral double-stranded RNA) or IFN α . Activation of the IFN signaling pathway was evaluated by Western blot of P-STAT1/STAT1 and P-STAT2/STAT2. Expression and release of IFN α , IFN β and the chemokine CXCL10 were determined by RT-PCR and ELISA, respectively. Viability assays were performed by Hoechst/Propidium Iodide staining. Expression of MHC class I proteins was evaluated by RT-PCR, immunofluorescence and flow cytometry.

Results: Pathway analysis of candidate genes expressed in human islets identified a central role for interferon-regulated pathways. TYK2 knock-down (KD) decreased by 50–70% (p 0.05) PIC-induced STAT1/2 activation in human β -cells. Both mRNA expression and release of IFN α , IFN β and CXCL10 were increased by 2–400 fold in human β -cells after PIC transfection, which was partially prevented by TYK2 KD in the case of IFN α and CXCL10, but not IFN β (p<0.001; n=3–4). Expression of MHC class I proteins, a hallmark of early β -cell inflammation, was prevented by TYK2 silencing after both PIC or IFN α treatments. This decreased type I IFN response was paralleled by prevention of PIC-induced apoptosis in TYK2-silenced β -cells (36% and 26% of protection in EndoC- β H1 and dispersed human islets, respectively; p 0.05; n=4–5). Protection against apoptosis was confirmed by lower expression of cleaved caspase 3 in TYK2-inhibited cells.

Conclusion: The present findings suggest that the T1D candidate gene TYK2 regulates apoptotic and pro-inflammatory pathways in human pancreatic β -cells via modulation of IFN signaling and expression of MHC class I proteins. TYK2 may play a key role in the “dialog” between β -cells and the immune system in early T1D.

The hepatokine fetuin-A has TLR4 dependent and independent effects in islets

F. Gerst^{1,2}, G. Kaiser^{1,2}, T. Sartorius¹, N. Stefan^{1,2}, H.-U. Häring^{1,2}, S. Ullrich^{1,2};

¹Internal Medicine IV, Endocrinology, Diabetology, Angiology, Nephrology, University Hospital Tübingen, ²Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the Eberhard-Karls-University of Tübingen, Germany.

Background and aims: An increased level of plasma fetuin-A in humans strongly predicts the incidence of T2DM. In adipocytes, fetuin-A augments fatty acid-induced inflammation in a TLR4-dependent manner. We previously showed that in mouse islets fetuin-A increased the mRNA levels of pro-inflammatory cytokines (IL-1 β , MCP-1) in a TLR2/4-dependent manner. In spite of increased cytokine production and JNK phosphorylation, chronic exposure to fetuin-A did not augment apoptosis. In contrast, palmitic acid induced JNK phosphorylation and apoptosis without stimulation of cytokine production. The present study aims to decipher the signalling pathways activated by fetuin-A and its contribution to the lipotoxic effect of palmitic acid.

Materials and methods: Isolated islets from WT and TLR4 KO mice were cultured in medium supplemented with palmitic acid (60 μ mol/l) in the presence of either serum albumin (0.6 mg/ml) or fetuin-A (0.6 mg/ml) for 1 h to 48 h. Protein phosphorylations were analyzed on western blots. Changes in gene expression were quantified by RT-PCR. Apoptosis was estimated by TUNEL staining of isolated islet cells and subcellular localisation of proteins by confocal microscopy.

Results: In agreement with observations made in other tissues, fetuin-A induced stimulation of cytokine production was mediated through TLR4, since the effect was absent in islets of TLR4 KO mice. When the islets of WT mice were treated with clodronate (0.5 mg/ml) in order to deplete them from immune cells, the effect of fetuin-A on cytokine production was abrogated. Furthermore, fetuin-A did not induce nuclear accumulation (i.e. activation) of the transcription factor NF κ B in isolated islet cells, suggesting that the endocrine cells were not the source of cytokines. Surprisingly, fetuin-A stimulated phosphorylation of the pro-apoptotic JNK in isolated islets of WT but also of TLR4 deficient islets. In contrast, palmitic acid stimulated JNK in a TLR4 dependent manner. Consequently, in TLR4 KO islet cells palmitic acid-induced apoptosis was inhibited, while addition of fetuin-A restored the cytotoxic effect of palmitic acid.

Conclusion: These results suggest that in islets fetuin-A may worsen lipotoxicity through TLR4-dependent stimulation of cytokine production in immune cells and TLR4-independent activation of JNK in endocrine cells.

93

Loss of the pro-apoptotic BH3-only protein BIM results in increased beta cell mass in a mouse model of type 2 diabetes

J.A. Wali¹, J. Ge¹, E. Mathieson¹, C. Varanasi¹, L. Jones², R. Laybutt³, I. Smyth², E.N. Gurzov¹, T.W. Kay¹, H.E. Thomas¹;

¹St Vincent's Institute, Melbourne, ²Monash University, Melbourne, ³Garvan Institute of Medical Research, Sydney, Australia.

Background and aims: Loss of beta cell mass is a feature of type 2 diabetes, and evidence suggests that this is the result of apoptosis. We identified that the high concentrations of glucose induce ER and oxidative stress, which results in islet cell apoptosis mediated by pro-apoptotic BH3-only molecules BIM and PUMA. Islets isolated from organ donors with type 2 diabetes had increased expression of BIM and PUMA compared with non-diabetic donors, suggesting these factors are also important in loss of beta cells in humans. We hypothesized that blocking beta cell apoptosis in type 2 diabetes would improve glucose homeostasis, and tested this by examining the effects of BIM deficiency in the leptin receptor mutant *Lepr^{db/db}* mouse model of type 2 diabetes.

Materials and methods: BIM-deficient mice were crossed with $Lepr^{db/db}$ mice to generate three groups of male and female mice: $Lepr^{db/db}BIM^{+/+}$, $Lepr^{db/db}BIM^{+/-}$ and $Lepr^{db/db}BIM^{-/-}$ mice. Corresponding non-diabetic $Lepr^{db/+}$ mouse groups were used as controls. Fasting blood glucose (FBG) was measured at 6, 10, 14 and 18 weeks of age. Intraperitoneal glucose tolerance test was performed in 16-week-old mice and serum insulin was quantified by ELISA. Islet morphology was studied in H&E, insulin and TUNEL stained pancreatic sections. To quantify islet volume, we performed optical projection tomography (OPT), 3-dimensional imaging of whole pancreas stained with anti-insulin antibodies. Abdominal fat was quantified after micro-CT scanning.

Results: Deficiency of BIM significantly protected $Lepr^{db/db}$ mice from development of hyperglycaemia. FBG in female $Lepr^{db/db}BIM^{-/-}$ mice was in the non-diabetic range (FBG in 18 week old mice: $Lepr^{db/db}BIM^{-/-}=10.1\pm 1.5$ vs $Lepr^{db/db}BIM^{+/+}=26.2\pm 0.7$ mmol/l). Compared to $Lepr^{db/db}BIM^{+/+}$ mice, $Lepr^{db/db}BIM^{-/-}$ mice also had improved glucose tolerance. $Lepr^{db/db}$ mice heterozygous for BIM ($Lepr^{db/db}BIM^{+/-}$) had an intermediate phenotype. We observed a striking increase in islet size in BIM-deficient $Lepr^{db/db}$ mice by histology, while the beta cell size was similar between $Lepr^{db/db}BIM^{+/+}$ and $Lepr^{db/db}BIM^{-/-}$ mice. This suggests that increase in islet size was due to an increase in number of beta cells. Quantification of islet volume with OPT revealed a significant increase in islet volume in BIM-deficient compared with wild-type $Lepr^{db/db}$ mice ($4.2\pm 0.7\times 10^6$ vs $2.1\pm 0.4\times 10^6$ μm^3). The increased islet volume was accompanied by a two-fold increase in serum insulin concentration (19.3 ± 2.1 vs 9.7 ± 2.3 $\mu g/L$). We detected reduced number of TUNEL positive cells in BIM-deficient compared with wild-type $Lepr^{db/db}$ islets indicating that the islet phenotype is secondary to apoptosis inhibition. Further, compared to $Lepr^{db/db}$ mice wild-type for BIM, $Lepr^{db/db}$ mice deficient in BIM gained more weight (20-week old female body weights: 66.2 ± 1.6 vs 60.8 ± 0.8 grams) and had increased abdominal fat (% abdominal fat volume: 73.9 ± 4.1 vs 42.2 ± 3.5). These changes in body weight could be due to increased circulating insulin concentration in $Lepr^{db/db}BIM^{-/-}$ mice.

Conclusion: Our data suggest that BIM has a direct role in beta cell apoptosis in vivo in type 2 diabetes, and indicate that inhibition of beta cell apoptosis can prevent the loss of islet cell mass, allowing the islet to compensate for the increasing insulin demand caused by insulin resistance and obesity.

Thrombospondin 1: a master regulator of the anti-oxidant defence in pancreatic beta cells

D.A. Cunha¹, P.-O. Carlsson², J.D. Molkentin³, M. Bugliani⁴, P. Marchetti⁴, D.L. Eizirik¹, M. Cnop¹;

¹ULB Center for Diabetes Research, Université Libre de Bruxelles, Brussels, Belgium, ²Department of Medical Cell Biology, Uppsala University, Uppsala, Sweden, ³Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, USA, ⁴Department of Endocrinology and Metabolism, University of Pisa, Italy.

Background and aims: Western diets rich in saturated fats contribute to the increasing prevalence of type 2 diabetes. Saturated fatty acids, such as palmitate, induce endoplasmic reticulum (ER) stress and cause lipotoxic beta-cell death. Thrombospondin 1 (THBS1) is a glycoprotein expressed in the ER and secreted to the intercellular space. THBS1 has been shown in other tissues to promote adaptive ER stress signaling. THBS1^{-/-} mice have impaired glucose tolerance and glucose-stimulated insulin release. In this study we interrogated the putative role of THBS1 in lipotoxic beta-cell death.

Materials and methods: Apoptosis was evaluated using nuclear dyes, mRNA expression by qPCR, and protein expression/phosphorylation by Western blot. Gene silencing and overexpression were achieved by RNA

interference and adenoviral vectors, respectively. The data are based on 3-5 independent experiments.

Results: Palmitate reduced THBS1 protein expression in human islets by $73\pm 3\%$ ($p<0.05$) and in rat beta-cells by $71\pm 3\%$ ($p<0.05$). THBS1 knockdown (KD) sensitized beta-cells to palmitate-induced apoptosis (from 24 ± 2 to $48\pm 2\%$ apoptosis, $p<0.05$), while its overexpression was protective (from 24 ± 2 to $18\pm 2\%$ apoptosis, $p<0.05$). Different from previous findings in cardiomyocytes, THBS1 KD or overexpression did not modulate ATF6 signaling in beta-cells. Reactive oxygen species were induced by THBS1 KD (by $43\pm 9\%$, $p<0.05$) and reduced by THBS1 overexpression (by $38\pm 4\%$, $p<0.05$) in palmitate-treated cells. The anti-oxidant enzymes glutathione s-transferase M1 (GSTM1) and catalase were induced by palmitate (by 5.3 ± 0.7 and 3.3 ± 0.3 -fold, respectively, $p<0.05$) and further increased by THBS1 overexpression (by $44\pm 9\%$ and $48\pm 2\%$ compared to palmitate, $p<0.05$). GSTM1 expression was reduced in islets from THBS1^{-/-} mice (by $55\pm 7\%$ compared to wild-type mice, $p<0.05$), showing that THBS1 also regulates the anti-oxidant response in vivo. THBS1 overexpression increased by $75\pm 9\%$ ($p<0.05$) the activity of an anti-oxidant response element (ARE) reporter. The transcription factor NRF2 is known to bind to ARE. NRF2 KD in THBS1 overexpressing cells resulted in decreased GSTM1 and catalase mRNA expression (by 5.6 ± 1.3 and 3.5 ± 0.5 -fold, $p<0.05$), showing that NRF2 mediates the THBS1-dependent induction of anti-oxidant stress enzymes. The PERK inhibitor GSK2606414 reduced NRF2 activation in THBS1 overexpressing cells by 2.5 ± 0.5 -fold and down-regulated GSTM1 and catalase mRNA by $60\pm 9\%$ and $57\pm 3\%$ ($p<0.05$), indicating that THBS1 activates NRF2 via the ER stress transducer PERK. Importantly, THBS1 KD induced JNK phosphorylation (by $75\pm 16\%$, $p<0.05$) and expression of the proapoptotic BCL-2 family member PUMA ($51\pm 8\%$, $p<0.05$), providing a mechanistic explanation for the increase in beta-cell apoptosis following THBS1 inhibition.

Conclusion: THBS1 activates NRF2 via PERK, thus orchestrating a protective anti-oxidant defense mechanism against lipotoxicity in beta-cells. These data contribute to a better understanding of the mechanisms leading to beta-cell failure during metabolic stress and point to THBS1 as an interesting target to prevent oxidative stress in type 2 diabetes.

The hippo kinase LATS2 impairs pancreatic beta cell survival and function

T. Yuan¹, S. Awal¹, J. Kerr-Conte², A. Ardestani¹;

¹Center for Biomolecular Interactions, Bremen, Germany, ²Thérapie Cellulaire du Diabète, Lille, France.

Background and aims: Both type 1 and type 2 diabetes mellitus result from an absolute or relative decline in pancreatic β -cell function and/or mass. Apoptosis and loss of function are hallmarks of β -cell failure and the fundamental cause of diabetes. Large-tumor suppressors 2 (LATS2), a core component of the Hippo signaling pathway, is a ubiquitously expressed serine/threonine kinase and involved in multiple cellular processes such as proliferation, stress responses, and apoptosis. So far, the role of LATS2 in the β -cell is not known. Our aim was to investigate whether LATS2 is activated in the β -cell under diabetic conditions and whether its hyper-activation or inhibition would regulate β -cell death and insulin secretion.

Materials and methods: Rat β -cell line INS-1E and isolated human islets were exposed to a diabetic milieu (IL-1 β /IFN γ or increased glucose concentration (22.2 mM)). Phospho-LATS1/2, LATS2, MOB1 and β -cell apoptosis (Caspase 3 & PARP cleavage) were analyzed by Western blotting. β -cell apoptosis was also analyzed by TUNEL staining and insulin, Pdx1, Nkx2.2, Nkx6.1, Neurod1, MafA, GCK, Slc2a2, KCNG11 and Abcc8 mRNA expression by real-time PCR (RT-PCR). LATS2 was overexpressed by plasmid transfection or adenovirus infection, LATS2

inactivation was performed by overexpressing dominant-negative LATS2 (dn-LATS2) or specific siRNA to LATS2 in both INS-1E cells and human islets. Insulin secretion in response to glucose (GSIS at 2.8 mM and 16.7 mM glucose), Glibenclamide (1 μ M) and KCl (35 mM) in human islets in vitro were examined by ELISA.

Results: LATS1/2 phosphorylation (at S909/872 for LATS1 and LATS2) was increased in INS-1E cells exposed to pro-inflammatory cytokines: IL-1 β /IFN γ or increased glucose concentration, indicating higher activity of LATS kinases under diabetic conditions. This correlated with MOB1 (LATS2-associated protein) up-regulation and increased β -cell apoptosis. LATS2 overexpression increased the number of TUNEL-positive β -cells in human islets and induced caspase-3 and PARP cleavage in human and rodent β -cells. Inhibition of endogenous LATS2 activity by siRNA knockdown or overexpression of dominant negative LATS2 protected INS-1E cells and human islets from chronically elevated glucose- and cytokines-induced apoptosis. LATS2 silencing abolished diabetic milieu-induced MOB1 up-regulation suggesting LATS2-dependent regulation of MOB1 in β -cells. Consistently, MOB1 knockdown blocked LATS2- and glucotoxicity-induced caspase-3 and PARP cleavage in INS-1E cells indicating a major role of MOB1 in LATS2-induced β -cell apoptosis. Also, LATS2 overexpression impaired GSIS in human islets without significant changes neither on insulin content and gene expression nor on genes involved in glucose sensing (Slc2a2 and GCK), insulin transcription (Pdx1, NeuroD, MafA) and ATP-dependent K⁺ channel subunits (Kcnj11 and abcc8). LATS2 overexpression also abolished insulin secretion stimulated by the insulin secretagogues KCl and glibenclamide, suggesting that the insulin secretory defect may occur at a step down-stream of calcium influx.

Conclusion: Our results show that LATS2 hyper-activation leads to β -cell death and loss of function and its inhibition protects from apoptosis. Blocking of LATS2 may be a successful strategy to improve β -cell survival and function in diabetes.

Metabolic stress induces aberrant G-protein prenylation in pancreatic beta cells

A. Kowluru¹, M. Goalstone², V. Sidarala¹, K. Syeda¹, R.A. Kowluru³; ¹Pharmaceutical Sciences, Wayne State University, Detroit, ²Medicine, University of Colorado, Denver, ³Ophthalmology, Anatomy and Cell Biology, Wayne State University, Detroit, USA.

Background and aims: Activation of specific small G-proteins [Arf6, Cdc42 and Rac1] is implicated in glucose-stimulated insulin secretion [GSIS] in clonal β -cells, normal rodent and human islets. We recently demonstrated requisite roles for G-protein prenylation in GSIS. We identified three classes of prenylating enzymes in pancreatic β -cells. Farnesyltransferase [FTase] and geranylgeranyltransferases [GGTase-I] prenylate Ras and Rho G-proteins, respectively. GGTase-II mediates prenylation of Rab G-proteins. The aim of the current study is to assess alterations, if any, in FTase/GGTase-I signaling in pancreatic β -cells in vitro and in vivo models of metabolic stress, impaired insulin secretion and T2DM.

Materials and methods: Normal rat islets or INS-1 832/13 β -cells were exposed to glucotoxic [20 mM; 24 hr], lipotoxic [0.3 mM palmitate; 24 hr] or thapsigargin [0.25 μ M; 24 hr] conditions. FTase and GGTase-I activities were assayed by radiometric methods. Caspase-3 activation and FTase/GGTase- α degradation were quantified by Western blotting.

Results: Exposure of INS-1 832/13 β -cells to gluco- or lipotoxic conditions markedly attenuated [\sim 50%] FTase and GGTase activities. A significant increase in caspase-3 activity and degradation of the common α -subunit of FTase/GGTase [FTase/GGTase- α] were also seen under these conditions. Thapsigargin, a known inducer of endoplasmic reticulum [ER] stress, promoted caspase-3 activation, FTase/GGTase- α degradation

and reduction [\sim 70%] of FTase and GGTase activities. Compatible with our in vitro findings, caspase-3 activity and FTase/GGTase- α degradation were markedly increased in islets derived from the Zucker diabetic fatty [13 weeks] rats compared to those from the age-matched Zucker lean controls. Consequentially, a significant increase in the abundance of unprenylated Rap1, a geranylgeranylated protein, was noted in pancreatic β -cells exposed to gluco or lipotoxic conditions. In addition, forced inactivation of G-protein prenylation [via depletion of endogenous pools of mevalonic acid] using simvastatin also resulted in accumulation of unprenylated Rap1 in these cells. Lastly, glucotoxic conditions promoted sustained activation of Rac1, a geranylgeranylated protein, activation of stress kinase [p38MAPK], nuclear lamin-B degradation and inhibition of GSIS in rat islets and INS-1 832/13 cells.

Conclusion: Based on our findings we propose that metabolic stress induces aberrant G-protein prenylation signaling events leading to stress kinase activation and loss in β -cell function including GSIS.

Unravelling the effects of endogenous incretin hormones on glucose metabolism after Roux-en-Y gastric bypass surgery

M.S. Svane^{1,2}, K.N. Bojsen-Møller^{1,2}, S. Nielsen¹, N.B. Jørgensen^{1,2}, C. Dirksen^{1,2}, V.B. Kristiansen³, B. Hartmann², J.J. Holst², S. Madsbad^{1,2}; ¹Dept. of Endocrinology, Hvidovre Hospital, Hvidovre, ²NNF Center of Basic Metabolic Research, Copenhagen, ³Dept. of Surgical Gastroenterology, Hvidovre Hospital, Hvidovre, Denmark.

Background and aims: Roux-en-Y gastric bypass (RYGB) induces weight loss and diabetes remission. Exaggerated meal-induced secretion of glucagon-like peptide-1 (GLP-1) is important for enhanced postprandial insulin secretion and improved glucose metabolism after surgery, but the role of glucose-dependent insulinotropic polypeptide (GIP) is debated. Administration of a DPP-4 inhibitor as sitagliptin (sita) prevents the degradation of the active forms of GLP-1 and GIP, while it is possible to block the effect of GLP-1 with the GLP-1 receptor antagonist exendin 9-39 (Ex9). We investigated the individual and combined effects of DPP-4 inhibition and GLP-1 receptor blockade to understand the relative importance of the endogenous incretin hormones on glucose metabolism after RYGB.

Materials and methods: In a placebo-controlled, single-blinded, crossover design, twelve glucose tolerant patients (age 35.4±7 (mean±SEM) years, gender (f/m) 8/4, BMI 33.5±6 kg/m²) were studied 5.3±1 month after RYGB. On four separate experimental days patients underwent a standard 4 h mixed meal test (356 kcal, 53E% carbohydrate, 33E% fat, 14E% protein) with either 1) placebo (plac); 2) sita (100 mg 12 h and 2 h before study start); 3) Ex9 infusion (900 pmol×kg⁻¹×min⁻¹); or both 4) sita and Ex9 (Ex9/sita) in a randomized order. Pre-hepatic insulin secretion rates (ISR) were calculated from deconvolution of C-peptide and beta-cell glucose sensitivity (beta-GS) was used to characterize the dose-response relationship between glucose concentration and ISR. Results were analysed by linear mixed effects models.

Results: GLP-1 receptor antagonism by Ex9 infusion increased glucose excursions compared with placebo while no effect of DPP-4 inhibition was seen (incremental (i)-AUC glucose: plac 92±44 mmol/L×min, Ex9 192±44 p<0.01, sita 112±43 p=0.47). Ex9 and Ex9/sita had comparable effects on glucose concentrations (iAUC glucose: Ex9 192±44 vs. Ex9/sita 163±39, p=0.27). Insulin secretion evaluated by iAUC ISR and beta-GS decreased during Ex9 infusion, whereas no significant effect of sita was seen compared with placebo (iAUC ISR: plac 933±96 pmol×kg⁻¹, Ex9 713±83 p<0.01, sita 963±123 p=0.95. Beta-GS: plac 4.8±0.8 (pmol×kg⁻¹×min⁻¹)/mmol/L, Ex9 3.8±0.7 p=0.01, sita 5.7±1.2 p=0.26). Both measures of beta-cell function deteriorated equally during Ex9 infusions with and without sita (iAUC ISR: Ex9 713±83 vs. Ex9/sita 660±53, p=0.65 and beta-GS: Ex9 3.8±0.7 vs. Ex9/sita 3.1±0.5 p=0.09). Total AUC of intact GLP-1 increased 3-fold (p<0.01) and intact GIP 1.6-fold (p<0.01) on sita days, thereby indicating an effective DPP-4 inhibition.

Conclusion: After RYGB, infusion of the GLP-1 receptor antagonist, Ex9, induced deteriorated glucose tolerance and impaired postprandial insulin secretion, whereas DPP-4 inhibition had no effect on glucose tolerance or insulin secretion. DPP-4 inhibition also failed to improve beta-cell function when the GLP-1 receptor was blocked. This finding underscores the importance of the exaggerated GLP-1 secretion for improved glycaemic control after RYGB, but does not support a major role of GIP for improved glucose tolerance and beta-cell function after RYGB.

The expression of genes involved in intestinal gluconeogenesis is altered in morbidly obese subjects with higher insulin resistance

C. Gutiérrez Repiso¹, S. García Serrano^{1,2}, F. Rodríguez Pacheco^{1,2}, J. García Arnés¹, S. Valdés^{1,2}, F. Soriguer^{1,2}, F.J. Moreno Ruíz³, A. Rodríguez Cañete³, G. Alcáin Martínez⁴, L. Vázquez Pedreño⁵, E. García Fuentes^{1,6};

¹UGC de Endocrinología y Nutrición, Instituto de Investigación Biomédica de Málaga (IBIMA), Hospital Regional Universitario, ²CIBERDEM, Instituto de Salud Carlos III, ³UGC de Cirugía General, Digestiva y Trasplantes, Instituto de Investigación Biomédica de Málaga (IBIMA), Hospital Regional Universitario, ⁴UGC de Aparato Digestivo, Instituto de Investigación Biomédica de Málaga (IBIMA), Hospital Universitario Virgen de la Victoria, ⁵UGC de Aparato Digestivo, Hospital Regional Universitario, ⁶CIBERDEM, CIBEROBN, Instituto de Salud Carlos III, Málaga, Spain.

Background and aims: It has been suggested that small intestine might possess the capacity to produce glucose, being induced in insulin resistance states. It has been shown that genes involved in gluconeogenesis are expressed in human small intestine. However, there is little information about intestinal gluconeogenesis in humans and the alterations that high insulin resistance may produce. The aim of this study is to evaluate the expression of genes involved in intestinal gluconeogenesis in morbidly obese subjects in states of insulin resistance and also to evaluate the effect of metformin in their expression.

Materials and methods: The study was undertaken in 45 morbidly obese subjects who underwent to Roux-en-Y gastric bypass. The morbidly obese subjects were classified in subjects with homeostasis model assessment of insulin resistance (HOMA-IR) value lower than 4.7 (MO-low-IR), subjects with HOMA-IR value higher than 4.7 (MO-high-IR) (both groups without treatment for T2D) and subjects with T2D who were only receiving metformin treatment (MO-metf-T2D). The jejunal biopsy samples used to evaluate the mRNA expression levels were obtained during the bariatric surgery, 40 cm from the ligament of Treitz.

Results: In MO-high-IR group, glutaminase (GLS) (p=0.034), phosphoenolpyruvate carboxykinase (PEPCK) (p=0.027) and glucose 6-phosphatase (G6Pase) (p=0.024) mRNA expression levels were significantly higher than in MO-low-IR group. In MO-metf-T2D group, G6Pase (p=0.014) and GLS (p=0.049) mRNA expression levels were significantly higher than in MO-low-IR group, whilst PEPCK mRNA expression levels were significantly lower (p=0.001). In MO-metf-T2D group, PEPCK (p=0.001) mRNA expression levels were significantly lower than in MO-high-IR group. Weight, BMI and waist circumference correlated positively with PEPCK mRNA expression levels (r=0.416; p=0.025; r=0.398; p=0.033; r=0.446; p=0.043, respectively). Insulin levels correlated positively with PEPCK (r=0.347; p=0.045), fructose 1,6-bisphosphatase (FBPase) (r=0.319; p=0.046) and G6Pase (r=0.461; p=0.005) mRNA expression levels. HOMA-IR value correlated positively with G6Pase (r=0.424; p=0.010) mRNA expression levels. GLS mRNA expression levels correlated positively with FBPase mRNA expression levels (r=0.683; p<0.001). G6Pase mRNA expression correlated positively with GLS (r=0.703; p<0.001) and FBPase (r=0.654; p<0.001) mRNA expression levels.

Conclusion: The mRNA expression of most of the genes involved in gluconeogenesis is increased in the jejunum of morbidly obese subjects with higher insulin resistance. This altered jejunal mRNA expression is attenuated in those morbidly obese subjects treated with metformin.

CD163+ and CD206+ adipose tissue immune cells in obese subjects with type 2 diabetes mellitus: the effect of gastric plication and duodenal-jejunal bypass liner implantation

A. Cinkajzlova, Z. Lacinova, J. Klouckova, P. Kavalkova, P. Trachta, M. Mraz, M. Haluzik;
3rd Department of Medicine, Charles University, Prague, Czech Republic.

Background and aims: CD163 and CD206 are considered the main markers of alternatively activated (M2) macrophages which are suggested as one of the main players in the resolution of adipose tissue low-grade inflammation. The aim of our study was to examine changes in CD163+ and CD206+ cells in subcutaneous adipose tissue (SCAT) of obese subjects with type 2 diabetes mellitus (T2DM) in the context of global metabolic improvements after selected bariatric procedures.

Materials and methods: Twenty-two obese subjects with T2DM undergoing either GP or DJBL were included into the study. Anthropometric and biochemical parameters were measured and SCAT samples from the abdominal region were taken at baseline, 1 and 6 (GP) or 10 months (DJBL) after intervention. M2 macrophage subpopulations were identified using flow cytometry and a combination of antigens including CD14, HLA-DR, CD163 and CD206.

Results: At baseline 2 different subsets of CD163+ (CD163+HLA-DR+CD14+ and CD163+HLA-DR+CD14-) and CD206+ cells (CD206+HLA-DR+CD14+ and CD206+HLA-DR+CD14-) were identified in SCAT according to the presence of CD14. Both interventions resulted in decreased body weight (BMI 43.2±1.8 vs. 36.0±2.1 kg/m², $p < 0.001$ for GP and 42.6±1.2 vs. 39.0±1.5 kg/m², $p < 0.001$ for DJBL) and improved glucose control (HbA1C 64.8±6.3 vs. 45.0±2.9 mmol/mol, $p = 0.004$ for GP and 74.2±5.6 vs. 53.8±5.0 mmol/mol, $p < 0.001$ for DJBL). In SCAT, both GP and DJBL significantly decreased CD163+HLA-DR+CD14+ (20.4±2.7 vs. 11.3±1.0%, $p = 0.010$ for GP and 19.9±1.9 vs. 12.6±0.6%, $p = 0.025$ for DJBL) and increased CD163+HLA-DR+CD14- cells (3.5±0.3 vs. 7.3±1.1%, $p = 0.001$ for GP and 3.4±0.4 vs. 5.3±0.5%, $p = 0.029$ for DJBL). CD206+HLA-DR+CD14+ cells also decreased (21.0±3.3 vs. 11.6±0.8%, $p = 0.013$ for GP and 18.1±1.4 vs. 11.9±1.3%, $p = 0.039$ for DJBL), while the CD206+HLA-DR+CD14- subset remained unchanged in both groups (2.0±0.2 vs. 2.7±0.3, $p = 0.43$ for GP and 2.3±0.3 vs. 2.0±0.2, $p = 0.62$ for DJBL).

Conclusion: Human adipose tissue immune cells with M2 macrophage phenotype seem to consist of several subpopulations which react differently to weight reduction. These changes might contribute to positive effects of GP and DJBL on metabolic control in obese T2DM subjects.

Effects of ursodeoxycholic acid and chenodeoxycholic acid on insulin secretion after Roux-en-Y gastric bypass

S. Nielsen^{1,2}, M.S. Svane^{1,2}, K.N. Bojsen-Møller^{1,2}, V. Kristiansen³, J.J. Holst^{2,4}, S. Madsbad^{1,2};

¹Department of Endocrinology, Hvidovre University Hospital, Hvidovre, ²The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, ³Department of Surgical Gastroenterology, Hvidovre University Hospital, Hvidovre, ⁴Department of Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: Roux-en-Y gastric bypass (RYGB) induces weight loss and improved glycaemic control. Bile acids have been proposed as an important contributor to the improved glycaemic control postoperatively since the plasma bile acid concentration increases substantially after RYGB. However, causality between increased plasma bile acids and effects on the glucose-regulatory pathways remain to be demonstrated. In healthy subjects and type 2 diabetic patients intragastric, intraduodenal and

intrarectal infusions with bile acids increase secretion of glucagon-like peptide-1 (GLP-1), an important insulinotropic hormone. After RYGB, intraluminal bile acids may thus also contribute to increased postprandial GLP-1 secretion and thereby to increased postprandial insulin secretion. RYGB changes the gastrointestinal anatomy and makes it possible to reach the GLP-1 producing L-cells in the distal part of the intestine by an oral route. Therefore, we evaluated the effects of oral administration of ursodeoxycholic acid (UDCA) and chenodeoxycholic acid (CDCA) on insulin secretion in RYGB-operated patients.

Materials and methods: In a placebo-controlled, crossover study, we examined insulin secretion and glucose concentration in 10 RYGB-operated patients with normal glucose tolerance (age (mean±SEM) 37.9±3.4 years, BMI 29.2±1.3 kg/m², fasting plasma glucose 4.96±0.13 mmol/litre) at 32.6±1.1 months postoperatively. On three different days the patients ingested either 1) UDCA (750 mg); 2) CDCA (1250 mg) suspended in 150 mL water; or 3) 150 mL water alone (placebo). Blood samples were drawn for the following 180 minutes. Insulin secretion was evaluated using delta C-peptide_{0-peak} and positive incremental AUC (pi-AUC, i.e. AUC above fasting concentration). Linear mixed-effects models were used for statistical analysis.

Results: Oral intake of CDCA increased insulin secretion slightly, but significantly, compared with placebo (delta C-peptide_{0-peak}: placebo: 45±13 pmol/L, CDCA: 140±27 pmol/L, $p = 0.0012$; pi-AUC: placebo: 1900±643 pmol/L×min, CDCA: 7094±1447 pmol/L×min, $p = 0.02$). UDCA did not affect insulin secretion compared with placebo (UDCA: delta C-peptide_{0-peak}: 72±13 pmol/L, $p = 0.23$; pi-AUC: 3119±1234 pmol/L×min, $p = 0.47$). Plasma glucose was not affected by oral intake of neither UDCA nor CDCA.

Conclusion: In RYGB-operated patients with normal glucose tolerance, oral administration of CDCA increased insulin secretion significantly compared with placebo, whereas no effect was seen after oral administration of UDCA. However, the effect was small and no effect on glucose concentration was observed questioning a major role of bile acids for the improved glycaemic control after RYGB.

Roux-en-Y gastric bypass improves gastrointestinal-mediated glucose disposal in type 2 diabetes whereas gastric banding and caloric restriction do not

T. Jorsal¹, B. Mortensen¹, M. Hansen¹, R. Dutia², B. Laferrere², F.K. Knop¹;

¹Department of Medicine, Center for Diabetes Research, Hellerup, Denmark, ²New York Obesity Nutrition Center, New York, USA.

Background and aims: The mechanisms by which Roux-en-Y gastric bypass surgery (RYGB) mediates its glucose-lowering effect in type 2 diabetes are debated. The two predominant hypotheses include 1) improved glucose handling driven by gastrointestinal (GI) factors elicited by rerouting of nutrients through the GI tract, and 2) post-surgery caloric restriction promoting beneficial effects on glucose metabolism (independent of the altered GI anatomy/physiology). We evaluated the impact of RYGB vs laparoscopic adjustable gastric banding (LAGB) and surgery-matched caloric restriction alone (CAL), respectively, on GI-mediated glucose disposal (GIGD) in patients with type 2 diabetes.

Materials and methods: GIGD was calculated by comparing glucose amounts utilised during 50 g-OGTT and isoglycaemic i.v. glucose infusion (IIGI) (using variable glucose infusion rates), respectively (100%×(glucoseOGTT - glucoseIIGI / glucoseOGTT)), in obese patients with type 2 diabetes before and 1 month after either RYGB (n=40), LAGB (n=16) or CAL (n=11).

Results: As previously reported, all groups showed a significant and similar degree of weight loss, and AUC for plasma glucose during OGTT improved in all groups with RYGB eliciting the most robust improvement. We observed a significantly increased GIGD following RYGB ($\Delta 13.0 \pm 4.8\%$, $p < 0.01$), whereas GIGD changes were insignificant after LAGB ($\Delta -1.7 \pm 9.5\%$, $p = 0.86$) and CAL ($\Delta 9.5 \pm 9.1\%$, $p = 0.32$).

Conclusion: These data suggest that the improved glucose tolerance observed after RYGB is mainly driven by nutrient-rerouting through the GI tract rather than surgery-induced caloric restriction and ascribe improved GIGD a key role in remission of the diabetic state often observed in patients with type 2 diabetes undergoing RYGB.

Conclusion: Bariatric surgery in morbidly obese diabetic patients normalizes splanchnic vascular responses. Further studies are needed and should focus on investigating the many factors that affect splanchnic blood flow kinetics after a meal, and their association to insulin secretion, systemic delivery and hepatic clearance rate.

Bariatric surgery normalises splanchnic vascular responses to a mixed-meal and to GIP infusion

H. Honka¹, J. Koffert^{1,2}, S. Kauhanen³, N. Kudomi⁴, J. Linden¹, J. Teuho¹, A. Lindqvist⁵, N. Wierup⁵, L. Groop⁵, P. Nuutila^{1,6};

¹Turku PET Centre, University of Turku, ²Department of Gastroenterology, Turku University Hospital, ³Division of Digestive Surgery and Urology, Turku University Hospital, Turku, Finland, ⁴Department of Medical Physics, Kagawa University, Kagawa, Japan, ⁵Lund University, Lund, Sweden, ⁶Department of Endocrinology, Turku University Hospital, Turku, Finland.

Background and aims: Splanchnic vasculature regulates intermediary metabolism by facilitating nutrient delivery from intestine into systemic circulation and pancreas, and by affecting hepatic insulin clearance. Recent studies have suggested that disturbances in splanchnic vascular functions are associated with dysglycemia predisposing to development of type 2 diabetes. The present study was conducted to investigate the splanchnic vascular responses to a mixed-meal test, and to glucose-dependent insulinotropic polypeptide (GIP) infusion before and after bariatric surgery.

Materials and methods: Ten morbidly obese ($40.8 \pm 5.9 \text{ kg m}^{-2}$) diabetic subjects and 10 age-matched, lean ($22.9 \pm 2.1 \text{ kg m}^{-2}$) subjects were recruited. Small intestinal, pancreatic and hepatic blood flow (BF) and volume (BV) before and after 300-kcal mixed-meal, and during GIP infusion ($2 \text{ pmol kg}^{-1} \text{ min}^{-1}$) were measured using radiotracers [¹⁵O]H₂O and [¹⁵O]CO, and PET. A standard 75-g oral glucose tolerance test was performed, and during imaging studies blood was continuously drawn to measure glucose, insulin, and incretin hormones (GIP and GLP-1). In obese subjects, these procedures were repeated six weeks after bariatric surgery.

Results: Compared to controls, obese diabetic subjects were slightly hyperglycemic (fasting plasma glucose 6.8 ± 0.8 vs. 5.0 ± 0.4 mM, $P < 0.0001$) prior to surgery. In both groups, meal ingestion provoked significant increases in small intestinal BF ($+61.8$ and $+92.2\%$ vs. baseline, for lean and obese subjects, respectively, both $P < 0.05$). While pancreatic BF was increased in lean subjects (1.9 ± 0.6 vs. $1.6 \pm 0.4 \text{ ml ml}^{-1} \text{ min}^{-1}$, $P < 0.05$), this was not observed in obese subjects (NS). During GIP infusion, small intestinal BF was increased in both groups ($+141$ and $+112\%$ vs. baseline, for lean and obese subjects, respectively, both $P < 0.05$). In contrast, pancreatic BF was decreased (1.2 ± 0.3 vs. $1.6 \pm 0.4 \text{ ml ml}^{-1} \text{ min}^{-1}$, $P = 0.01$) only in lean subjects, whereas no response was observed in obese subjects (NS). Hepatic BV was decreased after meal ingestion and during GIP infusion in both groups (from -6.3 to -11.9% , $P < 0.05$). Six weeks after bariatric surgery, 12% excess body weight loss was observed (-13.9 kg , $P < 0.01$), and diabetes remission rate of 80% was reached. Postoperatively, small intestinal vascular responses to meal and to GIP infusion ($+167$ and $+93.6\%$ vs. baseline, respectively, both $P < 0.05$) were unchanged when compared with the preoperative state. However, after surgery pancreatic vascular responses to meal (1.4 ± 0.2 vs. $1.0 \pm 0.3 \text{ ml ml}^{-1} \text{ min}^{-1}$, $P < 0.01$) and to GIP infusion (0.9 ± 0.3 vs. $1.1 \pm 0.3 \text{ ml ml}^{-1} \text{ min}^{-1}$, $P < 0.05$) were normalized and essentially similar to those of lean subjects.

Sequencing of 12,940 exomes identifies additional coding variants in *G6PC2* which influence fasting glucose levels through effects on protein stability or activity

H.J. Ng¹, A. Mahajan², H. Highland³, X. Sim⁴, A. Manning⁵, M. Rivas², A. Locke⁴, N. Grarup⁶, N.L. Beer¹, J.K. Rundle¹, A. Raimondo¹, A.P. Morris², C.M. Lindgren^{2,5}, A.L. Gloyn^{1,2}, T2D-GENES and GoT2D Consortia;

¹OCDEM, University of Oxford, ²Wellcome Trust Centre for Human Genetics, University of Oxford, UK, ³The University of Texas Health Science Center, Houston, ⁴University of Michigan, Ann Arbor, ⁵Broad Institute, Cambridge, USA, ⁶University of Copenhagen, Denmark.

Background and aims: We recently identified coding variants in *G6PC2* (encoding the islet-specific glucose-6-phosphatase catalytic subunit) influencing fasting glucose (FG) levels in non-diabetic Europeans and demonstrated that these variants affected protein stability. In addition to single variant associations, gene-based analyses also revealed a robust association driven by multiple low-frequency/rare variants in the exome array analysis. To achieve a comprehensive assessment of the impact of coding variation in *G6PC2* on FG levels, especially that of rare variants not captured on the array, we combined exome sequence data with array data to identify additional coding variants. We coupled genetic analyses with functional characterisation to identify nonsynonymous *G6PC2* variants altering protein function, thus impacting on FG levels.

Materials and methods: Exome sequence data from 12,940 individuals consisting of type 2 diabetes cases and controls from five major ancestries was used to catalogue coding variants in *G6PC2*. For analysis of glycaemic traits, 5,132 non-diabetic exome sequences were combined with previously published exome array data from 33,407 non-diabetic Europeans. Single variant analyses were performed within each ethnic group then combined in a trans-ethnic meta-analysis. *G6PC2* variants were characterised by assessing effects on protein expression (western blot) and/or activity (phosphatase assay).

Results: We identified 69 coding variants in *G6PC2* in our exome array and sequence data, including 3 previously reported functional variants that were shown to influence FG levels (H177Y, Y207S, V219L). We selected 10 further variants, all rare (minor allele frequency [MAF]<0.005), for functional follow-up based on either evidence of association with FG levels (S30F, I171T, S324P; single variant $P<0.05$), or biological relevance (variant maps to conserved active site). All the variants studied except for I171T-G6PC2 had significantly reduced protein levels (mean 12.1% of wild type [WT]; $P<0.001$) due to enhanced proteasome-mediated degradation. I171T-G6PC2 was expressed at levels similar to WT-G6PC2, however its position within the active site suggested an alternative mechanism. This was confirmed by activity assays which showed that the missense substitution affected protein activity. Using a glucose-6-phosphatase homologous model, phosphatase activity of the variant was decreased by 38.9% at 2.5 mM glucose-6-phosphate compared to WT ($P<0.05$). Both S324P and I171T are rare functional variants (MAF=0.0044 and 0.0012 respectively) that contributed to the gene-based signal at *G6PC2* in the exome array analysis.

Conclusion: We identified additional coding variants in *G6PC2*, mostly rare, providing a more complete inventory of genetic variation in this key regulator of beta cell function. Functional investigation demonstrated that many of these result in marked protein instability whilst one variant alters protein activity, consistent with a role in modulating FG levels.

Role of the type 2 diabetes genome-wide association studies gene *SLC30A8* in the pancreatic alpha cell

A.M. Solomou¹, G. Meur¹, E.A. Bellomo¹, D.J. Hodson¹, P.L. Herrera², S. Migrenne³, C. Magnan³, G.A. Rutter¹;

¹Imperial College London, UK, ²Genetic Medicine and Development, University of Geneva, Switzerland, ³University Paris, France.

Background and aims: Genome-wide association studies have revealed >90 loci in the human genome with a significant impact on type 2 diabetes risk. One such locus encodes a non-synonymous single nucleotide polymorphism in the *SLC30A8* gene encoding the zinc transporter ZnT8, expressed almost exclusively in pancreatic islets. Changes observed in humans containing risk alleles and animals lacking ZnT8 have previously been attributed to alterations in insulin secretion from beta-cells. Though the role of the ZnT8 transporter in beta-cells has been studied extensively its role on glucagon secretion is largely unknown. Here, we investigate the role of ZnT8 in the alpha-cell by generating animals deleted for *slc30a8* selectively in these cells.

Materials and methods: *Slc30a8* was inactivated in alpha-cells by crossing animals bearing a floxed *Slc30a8* gene with mice expressing Cre recombinase under a 1.6 kB fragment of the pre-proglucagon promoter, plus tdRFP expressed at the *Rosa26* locus distal to a LoxP-STOP-LoxP cassette. Deletion was confirmed by qPCR on FACS-sorted alpha-cells. Glucose homeostasis was assessed by glucose tolerance and insulin tolerance test and by hypoglycaemic clamp studies. Intracellular free Ca²⁺ and Zn²⁺ were measured in tdRFP-labelled alpha-cells within the intact islet using the trappable fluorescent probes Fluo-2 and FluoZin-3, respectively.

Results: Glucose and insulin tolerance were normal in α Slc30a8KO mice. However, female KO mice required lower glucose infusion rates (KO 18.8±1.62 mg/min/kg vs control 28±1.27 mg/min/kg, $P<0.001$, n=4-6) during hypoglycaemic clamps, and displayed enhanced glucagon release. Correspondingly, isolated islets from KO mice released more glucagon at 1 mM glucose than WT islets (0.18±0.009 vs 0.1±0.03 as a % of total, $P<0.01$, n=5) despite unchanged intracellular Ca²⁺ responses to glucose withdrawal (1 vs 17 mM). Additionally there was a tendency towards a higher α : β cell area in KO mice (0.2±0.015 vs 0.16±0.01, $P<0.5$, n=7). Cytoplasmic free Zn²⁺ concentrations were significantly lower in α Slc30a8KO alpha-cells (KO 1.14±0.007 vs control 1.33±0.02 F1/Fmin, $P<0.0001$, n=4). The expression of other ZnT family members was unchanged.

Conclusion: ZnT8 deletion from the mouse alpha-cell results in decreased intracellular zinc levels and increased glucagon secretion from isolated islets in vitro at low glucose conditions and in vivo during hypoglycaemia. These findings suggest that altered ZnT8 expression may affect glucagon levels in carriers of *SLC30A8* variants in man, and may thus contribute to diabetes risk.

A genome wide association study of IVGTT based measures of first phase insulin secretion reveals new physiology of known and novel variants

N. van Leeuwen¹, A.R. Wood², A. Jackson³, A. Jonsson⁴, N. Wang⁵, U. Smith⁶, L. Boquete Vilarino², A. Stancakova⁷, M. Walker⁸, R. Hanson⁹, T.M. Frayling², GUINNESS consortium;

¹Molecular Cell Biology, LUMC, Leiden, Netherlands, ²Institute of Biomedical and Clinical Sciences, University of Exeter Medical School, Exeter, UK, ³Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, USA, ⁴Faculty of Health and Medical Science, University of Copenhagen, Denmark, ⁵Department of Preventive Medicine, Keck School of Medicine of USC, Los Angeles, USA, ⁶Sahlgrenska Academy and Lundberg Laboratory for Diabetes Research, University of Gothenburg, Sweden, ⁷Institute of Clinical Science, Internal Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland, ⁸Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK, ⁹Phoenix Epidemiology and Clinical Research Branch, The National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, USA.

Background and aims: Deterioration of insulin secretory capacity plays an important role in the development of type 2 diabetes yet the mechanisms underlying the process are not fully understood. As part of the GUINNESS consortium we meta-analysed 8 GWAS and 2 metabochip studies where first phase insulin secretion has been investigated through intravenous glucose tolerance tests (IVGTT) in an attempt to identify the genetic factors involved.

Materials and methods: The meta-analysis included 5 European (n=2090) and 3 non-European (n=1655) studies with GWAS data and 2 European studies with metabochip data (n=741). First phase insulin secretion was assessed with an IVGTT or hyperglycemic clamp and three different traits were defined in all cohorts: Acute Insulin Response to glucose (AIR), Peak Insulin (PeakIns) and Disposition Index (DI) (n=4486), all accounting for fasting glucose levels. GWAS studies were imputed using the 1000G reference panel. Variants were tested for association using linear regression adjusting for age and sex. In sub-analyses, BMI and Insulin Sensitivity Index (SI) were also used as additional covariates.

Results: Of known common type 2 diabetes variants, 7 were associated with both PeakIns and AIR at $p < 0.01$, two *MTNR1B* and *CDKAL1* at genome wide significance for both traits (PeakIns $p = 8 \times 10^{-16}$, $p = 6 \times 10^{-13}$; AIR $p = 1 \times 10^{-12}$, $p = 1 \times 10^{-9}$). Comparing these associations to type 2 diabetes risks and measures based on oral glucose tolerance tests (OGTT) revealed some interesting patterns. The variant at *TCF7L2* is only modestly associated with first phase insulin despite having the strongest effect on diabetes risk. Whereas the diabetes variants at *HNF1A* ($p = 4 \times 10^{-5}$ PeakIns) and *ZFAND6* ($p = 8 \times 10^{-4}$ PeakIns) showed much stronger signals despite being unclassified in previous studies of diabetes intermediate traits using OGTT. Adjustments for BMI and SI did not substantially influence results. Putative novel associations for AIR were observed in population-specific analyses on chromosome 2 and 11 (both $P < 5 \times 10^{-8}$) but these low frequency variants need further validation.

Conclusion: Our genome wide analysis was performed on the largest dataset for intravenously measured first phase insulin secretion. Common type 2 diabetes risk alleles at the *MTNR1B* and *CDKAL1* loci were the most strongly associated with our measures. For other variants, including those in *HNF1A* and *ZFAND6* our analyses provide new insight into physiological mechanisms of diabetes risk.

The impact of known type 2 diabetes associated variants on circulating levels of GLP-1, GIP and glucagon during an oral glucose tolerance test

A. Jonsson¹, S.S. Torekov^{1,2}, T. Schnurr¹, C.T. Have¹, Y. Mahendran^{1,3}, N. Grarup¹, N.B. Johansen^{3,4}, K. Færch⁴, D.R. Witte^{3,5}, T. Lauritzen⁵, J.J. Holst^{1,2}, M.E. Jørgensen⁴, O. Pedersen¹, T. Hansen¹;

¹NNF Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, University of Copenhagen, ²Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, ³The Danish Diabetes Academy, Odense, ⁴Steno Diabetes Center, Gentofte, ⁵Institute of Public Health, University of Aarhus, Denmark.

Background and aims: Large-scale genome wide association studies (GWAS) have currently identified 68 genetic determinants of type 2 diabetes. For many of those variants, it is unclear through which mechanisms they exert their effect and little is known about whether these genes also affect incretin hormone levels and/or alpha-cell function. Our aim is to examine the impact of known type 2 diabetes associated variants on circulating levels of glucagon-like peptide-1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP) and glucagon during an oral glucose tolerance test (OGTT).

Materials and methods: Plasma levels of GLP-1, GIP and glucagon were examined in samples obtained during an OGTT in 1,547 individuals from the ADDITION-PRO cohort. Participants were given a standard 75 g OGTT after an overnight fast of ≥ 7 hours and blood samples were drawn at 0, 30 and 120 min for assessment of plasma GLP-1, GIP and glucagon levels. The incremental area under the curve of plasma GLP-1, GIP and glucagon were calculated from 0-30 minutes and from 0-120 minutes during the OGTT. Associations between 68 genetic variants and plasma levels of GLP-1, GIP and glucagon were studied using a linear mixed model (EMMAX) implemented in the EPACTS software package by the use of inverse-normalized residuals of the traits adjusted for age, sex and BMI.

Results: None of the associations of the 68 known type 2 diabetes risk variants with circulating plasma levels of GLP-1, GIP or glucagon during the OGTT were significant after correction for multiple testing. However, nominally associated ($P < 0.05$) variants are reported in Table 1.

Conclusion: Known type 2 diabetes risk variants seem not to be strongly associated with altered secretion of GLP-1, GIP or glucagon. Large-scale genome-wide association studies of incretin hormone and glucagon release as well as studies of incretin hormone and glucagon action are needed in order to explain the genetic influence on these traits.

Effect of 36 hours fasting on genome-wide muscle gene expression in low and normal birth weight men

L. Gillberg¹, S.W. Jørgensen¹, A. Perflyev², T. Rönn², A. Vaag¹, C. Ling²;

¹Department of Endocrinology, Rigshospitalet, Copenhagen, Denmark, ²Department of Clinical Sciences, Lund University Diabetes Centre, Malmö, Sweden.

Background and aims: An adverse fetal environment might cause low birth weight (LBW) that is associated with increased risk of metabolic diseases. We recently showed that healthy young LBW men cope in a metabolically preferential way with 36 hours of fasting compared to normal birth weight (NBW) men. We hypothesized that fasting might unmask differential metabolic and molecular changes in insulin sensitive tissues from LBW individuals. Therefore, we analyzed genome-wide gene expression in skeletal muscle from 20 young LBW and 17 matched NBW men during 36 h fasting, and after overnight fast in 8 LBW and 8 NBW men.

Materials and methods: Gene expression of more than 99% RefSeq genes was analyzed with Affymetrix HumanGene 1.0 ST arrays. The effect of fasting and LBW was analyzed with non-parametric tests and false discovery rate (FDR) was applied to correct for multiple testing.

Results: The fasting intervention caused increased lipolysis and FFA levels as well as whole-body insulin resistance in the young healthy men. Gene expression of 28,829 transcripts was examined in skeletal muscle. After FDR correction, we did not find any significant transcriptional differences in muscle from LBW versus NBW men. Therefore, we combined the groups when investigating the fasting induced mRNA response. Interestingly, 1,706 (6% of all) transcripts changed significantly in response to 36 h fasting with mTOR signaling, Wnt signaling and cancer related KEGG pathways being up-regulated whereas metabolic pathways including fatty acid synthesis and citrate cycle were down-regulated during 36 h fasting.

Conclusion: The genome-wide transcriptional profile in skeletal muscle in young healthy LBW men was not significantly different than in matched NBW men. In response to 36 h fasting, widespread mRNA changes were observed in skeletal muscle in the combined group of LBW and NBW men. Up-regulation of genes involved in mTOR signaling and Wnt signaling may contribute to beneficial metabolic effects of fasting.

Selective metabolite biomarkers of isolated IFG (iIFG) and isolated IGT (iIGT)

J.E. Cobb¹, A. Eckhart¹, A. Motsinger², B. Carr³, E. Ferrannini⁴;

¹Metabolon, Durham, ²North Carolina State University, Raleigh, USA, ³Vhi Healthcare, Dublin, Ireland, ⁴CNR Institute of Clinical Physiology, Pisa, Italy.

Background and aims: IFG and IGT are distinct prediabetic states which may be characterized by different metabolite profiles. This work focused on identifying metabolites selective for the non-overlapping conditions of iIFG and iIGT.

Materials and methods: A targeted metabolomic analysis of fasting plasma samples taken at time=0 of an OGTT was performed. Quantitative measurements for a panel of 23 metabolites previously associated with prediabetes and type 2 diabetes were made using the isotope dilution method. The data was rank normalized using the GenAbel package in R to create a normal distribution. The associations of metabolites for normal (normal glucose tolerance & normal fasting glucose) vs iIFT or iIGT were made using logistic regressions controlling for age, sex, and BMI. Odds

ratios for a one SD change in the metabolite level, 95% confidence intervals and p values were calculated for each metabolite and reported as (OR (95% CI) p value). P values were adjusted with a false discovery rate of 0.1. Candidate biomarkers were identified using samples from the observational RISC study 3 year follow-up (normal n=623, iIFG n=220, iIGT n=56). The resulting candidate biomarkers were then validated in a second cohort, the DMVhi study (part of the DEXLIFE project), comprised of subjects at risk for type 2 diabetes (iIFG, iIGT, or FINDRISC score >12; normal n=485, iIFG n=104, iIGT n=31).

Results: In the RISC samples, 2-oxoleucine was associated with iIFG (1.36 (1.1-1.7) 3E-3) and had no significant association with iIGT. 2-Oxovaline was associated with iIFG (1.45 (1.2-1.7) 4E-5) and less so with iIGT (1.49 (1.1-2.0) 9E-3). alpha-Hydroxybutyric acid (AHB) was associated with iIGT (2.54 (1.9-3.5) 5E-9) and was not significantly associated with iIFG. Similar results were found in the DMVhi samples. Both 2-oxoleucine (1.65 (1.3-2.2) 0.001) and 2-oxovaline (1.58 (1.2-2.0) 0.001) were associated with iIFG and were not significantly associated with iIGT. AHB was associated with iIGT (2.75 (1.8-4.2) 4E-5) but less so with iIFG (1.31 (1.0-1.7) 0.05). In both cohorts, all three metabolites are associated with subjects having combined IFG and IGT.

Conclusion: Two branched-chain 2-oxoacids, 2-oxoleucine and 2-oxovaline, were found to be selective biomarkers for iIFG and AHB was found to be a selective biomarker for iIGT. The former are associated with elevated fasting glucose and the latter with impaired glucose disposal and may reflect different pathophysiological aspects of prediabetes. These biomarkers of different prediabetic states may have utility in identifying and stratifying subjects at risk for type 2 diabetes. Finally, these findings were seen in two different European cohorts having a total of 1519 subjects.

Efficacy and safety of gemigliptin/metformin initial combination therapy versus either as monotherapy in drug-naïve patients with type 2 diabetes

S. Lim¹, K. Min², J.-M. Yu³, P. Chamnan⁴, E. Kim⁵, K.-H. Yoon⁶, S. Kwon⁷, M. Moon⁸, K. Lee⁹, D.-J. Kim¹⁰, M. Kim¹¹, M. Wongtanate¹², E. Kim¹³, S.-H. Kim¹³, M.-K. Lee¹⁴;

¹Seoul National University Bundang Hospital, Seongnam, ²Eulji University Medical Center, Seoul, ³Kangnam Sacred Heart Hospital, Seoul, Republic of Korea, ⁴Sunpasithiprasong Hospital, Ubon Ratchathani, Thailand, ⁵Ulsan University Hospital, Ulsan, ⁶The Catholic University of Korea, Seoul St. Mary's Hospital, Seoul, ⁷Samsung Changwon Hospital, Changwon, ⁸Seoul National University Boramae Medical Center, Seoul, ⁹Ajou University Hospital, Suwon, ¹⁰Inje University Ilsan Paik Hospital, Goyang, ¹¹Inje University Haeundae Paik Hospital, Busan, Republic of Korea, ¹²Nan Hospital, Nan, Thailand, ¹³LG Life Sciences, Seoul, ¹⁴Samsung Medical Center, Sungkyunkwan University, Seoul, Republic of Korea.

Background and aims: This study evaluated the efficacy and safety of initial combination therapy with gemigliptin and metformin vs. gemigliptin or metformin monotherapy in drug-naïve patients with type 2 diabetes.

Materials and methods: In this randomized, double-blind, active-controlled, Phase III trial, eligible patients with HbA1c greater than 7.5% were randomized to gemigliptin 50 mg q.d + metformin GR q.d (GEMI/MET, n=141), gemigliptin 50 mg q.d (GEMI, n=142), or metformin GR q.d (MET, n=150). From weeks 2-6, metformin GR was up-titrated in 500 mg/day increments to 2000 mg/day maximum in the gemigliptin/metformin and metformin groups. The primary endpoint was change from baseline in HbA1c after 24 weeks.

Results: Baseline demographics and clinical characteristics were generally well balanced across treatment groups (mean HbA1c 8.68%; age 53.9 years; BMI 25.9 kg/m², duration of T2DM 3.92 years). Mean daily metformin doses at week 24 were 1699 mg and 1868 mg for GEMI/MET and MET respectively. All treatment groups showed statistically significant reductions in HbA1c from baseline at week 24. Mean change in HbA1c from baseline was -2.06% for GEMI/MET versus -1.24% for GEMI and -1.47% for MET respectively (p<0.0001 for all comparisons of combination therapy vs. monotherapy). The differences in proportions achieving an HbA1c <7 or <6.5% were also statistically significant (p<0.0001) between the combination therapy and the respective monotherapy groups. After 24 weeks, FPG decreased in all treatment groups, to the greatest extent with GEMI/MET (Table). Adverse events (AEs) were reported in 61.0%, 53.5% and 58% of subjects on GEMI/MET, GEMI and MET, respectively. The GEMI group had the lowest incidence of drug-related adverse events relative to other groups. The incidence of hypoglycemia was very low (0.0~2.13%) and similar among treatment groups.

Conclusion: Initial combination therapy with gemigliptin and metformin was more effective in glycemic control than their monotherapy and was well tolerated in patients with type 2 diabetes.

Omarigliptin, a once-weekly DPP-4 inhibitor, provides similar glycaemic control to sitagliptin in patients with type 2 diabetes mellitus inadequately controlled on metformin

I. Gantz, E. Lai, S. Suryawanshi, P. Andryuk, S.S. Engel; Merck & Co., Inc., Kenilworth, USA.

Background and aims: Omarigliptin (OMARI; MK-3102) is a potent, oral, once-weekly, dipeptidyl peptidase-4 (DPP-4) inhibitor in development for the treatment of patients with type 2 diabetes mellitus (T2DM). The convenience of an effective, well-tolerated, weekly oral drug may improve medication adherence. This global study compared the efficacy of OMARI 25 mg once weekly (q.w.) with that of sitagliptin (SITA) 100 mg daily (q.d.) in patients with T2DM and inadequate glycemic control on metformin monotherapy. The study also assessed the safety and tolerability of OMARI.

Materials and methods: This was a randomised, double-blind, non-inferiority study. Patients on metformin 1500 mg and an A1C ≥6.5% to ≤9.0% who met all other enrollment criteria entered a 2-week, single-blind, placebo run-in period, and were then randomised 1:1 to OMARI 25 mg q.w. or SITA 100 mg q.d. The primary efficacy analyses used the Full Analysis Set (FAS) population: patients who received at least one dose of study therapy and had a baseline or at least one post-randomization measurement. The primary hypothesis of non-inferiority (using an upper bound of 0.3%) of OMARI versus SITA in decreasing A1C at Week 24 was assessed using a constrained longitudinal data analysis model.

Results: Baseline characteristics were balanced across the two groups; baseline A1C was approximately 7.5%. At Week 24, OMARI and SITA both reduced A1C and FPG from baseline (Table). The upper bound of the two-sided 95% confidence interval for the between-group difference in reduction of A1C was 0.08% confirming non-inferiority. Changes from baseline in A1C were greater in subgroups with higher baseline A1C (Table). The percentage of patients with one or more adverse event was 36.3% and 40.6% in the OMARI and SITA groups, respectively, with no notable differences in specific adverse events. The incidences of serious adverse events, drug-related adverse events and discontinuations were similar between treatment groups. The incidences of hypoglycemia were 3.7% and 4.7% in the OMARI and SITA groups, respectively, with 1 severe hypoglycemia event reported in the OMARI group.

Conclusion: In patients with T2DM and inadequate glycemic control on metformin, once-weekly OMARI 25 mg provided similar improvement in glycemic control compared to SITA 100 mg q.d. Treatment with both agents was associated with a low incidence of hypoglycaemia and both agents were well-tolerated.

Improved glucose control without increased hypoglycaemia risk with insulin glargine/lixisenatide fixed-ratio combination (LixiLan) vs insulin glargine alone

R. Berria¹, B. Guerci^{2,3}, S. Paranjape¹, E. Souhami⁴, V. Aroda^{5,6}, J. Rosenstock⁷;

¹Sanofi, Bridgewater, USA, ²Brabois Hospital, Vandoeuvre Lès Nancy, ³CIC INSERM ILCV, University Hospital of Nancy, Vandoeuvre Lès Nancy, ⁴Diabetes Division Clinical Development Department, Sanofi, Chilly-Mazarin, France, ⁵Medstar Health Research Institute, Hyattsville, ⁶Georgetown University Medical School, Washington, ⁷Dallas Diabetes and Endocrine Center, Dallas, USA.

Background and aims: In a 24-week, proof-of-concept study in insulin-naïve patients with type 2 diabetes on metformin (N=323; mean baseline HbA_{1c} 8.0%, age 56.7 yrs, diabetes duration 6.7 yrs), once-daily LixiLan demonstrated greater HbA_{1c} reductions than insulin glargine alone, with a change from baseline of -1.8% vs -1.6%, respectively (p=0.01); endpoint HbA_{1c} of 6.3% vs 6.5%, respectively, and 84% vs 78% of patients achieved HbA_{1c} <7%. The rate of symptomatic hypoglycaemia was similar (~25%) in both groups. This post hoc exploratory analysis was conducted to determine whether the risk of symptomatic hypoglycaemia was impacted by the magnitude of HbA_{1c} reductions.

Materials and methods: Hypoglycaemia rates were assessed in subgroups based on achieving HbA_{1c} categories (<6%; ≥6 - <6.5%; ≥6.5 - <7%; ≥7%) and reduction in HbA_{1c} from baseline (≤1%; >1 - ≤1.5%; >1.5 - ≤2%; >2%) at Week 24, last observation carried forward. Cochran-Armitage Trend Tests (2-sided) and a regression analysis assessing non-homogeneous rates of hypoglycaemia across groups were performed.

Results: Neither test showed a relationship between hypoglycaemia rates and HbA_{1c} (p>0.1; Table).

Conclusion: Reaching lower near-normal HbA_{1c} levels and achieving greater HbA_{1c} reductions with LixiLan vs insulin glargine alone did not increase rates of hypoglycaemia at any level of glucose control.

Table. Number* of patients reporting symptomatic hypoglycaemia† in each HbA_{1c} category or mean change subgroup at Week 24

Parameter	HbA _{1c}	Incidence of symptomatic hypoglycaemia, n/N [†]	
		LixiLan N=160 (%)	Insulin glargine alone N=161 (%)
HbA _{1c} level reached at	<6%	12/52 (23.1)	9/29 (31.0)
Week 24 [‡]	≥6 - <6.5%	15/60 (25.0)	14/62 (22.6)
	≥6.5 - <7%	5/23 (21.7)	11/35 (31.4)
	≥7%	8/25 (32.0)	6/35 (17.1)
Absolute mean reduction in HbA _{1c} from baseline [§]	≤1%	10/29 (34.5)	9/48 (18.8)
	>1 - ≤1.5%	10/44 (22.7)	15/42 (35.7)
	>1.5 - ≤2%	4/30 (13.3)	6/25 (24.0)
	>2%	16/57 (28.1)	10/46 (21.7)

*Data are for patients from the modified intent-to-treat population with relevant baseline and Week 24 last observation carried forward measurements.

[†]Symptomatic hypoglycaemia was defined as an event with typical symptoms of hypoglycaemia and 'documented' when accompanied by a measured plasma glucose concentration of ≤3.9 mmol/L (70 mg/dL).

[‡]While n indicates the number of patients with symptomatic hypoglycaemia, N shows the number of patients achieving a specific HbA_{1c} level or reduction. A total of 40 patients in each treatment group had symptomatic hypoglycaemia during the 24-week treatment period.

[§]There was no statistically significant relationship between hypoglycaemia rates and HbA_{1c} levels reached at Week 24 and absolute mean reduction in HbA_{1c} from baseline (p>0.1).

A randomised, double-blind, placebo-controlled, 39 week trial of ITCA 650 as add-on therapy in type 2 diabetes

M.A. Baron¹, J. Buse², R. Azeem¹, L. Kjems¹, J. Rosenstock³;

¹Intarcia Therapeutics, Inc., Boston, ²University of North Carolina School of Medicine, Chapel Hill, ³Dallas Diabetes and Endocrine Center at Medical City, Dallas, USA.

Background and aims: ITCA 650, an injection-free glucagon-like peptide-1 (GLP-1) receptor agonist delivers continuous subcutaneous (SC) exenatide for up to 12 months from a single sub-dermal placement of the osmotic minipump.

Materials and methods: This first pivotal Phase 3 study randomized (1:1:1) type 2 diabetes (T2DM) subjects with HbA_{1c} ≥7.5 to ≤10% on diet and exercise or oral antidiabetics to ITCA 650 40 or 60 mcg/d or placebo (PBO), starting with 20 mcg/d for 13 weeks, then 40 or 60 mcg/d for 26 wks. HbA_{1c}, body weight, and % achieving HbA_{1c} <7% were tested hierarchically.

Results: Baseline characteristics were similar in the 3 groups (n=460): mean HbA_{1c} 8.5%; BMI 33.5 kg/m², diabetes duration 9 years. Efficacy endpoints were statistically significant for both doses vs PBO. Mean reduction in HbA_{1c} from baseline was -1.1% (97.5% CI: -1.29, -0.71) and -1.2% (97.5% CI: -1.37, -0.80) with 40 and 60 mcg/d (p=0.001 vs PBO) at Week 39 (last observation carried forward). Greater reductions in HbA_{1c} (-1.7%) occurred in subjects not taking sulfonylureas (SUs), most of whom were on metformin monotherapy. Progressive weight loss was dose dependent (Figure). ITCA 650 60 mcg/d resulted in greater weight loss, more subjects achieving HbA_{1c} <7%, and less need for rescue therapy. Gastrointestinal adverse events consistent with the GLP-1 class were most common and decreased over time. ITCA 650 was well tolerated with a low rate of discontinuation for adverse events.

Conclusion: ITCA 650 ensured consistent SC delivery of exenatide over 39 weeks and resulted in meaningful reductions in HbA_{1c} and body weight in inadequately controlled T2DM.

Once a month treatment with HM11260C improves glycaemic control in type 2 diabetes mellitus: interim data from a 16-week study

S. Del Prato¹, J. Kang², S. Choi², W. Lee², O. Han², S. Kil², K. Gee², I. Choi², S. Kwon², M. Trautmann³, M. Hompesch³;

¹Department of Clinical and Experimental Medicine, University of Pisa, Italy, ²Hanmi Pharmaceutical, Co., Ltd., Seoul, Republic of Korea, ³Profil Institute for Clinical Research, Inc., Chula Vista, USA.

Background and aims: HM11260C (HM) is a novel ultra-long acting GLP-1R agonist with a T_{1/2} of ~158 hrs. This 16-week, randomized, placebo (PBO) controlled, double-blind parallel group study was designed to investigate efficacy, safety, and tolerability of a range of once monthly (QM) HM doses in subjects with T2DM.

Materials and methods: We report interim data from 86 patients (mean age 56 yrs, BMI 32.1 kg/m², T2DM duration 95.4 months) out of 209 patients with unsatisfactory glycemic control while on a stable dose of metformin (≥3 months) before entering this study. Patients were randomized to one of three HM QM doses (8, 12 and 16 mg) or PBO, followed by a 4-week titration period.

Results: Overall, all HM doses produced remarkable reductions in HbA1c, fasting plasma glucose, and 7-point daily glucose (Table 1). Percentage of patients on HM achieving A1c Target <7% was 73.3% (8 and 16 mg) and 64.3% (12 mg) vs. 22.2% on PBO. With HM, the reduction in body weight ranged from 2.16% to 2.80% vs. 1.24% on PBO. The most frequent AEs in HM-treated patients were mild or moderate gastrointestinal events. No increase in heart rate was recorded.

Conclusion: All QM doses of HM demonstrated clinically meaningful improvement in blood glucose and body weight loss. The current results will have to be confirmed upon completion of the trial and warrant further studies to evaluate the long-term efficacy and safety of a monthly regimen with HM in T2DM.

Efficacy and safety of liraglutide added to insulin therapy in patients with type 1 diabetes: the Lira-1 study

T.F. Dejgaard^{1,2}, C.S. Frandsen², F.K. Knop^{3,4}, L. Tarnow⁵, T.S. Hansen¹, T.P. Almdal³, U. Pedersen-Bjergaard⁵, S. Urhammer⁶, T.J. Jensen⁷, J.J. Holst⁴, S. Madsbad², H.U. Andersen¹;

¹Steno Diabetes Center, Gentofte, ²Hvidovre Hospital, University of Copenhagen, Hvidovre, ³Gentofte Hospital, University of Copenhagen, Gentofte, ⁴The NNF Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, ⁵Nordsjællands Hospital, University of Copenhagen, Hillerød, ⁶Frederiksberg Hospital, University of Copenhagen, Frederiksberg, ⁷Rigshospitalet, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Weight gain and hypoglycaemia are common side effects to insulin therapy in type 1 diabetes (T1D). The combination of insulin and glucagon-like peptide-1 receptor agonist (GLP-1RA) therapy has proven effective in reducing weight gain and insulin dose in type 2 diabetes and may have similar effects in patients with T1D.

Materials and methods: This 26-week trial is the first randomised, double-blinded, placebo controlled study to evaluate efficacy and safety of GLP-1RA treatment in poorly controlled, overweight patients with T1D. In total 100 patients with T1D, HbA1c >64 mmol/mol and BMI >25 kg/m², were randomised to liraglutide 1.8 mg once daily or placebo added to intensive insulin therapy.

Results: Mean baseline characteristics were similar between groups (liraglutide ±SD; placebo ±SD) age 47 ±13; 49 ±12 years (p=0.355), HbA1c 73 ±8; 73 ±8 mmol/mol (p=0.827), total daily insulin dose 60 ±23; 61 ±21 IU/day (p=0.813) and bodyweight 93.4 ±14.2; 94.0 ±12.5 kg (p=0.828) except diabetes duration 20 ±12; 25 ±12 years (p=0.049). After 12 weeks of treatment, liraglutide reduced HbA1c, bodyweight and daily insulin dose compared with placebo. At the end of treatment no difference in HbA1c between groups was found. Bodyweight and daily insulin dose remained reduced in the liraglutide group compared to placebo. Frequency of hypoglycaemia did not differ between groups. Heart rate increased with liraglutide treatment, while no differences in systolic or diastolic blood pressure was found by 24-hour ambulatory blood pressure monitoring (table). Gastrointestinal AEs occurred more frequently with liraglutide than placebo, i.e. nausea (48% vs.7%).

Conclusion: In conclusion, liraglutide added to insulin treatment in overweight and poorly controlled patients with T1D reduced bodyweight and daily insulin dose, but increased heart rate and did not improve HbA1c compared with placebo at end of treatment.

Key Results: Liraglutide 1.8 mg vs. placebo as add-on to intensive insulin treatment

A reduced incretin effect can be detected in non-diabetic women with previous gestational diabetes even before the development of diabetes S. Foghsgaard^{1,2}, L. Vedtofte¹, E. Bahne¹, E.S. Andersen¹, C. Andreasen¹, T.D. Clausen³, J.A. Svare⁴, J.J. Holst², E.R. Mathiesen⁵, P. Damm⁶, F.K. Knop¹, T. Vilsbøll¹;

¹Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Hellerup, ²NNF Center for Basic Metabolic Research, Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, ³Department of Gynaecology and Obstetrics, Nordsjællands Hospital, University of Copenhagen, Hillerød, ⁴Department of Gynaecology and Obstetrics, Herlev Hospital, University of Copenhagen, Herlev, ⁵Center for Pregnant Women with Diabetes, Department of Endocrinology, Rigshospitalet, University of Copenhagen, Copenhagen, ⁶Center for Pregnant Women with Diabetes, Department of Obstetrics, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark.

Background and aims: The incretin effect is decreased in patients with type 2 diabetes, which prompted us to study whether reduced incretin effect can be detected in high-risk individuals such as women with previous gestational diabetes mellitus (GDM).

Materials and methods: One hundred and two non-diabetic women with previous GDM were examined on two separate occasions: 1) 4-hour 75 g OGTT and 2) isoglycaemic i.v. glucose infusion (IIGI). Based on the fasting plasma glucose (FPG) and the 2-hour plasma glucose concentrations of the OGTT, the women were classified as having normal glucose tolerance (NGT) or prediabetes (impaired fasting glucose and/or impaired glucose tolerance) (WHO 2006).

Results: Sixty three of the women (62%) were diagnosed with prediabetes (age: 38±5 years (mean ± SD); BMI: 32±4 kg/m²; waist:hip ratio: 0.9±0.1; HbA_{1c}: 34±4 mmol/mol; insulin resistance according to homeostatic model assessment 2 (HOMA2_{IR}): 1.8±0.8), and 39 (38%) had NGT (age: 39±5 years; BMI: 31±5 kg/m²; waist:hip ratio: 0.9±0.1; HbA_{1c}: 33±4 mmol/mol; HOMA2_{IR}: 1.9±1.1). Women with prediabetes had higher FPG (5.5±0.5 vs. 5.2±0.4 mmol/l, *p*=0.002) and 2-hour plasma glucose during OGTT (9.2±1.1 vs. 7.0±0.8 mmol/l, *p*<0.0001) as well as lower insulin sensitivity measured by Matsuda Index (2.6±1.3 vs. 3.3±1.8 *p*<0.005) compared to women with NGT. The incretin effect was calculated from insulin responses during the two experimental days [$100\% \times (AUC_{\text{insulin, OGTT}} - AUC_{\text{insulin, IIGI}}) / AUC_{\text{insulin, OGTT}}$] and amounted to 41±18% and 54±13% in women prediabetes and NGT, respectively (*p*=0.0003) (Figure). The groups were similar with respect to age, BMI, waist:hip ratio, HbA_{1c}, HOMA2_{IR}, fasting insulin (110±58 vs. 96±60 pmol/l, *p*=0.078), number of previous GDM-pregnancies (1.2±0.4 vs. 1.1±0.3, *p*=0.448) and duration since index pregnancy (5.2±2.7 vs. 4.9±2.5 years, *p*=0.658).

Conclusion: Our results show that prediabetes is prevalent in women with previous GDM, and alterations in the incretin effect can be detected in these high-risk individuals even before the development of type 2 diabetes.

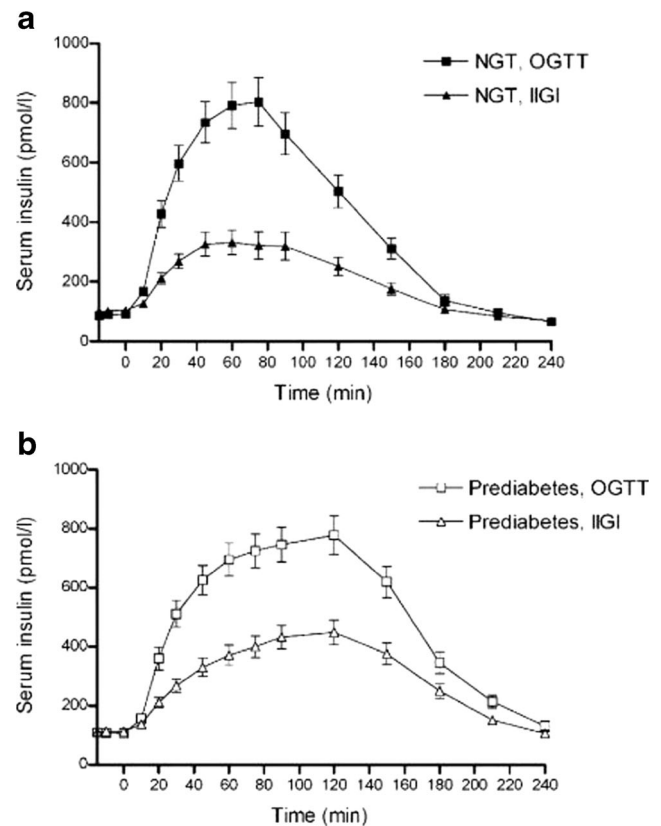

Figure: Insulin response during OGTT and isoglycaemic i.v. glucose infusion (IIGI) presented as mean ± SEM. A) Normal glucose tolerant women (NGT): Incretin effect [$100\% \times (AUC_{\text{insulin, OGTT}} - AUC_{\text{insulin, IIGI}}) / AUC_{\text{insulin, OGTT}}$] amounted to 54 ± 2% (mean ± SEM). B) Women with prediabetes: Incretin effect amounted to 41 ± 2%.

Insulin resistance and large amounts of visceral fat characterise women with previous gestational diabetes and non-alcoholic fatty liver disease

L. Vedtofte¹, S. Foghsgaard^{1,2}, C. Andreasen¹, E.S. Andersen¹, E. Bahne¹, C. Strandberg³, T. Buhl⁴, J.J. Holst², J.A. Svare⁵, T.D. Clausen⁶, E.R. Mathiesen⁷, P. Damm⁸, L.L. Gluud¹, F.K. Knop^{1,9}, T. Vilsbøll¹;

¹Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Hellerup, ²University of Copenhagen, NNF Center for Basic Metabolic Research, Section for Translational Metabolic Physiology, Copenhagen, ³Department of Radiology, Gentofte Hospital, University of Copenhagen, Hellerup, ⁴Department of Nuclear Medicine, Gentofte Hospital, University of Copenhagen, Hellerup, ⁵Department of Obstetrics and Gynaecology, Herlev Hospital, University of Copenhagen, Herlev, ⁶Department of Gynaecology and Obstetrics, Nordsjællands Hospital, University of Copenhagen, Hillerød, ⁷Center for Pregnant Women with Diabetes, Department of Endocrinology, Rigshospitalet, University of Copenhagen, Copenhagen, ⁸Center for Pregnant Women with Diabetes, Department of Obstetrics, Rigshospitalet, University of Copenhagen, ⁹NNF Center for Basic Metabolic Research, Section for Translational Metabolic Physiology, Faculty of Health and Medical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Denmark.

Background and aims: Non-alcoholic fatty liver disease (NAFLD), a condition with fat accumulation in the liver in the absence of significant

alcohol consumption, is the most common liver disease in Western countries. The disease spectrum spans from simple steatosis to liver cirrhosis. In type 2 diabetes, NAFLD is linked to cardiovascular disease and hepatocellular carcinoma, which can occur in patients with or without cirrhosis. Because of their high risk of type 2 diabetes, women with previous gestational diabetes (GDM) may have a high risk of developing NAFLD.

Materials and methods: Non-diabetic women with previous GDM ($n=98$, age: 38 ± 5 years) underwent 75 g OGTT, dual energy X-ray absorptiometry whole body scan and ultrasound scan and elastography of the liver to evaluate steatosis (NAFLD). Elastography is a novel, non-invasive way of measuring steatosis. The median of ten representative elastographic measurements is provided as the E-median index. Insulin resistance was evaluated by the HOMA2-IR. Values are mean \pm SD for age and BMI and mean \pm SEM for the remaining variables.

Results: Twenty-six (27%) women had NAFLD based on the ultrasound scan and 72 (73%) were without steatosis. None had cirrhosis. When comparing the two groups, women with NAFLD had significantly higher BMI (34 ± 5 vs. 31 ± 4 kg/m², $p=0.001$) and android-to-gynoid fat-ratio (1.2 ± 0 vs. 1.1 ± 0 , $p=0.021$). Women with NAFLD also had larger visceral fat mass ($1,488\pm 136$ vs. $1,009\pm 60$ g, $p=0.003$), were more insulin resistant (2.5 ± 0 vs. 1.7 ± 0 , $p=0.019$), had higher fasting C-peptide (672 ± 61 vs. 496 ± 21 pmol/l, $p=0.011$), E-median index (1.7 ± 0 vs. 0.9 ± 0 , $p=0.001$), and liver enzyme levels (alanine aminotransferase: 34 ± 4 vs. 23 ± 1 U/l, $p=0.017$; aspartate aminotransferase: 31 ± 2 vs. 26 ± 1 U/L, $p=0.018$) and lower plasma high density lipoprotein cholesterol (1.1 ± 0 vs. 1.3 ± 0 mmol/l, $p=0.019$). Multivariable logistic regression analysis showed that visceral fat mass ($p=0.0011$) and the aspartate aminotransferase level ($p=0.001$) were independent predictors of NAFLD.

Conclusion: The results show that a large proportion of women with previous GDM and insulin resistance have NAFLD at a young age. We have identified predictors to be used for early identification of these women for best possible management of comorbidities in order to prevent future liver disease and cardiovascular events.

Decreased gene expression of leptin, adiponectin and resistin in subcutaneous adipose tissue biopsies from adult offspring of women with diabetes in pregnancy

A. Houshmand-Oeregaard^{1,2}, N.S. Hansen^{1,3}, L. Kelstrup^{2,3}, L. Hjort^{1,3}, C. Broholm¹, E.R. Mathiesen^{2,3}, T.D. Clausen^{3,4}, P. Damm^{2,3}, A.A. Vaag^{1,3};

¹Department of Endocrinology, Rigshospitalet, ²Center for Pregnant Women with Diabetes, Department of Obstetrics and Gynecology, Rigshospitalet, ³Faculty of Health and Medical Sciences, University of Copenhagen, ⁴Department of Obstetrics and Gynecology, Hilleroed Hospital, Copenhagen, Denmark.

Background and aims: Offspring exposed to intrauterine hyperglycaemia are at increased risk of developing adiposity and type 2 diabetes (T2D). Adipose tissue secretes adipokines such as leptin, adiponectin, and resistin, all of which play important roles in lipid and carbohydrate metabolism, as well as in the development of adiposity and T2D. We hypothesized that the plasma levels, and/or expression levels of the genes encoding these adipokines in subcutaneous adipose tissue (SAT), may be altered in adult offspring of women with diabetes in pregnancy compared to unexposed controls.

Materials and methods: We obtained a total of 166 biopsies from subcutaneous adipose tissue (SAT) in adult offspring of women with gestational diabetes mellitus (O-GDM ($n=60$)) or type 1 diabetes in pregnancy (O-T1D ($n=63$)), and offspring of women (controls) from the background population (O-BP ($n=43$)). All subjects were born between 1978 and 1985 and data was collected in 2012–2013. The subjects underwent clinical

examinations with anthropometric measurements and 2-hour 75 g oral glucose tolerance tests (OGTT's), as well as a dual energy x-ray absorptiometry (DEXA) whole-body scanning. Women with T1D were characterized by increased average plasma glucose levels during pregnancy compared with women with GDM during pregnancy. Gene expression of leptin, adiponectin and resistin in SAT was examined by real-time PCR and plasma levels were measured by Meso Scale Discovery.

Results: No significant differences were found in average BMI, waist-hip ratio, or body composition between the three groups. Compared to O-BP, 2-hour plasma glucose was significantly higher in O-GDM ($p=0.019$) and O-T1D ($p=0.001$). Plasma levels of leptin were increased in O-GDM and in O-T1D compared to O-BP, but only the difference between O-T1D and O-BP reached statistical significance ($p=0.05$). Measurement of plasma adiponectin and resistin levels are ongoing. Interestingly, significantly lower levels of gene expression of all three adipokines were found in O-GDM compared with O-BP: leptin (1.18 vs. 1.63; $p=0.003$), adiponectin (1.32 vs. 1.99; $p=0.0003$) and resistin (1.07 vs. 7.01; $p<0.0001$). Similarly, in O-T1D compared with O-BP, significantly decreased levels of adiponectin (1.56 vs. 1.99; $p=0.03$) and resistin (3.56 vs. 7.01; $p=0.001$) were found. The gene expression of leptin in O-T1D was similar to that in O-BP.

Conclusion: Despite borderline increased plasma leptin levels, the gene expression of leptin in SAT was markedly reduced in O-GDM compared with O-BP controls. Furthermore, the gene expression of the two other adipokines, adiponectin and resistin, was also significantly reduced in O-GDM compared with O-BP. O-T1D was exposed to a higher degree of intrauterine hyperglycaemia, yet the adipokine gene expression differences in O-T1D compared with O-BP were quantitatively less pronounced, indicating that the quantitatively more pronounced changes seen in O-GDM compared with O-BP cannot be explained by intrauterine hyperglycaemia alone.

DNA methylation and gene expression of PPARGC1A in muscle and fat biopsies from adult offspring of women with diabetes in pregnancy

L. Kelstrup¹, L. Hjort², A. Houshmand-Oeregaard¹, T.D. Clausen^{1,3}, N.S. Hansen², C. Broholm², L. Borch-Johnsen¹, E. Mathiesen^{4,5}, A.A. Vaag^{2,5}, P. Damm^{1,5};

¹Department of Obstetrics, Center for Pregnant Women with Diabetes, ²Department of Endocrinology, Diabetes and Metabolism, Copenhagen, ³Department of Obstetrics and Gynecology, Hilleroed Hospital, Hillerød, ⁴Department of Endocrinology, Center for Pregnant Women with Diabetes, Copenhagen, ⁵Faculty of Health and Medical Sciences, University of Copenhagen, Denmark.

Background and aims: Fetal exposure to intrauterine hyperglycemia is associated with increased risk of type 2 diabetes (T2DM) later in life, but the underlying mechanisms are unknown. Epigenetics has been proposed as a link between environmental exposures and the phenotype. Methylation of CpG-sites in the DNA is the most studied epigenetic marker. Increased CpG methylation and reduced gene expression of the metabolic regulator peroxisome proliferator-activated receptor gamma co-activator 1 alpha (PPARGC1A) in skeletal muscle and subcutaneous adipose tissue (SAT) has been reported in patients with T2DM. We aimed to investigate DNA methylation and gene expression of PPARGC1A in skeletal muscle and SAT from adult offspring of women with diet-treated gestational diabetes (O-GDM, $N=83$) or with type 1 diabetes (O-T1DM, $N=67$) and from the background population (O-BP, $N=58$) (Total $N=208$).

Materials and methods: The adult offspring (26–35 year) underwent a 2-hour 75 g OGTT and tissue sampling from the vastus lateralis muscle and abdominal SAT. PPARGC1A promoter DNA methylation was studied by pyrosequencing at three CpG sites. PPARGC1A gene expression was assessed using real-time quantitative PCR.

Results: Plasma glucose during OGTT was significantly higher for both groups exposed to intrauterine hyperglycemia compared to O-BP (O-GDM: [30 min: $p=0.005$] and [120 min: $p=0.019$]; O-T1DM: [30 min: $p=0.001$]). Average PPARGC1A promoter DNA methylation was higher in O-GDM in muscle ($p=0.05$) and SAT ($p=0.02$) compared to O-BP, while no differences neither in muscle or SAT was found between O-T1DM and O-BP. PPARGC1A gene expression in muscle was significantly lower in O-GDM compared to O-BP ($p=0.0003$), while no difference was found between O-T1DM and O-BP. PPARGC1A gene expression in SAT was similar in all three groups.

Conclusion: Both groups of adult offspring of women with diabetes in pregnancy had elevated glucose levels during OGTT. O-GDM presented significantly altered DNA methylation in both skeletal muscle and SAT and decreased PPARGC1A gene expression in skeletal muscle. The findings in O-GDM may contribute to the increased risk of developing T2DM, but our negative findings in O-T1DM despite fetal exposure to more severe hyperglycemia indicate that other mechanisms than only exposure to intrauterine hyperglycaemia or other mechanisms in terms of epigenetic markers may be involved in fetal programming of adult adverse metabolic health.

Effects of a hyperglycaemic intrauterine environment on offsprings epigenome and risk of cardio-metabolic disease later in life

L. Hjort¹, L. Groth Grunnet¹, A. Olsson¹, D. Martino², F. B Hu³, C. Zhang⁴, R. Saffery², S. Olsen⁵, A. Vaag¹;

¹Copenhagen University Hospital, Copenhagen, Denmark, ²Murdoch Childrens Research Institute, Parkville, Australia, ³Harvard Medical and Public Health School, Boston, ⁴National Institute of Child Health and Human Development, Bethesda, USA, ⁵Statens Serum Institut, Copenhagen, Denmark.

Background and aims: Offspring of women with Gestational Diabetes Mellitus (GDM) are at high risk of developing Type 2 Diabetes (T2D) later in life, but the putative epigenetic mechanisms underlying this association remain unknown. Using an epigenome-wide approach in a subcohort of the Danish National Birth Cohort, we aimed to explore whether DNA methylation in blood differed in 9-14 year old offspring of GDM women versus matched controls.

Materials and methods: We recruited 623 GDM- and 617 control offspring. DNA from 95 GDM offspring and 95 controls were analyzed for genome-wide DNA methylation profiles using the Infinium HumanMethylation450 BeadChip.

Results: BMI, fat percentage, fasting glucose, insulin and c-peptide levels were higher among GDM offspring compared to controls ($P\leq 0.04$). We did not find any differentially methylated positions at the genome-wide significance level (Bonferroni adjusted), but identified 1,828 sites potentially differentially methylated between the groups ($P\leq 0.01$, unadjusted). When performing a differential methylated region (DMR) analysis, we identified a small non-coding RNA, VTRNA2-1, that reached genome-wide significance, covering 16 CpG sites overall presenting lower methylation in the GDM group ($P=0.02$, adjusted). Multiple examples of differential methylation within the same gene were noted, suggesting a coordinated change in methylation, and several localized to genes previously associated with DNA methylation changes, in earlier studies of GDM cord blood and placenta samples. From the top ten probes based on P-value, PTCH1 was identified with decreased methylation in GDM offspring and associated with increased glucose levels among the offspring ($P=0.02$).

Conclusion: Our data suggests that offspring of GDM women exhibit pre-diabetes traits at preadolescent age. A substantial proportion of methylation differences observed in previous GDM cord blood/placenta studies are likely to resolve during childhood, thus, the persistent marks identified in this study may serve as interesting sites in investigation of causal relation to the increased T2D risk later in life. Validation studies of the identified 1,828 sites are in progress in the entire cohort of 1,240 children.

¹Endocrinology, Complejo Hospitalario Universitario Insular Materno-Infantil (CHUIMI), ²Instituto Universitario de Investigaciones Biomedicas y Sanitarias, Universidad de Las Palmas de Gran Canaria (ULPGC), ³Gynaecology and Obstetrics, CHUIMI, ⁴Research Unit, CHUIMI, ⁵ULPGC, ⁶Pathology, Complejo Hospitalario Universitario Insular Materno-Infantil, Las Palmas de Gran Canaria, Spain.

Background and aims: Offspring of mothers with type 1 diabetes (T1D) have a lower risk of T1D than offspring of fathers with T1D. This could be explained by intrauterine, epigenetic effects, detectable already at the time of birth. Our aim was to assess the effect of maternal T1D on the placental expression of miRNAs and DNA methylation and their effect on gene expression.

Materials and methods: Samples of the maternal and foetal sides of the placenta were obtained from women with T1D and type 2 diabetes (T2D), women whose partner had T1D and controls matched for age and gestational age. Five "pools" of 8-10 samples of maternal and 5 of foetal placenta were analysed. DNA methylation patterns (Methylation-specific digital karyotyping) were analysed and compared. Genes in which high methylation (fold-change of tags < -1) levels coincided with a reduction in the mRNA expression level (fold-change < -1.5) were identified. Massive sequencing of miRNAs was performed. Potential target genes of novel miRNAs were sought (simulation, miRDB). We selected miRNAs that showed a difference in expression between groups ($p < 0.1$) and a difference (in the opposite direction) in the expression levels of the target mRNA (fold-change below -0.5/above 0.5). We report the changes identified in the foetal side of the placentas in T1D

Results: A total of 38 women with T1D and 32 with T2D, 15 women whose partners had T1D and 59 controls have been included [age 32.3(5.9), 32.3(5.8), 28.4(5.1) and 29.8 (5.8), years; gestational age 38.7(1.6), 38.5(1.5), 38.4(1.3) and 39.5 (1.4) weeks, respectively]; pregestational HbA1c in the women with diabetes 7.3(1.9) and 7.0(1.2)% and third trimester HbA1c 6.4(0.9) and 6.1(0.7) %. We identified 13 genes with relevantly different methylation in the foetal placenta of mothers with T1D, as well as 5 new and 8 known miRNAs (See table). The latter have consequences on the expression of genes involved in immune response, aminoacid and protein metabolism and insulin signalling.

Conclusion: Epigenetic effects of maternal T1D can be detected at birth and the most relevant seem to be due to hyperglycaemia, rather than autoimmunity, as suggested by a lack of difference with the T2D group. The implications of these preliminary findings are still to be clarified.

OP 21 The multifaceted danger of hypoglycaemia

121

The risk of severe hypoglycaemia events in working-age adults and use of basal insulins NPH, glargine and detemir: a nationwide register study in Finland

A.Y. Strandberg¹, T.E. Strandberg², H. Khanfir³, S. Mäkimattila⁴, T. Saukkonen⁴, F. Hoti³;

¹Aava Medical Centre, Kerava, ²Institute of Health Sciences/Geriatrics, University of Oulu, ³EPID Research, Espoo, ⁴Novo Nordisk Farma, Espoo, Finland.

Background and aims: Hypoglycaemia is a common and costly side effect of insulin treatment. The risk of hypoglycaemia increases with the duration of treatment and with advancing age. In comparison to the earlier generation basal insulin NPH, modern, longer acting basal insulins glargine and detemir have shown a lower incidence of hypoglycaemia in clinical studies. In real-life care the benefits have not been fully demonstrated, especially among the working-age population, for whom the target levels of glucose control are strict than for older persons. We evaluated the risk of severe hypoglycaemia events among new users of NPH, glargine and detemir in a real-world setting among working-age adults in Finland.

Materials and methods: Persons aged 18–65 years with diabetes and recently prescribed with basal insulin (NPH, glargine, detemir) during 2006–2009 were identified from the Finnish national prescription register. During this period all three insulins were fully reimbursed for patients with diabetes. The study patients were followed up until the first event of severe hypoglycaemia or death by the end of 2009, utilizing the nationwide hospital discharge register and cause of death register. The Poisson model was used to evaluate the absolute risk (with 95% confidence intervals) for severe hypoglycaemia events for new users of NPH, glargine or detemir during follow-up. The risk between the study insulins was compared with Cox's proportional hazards model adjusting for age, gender, type of diabetes, use of sulfonylurea, use of other than study insulin, history of hospitalizations due to severe hypoglycaemia, and switch of study insulin. Several sensitivity analyses were performed to test the robustness of the results with respect to the exposure definitions and possible confounders.

Results: During the follow-up of up to four years, (mean 1.8 years) there were 16,985 persons (2,604 with type 1, 13,254 with type 2, and 1,127 with unclassified diabetes mellitus) who initiated basal insulin treatment. 5,586 patients initiated NPH, 7,499 glargine, and 3,900 detemir. During the 27,815 person-years of follow-up, 2,730 (16%) people switched insulin at least once, and 536 (3%) people were hospitalized due to an event of severe hypoglycaemia with 190, 222 and 76 during exposure to insulin NPH, glargine or detemir, respectively. The type of insulin in use was not specified for 48 events. The absolute rate (per 1000 patient-years) of severe hypoglycaemia was 20.6 (95% CI 17.9, 23.8) for NPH, 17.8 (15.6, 20.3) for glargine, and 12.4 (9.9, 15.5) for detemir initiators. With NPH as reference, the adjusted hazard ratio (HR) for the risk was 0.92 (95% CI 0.74, 1.15, $p=0.47$) for glargine, and significantly lower 0.70 (0.52–0.94, $p<0.05$) for detemir. The corresponding risk was also significantly lower (HR 0.76 [0.58, 0.99, $p<0.05$]) for detemir compared to glargine.

Conclusion: We observed significant differences in the risk of severe hypoglycaemia between different basal insulins among working-aged adults with diabetes in Finland. Use of insulin detemir was associated with a significantly lower risk of severe hypoglycaemia requiring hospital care compared to glargine and NPH. The results suggest that in routine practice the burden of hypoglycaemia may be reduced by the choice of basal insulin. Supported by: Novo Nordisk, Gustaf V and Queen Victoria Frimurarestiftelse

Reactive hypoglycaemia after Roux-en-Y gastric bypass in type 2 diabetic subjects

M. Nannipieri¹, D. Guarino¹, M. Seghieri¹, E. Rebelou¹, A. Mari², D. Colligiani¹, D. Moriconi¹, S. Baldi¹, M. Anselmino³, E. Ferrannini⁴;
¹Dpt Clinical and Experimental Medicine, University of Pisa, ²Biomedical Engineering of Padua, CNR Institute, Padua, ³Bariatric Surgery Unit, Azienda Ospedaliera Universitaria Pisana, Pisa, ⁴Clinical Physiology, CNR Institute, Pisa, Italy.

Background and aims: Reactive hypoglycaemia (Hypo) is a well-recognised complication of RYGB surgery in non-diabetic subjects. In type 2 diabetes (T2DM), RYGB improves glucose metabolism, but whether this improvement is related to the later development of reactive hypoglycaemia is not known. Our aim was to investigate presence and mechanisms of postprandial Hypo in T2DM undergoing RYGB.

Materials and methods: 32 obese T2DM subjects treated with RYGB received a 5-hr OGTT before and 12–18 months after surgery. Hypo was defined as a plasma glucose ≤ 3.3 mmol/L in subjects off hypoglycaemic agents. Insulin sensitivity was assessed by Matsuda index and β -cell function by modelling analysis of the C-peptide response to the OGTT.

Results: Hypo occurred in 10 of 32 RYGB patients. Age did not discriminate Hypo from non-Hypo (NH) subjects. Presurgery BMI was lower in Hypo than NH (42.8 ± 6.4 vs 46.0 ± 5.9 kg/m², $p=0.03$). Pre-surgery fasting glycaemia was similar in both groups, as was mean plasma glucose during OGTT (11.0 ± 2.1 vs 10.4 ± 2.0 mM, $p=ns$). Pre-surgery mean insulin during OGTT and insulin secretion rate (basal and total) were similar in both groups. Post-surgery, mean insulin was reduced to a similar extent in both groups ($p=0.003$), whereas insulin secretion was unchanged. Baseline peripheral insulin sensitivity was higher in Hypo than NH and after surgery it improved more in Hypo than in NH (4.3 ± 2.3 vs 9.0 ± 3.1 and 2.8 ± 1.1 vs 5.5 ± 2.6 mL.min⁻¹.m⁻², $p<0.0001$ for time, $p=0.05$ for interaction time*Hypo). Baseline β -cell glucose sensitivity was similar in the two groups (29 ± 22 vs 25 ± 34 pmol.min⁻¹.m⁻².mM⁻¹), but after surgery it increased more in Hypo than NH (82 ± 49 vs 34 ± 23 pmol.min⁻¹.m⁻².mM⁻¹, $p=0.0018$ for interaction time*Hypo). Baseline insulin clearance was similar, but post-surgery it improved in Hypo ($p=0.004$ interaction time*Hypo). No differences in fasting or postglucose GLP1 and glucagon were found between Hypo and NH, whereas fasting plasma PYY concentrations before surgery were significantly higher in Hypo compared to NH ($p=0.04$). In logistic regression, presurgery insulin sensitivity (positive, $p=0.03$) and fasting PYY (positive, $p=0.04$) were the only predictors of reactive hypoglycaemia after surgery.

Conclusion: A better insulin sensitivity and higher fasting PYY concentrations before surgery are associated with a higher risk of post-surgery reactive hypoglycaemia in T2DM subjects. Independently of diabetes remission, improvement in β -cell glucose sensitivity in association with peripheral insulin sensitivity is responsible for postprandial hypoglycaemia after RYGB.

Hypoglycaemia association with hospitalisation and mortality in older patients with type 2 diabetes mellitus initiating Basal Insulin (BI) in a US medicare advantage population

J. Escalada¹, L. Liao², C. Pan³, H. Wang², M. Bala⁴;

¹Department of Endocrinology and Nutrition, Clinica Universidad de Navarra, Pamplona, Spain, ²Sanofi, Bridgewater, ³ProUnlimited, Boca Raton, ⁴Sanofi, Cambridge, USA.

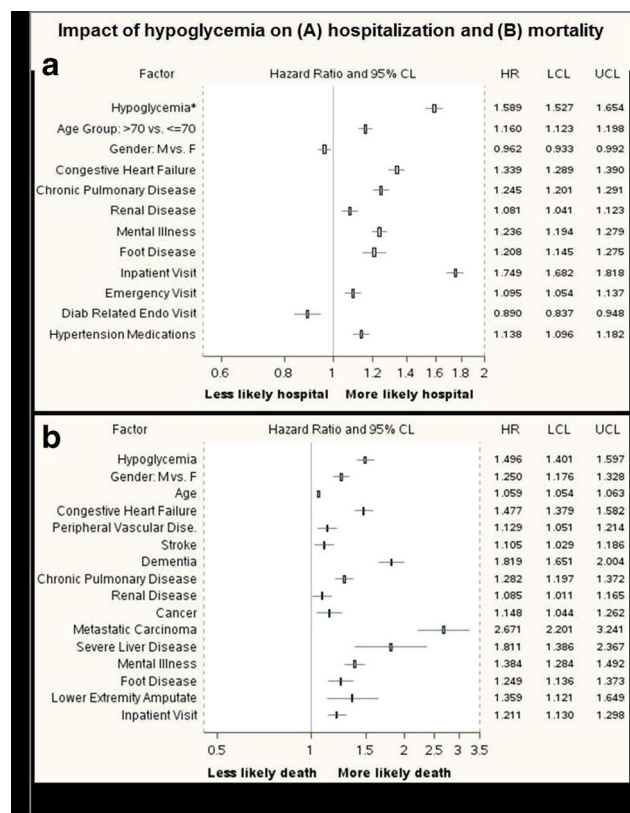

Background and aims: Hypoglycemia has been associated with an increased risk of cardiovascular (CV) events and all-cause mortality. Older patients initiating basal insulin are at particular risk of experiencing severe hypoglycemic events given the observed increase in hypoglycemic rates

in this population, and the established risk between insulin and hypoglycemia. We performed a retrospective US health insurance claims database study to assess the current burden of hypoglycemia in older patients initiating basal insulin treatment, investigating whether there is an association between hypoglycemia, hospitalization, and all-cause mortality.

Materials and methods: The Clinformatics® Data Mart Medicare Advantage database was used to identify patients with T2DM who initiated Basal insulin between January 2007 and December 2013. All patients had a minimum of one year continuous health coverage prior to and after basal insulin initialization. A Cox proportional hazard model was employed to evaluate the risk of all-cause hospitalization and death, with medically attended hypoglycemia (HG) as a time-varying covariate adjusting for demographic, comorbidities and medication history.

Results: Of the total 31,035 patients analyzed, 16,534 (53%) experienced hospitalization and 4414 (14%) died during a mean follow-up of 2.9 year. A greater proportion of patients with HG recorded during the first-year post BI initiation required hospitalization than those without HG (75.6% vs 50.8%), experiencing 1.43 and 0.65 hospitalization episodes/patient-year, respectively. Patients with HG were more likely to die than those without HG (21.1% vs 13.4%). After accounting for other risk factors, HG was associated with an elevated risk of all-cause hospitalization (HR 1.60; 95%CI: 1.53-1.65) and death (HR 1.50; 95%CI: 1.40-1.60). (Figure: Hazard ratio analysis for all-cause hospitalization and death)

Conclusion: In a large US Medicare Advantage population with T2DM, HG is a strong independent risk factor for hospitalization and death following BI initiation, suggesting the need for a new BI with a favorable HG profile in this older population.

*Hypoglycemia: indicator of medically attended hypoglycemia occurring before hospitalization or death. HR, hazard ratio; LCL, lower confidence limit; UCL, upper confidence limit.

Reduced cognitive function in people with type 1 diabetes and impaired awareness of hypoglycaemiaM.R. Bjørgaas¹, T.I. Hansen², E.C.D. Haferstrom³, S.E. Olsen⁴, A.K. Häberg²;¹Department of Endocrinology, Trondheim University Hospital, ²Department of Neuroscience, Norwegian University of Science and Technology (NTNU), ³Department of Medical Imaging, Trondheim University Hospital, ⁴Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology (NTNU), Trondheim, Norway.**Background and aims:** Impaired awareness of hypoglycaemia (IAH) implies an increased risk of severe hypoglycaemia (SH) in type 1 diabetes (T1D). Recurrent SHs may impair brain function, and the hippocampus is especially vulnerable. We aimed to investigate whether T1D patients with IAH have reduced cognitive function compared to T1D patients without IAH.**Materials and methods:** In total 105 participants (33 T1D with IAH (Gold score \geq 4), 35 T1D with normal awareness (NAH; Gold score \leq 2), and 37 healthy controls) completed a web-based neuropsychological test battery assessing verbal-, spatial-, and working memory, executive function, processing speed and pattern separation. Raw scores were transformed to z-scores using the results of the healthy controls as reference.**Results:** As shown in Table 1, age (~47 years) and gender distribution was similar in the IAH, NAH and healthy control groups. In the IAH and NAH subjects, diabetes duration (~30 years), mean HbA_{1c} (~8%), and percentage of subjects with no retinopathy (48.% vs. 45.7%) did not differ between groups (Student t-test and Chi square tests p-values 0.984-0.194). No participant had severe hypoglycaemia the day before testing or biochemical hypoglycaemia during testing (Table 1). IAH-subjects had lower z-scores than NAH-subjects in tests of verbal memory delayed recall ($t(62)=2.4$, $p=0.018$, $d=0.60$), spatial memory immediate recall ($t(57.5)=2.1$, $p=0.043$, $d=0.51$), pattern separation ($t(59)=2.8$, $p=0.007$, $d=0.72$), and in processing speed and executive function ($t(60)=2.2$, $p=0.032$, $d=0.57$).**Conclusion:** T1D participants with IAH had lower performance in neuropsychological tests than NAH participants. These differences were most pronounced in tests associated with hippocampal function.**Table 1. Characteristics of the participants¹**

Interim results on the relationship between mild-moderate and severe hypoglycaemia and cardiovascular disease in a cohort of sulfonylurea usersA.P. Nunes¹, J. Yang¹, K. Tunceli², K. Kurtyka², L. Radican², S.S. Engel², S. Yu², M.C. Doherty¹, D.D. Dore¹;¹Optum Epidemiology, Waltham, ²Merck Sharp & Dohme Corp., Kenilworth, USA.**Background and aims:** Severe hypoglycemia is associated with higher risk for cardiovascular disease (CVD), but most hypoglycemic events are non-severe. Little is known about the CVD effects of mild-to-moderate hypoglycemia, which is less likely to be encoded in administrative databases. We used electronic health records (EHR) to identify a large cohort of sulfonylurea (SU) users and examine the association between baseline hypoglycemia by severity and CVD outcomes at follow-up.**Materials and methods:** Patients with type 2 diabetes prescribed SUs were identified from the Humedica Research Database from January 2009 to March 2014. This database includes EHRs on over 30 million patients throughout the United States. Hypoglycemia occurrence was identified using an algorithm incorporating International Classification of Diseases, Ninth Revision (ICD-9) diagnostic codes and natural language processing (NLP) of free text clinical notes to improve capture of non-severe hypoglycemic events. We identified mentions of hypoglycemia and synonyms within the free text from note sections likely to indicate the patient's current status/experience (History of Present Illness, Diagnoses, Problems, and Patient Complaints) and did not include records of patient counseling about the risk of hypoglycemia or other false-positive scenarios. Mentions of hypoglycemia associated with negations or a non-confirmatory sentiment (e.g. denies hypoglycemia) were not considered. We categorized hypoglycemic events as serious, mild-moderate, or unknown based on descriptors within the free text and by site of care, treatments, and comorbidities. Frequency of hypoglycemia events, by seriousness, was assessed as a determinant of CVD outcomes, acute myocardial infarction (AMI) and congestive heart failure (CHF), identified from diagnoses within the EHR. We compared the relative rates (RR) and 95% confidence intervals (CI) of CVD across categories of baseline hypoglycemia with adjustment for baseline covariates via Poisson regression models.**Results:** Of the 82,321 eligible patients, 4,922 (6%) had at least one hypoglycemia event in the year before cohort entry. In the follow-up period (Median: 164 days; 25th and 75th percentiles: 20 days, 601 days), 47% had an observed diagnosis for any CVD, 2% had a diagnosis for AMI, and 15% had a diagnosis for CHF. Severe hypoglycemia frequency was positively associated with CHF (RR per episode: 1.69, CI 1.55-1.84) and AMI (RR 1.66, CI 1.31-2.09). Mild-moderate hypoglycemia and hypoglycemia of unknown seriousness were more strongly associated with CHF (Mild-Moderate RR 1.48, CI 0.93-2.34; Unknown Seriousness RR 1.43, CI 1.37-1.48) relative to AMI (Mild-Moderate RR 0.96, CI 0.15-6.3; Unknown Seriousness RR 1.19, CI 1.06-1.35). Restricting to patients with active sulfonylurea use at the time of hypoglycemia assessment yielded comparable results.**Conclusion:** The association between hypoglycemia and CVD may be dependent on the subtype of CVD and the seriousness of hypoglycemia. Hypoglycemia characterized as mild-moderate or unknown had attenuated associations with AMI. Limitations of this study include differential documentation of hypoglycemia, lack of validation of the NLP algorithm, incomplete capture of non-serious hypoglycemic events and residual confounding.

Cardiac autonomic regulation during experimental hypoglycaemia in type 1 diabetes with impaired awareness of hypoglycaemiaE. Walkinshaw¹, S.A. Little², A. Bernjak¹, A. Lubina-Solomon¹, E. Chow¹, J.A.M. Shaw², S.R. Heller¹;¹Human Metabolism, University of Sheffield, ²Institute of Cellular Medicine, Newcastle University, Newcastle Upon Tyne, UK.

Background and aims: Impaired awareness of hypoglycaemia (IAH) affects 25% of patients with type 1 diabetes (T1DM) and increases the risk of severe hypoglycaemia (SH). Previous studies report decreased vagal outflow during hypoglycaemia in T1DM, potentially increasing vulnerability to cardiac arrhythmias. Our aim was to investigate the effect of experimental hypoglycaemia on cardiac autonomic regulation in patients with IAH.

Materials and methods: Ten participants with T1DM and intact hypoglycaemia awareness, eight with IAH (Gold score \geq 4), six with previously impaired but restored awareness (Gold score $<$ 4) and ten without diabetes underwent a stepped hyperinsulinaemic hypoglycaemic clamp study. Glucose was stabilised at 5 mmol/l at time 20 minutes (T20) and reduced step-wise to a nadir of 2.4 mmol/l at time 180 minutes (T180). Heart rate variability was measured during each glucose step.

Results: An increase in heart rate (HR) and a corresponding reduction in high frequency (HF) power, suggesting vagal withdrawal was seen in participants without diabetes with recovery by T180 (HR at T20 65.3; T100 68.7, $p=0.057$; T180 62.8). HR increased in subjects with diabetes and intact awareness of hypoglycaemia without signs of recovery by T180 (HR T20 72.2; HR T180 80.7, $p=0.008$). Increases in normalised low frequency (LFnorm), indicating elevated sympathetic contribution, were higher in participants with diabetes than subjects without diabetes. Participants with IAH had a peak heart rate at T100 with evidence of recovery by T180 (HR T20 79.43, T100 83.61, T180 81.70 $p=0.041$). This was accompanied by small, non-significant reductions in HF power and increases in LFnorm which recovered by T180. Participants with restored awareness showed early changes in heart rate variability with a peak in heart rate at time 60 minutes (T60) and recovery by 140 minutes. Reductions in HF power ($p=0.02$) and LFnorm ($p=0.013$) peaked at T60 with similar patterns of recovery. Rises in plasma metanephrine were lower in participants with IAH and restored awareness of hypoglycaemia (Table 1).

Conclusion: Changes in cardiac autonomic regulation during experimental hypoglycaemia are time dependent and differ according to self-reported awareness of hypoglycaemia in T1DM. In subjects with IAH, hypoglycaemia had a diminished effect on sympathetic activation, blunting hypoglycaemia recognition through autonomic symptoms but, potentially providing cardiovascular protection against arrhythmias. This corresponds to a reduction in metanephrine response to hypoglycaemia.

	40 minutes (Glucose 5.0 mmol/L)	200 minutes (Glucose 2.4 mmol/L)	Fold Change	p value (paired t test)

OP 22 Management of cardiovascular risk factors

127

Therapeutic inertia for glycaemic and blood pressure control in patients with type 2 diabetes mellitus and the cardiovascular consequencesS. Paul¹, J. Shaw², K. Klein¹;¹Clinical Trials and Biostatistics Unit, Brisbane, ²Baker IDI, Melbourne, Australia.

Background and aims: The delay or failure to intensify treatment for better glycaemic and blood pressure (BP) control (therapeutic inertia, TI) in patients with poor glucose and BP control, the risk burden and the effects of TI on cardiovascular (CV) risk in newly diagnosed T2DM patients have not been explored. The aims of this longitudinal cohort study were to evaluate the prevalence of TI, the extent of potentially avoidable glycaemic and BP burden, and the association of TI and TI-associated glycaemic and BP burden with the risk of composite of myocardial infarction (MI), heart failure (HF) and stroke.

Materials and methods: A cohort of 1,145,979 patients, aged \leq 70 yrs with diagnosis of T2DM from 2000 were selected from the Centricity EMR Database of USA, with follow-up data available till September 2014. CEMR provides longitudinal patient-level data on over 38 million insured and non-insured patients from about 35,000 care providers (70% primary care providers) derived from clinical practices across 49 US states. Longitudinal follow-up data on HbA1c, BP, prescriptions and doses for anti-diabetes drugs (ADDs) and anti-hypertensive drugs (AHDs), and CV events with dates of events were extracted. TI for glucose and BP control were defined as failure to take at least 2 ADDs (ADD2) and at least 2 AHDs (AHD2), respectively, in patients with HbA1c and BP persistently above target for 2 years. 474,429 patients had a minimum of 2 yrs of follow-up data post diagnosis of diabetes.

Results: Patients were 49% male, mean (SD) age 58 (11) yr, HbA1c 8.4 (2)%, SBP 132 (18) mmHg, 59% had HbA1c \geq 7.5%, and 29% had SBP \geq 140 mmHg at diagnosis. The proportions of patients with ischemic heart disease, hypertension and chronic kidney disease prior to diagnosis of diabetes were 1.2%, 12.3% and 0.8% respectively. In patients with HbA1c \geq 7.5% at diagnosis, more than 47%/29% had HbA1c consistently above 7%/7.5% during 2 yrs post diagnosis. In patients with HbA1c consistently above 7%/7.5% over 2 yrs, 40%/36% never received ADD2, only 46%/51% received ADD2 within 2 yrs, and the median time to intensification with ADD2 in these patients were 15/13 months. Only 7% patients had SBP \geq 140 mmHg consistently over 2 yrs, 9% of these did not receive AHD2, and the median time to intensification by AHD2 was 7 months. During 4 yrs of median follow-up, 0.82% had MI, 0.67% had HF, 1.72% had stroke, and 3.1% experienced at least one of these events. Adjusting for age, sex, ethnicity, smoking status, renal diseases, stratified by year of diagnosis of diabetes, in patients without history of CVD, TI for glycaemia and blood pressure was associated with 38% (95% CI of HR: 1.14, 1.66) and 20% (95% CI of HR: 1.05, 1.38) increased risk of a composite of MI, HF and stroke, respectively. Those with HbA1c consistently above 7.5% over 2 yrs, independently had 80% (95% CI of HR: 1.69, 1.93) increased risk of composite CV events, compared to those with HbA1c below 7.5%.

Conclusion: This study shows that in a large population of people with newly diagnosed diabetes, aged \leq 70 yrs, and with minimal prior CVD, there was a high prevalence of TI, a significant glycaemic burden over two years even with intensified treatment, and an association of TI with an increased CV risk over 4 years. Greater efforts are needed to understand, identify and appropriately manage this group of patients.

128

Increased risk of cardiovascular-related events associated with sulfonylurea compared to other antihyperglycaemic drugs: a Bayesian meta-analysis of survival data

C.A. Baxter¹, R. Das¹, H. Langerman¹, E.J. Mills², E. Druyts², G. Siliman², C. Balijepalli², K. Thorlund²;

¹MSD Ltd, Hoddesdon, UK, ²Redwood Outcomes, Vancouver, Canada.

Background and aims: Studies suggest different glucose-lowering treatments can have different, and even divergent, effects on cardiovascular risk and mortality. We conducted a systematic review involving studies that compared sulfonylurea to placebo/no intervention or other anti-diabetic drugs.

Materials and methods: Since events occur at differing time points among included studies, we employed a complementary-log-log link model in the Bayesian framework to obtain comparative hazard ratios (HR) between interventions. Conventional pairwise meta-analyses were used to pool adjusted hazard ratios for observational studies.

Results: We identified 91 RCTs including 36,573 patients and 26 observational studies including 1,553,856 patients. Analyses of RCT data demonstrated an increased risk of all-cause mortality and cardiovascular-related mortality for sulfonylureas compared to all treatments combined (HR 1.26 [1.10; 1.44] and 1.46 [1.21; 1.77], respectively). These results were confirmed in the analyses of the observational studies. The risk of myocardial infarction was significantly higher for sulfonylureas compared to DPP-4 inhibitors (HR 2.54 [1.14; 6.57]) and elevated compared to SGLT-2 inhibitors HR 41.80 [1.64; 360.4]), but not other classes of treatments. Observational studies confirmed an increased risk of myocardial infarction for sulfonylureas compared to all other treatments combined. The RCTs showed that the risk of stroke was significantly higher for sulfonylureas compared to DPP-4 inhibitors, GLP-1 agonists, TZDs and insulin (HR 9.40 [3.27; 41.9], 45.40 [1.99; 362.7], 1.75 [1.20; 2.69], and 1.46 [1.01; 2.14], respectively). No observational evidence was available on the risk of stroke.

Conclusion: Our findings in RCTs demonstrate a higher risk of cardiovascular-related events associated with sulfonylureas compared to other anti-diabetic drugs that increases over time. The analyses on the observational studies confirmed our results. These findings should inform guidelines for patients with elevated risk of CV events.

Second-line treatment with sulfonylurea compared to DPP4 inhibitors is associated with risk of cardiovascular disease, all-cause mortality and severe hypoglycaemia

J.W. Eriksson¹, J. Bodegard², A. Norhammar³, D. Nathanson³, M. Thuresson⁴, T. Nyström³, A. Norhammar³;

¹Uppsala University, ²AstraZeneca, Södertälje, ³Karolinska Institutet, Stockholm, ⁴Statisticon, Uppsala, Sweden.

Background and aims: To compare the risk of cardiovascular disease (CVD), all-cause mortality and severe hypoglycaemia in type 2 diabetes (T2DM) patients who initiate second-line treatment with either sulfonylurea (SU) or DPP4 inhibitors (DPP4i).

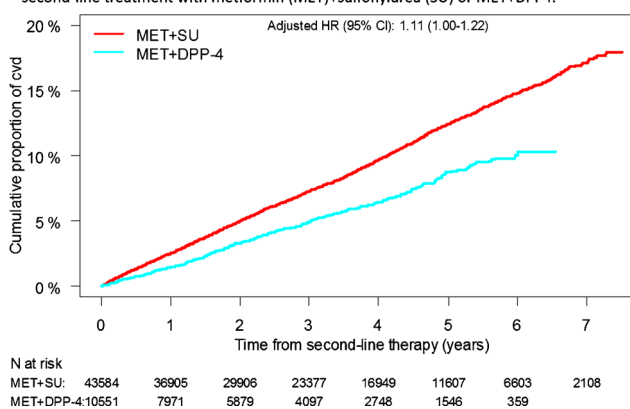

Materials and methods: T2DM patients who were treated with one non-insulin antidiabetic drug (NIAD) and that added a second glucose lowering drug during 2006–2013 were identified in the Swedish Prescribed Drug Register and linked with National Patient-, and Cause of Death registers. Index date was defined as the date of patients second NIAD dispense after monotherapy on NIAD. Cox survival models, adjusted for age, gender, time on first-line treatment, previous CVD and fragility (3 or more days in hospital the year prior to index) were used to estimate event risks during follow-up. Cardiovascular disease was defined as hospitalization due to unstable angina, myocardial infarction or embolic stroke, or

cardiovascular related death; severe hypoglycemia as any hospitalisation with diabetic hypoglycemia diagnosis.

Results: In the 68,351 patients who were started on dual NIAD treatment; the two most frequent dual-combination were metformin+SU (64%) followed by metformin+DPP4i (15%). Metformin+SU vs metformin+DPP4 were similar in age (65 vs 61 years), gender (59 vs 62% were men), had similar history of cardiovascular-, (32 vs 28%) and microvascular disease (18 vs 15%). Blood pressure-, lipid lowering and low dose aspirin treatment were also similar in the two groups. Addition with SU compared with DPP4 in second-line treatment was associated with higher risk of subsequent fatal/nonfatal CVD-, all-cause mortality and severe hypoglycemia; hazard ratios (95% CI): 1.11 (1.00-1.22), 1.20 (1.07-1.33) and 1.62 (1.11-2.36) respectively.

Conclusion: In T2DM patients, second-line treatment with sulfonylurea compared to DPP4i was associated with an increased risk of subsequent cardiovascular events, all-cause mortality and, severe hypoglycemia. Ongoing and future randomized trials will be important to elucidate possible causal relationships between treatments and the reported complications.

Figure: Adjusted risk of fatal/nonfatal CVD in patients who were either initiated on second-line treatment with metformin (MET)+sulfonylurea (SU) or MET+DPP4.

Treatment characteristics and outcomes associated with sulphonylurea versus metformin therapy in incident type 2 diabetes mellitus patients: results of the German CREST study

B. Berg¹, T. Wilke¹, A. Groth¹, S. Müller¹, S. Stephens², N. Hammar³, A. Fuchs⁴, K. Tsai⁵, U. Maywald⁴;

¹Institut für Pharmakoökonomie und Arzneimittellistik, University of Wismar, Germany, ²Pharmerit International, York, UK, ³AstraZeneca UK and Institute of Environmental Medicine, Karolinska Institute, Stockholm, Sweden, ⁴AOK Plus, Dresden, Germany, ⁵AstraZeneca US, Gaitersburg, USA.

Background and aims: The aim of this study was to analyse (1) characteristics of incident T2DM-patients having started either a MET or SU monotherapy and (2) whether these therapies are associated with different mortality, T2DM-related hospitalizations and macrovascular events (MACE).

Materials and methods: This was a cohort study using a German AOK PLUS-claims data set covering the years 2010–12. Incident T2DM patients having started either a MET/SU monotherapy between 01/07/2010–31/12/2011 without having received any prior antidiabetic medication during the preceding 180 days were included. Observation started with the first MET/SU prescription. Follow-up-time for each patient was at least 12 months, or, in case of death or therapy discontinuation (treatment gap > 180 days or prescription of another agent), until that date. Event rates per 1,000 patient years were compared between the two patient groups using incidence rate ratios (IRR), Kaplan Meier curves, and Log

Rank tests. Furthermore, a Upropensity score matched (PSM) comparison of event rates between the two groups and a multivariate Cox regression analysis were carried out.

Results: We observed 35,661 incident T2DM- patients. Of them, 904 (2.5%)/7,874 (22.1%) started a SU/MET monotherapy, respectively. A mean age of 70.1/61.4 years ($p < 0.001$), 54.6%/50.3% ($p < 0.001$) female gender and a mean Charlson Comorbidity Index excluding age factor of 2.23/1.44 ($p < 0.001$) were observed in the respective SU/MET groups. In the unmatched patient sample comparisons, the mortality rate (all rates per 1,000 patient-years) in the SU/MET groups was 82.5/25.5, respectively (IRR=3.24, $p < 0.001$), for MACE 94.3/56.9 (IRR=1.66, $p < 0.001$), and for T2DM-hospitalizations 32.1/11.2, respectively (IRR=2.87, $p < 0.001$). In the PSM comparison which included 1,460 patients (730 patients per group), the mortality rates in the SU/MET groups were 56.3/40.3, respectively (IRR=1.40, $p > 0.100$), for MACE/T2DM-related hospitalizations they were 82.5/61.1 (IRR=1.35, $p > 0.100$), and 30.1/6.9 (IRR=4.34, $p < 0.005$), respectively. In the multivariate Cox regression analysis, SU monotherapy was associated with higher T2DM-hospitalization risk (HR 2.822; $p < 0.001$), higher MACE risk (HR 1.342; $p < 0.050$), higher T2DM-related hospitalization risk (HR 2.014; $p < 0.001$), and higher composite event risk (HR 1.776; $p < 0.001$).

Conclusion: Among incident T2DM patients initiating first line treatment, those receiving SU therapy are older, more likely to be female, more comorbid, and discontinue their monotherapy earlier than patients treated with MET; a substantial number may also face MET contraindications. Taking these differences in patient characteristics into account, patients treated with SU seem to be at increased risk of death, MACE and T2DM-hospitalization compared to MET treated patients in Germany. Residual confounding cannot be excluded as at least a partial explanation to these findings.

Dual antiplatelet therapy after acute coronary syndrome in patients with and without diabetes: a Swedish nationwide population-based cohort study

A. Deleskog¹, O.Ö. Braun², P. Hasvold¹, M. Thuresson³, O. Angerås⁴; ¹AstraZeneca, Nordic-Baltic, Södertälje, ²Department of Cardiology, University, Lund, ³Statisticon AB, Uppsala, ⁴Department of Cardiology, Sahlgrenska University Hospital, Gothenburg, Sweden.

Background and aims: Diabetes mellitus confers a high risk for recurrent ischemic events, including death, in patients with acute coronary syndromes (ACS). Patients with diabetes have platelet hyper-reactivity, as well as impaired platelet inhibition, in response to clopidogrel, suggesting that they might receive a greater benefit from more potent antiplatelet regimens. To characterize patients with ACS with and without diabetes and describe the dual antiplatelet therapy (DAPT; P2Y₁₂ antagonist and acetylsalicylic acid) regimen in these populations.

Materials and methods: This observational cohort study linked morbidity, mortality, and medication data from Swedish national registries from patients with ACS alive after discharge from the hospital in 2013. Patients were categorized by diagnosis of diabetes or not. Chi-squared test was used to test for statistically significant differences between groups.

Results: In total, 17,135 patients with ACS were identified, 4122 with diabetes and 13,013 without diabetes, with a median age of 72 vs. 71 years, respectively. Patients with diabetes more frequently had a history of more than one myocardial infarction than non-diabetics (20% vs. 11%). Patients with diabetes underwent revascularization less often compared with patients without diabetes (61% vs. 66%). Among patients with diabetes, 50% were treated with percutaneous coronary intervention (PCI) vs. 59% of patients without diabetes. However, 11% of patients with diabetes were treated with coronary artery bypass graft (CABG) surgery vs. 7% of patients without diabetes. In total, 71% of patients with

diabetes received DAPT vs. 76% of patients without diabetes. Among patients receiving DAPT, a larger proportion of patients with diabetes were treated with clopidogrel (44%), compared with patients without diabetes (36%). Consequently, 56% of patients with diabetes received a newer P2Y₁₂ antagonist (prasugrel or ticagrelor) vs. 64% of diabetic patients without diabetes. All reported differences between groups were statistically significant. There was no difference in DAPT duration between patients with and without diabetes.

Conclusion: Patients with ACS and diabetes were less often revascularized and less often prescribed DAPT, compared with ACS patients without diabetes. Among patients receiving DAPT, patients with diabetes less often received newer P2Y₁₂ antagonists. Possibly, patients with diabetes could benefit from more frequent revascularization and from receiving more potent DAPT to prevent future ischemic events.

132

No difference in Major Adverse Cardiovascular Events (MACE+) with Basal Insulin peglispro (BIL) vs comparator insulins in patients with type 1 or type 2 diabetes

R.M. Bergenstal¹, A.M. Lincoff², Á. Rodríguez³, L. Chen⁴, Y. Qu⁴, M.J. Prince⁴, B.J. Hoogwerf⁴;

¹International Diabetes Center, Minneapolis, ²Cardiovascular Medicine, C5 Research, Cleveland, USA, ³Lilly Spain, Avda. Industria 30, Spain, ⁴Eli Lilly and Company, Indianapolis, USA.

Background and aims: Diabetes mellitus is associated with an increased risk for cardiovascular disease (CVD). Whether insulin use contributes to CVD risk is still uncertain. In order to identify possible differences in CV risk among different insulin therapies, we performed pre-specified meta-analyses across the clinical program for BIL, in which patients were randomised to treatment with either BIL or comparator insulin (glargine [GL] or NPH).

Materials and methods: One Phase 2 (12-week) and 6 Phase 3 (26–78-week) studies of BIL compared to GL or NPH were included, where more patients were randomised to BIL. The participants were diverse with respect to demographics, baseline glycaemic control, and concomitant disease or medications. For any potential CV or neurovascular event, relevant medical information was collected and provided to an external clinical events committee, where each instance was prospectively adjudicated by blinded, independent experts. Cox regression analysis was used to calculate the estimated risks. The primary endpoint was a composite of adjudicated MACE+ (CV death, nonfatal MI, nonfatal stroke, or hospitalization for unstable angina).

Results: The pooled population included 5872 patients. Mean age (SD) was 54.1 (13.3) years; 56% were male, 16% were Hispanic or Latino, and 5%, 5%, and 88% were Asian, black, or white, respectively. Baseline demographic and clinical characteristics, including use of statins or other lipid-lowering drugs, were comparable between BIL and comparators. A total of 83 patients experienced at least 1 MACE+ and 70 patients experienced at least 1 MACE (CV death, nonfatal MI, or nonfatal stroke). Overall, there were no treatment-associated differences in time to MACE+ (hazard ratio [HR] for BIL vs comparator insulin [95% CI]: 0.82 [0.53, 1.27]) or MACE (HR [95% CI]: 0.83 [0.51, 1.33]). Although there were only 12 MACE+ in patients with T1D, the HR favoring BIL was statistically significant (table). There were no differences in the incidence rates for MACE+, MACE and all-cause death between BIL and comparators. Sub-group analyses did not identify any population with increased treatment-associated risk.

Conclusion: Treatment with BIL vs comparator insulin in patients with T1D or T2D was not associated with increased risk for major CV events.

Recruitment of beta cells during glucose stimulation in mouse pancreas tissue slices

D. Jurij¹, M. Skelin Klemen¹, M. Slak Rupnik², A. Stožer¹;

¹Institute of Physiology, Medical Faculty, Maribor, Slovenia, ²Medical University Vienna, Austria.

Background and aims: Beta cells in the islet of Langerhans respond to glucose with a tonic increase in intracellular calcium concentration ([Ca²⁺]_i), with superimposed high frequency [Ca²⁺]_i oscillations. The pattern of activity is aligned across different cells due to gap-junctional coupling between cells. We recently introduced functional multicellular [Ca²⁺]_i imaging (fMCI) to study [Ca²⁺]_i changes in a large number of beta cells from all layers of an islet in acute pancreas tissue slices. In the present paper, we describe how stimulus strength (i.e., glucose concentration) modulates parameters of the [Ca²⁺]_i response in populations of beta cells in islets of Langerhans of NMRI mice.

Materials and methods: [Ca²⁺]_i patterns in beta cells were obtained using confocal fMCI imaging in acute mouse pancreas tissue slices. Islets of Langerhans were loaded with the fluorescent calcium indicator Oregon Green 488 BAPTA-1 and stimulated with different concentrations of glucose in the form of pulses of a single stimulatory concentration and staircase stimulations with increasing or decreasing concentrations. Regions of interest were selected based on cell morphology and further analyzed for cell activity off-line.

Results: Glucose dependence of the [Ca²⁺]_i response is very steep. Beta cells in an islet start to activate at 7 mM glucose and all cells are active at 10 mM glucose (EC₅₀=8 mM glucose). The onsets of [Ca²⁺]_i responses are delayed relative to the beginning of stimulation and this delay depends on glucose concentration. During stimulation with 7 mM glucose, all cells that become active at this concentration are recruited over a period of 25 minutes. Increasing the concentration improves the synchrony of the response onsets. At 12 mM glucose, the last cells that respond to this concentration responded 7 minutes after stimulation onset. Similarly to the increase in basal [Ca²⁺]_i, the superimposed high frequency oscillations depend on concentration of glucose. Two crucial parameters of the superimposed oscillatory behavior, namely frequency and duration of oscillations, respond to an increasing concentration of glucose such that the former gradually increases from 7 to 12 mM glucose and declines beyond this concentration (16 mM), whereas the latter continuously increases with increasing glucose concentrations.

Conclusion: Combining fMCI and the acute tissue slice technique, we were able to study the responses of large populations of beta cells to different stimulatory concentrations of glucose in situ. Glucose modulates both the basal [Ca²⁺]_i response and the superimposed [Ca²⁺]_i oscillations. Increasing glucose concentrations recruit cells within an islet in a concentration and time dependent manner. The dose-response curve is very steep, with an EC₅₀ of 8 mM. In addition the frequency of superimposed [Ca²⁺]_i oscillations as well as the duration of oscillations increase across the physiological range of concentrations (7-12 mM). Taken together, this indicates that at low levels of stimulation (7-9 mM), recruitment of beta cells significantly contributes and is arguably the most important mechanism of response to increasing concentrations of glucose, whereas at higher concentrations (9-16), the increased frequency and duration of oscillations are the predominate. Our findings might have important implications for responsiveness under pathological conditions when concentrations of glucose progressively increase.

Porcine neonatal islets with eGFP-labeled beta cells as novel tool in diabetes research

E. Kemter¹, A. Wolf², A. Wuensch¹, M. Kurome¹, B. Kessler¹, V. Zakhartchenko¹, M. Loehn², Y. Ivashchenko², A. Schulte², E. Wolf¹;
¹Chair for Molecular Breeding and Biotechnology, GeneCenter, LMU München, Munich, ²Diabetes Division, Sanofi-Aventis, Frankfurt, Germany.

Background and aims: Due to the easy availability of pancreata of pigs and high similarity between porcine and human islets, porcine islets might be of great interest for studying beta-cell biology and for screening compounds affecting beta-cell proliferation and function. Further, availability of efficient tools of genetic modification in pigs enables specific labeling of beta-cells by fluorescent reporter gene expression for *in vivo* imaging of islets and FACS sorting of beta-cells.

Materials and methods: We established a routine procedure for isolation of porcine neonatal islet cell clusters (NICCs). Briefly, pancreata of piglets (<8 days old) were minced and shortly digested with collagenase. The suspension was sieved through a 500- μ m mesh and exocrine cells were removed within the first three days in culture. Best culture conditions proved to be recovery media of Ham's F12/M199 with additives of protease inhibitors, antioxidants and additional nutrients for the first three post-isolation days followed by maturation media of Ham's F10 with IBMX. After *in vitro* maturation, NICCs were characterized by immunofluorescence (IF) analysis, glucose stimulated insulin secretion (GSIS) assays, and proliferation assays. To generate islets donor pigs with eGFP labeled beta-cells, porcine kidney cells were transfected with a porcine INS promoter-eGFP expression vector, pools of stable transfected cell clones were used for somatic cell nuclear transfer (SCNT), and cloned embryos were transferred to recipient gilts. Offspring were genotyped by PCR and Southern blot analysis and characterized for reporter gene expression.

Results: Our isolation protocol facilitated a yield of 10-30 thousand NICCs per donor piglet (culture day 5). IF analysis demonstrated that NICCs contained similar proportions of insulin- and glucagon-positive cells. GSIS assays revealed on average 3.2-fold increased insulin secretion in high- vs. low-glucose medium. NICC derived beta-cell proliferation was significantly ($p < 0.001$) increased by a GSK3 β inhibitor and significantly ($p < 0.001$) impaired by a CDK4 inhibitor. A total of 12 live INS-eGFP transgenic founder piglets were born, with a total of 10 different transgene integration patterns. Fluorescence microscopy and immunohistochemistry for GFP in sections of pancreas and a panel of other tissues demonstrated islet-specific transgene expression. Consistent with these results, isolated NICCs of the transgenic founder pigs showed different levels of eGFP fluorescence (1 strong, 1 weak, all others intermediate). Double-immunofluorescence analysis identified eGFP expression specifically in the beta-cells; eGFP was neither detected in glucagon positive alpha-cells nor in somatostatin positive delta-cells. Two founders with high and intermediate beta-cell specific eGFP expression were successfully reproduced by SCNT to set up breeding lines of donor pigs for large-scale NICC isolation.

Conclusion: Porcine islets expressing beta-cell specific eGFP marker protein will enable *in vivo* imaging of islets, e.g. in the setting of islet transplantation. Further, eGFP-labeled beta-cells enable efficient and specific FACS sorting of beta-cells which may provide a useful screening system for compounds affecting beta-cell proliferation and function.

Electrophysiological characterisation of the human beta cell line EndoC- β H2

B. Hastoy¹, M. Chibalina¹, M. Godazgar¹, R. Scharfmann², P. Rorsman¹;
¹Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford University, Headington, UK, ²INSERM U1019, Cochin Institute, Université Paris Descartes, Paris, France.

Background and aims: We have characterised the novel human beta cell-line EndoC- β H2 in terms of glucose-induced insulin secretion (GISS), depolarization-evoked exocytosis and properties of voltage-gated ion channels.

Materials and methods: Insulin secretion was tested by static incubations. Secretion rates have been normalised to insulin content. Cytosolic calcium levels ($[Ca^{2+}]_i$) were monitored in cells transfected with the genetically encoded calcium sensor GCaMP5. Exocytosis was assessed by whole-cell capacitance measurement. Membrane potential and currents were recorded using the perforated patch or standard whole-cell configuration of the patch-clamp technique. Membrane currents were isolated using specific blockers.

Results: Basal insulin secretion at 1 mmol/l glucose amounted to 2%. Glucose (6 or 20 mmol/l) stimulated insulin secretion 1.5- ($p < 0.05$) to 2-fold ($p < 0.01$), respectively. This was associated with initiation of action potential firing and elevation of $[Ca^{2+}]_i$. The effects of glucose on insulin secretion, electrical activity and $[Ca^{2+}]_i$ were mimicked by tolbutamide (0.5 mmol/l) and reversed by diazoxide (0.2 mmol/l), consistent with a key role of ATP-regulated potassium channels. Forskolin potentiated GISS evoked by 6 mmol/l glucose ~3-fold. Exocytosis, evoked by a train of ten 500 ms depolarizations, was biphasic with the largest responses occurring during the initial 3 depolarizations with subsequent depolarizations eliciting progressively smaller responses. The cumulative increase of capacitance is of 15 fF.pF⁻¹ (increase in cell capacitance normalized to cell size, $n = 9$). The contribution of different voltage-gated calcium channels to calcium entry was evaluated using an action potential-like voltage-clamp command (based on spontaneous glucose-induced action potentials recorded in EndoC- β H2 cells). The inward current evoked by the action potential waveform amounted to 8 pA.pF⁻¹ ($n = 7$) of which 10% was due to tetrodotoxin (TTX)-sensitive sodium channels, 10% due to SNX482-sensitive R-type calcium channels with the remaining 80% attributable to isradipine-sensitive and ω -agaotoxin-sensitive L- and P/Q-type calcium channels.

Conclusion: The complement of voltage-gated ion channels in EndoC- β H2 is very similar to that seen in primary human beta-cells. We conclude that EndoC- β H2 cell line is good glucose-sensitive model of insulin secretion and electrical activity of primary human beta-cells.

Human pancreatic microislets as a standardised model for glucose-stimulated insulin and glucagon secretion

E.-M. Andersson, I. Ahlstedt, M. Sörhede-Winzell, C. Ämmälä;
 Diabetes Bioscience, AstraZeneca R&D, Mölndal, Sweden.

Background and aims: Isolated human pancreatic islets represent a useful tool to study islet function and hormone secretion *in vitro*. Nevertheless, insulin response to glucose is known to vary considerable between different donor preparations, and glucagon secretion is challenging to measure in primary human islets. In addition to this, both donor characteristics and isolation procedures add inconsistency regarding islet size and function. The aim of this study was to evaluate InSight™ microislets from InSphero as an alternative model to primary human islets for the assessment of insulin and glucagon secretion.

Materials and methods: The assay-ready 3D InSight™ Human Pancreatic Microislets are produced from dispersed human islets using the hanging-drop technique and delivered with one microislet per well in a

96-well GravityTRAP™ plate. Three different lots/donors were evaluated with the focus on insulin and glucagon secretion. The microislets' ability to regulate insulin and glucagon release in response to glucose was measured at different occasions up to three weeks after delivery. The possibility to re-use the microislets was also evaluated. Insulin and glucagon levels were measured after two hours of stimulation with different glucose concentration (2.8–22.2 mM), with or without addition of the glucagon-like peptide 1 (GLP-1) analogue Exendin-4 (10 nM), and measured using hormone specific ELISA kits (Mercodia). In order to expose the islets to a diabetogenic milieu, high glucose (22.2 mM) and interleukin 1 β (IL-1 β , 20 ng/ml) were added. Glucose-stimulated insulin secretion (GSIS) was measured after 24 hours of incubation in high glucose conditions. In parallel experiments human primary islets were exposed to the same conditions and GSIS measured. Briefly, five islets/well were transferred into a 96 well plate and insulin secretion was measured after 1 h incubation in 2.8 or 11.1 mM glucose.

Results: Both insulin and glucagon secretion could be readily measured in all three lots of microislets. The half maximal effect of glucose (EC_{50}) in stimulation of insulin secretion was 7.1 mM (n=6) while the EC_{50} for inhibition of glucagon secretion was 2.1 mM (n=3). The microislets responded to Exendin-4 with a modest but stable 1.4 ± 0.05 fold increase in insulin secretion (11.1 mM glucose). The microislet plates could be re-used for hormone secretion experiments at least two times during the three week period tested, with similar insulin and glucagon responses to glucose. Diabetogenic culture conditions reduced the insulin secretion stimulation index (11.1 mM glucose/2.8 mM glucose) from 16.6 ± 1.4 in microislets cultured at 5.8 mM glucose, to 1.9 ± 0.3 after cultured in high glucose (22.2 mM) and to 1.6 ± 0.3 in microislets with high glucose + IL-1 β pre-treatment. This was comparable to a similar experiment using primary human islets with corresponding stimulation indices; 17.4, 1.7 and 1.5. In both preparations, the decreased stimulation index was a consequence of both increased basal secretion (2.8 mM) and decreased capacity to secrete insulin upon glucose stimulation (11 mM).

Conclusion: The human pancreatic microislets constitute a robust and reproducible tool for islet research where both insulin and glucagon secretion can easily be measured in a 96-well plate format in the same experiment. There was no apparent difference in GSIS between the microislets compared to primary human islets.

137

Defining the islet 'GPCR peptidome': quantification and functional modelling of all GPCR peptide ligand signalling pathways in human and mouse islets

S. Amisten, R. Hawkes, P. Atanes, G. Huang, S. Persaud; King's College London, UK.

Background and aims: Human islets express 293 G-protein coupled receptors (GPCRs), and 110 of these GPCRs (37.5%) have polypeptides ('peptides') as ligands. Autocrine GPCR signaling in islets, where islet cells express both a receptor and its cognate ligand, plays an important role in regulating islet function. Some islet autocrine signaling pathways are well characterised (e.g. glucagon/glucagon receptor, serotonin/serotonin receptors) but no systematic study has been undertaken to define the human and mouse islet 'GPCR peptidomes' and to define how similar the human and mouse GPCR peptidomes are. The aim of this study is to quantify the expression of all known human GPCR peptide ligands and their mouse orthologs and to create an atlas describing all known islet GPCR/peptide ligand signaling pathways in human and mouse islets.

Materials and methods: Human islets were isolated from heart beating donors at our islet isolation centre. Mouse islets were isolated from 8 week old male ICR mice using collagenase digestion and handpicked. mRNA was extracted from islets using the TRIzol method and reverse transcribed into cDNA. Peptide ligand mRNA expression was quantified relative GAPDH by quantitative real-time PCR. An atlas of all GPCR/peptide

ligand signaling pathways was constructed by manually extracting data from guidetopharmacology.org and PubMed.

Results: The expression of 138 GPCR peptide ligand genes (encoding 212 mature GPCR peptide ligands) was quantified in human islets, and mRNAs of 114 (82.6%) GPCR peptide ligand genes (encoding 173 mature GPCR peptide ligands) were found to be expressed in human islets. Mouse equivalents exist of 126 (91.3%) of the 138 human GPCR peptide ligands, as the remaining 12 (8.7%) GPCR peptide ligand genes are absent from the mouse genome. mRNAs of 102 (81%) GPCR peptide ligand genes, encoding 163 different GPCR peptide ligands, were expressed in mouse islets. The 10 most abundant GPCR peptide ligand mRNAs in human islets are: glucagon (GCG)>somatostatin (SST)>amylin (IAPP)>pancreatic polypeptide (PPY) >>neuropeptide Y (NPY)>interleukin-8 (CXCL8)>ghrelin (GHRL)>Wnt protein 4 (WNT4)>Complement 3a (C3)>angiotensin (AGT). In mouse islets, the 10 most abundant GPCR peptide ligand mRNAs are: glucagon (Gcg)>amylin (Iapp)>somatostatin (Sst)>pancreatic polypeptide (Ppy) >>peptide YY (Pyy)>urocortin 3 (Ucn3)>R-spondin-4 (Rspo4)>dynorphin (Pdyn)>neuropeptide Y (Npy)>Wnt protein 4 (Wnt4). A detailed islet pathway atlas outlining all auto- and exocrine signaling pathways involving GPCRs and peptide ligand in human and mouse islets was constructed. 323 GPCR/peptide signaling pathways were identified in human islets, consisting of 239 (74%) autocrine and 84 (26%) exocrine signaling pathways. In mouse islets, 283 GPCR/peptide signaling pathways were identified, made up of 249 (88%) autocrine and 34 (12%) exocrine pathways.

Conclusion: Human and mouse islets express a large number of peptide ligands of G-protein coupled receptors. Although the human and mouse islet GPCR peptide ligand repertoires seem similar at a first glance, there are fundamental differences in both peptide mRNA expression levels and auto- and exocrine signaling pathways. These differences are very likely to influence islet function, so great caution is warranted when translating mouse islet functional data to a human islet context.

Reduced glucose-stimulated insulin release from human type 2 diabetic islets associates with multiple metabolomic changes in the secretome

M. Suleiman¹, M. Bugliani¹, L. Marselli¹, J. Cobb², M. Occhipinti¹, P. Marchetti¹, E. Ferrannini³;

¹University of Pisa, Italy, ²Metabolon, Inc., Durham, USA, ³CNR Institute of Clinical Physiology, Pisa, Italy.

Background and aims: Beta cell insulin secretory failure is the hallmark of type 2 diabetes (T2D). The associated molecular changes are still largely unclear in the beta cell.

Materials and methods: We evaluated glucose-stimulated insulin release (by the batch sequential incubation method - 45 min), metabolomic features in the secretome (using a screening metabolomic platform), and gene expression profiles (with beta cells obtained by laser capture microdissection) of islets from 17 non-diabetic (ND; 10 males/7 females; age: 68 ± 17 yrs; BMI: 26.0 ± 3.4 Kg/m²) and 14 T2D (12 males/2 females; age: 74 ± 7 yrs; BMI: 26.0 ± 3.1 Kg/m²) organ donors.

Results: Insulin release (μ U/ml) at 3.3 mmol/l glucose was 35 ± 19 with ND and 41 ± 42 with T2D islets (NS), and increased respectively to 188 ± 95 and 47 ± 52 in response to 16.7 mmol/l glucose ($p<0.01$). Accordingly, stimulation index was 5.6 ± 1.4 with ND and 1.1 ± 0.1 with T2D islets ($p<0.01$). Compared to ND islets, T2D islets showed a significant ($p\leq 0.05$) retention of glucose and release of aminoacids (glycine, alanine, phenylalanine, serine). Furthermore, T2D islets released significantly ($p=0.02$) more citrate into the incubation medium. Array data from ND and T2D beta cells, showed significantly decreased expression of enolase 1, mitochondrial aconitase 2, ATP citrate lyase, and dihydrolipoamide

dehydrogenase, and increased expression of aldolase B, lactate dehydrogenase A, phosphoenolpyruvate carboxykinase and oxoglutarate dehydrogenase.

Conclusion: Taken together, these results are compatible with metabolic overload and alterations of the late glycolytic and TCA cycle pathways in human T2D beta cells. If corrected, these changes could lead to improved glucose-stimulated insulin secretion.

OP 24 Brain reward and satiety

Brain reward-system activation in response to anticipation and consumption of palatable food is altered by GLP-1 receptor activation in humans

L. van Bloemendaal¹, D.J. Veltman², J.S. ten Kulve¹, P.F.C. Groot³, H.G. Ruhé⁴, F. Barkhof⁵, J.H. Sloan⁶, M. Diamant¹, R.G. IJzerman¹;

¹Diabetes Centre/Internal Medicine, ²Department of Psychiatry, VU University Medical Centre, ³Department of Radiology, Academic Medical Center, ⁴Department of Psychiatry, Academic Medical Center, ⁵Department of Radiology & Nuclear Medicine, VU University Medical Centre, Amsterdam, Netherlands, ⁶Lilly Research Laboratories, Eli Lilly and Company, Amsterdam, USA.

Background and aims: It has been suggested that obese individuals have increased brain reward system activation while anticipating food intake, which may lead to cravings for food, and decreased reward system activation during actual food consumption, which may induce overeating. Gut-derived hormones, such as glucagon-like peptide-1 (GLP-1), are likely involved in the regulation of food intake. GLP-1 receptor agonists improve glycaemic control and reduce food intake and body weight. We hypothesised that food intake reduction following GLP-1 receptor activation is mediated through brain areas regulating anticipatory and consummatory food reward.

Materials and methods: Obese T2DM patients (n=16; mean ± SD; BMI 34±4 kg/m²; HbA1C 6.9±0.9%, 8 males), age- and gender-matched normoglycaemic obese (n=16; BMI 33±3 kg/m²) and lean individuals (n=16; BMI 23±1 kg/m²) were studied in a randomised, crossover, placebo-controlled trial. Using functional MRI, we determined the acute effects of GLP-1 receptor activation on brain responses to anticipation and receipt of chocolate milk vs. tasteless solution. All subjects underwent three functional MRI sessions at separate visits with intravenous infusion of A) the GLP-1 receptor agonist exenatide, B) exenatide with prior GLP-1 receptor blockade by exendin 9-39 or C) placebo; during somatostatin pituitary-pancreatic clamps (glucose 5 mmol/L). We assessed the effects of BMI and GLP-1 receptor activation on brain responses in areas regulating reward, appetite and motivation (putamen, caudate nucleus, amygdala, insula and orbitofrontal cortex).

Results: BMI was negatively correlated with brain responses to receipt of chocolate milk and positively correlated with anticipation of receipt of chocolate milk in brain areas regulating reward, appetite and motivation (P<0.005). Exenatide vs. placebo increased brain responses to receipt of chocolate milk and decreased anticipation of receipt of chocolate milk (P<0.005). Exenatide vs. placebo reduced caloric intake during a subsequent choice buffet by 23% in lean subjects, by 24% in obese subjects and by 14% in obese T2DM patients. The exenatide-induced effects on brain activations and caloric intake were largely prevented by exendin 9-39.

Conclusion: GLP-1 receptor activation decreased anticipatory food reward, which may reduce cravings for food, and increased consummatory food reward, which may prevent overeating. Our findings provide novel insights into the mechanisms by which GLP-1 regulates food intake and how GLP-1 receptor agonists induce weight loss.

Insulin sensitisation normalises brain processing of satiation in non-obese insulin resistant menY.S. Cheah^{1,2}, S. Lee^{1,3}, F.O. Zelaya³, S.A. Amiel^{1,2};¹Diabetes Research, King's College London, ²Diabetes Centre, King's College Hospital NHS Foundation Trust, ³Department of Neuroimaging, Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK.

Background and aims: Altered activity of brain networks involved in appetite regulation are implicated in the aetiology of diabetes and obesity, conditions associated with insulin resistance. We characterised the effects of early systemic insulin resistance and the impact of insulin sensitisation on pre- and post-prandial brain activity in non-obese men.

Materials and methods: 16 healthy right-handed insulin resistant (IR) and 17 insulin sensitive (IS) men (HOMA2-IR 1.6 ± 0.3 , 0.5 ± 0.1 , age 34.9 ± 10.2 , 33.3 ± 7.1 years, BMI 26.2 ± 2.3 , 24.2 ± 1.9 kg/m², respectively) were studied twice in random order. Regional cerebral blood flow (CBF), a surrogate marker of resting neuronal activity, was measured using continuous arterial spin labelling magnetic resonance imaging in a 1.5 T MRI scanner before (-14 to -8 minutes) and after (0 to +6, +8 to +14, and +34 to +40 minutes) consuming 50 ml water or 630 kcal mixed meal after an overnight fast. Subjective measures of appetite were collected on a visual analogue scale after each scan. IR then completed 3 months metformin therapy with lifestyle advice before repeating MRI studies. Statistical parametric analysis of whole-brain CBF was performed using SPM-8. A cluster-forming uncorrected threshold of $Z > 2.31$ was used, with clusters surviving statistical significance ($p < 0.05$), corrected for multiple comparison.

Results: Within-group analyses showed no differences between pre-water and pre-meal CBF. Compared to water, food reduced CBF in centres that provide inhibitory control of eating (dorsolateral prefrontal cortex, DLPFC) in IR and in visual processing centres (lingual gyrus) in IS. Between-group analyses showed greater CBF in regions involved in hedonic processing (orbitofrontal, anterior cingulate cortices) in IR than IS before the meal and throughout the water study. After food, IR showed lower CBF in the default mode network (precuneus) and greater CBF in regions involved in processing interoceptive awareness (insula) than IS. In IR, insulin sensitisation improved HOMA2-IR (1.34 ± 0.46 , vs pre-treatment $p = 0.02$) and increased fullness ($p = 0.02$). Post-treatment, IR no longer showed a fall in DLPFC CBF post-meal compared to post-water. Compared to pre-treatment, the intervention was associated with decreased pre-ingestion CBF in the default mode network (posterior cingulate cortex) and in regions involved in memory and energy regulation (hippocampus) and increased it in lingual gyrus and reward processing centres (striatum), with similar findings post-water, whilst post-meal CBF decreased in insula and increased in striatum. Regression analyses showed a negative association between changes in HOMA-IR and post-meal CBF in striatum, where greatest improvements in insulin sensitivity were associated with greatest increases in striatal CBF.

Conclusion: In non-obese men with systemic insulin resistance, altered responses of brain regions involved in reward processing and hedonic evaluation, inhibitory control and interoception in anticipation of and in response to meal ingestion may promote excessive eating behaviours. Strategies that improve systemic insulin resistance ameliorate these alterations in ways that could improve satiation, enhancing appetite control. This mechanism may offer a target for preventing weight gain and diabetes.

Differences in brain responses to visual food stimuli among monozygotic twins discordant for BMIS. Doornweerd¹, R.G. IJzerman¹, L. van Bloemendaal¹, F. Barkhof², D.J. Veltman³, E.J. de Geus⁴;¹Diabetes Centre / Internal Medicine, ²Department of Radiology and Nuclear Medicine, ³Department of Psychiatry, ⁴Biological Psychology, Amsterdam, Netherlands.

Background and aims: It has been suggested that increased central reward and satiety responses to food stimuli play an important role in the development of obesity. Since our genetic variation has not changed substantially in the past decades, the recent increase in obesity rates is assumed to be driven by changes in the environment. Therefore, we aimed to investigate to what extent the previously observed increases in central reward and satiety responses to food cues in obese individuals are influenced by environmental factors.

Materials and methods: Monozygotic twins discordant for BMI provide a unique opportunity to investigate the effects of environmental factors on obesity, since these subjects share an identical genetic background. We included fifteen rare female monozygotic twin pairs from the Netherlands Twin Register, with a mean age of 49.0 ± 9.7 and a mean BMI difference of 4.18 ± 1.9 kg/m² in a cross-sectional study. We measured neural activity in reward and satiety related brain areas in response to visual food stimuli, using functional magnetic resonance imaging (fMRI), after an overnight fast. Subjects were presented pictures of high-calorie food, low-calorie food and non-food items. Imaging data were analysed using SPM8 and activation contrasts were computed (food versus non-food and high-calorie food versus non-food).

Results: In all subjects the viewing of food versus non-food pictures and high-calorie versus non-food pictures resulted in activation of limbic brain areas, such as amygdala, insula and orbitofrontal cortex, measured as changes in blood oxygen level dependent (BOLD) signal. When comparing leaner and heavier co-twins, no differences in brain activation were found when watching food versus non-food pictures. However, when watching high-calorie food versus non-food pictures, the heavier co-twins showed decreased, not increased, brain activation compared to their leaner co-twins within right orbitofrontal cortex, left insula and left caudate nucleus.

Conclusion: Contrary to previous studies in singletons, we found no increased brain activation in response to food versus non-food pictures in heavier compared to leaner individuals as measured with fMRI in a co-twin control study using monozygotic twins discordant for BMI. Indeed, in response to high-calorie food versus non-food pictures a decreased, not increased activation was found in heavier versus leaner co-twins. The increased activation in obese individuals observed in previous studies may reflect an influence of genetic factors on brain responses to food. The contradictory higher activation in leaner versus heavier co-twins in responses to high-calorie versus non-food pictures may be explained by an acquired higher attention to foods that are consciously being avoided in lean individuals in attempt to remain thin despite one's inherited risk of weight gain. Future studies should investigate the influence of genetic factors on previously observed increased brain responses to food in obese individuals.

Leptin-substitution increases connectivity in reward-related brain areas in patients with congenital lipodystrophy

H. Schlögl¹, K. Müller², A. Horstmann², K. Miehe¹, B. Pleger², H. Möller², A. Villringer², M. Faßhauer¹, M. Stumvoll¹;

¹University of Leipzig, Faculty of Medicine, ²Max-Planck-Institute for human Cognitive and Brain Sciences Leipzig, Germany.

Background and aims: In patients with congenital lipodystrophy (LD) leptin serum concentrations are reduced, serum triglycerides high and patients often suffer from a severe diabetes with high insulin demands. Furthermore, LD patients can develop a disturbed hunger/satiety regulation: after the consumption of a meal, satiety lasts only a short period of time, leading to short intervals between meals. To assess long term effects of leptin substitution on eating behavior and related brain connectivity in treatment naïve patients with congenital LD, we performed resting-state functional MRI (fMRI) before and during the initial 52 weeks of treatment.

Materials and methods: The study included eight leptin-treatment naïve LD patients (six females, age 36 ± 4 y, BMI 27 ± 2 kg/m²). MRI scannings were performed before leptin supplementation, and after one, four, 12, 26, and 52 weeks of treatment. In each session, patients consumed a meal consisting of 20% of their daily energy requirements. Before and after the meal, patients rated satiety feelings using 100 mm visual analog scales (VAS, 0 mm=no satiety; 100 mm=extreme satiety).

Results: Glycated haemoglobin (HbA1c) decreased by 17.1% after 52 weeks of leptin treatment (before leptin treatment $8.3 \pm 0.6\%$, after 52 weeks $6.7 \pm 0.5\%$, $p=.13$). Satiety ratings after the standard meal increased from 65 ± 10 mm to 93 ± 2 mm, $p=.04$ after 26 weeks and 71 ± 11 mm, $p=.55$ after 52 weeks. fMRI analysis showed connectivity increases in nucleus accumbens bilaterally ($T=4.17/4.38$), medial frontal gyrus ($T=4.77$), and hypothalamus ($T=4.85$) over the 52 weeks of treatment (Figure).

Conclusion: After leptin substitution, patients anecdotically described longer periods of satiety and reduced meal frequencies. Consistently, leptin treated patients showed increased satiety ratings in the VAS after a meal. Under leptin treatment, we also observed an increase of functional connectivity in nucleus accumbens, an important player in the dopaminergic reward system, suggesting a modulation of this network by leptin. Furthermore, we found an increased connectivity of the hypothalamus, the homeostatic control center of the brain, where humoral information from the body converges (Figure).

Specific deletion of lipoprotein lipase in ventromedian hypothalamus induces obesity and impairment of glucose homeostasis in mice

E. Laperrousaz, V.S. Moullé, N. Kassis, R.G. Denis, S. Luquet, C. Magnan, C. Cruciani-Guglielmacci; University Paris Diderot, France.

Background and aims: The Lipoprotein Lipase (LPL) is the key enzyme of triglycerides (TG) hydrolysis of chylomicrons and VLDL, allowing the storage of the TG in the adipose tissue. It also has a crucial role in the Central Nervous System (CNS) in the control of the energy balance: a neuronal deletion of LPL leads to the onset of obesity and a modification of locomotor activity and energy expenditure. We studied here its specific deletion in the ventro-median hypothalamus (VMH), an area known to control food intake and peripheral glucose homeostasis via the autonomous nervous system.

Materials and methods: We injected in the VMH of LPL lox/lox mice (and controls) an Adeno Associated Virus, expressing the fusion protein Cre-GFP, to get a specific and localized deletion of LPL. We measured food intake, time course of body weight, body composition, and metabolic parameters (by indirect calorimetry) and performed glucose and insulin tolerance tests. Tests and tissues sampling were performed at 10 days post injection (10d, before the onset of obesity) or 12 weeks post injection (12w, massive obesity).

Results: Compared to WT, LPL VMH^{-/-} mice have a significant increase of body weight 15 days post injection, without any hyperphagia. Obesity is massive at 12w and associated with insulin resistance and glucose intolerance. They show already at 10d post injection a significant decrease of locomotor activity, a decreased respiratory quotient during

24 h of fasting, and an increased food intake during refeeding. Early deregulation of insulin sensitivity is also present at 10d. Analysis of gene expression shows an early modulation of enzymes of ceramides metabolism and of FATP1 transporter.

Conclusion: A decrease of LPL hypothalamic activity leads to obesity associated with deregulation of glucose homeostasis. This phenotype is not linked to hyperphagia but likely to a modulation of locomotor activity and energy metabolism. Fine modulations of hypothalamic nervous activity (potentially due to intracellular variations, quantitative or qualitative, of cerebral ceramides content) could explain this phenotype.

GLP-1R activation by exendin-4 prevents neuronal loss in the piriform cortex of type 2 diabetic rats

G. Lietzau^{1,2}, V. Darsalia¹, C.-G. Östenson³, T. Nyström¹, C. Patrone¹; ¹Department of Clinical Science and Education, Karolinska Institutet, Södersjukhuset, Internal Medicine, Stockholm, Sweden, ²Department of Anatomy and Neurobiology, Medical University of Gdansk, Poland, ³Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Type 2 diabetes (T2D) accelerates the progression of cognitive decline and neurodegenerative diseases such as Alzheimer's (AD) and Parkinson's (PD). Impaired olfactory function, which is an early symptom of AD and PD has also been associated with T2D. The piriform cortex is a crucial area involved in the regulation of olfaction that has been shown to be vulnerable in AD and PD. However, olfactory dysfunction in T2D has not been previously linked to a specific brain neuropathology on histological and quantitative level. Aim of this study was to determine potential neuronal cell loss in the piriform cortex of T2D rats along aging. Others and we have recently shown that antidiabetic drugs targeting the Glucagon-like receptor 1 (GLP-1) are neuroprotective and can counteract neurodegeneration. Thus, we determined whether GLP-1R agonist Exendin-4 was able to counteract the T2D-induced neuronal loss.

Materials and methods: Young 3-month-old and middle-aged 13-month-old T2D Goto-Kakizaki (GK) rats were compared to age-matched Wistar rats (n=6 in each group). Additional groups of GK rats have been treated with Exendin-4 or vehicle for 4 weeks before sacrifice. Neuropathological assessments have been performed in the piriform cortex using stereology methods after immunohistochemistry of the specific neuronal marker NeuN and of the specific interneuronal marker Calbindin 28 KDa.

Results: The results show a significant decrease of the total neuronal number in the piriform cortex of GK versus Wistar rats along aging as assessed by NeuN staining (mean=48,207.4 in GK middle-aged vs. mean=66,256.9 in Wistar middle-aged; $p \leq 0.01$). We also demonstrate that interneurons positive for Calbindin 28 KDa are particularly vulnerable to the neuronal loss induced by T2D (mean=2,866.5 in GK middle-aged vs. mean=6,165.2 in Wistar middle-aged; $p \leq 0.001$). Interestingly, the GLP-1R agonist Exendin-4 substantially counteracted the neuronal loss observed in the piriform cortex of T2D animals as assessed by both NeuN (mean=47,560.6 in vehicle vs. mean=60,184.0 in Ex-4; $p \leq 0.001$) and Calbindin 28KDa (mean=3,890.2 in vehicle vs. mean=7,439.2 in Ex-4; $p \leq 0.0001$) staining.

Conclusion: Our results indicate neuronal pathology in the piriform cortex of the T2D brain along aging. These results could provide the neural anatomical basis of olfactory deficits in T2D. In addition, our results reveal a potentially novel finding at the basis of the detrimental effect of T2D in neurodegenerative diseases. Finally, by showing that neuronal loss in the piriform cortex can be pharmacologically counteracted by GLP-1R activation, our findings support recent research promoting the use of GLP-1R agonists against neurodegeneration.

Prepregnancy care for a region: exploring the clinical and economic effects

A.M. Egan¹, A. Danyliv^{1,2}, L. Carmody¹, B. Kirwan¹, F.P. Dunne¹;¹Galway Diabetes Research Centre, ²School of Business and Economics, National University of Ireland Galway, Ireland.

Background and aims: Prepregnancy care (PPC) has the potential to reduce the risk of adverse pregnancy outcomes in the setting of pregestational diabetes. Our aims were to implement and examine the effectiveness of a regional PPC program on pregnancy outcomes and to determine whether the additional costs of delivering the program are balanced against potential savings from averted complications.

Materials and methods: This prospective cohort study included 414 women with type 1 and type 2 diabetes attending five antenatal centers along the Irish Atlantic Seaboard between January 2006 and December 2014. PPC was offered to all women age 18–40 years via a diabetes register. Primary outcomes included: neonatal outcomes [shoulder dystocia, congenital malformation, stillbirth/neonatal death, admission to the neonatal intensive care unit (NICU)], hypertensive disorders of pregnancy, cesarean delivery, use of prepregnancy folic acid and glycemic control in pregnancy. Comparisons were made between those that did and did not attend PPC. A cost analysis took into account the direct cost of PPC and antenatal care delivery along with management of infant complications during the first 6 months post delivery.

Results: A total of 149 (36%) women attended and 265 (64%) did not attend PPC. Those women who attended were more likely to take preconceptional folic acid (97.3% vs 57.7%, $p<0.001$), have a lower 1st trimester HbA1c (6.8% vs 7.7%, $p<0.001$) and not smoke during pregnancy (91.3% vs 83.4%, $p=0.03$). Their offspring had lower rates of congenital malformations (0.81% vs 5.24%, $p=0.04$) and fewer admissions to the NICU (44.3% vs 62%, $p=0.02$). There were no significant differences between groups in relation to the other primary outcomes. Table 1 demonstrates the difference in average cost of complication treatment for those who did and did not attend PPC. A delivery in the PPC group was associated with an average saving of €3251. Although the major component of the difference is that associated with malformations, exclusion of any single component still yields a significant difference in total cost on the rank-sum test. When adjusted for age, ethnicity, BMI, smoking and parity, PPC remains significantly associated with a reduced total cost of €2578. This fully offsets the average cost of PPC delivery per pregnancy of €449.

Conclusion: A successful regional PPC program was implemented. Women who attended were better prepared for pregnancy and their offspring experienced significantly lower rates of congenital anomalies and NICU admissions. A significant cost saving is expected per pregnancy, even in the short-term.

Table 1 Average complication costs (€) of those who did and did not attend PPC

N		Group mean		Diff.	p-value	
		No PPC	PPC		t-test	rank-sum
		265	149	414		
Total Cost	mean (std.err.)	10,055.76 (874.34)	6,804.66 (480.67)	-3,251.10 (1,220.96)	0.001	0.010
Stillbirth	mean (std.err.)	59.71 (20.83)	26.55 (18.71)	-33.16 (31.13)	0.237	0.287
Mode of delivery	mean (std.err.)	3,802.00 (127.61)	3,707.52 (172.42)	-94.47 (213.72)	0.660	0.647
NICU admissions	mean (std.err.)	2,374.43 (233.61)	1,624.60 (268.82)	-749.83 (371.11)	0.036	0.003

The prevalence and prognosis of gestational diabetes mellitus after assisted reproductive technology

E. Cosson¹, A. Diallo², B. Merioud¹, I. Cédric¹, D. Sandre-Banon¹, Y. Jaber¹, I. Banu¹, C. Cussac-Pillegand¹, P. Valensi¹, L. Carbillon¹;¹AP-HP, Jean Verdier hospital, ²AP-HP, Lariboisière hospital, Bondy, France.

Background and aims: Pregnancies after assisted reproductive technology (ART) are associated with poor prognosis, including more gestational diabetes mellitus (GDM), perhaps due to confounding factors as age or twin pregnancies. Whether ART confers a worse prognosis for GDM is unknown.

Materials and methods: We analyzed the prevalence of GDM and of GDM-related events (preeclampsia or birth weight ≥ 4000 g or shoulder dystocia) in the 18,305 women without known diabetes who delivered in our hospital between January 2002 and December 2010 after natural pregnancies ($n=17,697$) or ART ($n=608$: 155 ovulation inductions, 453 procedures).

Results: The greater rate of GDM after ART than after natural pregnancies (17.6 vs 14.2%, $p<0.05$) was driven by ART procedures (18.3%) rather than by ovulation inductions (15.5%). In multivariate analysis taking into account the parameters associated with GDM in univariate analyses (French risk factors for GDM including age, body mass index, familial history of diabetes, history of GDM or macrosomic child; history of miscarriage; multi-parity; smoking before pregnancy; hypertension; twin pregnancy; origin/ethnicity), pregnancies after ART procedures as compared with pregnancies after natural pregnancies or ovulation induction were still associated with more GDM (odds ratio 1.32 [95% confidence interval 1.03–1.69], $p<0.05$). In women without twin pregnancies, the rate of GDM-related events were different across groups: no GDM 9.0%; natural pregnancies with GDM 14.8%; GDM after ovulation induction 13.0%; GDM after ART procedure 11.4% ($p<0.001$); as the rate of caesarian deliveries: 20.3; 27.7; 21.7 and 28.8%, respectively ($p<0.001$).

Conclusion: Independently of confounding factors, GDM is more usual during pregnancies following ART procedures. However, prognosis of GDM appears to be similar or even better after ovulation induction and ART procedures as/than after natural pregnancies.

Predictors of need for insulin therapy in gestational diabetes mellitus

K.A. Scheuneman¹, S.H. Koning¹, K. Hoogenberg², M.G. Baas², B.J. Schering¹, P.P. van den Berg³, K.M. Sollie³, A.J. van Loon⁴, F.J. Korteweg⁴, H.L. Lutgers¹, B.H.R. Wolffenbuttel¹;¹Department of Endocrinology, University of Groningen, University Medical Center Groningen, ²Department of Endocrinology, Martini Hospital, ³Department of Gynaecology and Obstetrics, University of Groningen, University Medical Center Groningen, ⁴Department of Gynaecology and Obstetrics, Martini Hospital, Groningen, Netherlands.

Background and aims: The incidence of Gestational Diabetes Mellitus (GDM) is increasing, due to an increase in obesity in pregnant women and more stringent guidelines for screening and detection. Hyperglycaemia during pregnancy may cause peri- and postnatal complications for both mother and newborn. This risk may be reduced by achieving adequate glycaemic control with dietary intervention and/or insulin therapy. The aim of this study was to identify relevant factors which predict the necessity of additional insulin therapy during pregnancy.

Materials and methods: Retrospective cohort study of singleton pregnancies of all women with GDM between January 2011 and September 2014 in a teaching and an academic hospital. Patients underwent a 75-gram OGTT if they had risk factors for GDM or symptoms suggestive of GDM (e.g. polyhydramnion, large for gestational age). GDM was

diagnosed if fasting plasma glucose was ≥ 7.0 mmol/l and/or 2-hour glucose ≥ 7.8 mmol/l. After GDM diagnosis, instruction for self-measurement of blood glucose (SMBG) and dietary advice was provided. Insulin therapy was started if with SMBG fasting glucose was ≥ 5.3 mmol/l or if 1-hour postprandial glucose values were ≥ 7.8 mmol/l, despite dietary intervention.

Results: A total of 820 women with GDM were referred for treatment. Their mean (\pm SD) age was 32 ± 5 years, BMI was 27.7 [IQR 24.0–31.9] kg/m². Of them, 460 women (56%) were able to maintain adequate glycaemic control with dietary restrictions only, while 360 (44%) required exogenous insulin. Of the women who required exogenous insulin, 142 women (39%) received thrice daily pre-prandial rapid-acting insulin, 164 women (46%) received basal-bolus insulin therapy and 39 women (11%) received NPH insulin once daily at bedtime. Insulin dose varied from 2 to 80U (median 22 [IQR 12–42]U). Logistic regression analysis showed the following significant predictors for the need of insulin therapy: history of GDM, a previous newborn with birthweight > 4500 gram or $> P95$, first-degree relative with type 2 diabetes, multiparity, mediterranean ethnicity, pre-pregnancy BMI ≥ 30 , and both increased fasting and 2-hour blood glucose during OGTT. The strongest predictor for insulin therapy was a fasting blood glucose of ≥ 5.5 mmol/l (RR 6.81 (CI 4.03–11.5, $p < 0.001$)). Maternal age, smoking during pregnancy, history of IUFD, chronic hypertension and other ethnic groups did not predict insulin need. The prediction model had an explained variance of 16%.

Conclusion: This study developed a prediction model to identify GDM patients with an increased likelihood for the need for exogenous insulin therapy. In GDM, fasting glucose ≥ 5.5 mmol/l is the strongest predictor for the need of insulin therapy.

148

Pregnancy outcomes of women with untreated GDM (according to the WHO 2013 diagnostic criteria)

A. Kun¹, J. Tomoczky², Z. Sudar³, Z. Kerényi⁴, A.G. Tabak^{5,6};
¹Department Obstetrics and Gynecology, ²Diabetes Outpatient Clinic, ³3rd Department of Internal Medicine, Tolna County Balassa Janos Hospital, Szekszard, ⁴Diabetes Outpatient Clinic, Toth Ilona Health Service, Csepel, ⁵1st Department of Medicine, Diabetes Unit, Semmelweis University Faculty of Medicine, Budapest, Hungary, ⁶Department of Epidemiology and Public Health, University College London, UK.

Background and aims: Based on the HAPO (Hypoglycemia and Adverse Pregnancy Outcomes) study results, WHO issued new recommendations for the diagnosis of gestational diabetes mellitus (GDM) in 2013. While the use of the new diagnostic criteria (not yet applied in Hungary) approximately doubles the prevalence of GDM, there are no Hungarian data on the pregnancy outcomes of untreated WHO 2013 GDM women. We aimed to compare pregnancy outcomes of women with untreated GDM (according to WHO 2013, WHO-GDM) and women with normal glucose tolerance (NGT).

Materials and methods: During a universal screening program in a Western Hungarian region 4677 pregnant women (age: 29.6 ± 5.6 years; mean \pm SD) had a 75 g OGTT with the determination of fasting, 60-minute and 120-minute glucose determination between 16/JAN/2009 and 10/APR/2013. NGT was diagnosed in $n=4113$, untreated WHO-GDM in $n=445$ cases.

Results: Untreated WHO-GDM women were older (1.6, SE 0.3 yrs), had higher fasting (difference: 1.0, SE 0.02), 60-minute (1.4, SE 0.11), and 120-minute (0.8, SE 0.07 mmol/l) blood glucose, and blood pressure (2.2, SE 0.5 / 1.4, SE 0.4 mmHg). No difference in marital status, education, and residency was found (all $p > 0.05$). While weight gain was similar in both groups (13.1, SE 0.3 vs. 13.0, SE 0.1 kg, $p=0.90$), GDM newborns had a higher birthweight (116, SE 26 g). Hypertension during pregnancy was more frequent in the GDM group (OR 1.44, 95%CI 1.02–2.03), as

well as induced delivery (OR 1.34, 95%CI 1.10–1.64), forceps or vacuum use (OR 1.31, 95%CI 1.08–1.60), acute cesarian section (OR 1.34, 95%CI 1.10–1.64), and macrosomia (> 4000 g, OR 1.64, 95%CI 1.23–2.20). No difference in the risk of preeclampsia and malformations ($p > 0.25$) was found.

Conclusion: According to the present analysis, the pregnancy outcomes of women diagnosed with GDM according to the novel WHO criteria were worse compared to normal glucose tolerant women. Randomized controlled trials are required to prove that the treatment of these women would improve their outcomes.

149

The effect of professional continuous glucose monitoring on glycaemic control and hypoglycaemia in insulin-requiring gestational diabetes mellitus

S.S. Paramasivam¹, A.T.B. Tan¹, S.P. Chan¹, K. Chinna², J. Ratnasingam¹, L. Ibrahim¹, L.L. Lim¹, P. Tan³, S.Z. Omar³, S.R. Vethakkan¹;

¹Endocrinology, ²Julius Centre, ³Obstetrics and Gynaecology, University Malaya Medical Centre, Kuala Lumpur, Malaysia.

Background and aims: Good glycaemic control in gestational diabetes mellitus (GDM) improves pregnancy outcomes and reduces perinatal morbidity. Continuous Glucose Monitoring (CGM) is ideal for monitoring glucose levels where tight glycaemic control without hypoglycaemia is required for short periods of time. CGM has been shown to improve glycaemic control and pregnancy outcomes in women with pre-gestational diabetes. However the same has not been established in GDM. Aim: To determine if professional CGM improves glycaemic control with less hypoglycaemia in insulin-requiring GDM.

Materials and methods: In this prospective, open-label trial, women with insulin-requiring GDM, gestation < 28 weeks, were randomized to 2 groups. Group 1 (CGM) ($n=25$) underwent professional CGM using the iPro2 Enlite 6-day sensor at 28, 32 and 36 weeks gestation while Group 2 (control) ($n=25$) did not. Patients in both groups performed 7 point finger-stick glucose profiles $3 \times$ /week, recorded hypoglycaemic events (symptoms without glucose readings or finger-stick fasting glucose < 3.5 /non-fasting glucose < 4.0 mmol/l) and were reviewed at 1–2 week intervals. In Group 1, both CGM and finger-stick data were used to manage diabetes while women in Group 2 were managed based on finger-stick data alone. HbA1c was measured at weeks 28, 33 and 37. Euglycaemia on CGMS was defined as 3.5–6.7 mmol/l.

Results: No significant difference was seen in mean age, pre-pregnancy BMI, HbA1c and total insulin dose between groups at baseline. The control group had a significant rise in mean HbA1c from week 28 ($5.27 \pm 0.52\%$) to 37 ($5.57 \pm 0.57\%$), while mean HbA1c in the CGM group did not significantly change from week 28 ($5.08 \pm 0.32\%$) to 37 ($5.17 \pm 0.41\%$). The control group also showed a significantly higher mean HbA1c at 33 and 37 weeks compared with the CGM group (5.42 ± 0.58 vs $5.08 \pm 0.37\%$; 5.57 ± 0.57 vs $5.17 \pm 0.41\%$). There was a significant difference in mean change in HbA1c between the groups from week 28 to 37 (CGM $+0.09\%$, control $+0.31\%$, $p=0.027$). 87.5% of patients in the CGM group had HbA1c $< 5.6\%$ at 37 weeks compared to only 52% of controls ($p=0.012$). Although 58.8% of patients in the CGM group had increased frequency of hypoglycaemia from week 28 to 37 compared to 37.5% in controls, mean increase in hypoglycaemia frequency was negligible (< 1 in CGM group, not significantly different from control group). Within the CGM group, mean time spent in euglycaemia significantly rose from the 1st to 3rd CGM (84.6 ± 9.3 vs 88.8 ± 7.0 , $p=0.016$) with significant decrease in time spent in hyperglycaemia (12.7 ± 9.9 vs 8.3 ± 6.3 , $p=0.017$). This was not accompanied by an increase in mean time spent in hypoglycaemia (2.7 ± 5.0 vs 2.9 ± 3.2 , $p=NS$). There was no significant difference in mean total insulin dose at 37 weeks between the groups. Offspring from the CGM group had lower mean birth weight compared to controls (2842.4 ± 448.6 vs 2976.0 ± 473.5 , $p=NS$).

Conclusion: Women who underwent CGM had significantly better glycaemic control compared to those who received usual antenatal care based on finger-stick glucose alone. Our findings suggest that use of CGM is associated with improvement in maternal glycaemic control and may prove beneficial in management of GDM.

Characteristics and risk factors for large-for-gestational age infants in a large cohort of pregnant women with type 1 diabetes

A. Morrens¹, J. Verhaeghe², C. Vanhole³, R. Devlieger², C. Mathieu¹, K. Benhalima¹;

¹Department of Endocrinology, ²Department of Obstetrics & Gynecology, ³Department of Pediatrics, UZ Gasthuisberg, KU Leuven, Belgium.

Background and aims: In women with type 1 diabetes (T1DM) the prevalence of large-for-gestational age infants (LGA) remains high, despite strict glycaemic control and intensive obstetrical follow-up. Our aim was to evaluate the prevalence and risk factors for LGA in T1DM in our university hospital during the last 3 decades.

Materials and methods: Retrospective analysis of the medical files of pregnant women with T1DM attending our hospital from 01-01-1992 till 31-07-2014. Clinical and biochemical characteristics associated with LGA were analyzed. Excessive weight gain during pregnancy was defined according to the 2009 Institute of Medicine recommendations. Lipid levels were measured before pregnancy or in the first trimester. The generalized mixed model was used to adjust for several pregnancies over time in the same women and to adjust for confounders such as weight, weight gain and HbA1c in the different trimesters.

Results: Over a 22-year period, 259 pregnancies in 180 T1DM women were identified. Mean diabetes duration of women was 13.7 ± 7.1 years, with a mean age at delivery of 29.5 ± 5.2 years. Of these women, 33.9% were overweight, 10.9% were obese before pregnancy and 35.1% had excessive weight gain. Despite an active policy of pregnancy planning, 10.0% of women had unplanned pregnancies. HbA1c before pregnancy was $6.9 \pm 0.9\%$, dropping to $6.6\% \pm 0.8$, $5.9\% \pm 0.7$ and $6.1\% \pm 0.6$ in the first, second and third trimester respectively. Insulin pumps were used by 84.6% of women. Comparing the first versus third decade, diabetes duration at conception increased (15.4 ± 8.39 vs. 11.7 ± 5.8 , $p=0.002$), women were older (30.4 ± 4.9 vs. 28.7 ± 3.9 , $p=0.03$), more women were overweight (29.3% vs. 23.3% , $p=0.009$) and more women had excessive weight gain (37.7% vs. 20.3% , $p=0.019$). Macrosomia (>4 Kg) was present in 16.2% of women, LGA was present in 45.2% and 67.2% received a cesarean section. These numbers did not change over time (resp. $p=0.92$, $p=0.19$ and $p=0.70$). Compared to women with a non-LGA baby, women with a LGA baby had a higher weight at delivery (84.1 ± 11.1 vs. 80.4 ± 10.8 , $p=0.016$), had more often excessive weight gain (45.3% vs. 25.2% , $p=0.003$) and were more often multiparous (61.3% vs. 46.2% , $p=0.01$). Glycaemic control was also less strict in the first and third trimester in women with a LGA baby (resp. $6.7\% \pm 0.9$ vs. $6.5\% \pm 0.8$, $p=0.01$ and $6.2\% \pm 0.5$ vs. $6.0\% \pm 0.6$, $p=0.01$), without difference in the frequency of non-planned pregnancies (9.4% vs. 10.6% , $p=0.65$). No differences in BMI before pregnancy (25.2 ± 3.7 kg/m² vs. 25.3 ± 3.8 kg/m², $p=0.80$), duration of diabetes (13.7 ± 6.7 years vs. 13.7 ± 7.4 years, $p=0.99$), age at delivery (29.5 ± 4.1 years vs. 29.6 ± 4.3 years, $p=0.92$), triglycerides levels (79 ± 36 mg/dl vs. 85 ± 41 mg/dL, $p=0.60$), HDL cholesterol (66 ± 16 mg/dL vs. 67 ± 17 mg/dl, $p=0.47$) and LDL cholesterol (87 ± 28 mg/dl vs. 91 ± 28 mg/dL, $p=0.70$) were seen between LGA and non-LGA groups. In the forward multivariate analysis, excessive weight gain ($p=0.013$) and HbA1c level in the first trimester ($p=0.006$) remained independent predictors for LGA, after adjustment for confounders.

Conclusion: LGA remains a frequent complication in T1DM. Excessive weight gain and HbA1c in early pregnancy are important risk factors for LGA in our population.

Basal insulin peglispro in combination with oral agents provides similar glycaemic control when given once daily in the morning or at bedtime in insulin naïve type 2 diabetic patients

Á. Rodríguez¹, F.J. Tinahones², L. Chen³, G. Grunberger⁴, S.J. Jacober³, J. Bue-Valleskey³,

¹Eli Lilly and Company, Alcobendas, ²Hospital Virgen de la Victoria, Malaga, Spain, ³Eli Lilly and Company, Indianapolis, ⁴Grunberger Diabetes Institute, Bloomfield Hills, USA.

Background and aims: Basal insulin peglispro (BIL) is a novel basal insulin with a flat profile which has a hepato-preferential action resulting from reduced peripheral effects. In clinical trials BIL treatment consistently improved glycaemic control and reduced nocturnal hypoglycaemia (hypo) compared to insulin glargine or NPH. Since the other BIL Phase 3 comparator trials were conducted using bedtime administration, this pre-specified secondary objective was intended to evaluate if administration of BIL in the morning (AM) was non-inferior (margin=0.4%) to bedtime administration (PM) in reducing HbA1c after 26 weeks of treatment.

Materials and methods: This secondary objective was part of a 26-week, Phase 3, open-label, treat-to-target study to compare the safety and efficacy of BIL to NPH when added to prestudy oral agents in 641 patients with type 2 diabetes mellitus. Changes to prestudy oral agents and doses were not permitted during the study. This analysis involves the 428 patients treated with BIL who were randomised to either AM (n=213) or PM (n=215) administration.

Results: After 26 weeks both AM and PM BIL administration significantly reduced HbA1c, with no significant difference between the AM and PM treatment groups (AM: 6.7 vs PM: 6.8%; treatment difference [95% CI]:

-0.13% [-0.29, 0.03%]; p=0.109). A similar proportion of patients in both groups achieved HbA1c <7.0%. No significant differences were found in fasting glucose, weight gain, or insulin dose between groups. However, significantly greater reductions in self-monitored blood glucose (BG) values were observed for the AM group at midday pre-meal (p=0.038), evening pre-meal (p=0.003), and bedtime (p=0.048) compared to the PM group (see table). There was no significant difference between groups in the percentage of patients reporting missed treatment doses. Total hypo rates (events/patient/30 days) were similar for AM vs PM dosing, as were rates of nocturnal hypo. A similar proportion of patients achieved HbA1c <7.0% without nocturnal hypo. However, there were higher rates of non-nocturnal (daytime) hypo in the AM group compared to the PM group (AM: 1.32 vs PM: 1.01; p=0.048). There was one case of severe hypo in each group.

Conclusion: These analyses showed that glycaemic control, as measured by HbA1c and fasting glucose, was similar regardless of whether BIL was administered in the morning or at bedtime, with no significant difference in mean insulin dose. However, morning administration of BIL was associated with lower daytime BG and a tendency for more daytime hypo in the absence of OAM adjustment, suggesting that individualised management of insulin and/or oral agents may be warranted.

Assessment of real-world efficacy and safety of basal insulin plus rapid-acting insulin vs basal insulin treatment among patients with type 2 diabetes in the UK

J. Lin¹, M. Jhaveri², L. Liao², B. Kitio-Dschassi³, M. Lingohr-Smith¹, ¹Novosys Health, Green Brook, ²Sanofi, Bridgewater, USA, ³Sanofi, Paris, France.

Background and aims: Basal insulin alone and basal insulin plus rapid-acting insulin (RAI) are commonly used as add-on therapies for patients with type 2 diabetes (T2DM) who have inadequate glycemic control with oral antidiabetic drugs. The objectives of this study were to evaluate the real world efficacy and safety of basal insulin plus RAI (basal+RAI) therapy and basal insulin alone therapy.

Materials and methods: Patients with a diagnosis of T2DM and a claim for basal insulin and/or RAI, regardless of daily dosing frequency (index event) were identified during 1/1/2004 to 12/31/2012 from The Health Improvement Network (THIN) U.K. database. T2DM patients were grouped into 2 cohorts; one treated with basal+RAI and the other treated with basal insulin alone. Patient characteristics, clinical outcomes, and healthcare resource use were evaluated and compared during a 12-month baseline period. Generalized linear models were used to control for key patient characteristics and evaluate adjusted treatment outcomes.

Results: Using THIN database, 3,186 T2DM patients were identified with basal+RAI usage and 7,277 were identified with basal alone usage. At baseline the mean age of the basal+RAI cohort was less than the basal alone cohort (61 vs. 67 years, p<0.001). Also, the basal+RAI cohort had a greater mean baseline weight (92.4 vs. 88.3 kg, p<0.001) and a higher mean HbA1c level (9.24% vs. 8.36%, p<0.001). After controlling for key patient characteristics, the mean change in HbA1c was -0.29% (greater reduction) (p<0.001) for the cohort treated with basal+RAI compared to

the cohort treated with basal alone. The frequency of hypoglycemia did not significantly differ among study cohorts. Using the regression adjustment, the incremental number of healthcare utilizations (4.1, $p < 0.0001$) and number of outpatient only healthcare utilizations (3.0, $p < 0.001$) for all causes during the follow-up period were greater for the cohort treated with basal+RAI in comparison to the cohort treated with basal alone.

Conclusion: In the real-world setting, while basal+RAI treatment is effective in reducing Hb HbA1c, the additional change in HbA1c (-0.29%) associated with basal+RAI vs. basal alone treatment was relatively low. Titration of RAI remains one of the challenges of treatment of patients with T2DM.

Effectiveness of intensification therapy in patients with type 2 diabetes who used basal insulin only

H. Nørrelund¹, L.M. Baggesen¹, M. Søgaard¹, L. Pedersen¹, E.S. Buhl², C.L. Haase², S.P. Johnsen¹, R.W. Thomsen¹;

¹Department of Clinical Epidemiology, Aarhus University Hospital, Aarhus, ²Novo Nordisk Scandinavia AB, Copenhagen, Denmark.

Background and aims: Limited data exist on the glycemic benefit of different intensification therapies in type 2 diabetes (T2D) patients who use basal insulin only in a routine clinical setting. We examined the effect of different intensification therapies on glycemic control among T2D patients who received basal insulin only therapy.

Materials and methods: We identified a cohort of all individuals with a first basal insulin only prescription in Northern Denmark, 2000–2012 and identified all add-on intensification therapy with bolus insulin, premixed insulin, or GLP-1 receptor agonists. We used Poisson regression to compute adjusted relative risks (aRRs) of reaching a HbA1c target value of $< 7.0\%$ adjusted for age, gender, comorbidities, and baseline HbA1c.

Results: We included 6,114 patients with a first basal insulin prescription and HbA1c measurements. Of these 2,156 (35.3%) received intensification therapy after a median of 11 months: 59.2% ($n = 1276$) were intensified with premixed insulin, 27.5% ($n = 592$) with bolus insulin, 11.8% ($n = 255$) with GLP-1 agonists, and only 1.5% ($n = 33$) received more than one add-on regimen simultaneously. Overall, 25.9% attained an HbA1c target of $< 7\%$ within 3–6 months after intensification. Reductions in median HbA1c were 0.9 percentage points (pp) for premixed insulin, 0.4 pp for bolus insulin, 0.9 pp for GLP-1 agonists, and 1.1 pp for patients with > 1 intensification drug. Compared with the large group of premixed insulin intensification as reference, aRRs of attaining an HbA1c $< 7\%$ were 1.01 (95% CI 0.84–1.21) for bolus insulin, and 1.28 (95% CI 1.02–1.60) for GLP-1 agonists.

Conclusion: In this population-based study one fourth of T2D patients reached a target HbA1c $< 7\%$ within 3–6 months after intensification of their basal insulin only therapy. GLP-1 agonists were associated with higher target attainment than premixed insulin intensification.

The significance of obtaining single patient evidence for the best insulin treatment in patients with type 1 diabetes with recurrent severe hypoglycaemia

B. Thorsteinnsson¹, P.L. Kristensen¹, H. Beck-Nielsen², K. Nørgaard³, H. Perrild⁴, J.S. Christiansen⁵, T. Jensen⁶, H.-H. Parving⁶, L. Tarnow^{1,7}, U. Pedersen-Bjergaard¹;

¹Endocrinology Section, Nordsjællands Hospital Hillerød, ²Odense University Hospital, ³Hvidovre University Hospital, ⁴Bispebjerg Hospital, Copenhagen, ⁵Aarhus University Hospital, ⁶Rigshospitalet, Copenhagen, ⁷Steno Diabetes Center, Gentofte, Denmark.

Background and aims: The scientific evidence for the benefit of insulin analogues on a single patient level in type 1 diabetes is sparse. We made a

post-hoc analysis of data from the HypoAna cross-over trial to test the hypothesis that obtaining single-patient evidence for the superior treatment can improve overall treatment outcomes compared to grouped treatment approach, based on either human insulin or analogue insulin.

Materials and methods: In a two-year, multicentre, prospective, randomised, open, blinded endpoint (PROBE) trial, 114 patients with type 1 diabetes and recurrent severe hypoglycaemia were treated with basal-bolus therapy based on analogue (detemir/aspart) and human (NPH/regular) insulin in a balanced cross-over design aiming at maintenance of baseline HbA1c. For each patient the superior treatment was considered that resulting in fewest events of severe hypoglycaemia defined by ADA criteria, or in case of similarity, that eventually resulting in a more than 0.4% lower HbA1c.

Results: A higher proportion of the patients ($n = 56$; 49%) had superior outcome with analogue insulin compared with equal outcome ($n = 30$; 26%) and better outcome on human insulin ($n = 28$; 25%) ($p = 0.0016$). The overall rate of severe hypoglycaemia during the superior treatment for each patient of 0.67 episode per patient-year was lower compared to the 1.1 and 1.6 episode per patient-year with analogue insulin and with human insulin, respectively ($p < 0.0001$). There was no clinically significant difference in HbA1c between the three groups.

Conclusion: In patients with type 1 diabetes and recurrent severe hypoglycaemia insulin treatment selected according to single-patient evidence may result in clinically significant improvement of outcomes compared to a grouped treatment approach based on either human or analogue insulin.

Insulin pump in difficult to control type 2 diabetes mellitus

P. Singh, D. Pandey, N. Trivedi;

Internal Medicine, Saint Vincent Hospital, Worcester, USA.

Background and aims: The prevalence of type 2 diabetes mellitus is increasing worldwide. Despite the availability of a number of anti-hyperglycemic agents, large percentage of diabetics remains poorly controlled. Due to the progressive loss of beta-cell functions, most type 2 diabetics eventually require intensification of insulin therapy. Delivering high doses of insulin by multiple daily injections present a therapeutic challenge. Continuous subcutaneous insulin infusion (CSII) through an insulin pump has been successfully used in type 1 diabetics; however, long term data is lacking in type 2 diabetes. OpT2mise trial tested CSII in type 2 diabetics, and showed a decrease of mean glycosylated hemoglobin (HbA1c) by 1.1% in the pump treatment group compared to 0.4% in the multiple daily injections (MDI). Nevertheless, all the previous trials including OpT2mise have a very short experience with the insulin pump (6–12 months). The long-term efficacy and safety of CSII in patients with type 2 diabetes has not been reported. We hereby, aim to present our five years experience with the use of insulin pumps in type 2 diabetics.

Materials and methods: Our study was single centered, outpatient-based, retrospective, un-blinded, and non-randomized chart review of all the patients with type 2 diabetes treated via insulin pump between 2005 and 2013. Inclusion criteria were, age between 18–75 years, with type 2 DM, HbA1c of more than 7% at initiation, and on insulin pump for more than 5 years. Additionally, all patients had one of the problems with the insulin therapy: dose more than 100 units, more than 4 injections, wide glycemic excursions, and/or intractable hypoglycemia. Exclusion criteria were type 1 diabetics. A total of 13 patients were identified. The primary endpoint was change in HbA1c from baseline to five years. HbA1c was assessed at baseline, at 3 months, 6 months, 9 months, 12 months, and at 5 years. We also reviewed the change in body mass index (BMI), basal insulin requirement, and hypoglycemia from baseline to one year. All oral anti-diabetic agents were discontinued with the exception of metformin. Data are presented as the mean (SD) and were

analyzed using unpaired t test. A p-value of less than 0.05 was considered statistically significant.

Results: At baseline, mean HbA1c was 8.89 ± 1.15 (Range 6.6–10.8). At 3, 6, 9, and 12 months the mean HbA1c was 7.58%, 7.55%, 8.33%, and 7.96% respectively. The HbA1c at 5 years was 7.7231 compared to baseline HbA1c of 8.89 (p value equals 0.007). These results were encouraging as in historical data from patients on multiple daily injections; there is a progressive increase of HbA1c. However, in our data after initial increase the patients have sustained decrease in HbA1c even at five years of follow up. Furthermore, we did not find any documented episode of severe hypoglycaemia. Moreover, CSII was not associated with significant increase in BMI, or basal insulin requirements.

Conclusion: The use of insulin pumps in patients with difficult to treat type 2 diabetes is safe and effective, with the beneficial effects persisting for five years of follow-up.

The dual-wave bolus provides better glycaemic control of the high-protein meal in type 1 diabetic children treated with insulin pumps: randomised cross-over study

K. Piechowiak, K. Dzygało, A. Szypowska;
Warsaw Medical University, Poland.

Background and aims: Insulin pumps apart from normal boluses have also the ability to deliver the insulin over a time by use of a dual-wave or square-wave bolus. It is well known that carbohydrates need to be covered with normal boluses as well as the fat content meals need dual-wave boluses. There is a lack of studies estimating the need for additional insulin for high-protein (H-P) meals. The aim of the study was to assess the differences in the postprandial glycaemic excursions following a high-protein, low-fat meal after administration of insulin by normal versus dual-wave bolus.

Materials and methods: We performed a randomized, double-blind, two-way crossover study. There were 38 patients included, 14 (37%) boys and 24 (63%) girls, aged 15.1 ± 1.7 years (range 11–18) with mean diabetes duration 9.2 ± 2.7 years, mean HbA1c $8.3 \pm 1.1\%$, mean daily insulin dose 0.75 ± 0.26 u/kg. Subjects were randomly assigned into two groups: group A consisted of patients who applied normal bolus or group B included subjects who applied dual wave bolus. All patients had a standardized (H-P) breakfast for 2 subsequent days. Insulin in normal bolus was calculated based on the number of carbohydrate units. One carbohydrate unit was defined as 10 grams of carbohydrate. Insulin in dual-wave bolus was calculated based on the number of carbohydrate units and protein-fat units. One protein-fat unit was defined as a 100 kcal from protein and/or fat. The same insulin-ratio was for one carbohydrate unit and one protein-fat unit. The primary outcome was postprandial glycemia (PPG) based on continuous glucose monitoring system and self-blood glucose measurements assessed in 60, 120 and 180 minutes after the meal bolus. Secondary outcome was the frequency of hypoglycemia (<65 mg/dl) during 3-h follow-up.

Results: Postprandial glycemia assessed in 180 min was significantly higher in group A compared to group B: 157 vs 115 mg/dl ($p < 0.0001$). There were no statistically significant differences in blood glucose levels between both groups during first 2 h after the meal bolus: 109 vs 104 mg/dl at the baseline ($p = 0.35$); 152 vs 151 mg/dl in 60 min ($p = 0.57$); and 177 vs 168 mg/dl ($p = 0.43$) in 120 min. 3 hours after the meal bolus we

observed 1 (2%) hypoglycemic episode in the group A and 6 (15%) hypoglycemic episodes in the group B ($p = 0.2$).

Conclusion: We demonstrated that applying the dual wave bolus for high protein meal improve postprandial glycaemic profile compared to normal bolus in type 1 diabetic children treated with insulin pumps. Reduction of postprandial hyperglycemia was not associated with increased risk of hypoglycemia.

Evaluation of the one-year efficacy, safety and glycaemic effects of evolocumab (AMG 145) in 4,802 subjects with, at high risk for, or at low risk for, diabetes mellitus

N. Sattar¹, D. Preiss¹, D. Blom², C.S. Djedjos³, M. Elliott⁴, A. Pellacani³, S.M. Wasserman³, M. Koren⁵, R. Holman⁶;

¹University of Glasgow, UK, ²Division of Lipidology, Department of Medicine, University of Cape Town, South Africa, ³Amgen Inc., Thousand Oaks, USA, ⁴Amgen Limited, Cambridge, UK, ⁵Jacksonville Center for Clinical Research, Jacksonville, USA, ⁶Diabetes Trials Unit, OXDEM, University of Oxford, UK.

Background and aims: Statins reduce cardiovascular risk but increase the risk of developing diabetes. We investigated the effects of the PCSK9 inhibitor evolocumab (AMG 145), a fully human monoclonal antibody to PCSK9, on measures of glycaemia and adverse event (AE) rates in subjects stratified by glycaemic status.

Materials and methods: In two open-label trials (OSLER-1 and OSLER-2), 4,802 subjects completed one of 13 phase 2 or 3 parent studies of evolocumab and were randomly assigned in a 2:1 ratio to receive either evolocumab 140 mg every 2 weeks or 420 mg monthly plus standard of care (SoC) or SoC alone. SoC included statin use for some patients. Changes in fasting plasma glucose (FPG), HbA1c, and AEs were evaluated over 48 weeks in three subject groups: 852 with type 2 diabetes mellitus (T2DM), 2,432 at high risk of developing T2DM (defined as metabolic syndrome, IFG, HbA1c >6% or BMI >30 kg/m²), and 1,518 at low risk of developing T2DM.

Results: LDL-C reductions for evolocumab + SoC compared with SoC were comparable across the 3 subgroups (57% to 60%). No notable differences were seen in median (SE) change in FPG from baseline to 48 weeks in patients on evolocumab + SoC compared with SoC alone (see Figure). Mean (SE) HbA1c changes at week 48 in patients on evolocumab + SoC and in patients on SoC alone were +0.16 (0.05) and +0.23 (0.06)% in patients with diabetes; +0.05 (0.01) and +0.06 (0.01)% in patients at high diabetes risk; and +0.06 (0.01) and +0.07 (0.01)% in patients at low risk of diabetes. Results were similar irrespective of parent-study drug assignment. Rates of AEs in patients on evolocumab + SoC vs. SoC alone were: 64% and 63% (T2DM); 69% and 64% (high diabetes risk); and 69% and 63% (low diabetes risk).

Conclusion: Evolocumab showed encouraging safety with no measurable effect on glycaemic parameters despite reducing LDL-C levels markedly.

Efficacy and safety of alirocumab in individuals with diabetes: analyses from the ODYSSEY LONG TERM study

H.M. Colhoun¹, H.N. Ginsberg², L.A. Leiter³, U. Chaudhari⁴, C. Lorenzato⁵, R. Pordy⁶, J.G. Robinson⁷;

¹University of Dundee, UK, ²Columbia University, New York, USA, ³Li Ka Shing Knowledge Institute and Keenan Research Centre for Biomedical Science, St. Michael's Hospital, University of Toronto, Canada, ⁴Sanofi, Bridgewater, USA, ⁵Sanofi, Chilly-Mazarin, France, ⁶Regeneron Pharmaceuticals, Inc., Tarrytown, ⁷University of Iowa, USA.

Background and aims: Diabetes (DM) increases risk for cardiovascular disease (CVD) and is often complicated by dyslipidaemia. The efficacy and safety of the PCSK9 inhibitor alirocumab (ALI) for lowering LDL-C in individuals with DM vs those without DM is unknown. We compared the effects of ALI in individuals with and without DM according to medical history at baseline in ODYSSEY LONG TERM.

Materials and methods: LONG TERM included 2341 individuals (832 with DM; 35.5%) at high CVD risk and LDL-C \geq 70 mg/dL on maximally tolerated statin \pm other lipid-lowering therapy, randomized (2:1) to ALI 150 mg or placebo (PBO) Q2W (as 1 mL injection) for 78 weeks. We report prespecified efficacy analyses at Week 24 and safety including all available data from baseline to Week 78 (all individuals to at least Week 52). Final study data will be presented at EASD.

Results: At baseline, mean LDL-C and HDL-C levels were slightly lower in individuals with DM than those without; individuals with DM also had higher TGs than those without DM (Table). LS mean (95% CI), PBO-corrected, reductions in LDL-C of 59% (63.2 to 54.8) were observed in ALI-treated individuals with DM at Week 24 (Table); LDL-C was reduced by 63.4% (66.5 to 60.3) in individuals without DM. Decreases in TGs and increases in HDL-C levels were also seen with ALI compared with PBO. These treatment effects were similar in individuals with or without DM. Adverse events occurring in \geq 5% of individuals in all subgroups were nasopharyngitis, URI and UTI, including those treated with

both ALI and PBO. In individuals with DM, injection site reactions (ISRs) occurred in 3.4% of ALI individuals vs 3.2% in PBO; myalgia occurred in 3.1% vs 2.9%, respectively. In those without DM, ISRs occurred in 7.0% (ALI) vs 4.9% (PBO); myalgia occurred in 5.9% vs 3.1%, respectively. Treatment-emergent CV events were positively adjudicated in 5.1% (ALI) and 7.2% (PBO) of individuals with DM; for those without DM, CV event rates were 3.4% (ALI) and 2.9% (PBO). In *post-hoc* analyses, rates of major CV events were 1.8% (ALI) and 4.3% (PBO) for those with DM and 1.2% (ALI) and 2.4% (PBO) for those without DM; hazard ratios (95% CI) vs PBO were 0.41 (0.18–0.96) [with DM] and 0.51 (0.23–1.13) [without DM].

Conclusion: Significant LDL-C reductions with ALI vs PBO were seen in individuals with DM; these reductions were similar to individuals without DM. ISRs and myalgia occurred more frequently with ALI than PBO in individuals without DM; in those with DM, rates were similar for ALI and PBO. Treatment with ALI for potential reduction of CV events is under evaluation in the large ongoing ODYSSEY OUTCOMES study which will include a sizeable proportion of individuals with DM.

Table. Summary of efficacy in response to treatment

Efficacy analysis (ITT)	Individuals with DM (N=818)		Individuals without DM (N=1492)		Interaction p-value*

Efficacy of one year of treatment with the PCSK9 inhibitor evolocumab (AMG 145) in 4,802 subjects with or without type 2 diabetes

D. Preiss¹, N. Sattar¹, J.G. Robinson², C.S. Djedjos³, M. Elliott⁴, A. Pellacani³, S.M. Wasserman³, D. Blom⁵, F. Raal⁶;

¹University of Glasgow, UK, ²Departments of Epidemiology and Medicine, University of Iowa, ³Amgen Inc., Thousand Oaks, USA, ⁴Amgen Limited, Cambridge, UK, ⁵Department of Medicine, University of Cape Town, South Africa, ⁶Department of Medicine, University of Witwatersrand, Johannesburg, South Africa.

Background and aims: Lipid-lowering therapy is a mainstay of treatment for subjects with type 2 diabetes mellitus (T2DM), who are at elevated risk for cardiovascular disease. In a pooled analysis of subjects with T2DM from 2 open-label extension trials, we evaluated the efficacy of one year of subcutaneous evolocumab (AMG 145) treatment added to standard of care (SoC) in subjects with or without T2DM at baseline.

Materials and methods: In total, 4,802 subjects completed one of 13 phase 2 or 3 studies and continued into OSLER-1 (phase 2 extension) or OSLER-2 (phase 3 extension). Subjects were randomly assigned 2:1 to either evolocumab 140 mg biweekly or 420 mg monthly plus SoC or SoC alone; randomization was irrespective of parent-study assignment. Changes in LDL-C (calculated) and other lipids were evaluated at week 48 in subjects with or without T2DM. LDL-C changes within T2DM subgroups (including low-, moderate-, or high-intensity statin; insulin or no insulin treatment; presence or absence of CVD; HbA_{1c} ≥ or < 8.0%; and eGFR ≥ or < 60 mL/min/1.73 m²) were also evaluated.

Results: In total, 563 subjects with and 2,637 without T2DM (defined by history, glycemic criteria, or baseline diabetes medication) received

evolocumab plus SoC in the open-label extension phase of the study. In subjects on evolocumab plus SoC, mean percent changes in LDL-C from baseline versus SoC at one year were -60% and -58% in those with and without T2DM, respectively. Similar changes in LDL-C were observed between treatment arms in T2DM subgroups (Figure). Changes in lipoprotein (a) (-30% and -29%) and TG (-14% and -11%) were also comparable in evolocumab plus SoC-treated subjects with and without T2DM, respectively, compared with SoC alone.

Conclusion: One year of treatment with evolocumab resulted in marked and comparable reductions in LDL-C in subjects with and without T2DM, and these changes were similar across T2DM subgroups, irrespective of baseline characteristics. Beneficial changes in other lipids were also observed in those receiving evolocumab plus SoC.

Lipid changes during 26-week treatment with the novel basal insulin peglispro (BIL) vs insulin glargine or NPH insulin in 6 IMAGINE Trials

B.J. Hoogwerf¹, H. Ginsberg², B. Cariou³, T. Orchard⁴, L. Chen¹, J. Luo¹, E.J. Bastyr III¹, J. Bue-Valleskey¹, A.M. Chang¹, S.J. Jacober¹, J.G. Jacobson¹, T. Iványi⁵;

¹Eli Lilly and Company, Indianapolis, ²Irving Institute for Clinical and Translational Research, New York, USA, ³L'institut du Thorax, Nantes University Hospital, Nantes, France, ⁴GSPH, University of Pittsburgh, Pittsburgh, USA, ⁵Eli Lilly and Company, Budapest, Hungary.

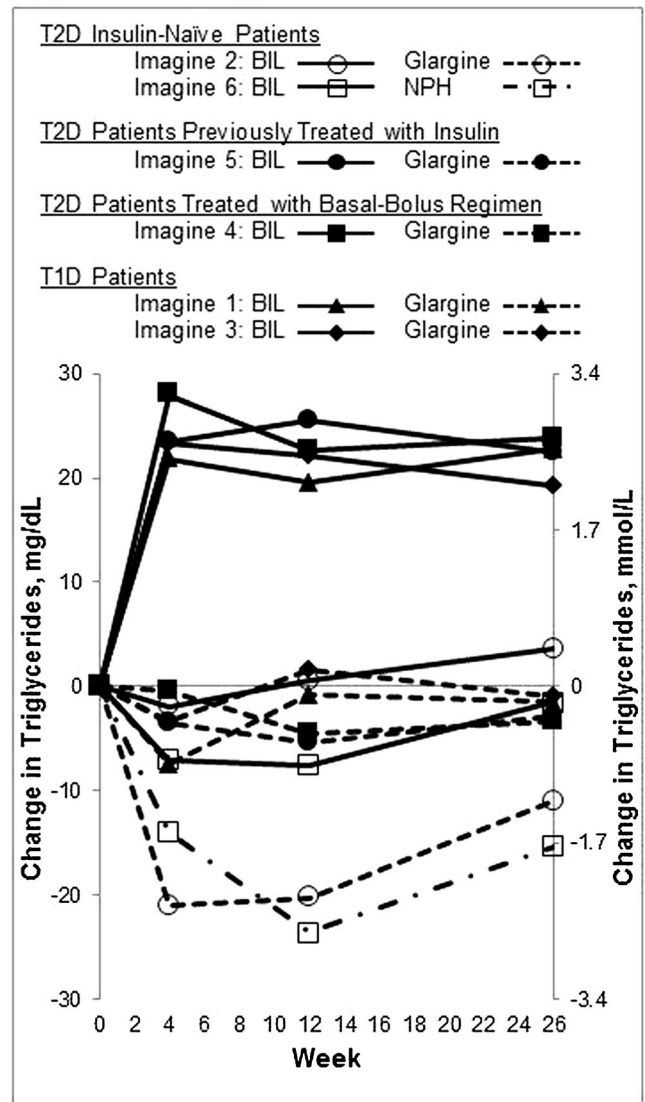

Background and aims: Basal insulin peglispro (BIL) is a novel basal insulin with a flat activity profile which has a hepato-preferential action resulting from reduced peripheral effects. Lipid changes observed with BIL in Phase 3 studies differ from those observed with the comparators insulin glargine and NPH insulin. To better understand these differences, we analysed fasting lipid data from the first 26 weeks of treatment from 6 Phase 3 trials of BIL. Five of these trials had subgroups from which apolipoproteins and free fatty acid data were collected.

Materials and methods: Trials were divided into 4 categories for analysis: trials of a basal insulin regimen in insulin-naïve patients with type 2 diabetes (T2D); trials of a basal insulin regimen in patients with T2D previously treated with insulin; trials of a basal-bolus insulin regimen in patients with T2D previously treated with insulin; and trials of a basal-bolus insulin regimen in patients with type 1 diabetes (T1D) previously treated with insulin.

Results: By week 26, in insulin-naïve patients with T2D, triglycerides decreased with glargine and NPH (-.12 mmol/L [-11 mg/dL] and -.17 mmol/L [-15 mg/dL], p<.05) but were unchanged from baseline with BIL (range: -.02 mmol/L [-1 mg/dL] to .04 mmol/L [4 mg/dL], p=NS). In

patients with T1D or T2D previously treated with insulin, triglycerides were stable with glargine ($p=NS$) and increased .21 to .27 mmol/L (19 to 24 mg/dL; 15 to 25%) with BIL ($p<.001$). After BIL discontinuation triglycerides decreased to pre-study levels. In all trials, with BIL, HDL-cholesterol (C) changed 0 to -.12 mmol/L (0 to -5 mg/dL); LDL-C changed 0 to .17 mmol/L (0 to 7 mg/dL). With glargine, HDL-C and LDL-C changed 0 to -.04 mmol/L (0 to -1 mg/dL) and .03 to .12 mmol/L (1 to 5 mg/dL), respectively. Apolipoproteins A1 and B were mostly unchanged with BIL. Among patients previously treated with insulin, there were no treatment differences in free fatty acids ($p=NS$); in insulin-naïve patients with T2D, free fatty acids decreased more with glargine than BIL ($p=.003$).

Conclusion: Lipids, free fatty acids and apolipoproteins A1 and B had little or no change with BIL in insulin-naïve patients with T2D; in contrast, GL and NPH lowered triglycerides. When BIL replaced conventional insulin treatments, increases in triglycerides were observed. Increased hepatic de novo lipogenesis, increased adipose tissue release and hepatic flux of free fatty acids, or decreased adipose tissue lipoprotein lipase activity, either alone or in combination, may also be the basis for differences in triglyceride concentrations between BIL and other insulins.

RESEARCH: superior effect of ezetimibe was sustained on LDL-C and the rate of achievement of target value in a 52-week analysis
M. Kawamura¹, T. Watanabe², K. Sakamoto³, K. Ashidate⁴, T. Kohro⁵, A. Tanaka⁶, Y. Mori⁷, M. Tagami⁸, T. Hirano⁹, T. Yamazaki¹⁰, T. Shiba³, RESEARCH Study Group, Tokyo, Japan, Yokohama, Japan;

¹Endocrinology and Meatabolism, Tokyo Teishin Hospital, ²Internal Medicine, Yokohama City Minato Red Cross Hospital, ³Department of Diabetes and Metabolism, Toho University Ohashi Medical Center, Tokyo, ⁴Internal Medicine, Kudanzaka Hospital, Tokyo, ⁵Clinical Informatics / Cardiology, Jichi Medical University, Shimono, ⁶Nutrition Clinic, Kagawa Nutrition University, Tokyo, ⁷Endocrinology and Meatabolism, Toranomon Hospital, Tokyo, ⁸Life-style related Disease Clinic, Sanraku Hospital, Tokyo, ⁹Diabetes, Endocrinology and Meatabolism, Showa University, Tokyo, ¹⁰Clinical Research Support Center, The University of Tokyo Hospital, Japan.

Background and aims: Lowering cholesterol levels decreases the risk of atherosclerotic diseases. Low-density lipoprotein cholesterol (LDL-C), other atherogenic lipid parameters, especially small dense LDL-C (sd-LDL) have been shown to increase the risk of coronary artery diseases(CAD). We evaluated long-term ezetimibe add-on therapy in type 2 diabetic (DM) patients with hypercholesterolemia not achieving LDL-C target value.

Materials and methods: A total of 109 DM patients not attaining LDL-C target value despite usual-dose statin therapy in Japan were recruited. We investigated the difference in cholesterol lowering effect between ezetimibe add-on statin (E) group and double-dose statin (S) group. Changes of lipid parameters were assessed in a randomized, multicenter, 52 weeks and open label study. We determined sd-LDL levels by the precipitation method. The participants were randomly assigned to 2 groups, E group (n=31) with ezetimibe 10 mg + atorvastatin 10 mg or pitavastatin 1 mg combination and S group (n=38) with atorvastatin 20 mg or pitavastatin 2 mg.

Results: At the baseline(0 week), there was no difference between the groups in age, body mass index (BMI), sex ratio, HDL-C, triglyceride (TG), hemoglobin A1c (A1c) and high-sensitivity C-reactive protein (hs-CRP). However, sd-LDL and nonHDL-C were significantly higher in D group than in E group. Then, both of the groups showed significant decrease in LDL-C, sd-LDL and non HDL-C during the study. LDL-C, sd-LDL and non HDL-C were significantly lower in the E group than in the S group at the end of the study.

Conclusion: In the present 52-week long-term period, ezetimibe add-on therapy showed a robust advantage in lowering LDL-C and in attaining target LDL-C values compared with the doubling of statin dose. Moreover, it's meaningful that sd-LDL, powerfully atherogenic lipoprotein, was decreased prominently by ezetimibe add-on therapy. DM patients with hypercholesterolemia are at high risk for CAD, and adding ezetimibe onto usual-dose statin treatment in Japan has been suggested as the first-line therapy for those DM patients who failed to attain the target LDL-C value.

Efficacy and safety of liraglutide versus sulphonylurea both in combination with metformin during Ramadan in subjects with type 2 diabetes (LIRA-Ramadan): a randomised trial

S. Azar¹, A. Ehtay², W. Wan Bebakar³, S. Al Araj⁴, A. Berrah⁵, M. Omar⁶, A. Mutha⁷, K. Tornøe⁸, M. Kalfot⁸, N. Shehadeh⁹;

¹American University of Beirut, ²Lebanese University Medical School, Rafik Hariri University Hospital, Beirut, Lebanon, ³Universiti Sains Malaysia, Pulau Pinang, Malaysia, ⁴Ras-Alkhaimah Medical and Health Sciences University, Ras-Alkhaimah, United Arab Emirates, ⁵University Hospital Bab El Oued, Algiers, Algeria, ⁶University of Kwazulu-Natal, Durban, South Africa, ⁷diabetes Care and Research Centre, Maharashtra, India, ⁸Novo Nordisk, Søborg, Denmark, ⁹Meyer Children's Hospital of Haifa at Rambam Medical Center, Rambam, Israel.

Background and aims: There are approximately 50 million Muslims worldwide with diabetes who fast during Ramadan, 79% of which are estimated to have type 2 diabetes (T2D). Fasting during Ramadan leads to a 5- and 7.5-fold increased risk of severe hyper- and hypoglycaemia, respectively. Furthermore, adjustment of glucose-lowering medication and closer follow-up during Ramadan may be necessary. The effect of liraglutide vs sulphonylurea (SU), both + metformin (Met), on change in glycaemic control in subjects with T2D who fasted during Ramadan was examined.

Materials and methods: In this up to 33-week, open-label trial, adults (HbA1c 7-10%; BMI >20 kg/m²; stable SU + Met; intent to fast during Ramadan) were randomised to either switch to once-daily liraglutide 1.8 mg (N=172) or continue pretrial SU (N=171), both + Met. After 3-week dose escalation, a 6-19-week maintenance period preceded Ramadan. Primary endpoint was change in fructosamine from start to end of Ramadan (liraglutide N=151; SU N=165) (Table).

Results: During Ramadan, despite lower fructosamine and HbA1c at start of Ramadan in the liraglutide arm, a similar reduction in fructosamine and HbA1c with liraglutide and SU was seen. Confirmed hypoglycaemic episodes appeared to be lower with liraglutide and fewer subjects withdrew during Ramadan (liraglutide 3, SU 11). At end of Ramadan, more subjects reached the composite endpoint of HbA1c <7%, no weight gain and no confirmed hypoglycaemia with liraglutide (51.3% vs 17.7%; odds ratio 4.90; 95% confidence interval 2.79-8.62; p<0.0001). For changes in blood pressure during Ramadan, reduction in systolic blood pressure was greater with liraglutide than SU (estimated treatment difference: -4.01 mmHg; p=0.0061); there was no difference for diastolic blood pressure. AE frequencies appeared at similar levels: liraglutide 23.7%; SU 20.9%. Gastrointestinal AEs were more common for liraglutide (10.5%; SU 3.7%). A low incidence of SAEs was observed (liraglutide 1.3%; SU 0%).

Conclusion: During Ramadan, liraglutide showed similar improvements in glycaemic control from lower fructosamine and & HbA1c levels compared to SU with a similar number of AEs, fewer confirmed hypoglycaemic episodes and better weight control.

SGLT2 inhibitor dapagliflozin ameliorates diabetic nephropathy by inhibiting high-glucose-induced oxidative stress in a mouse model of type 1 diabetes

T. Hatanaka, D. Ogawa, N. Terami, N. Nishii, A. Nakatsuka, J. Eguchi, J. Wada;

Departments of Medicine and Clinical Science, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Japan.

Background and aims: Previously, we demonstrated that dapagliflozin, a sodium glucose cotransporter 2 (SGLT2) inhibitor, protects against diabetic nephropathy; however, it was unclear whether it is mediated by a direct action on kidney. Therefore, we investigated the effect of dapagliflozin on early stage of diabetic nephropathy using a mouse model of type 1 diabetes and cultured murine proximal tubular epithelial cells. **Materials and methods:** Eight-week-old Akita mice were treated with 1.0 mg/kg of dapagliflozin (n=5) or 10-20 unit/kg/day of insulin (n=5) for 12 weeks. Control C57BL/6 mice (n=6) and Akita mice (n=6) received saline for 12 weeks. Murine proximal tubular epithelial (mProx24) cells were cultured and treated with dapagliflozin and transfected with *Slc5a2* (encoding SGLT2) siRNA.

Results: Compared with control Akita mice, dapagliflozin and insulin equally decreased blood glucose and hemoglobin A1c levels (dapagliflozin: $6.8 \pm 0.2\%$; insulin: $6.4 \pm 0.2\%$; Akita: $9.2 \pm 0.2\%$). Urinary albumin excretion (UAE) was higher in Akita group compared with that in the C57BL/6 group, and was significantly lower in both dapagliflozin and insulin groups. Moreover, dapagliflozin was more effective than insulin in reducing UAE. ROS production, which was detected by dihydroethidium, was higher in the cortex of Akita group than in that of C57BL/6 group, and it was suppressed by insulin and more efficiently by dapagliflozin. Similarly, Nox4, a subunit of NADPH oxidase, was upregulated in the cortex of Akita group compared with the C57BL/6 group, but it was attenuated in the dapagliflozin group and in the insulin group, though less effectively by the latter. As demonstrated by qRT-PCR analysis of kidney tissue, expression of Nox4 was significantly suppressed by dapagliflozin, but not by insulin. Moreover, Western blotting showed that dapagliflozin, but not insulin, suppressed the Nox4 protein expression. Collectively, oxidative stress induced by diabetes was suppressed by glycemic control using insulin, and was more strongly suppressed by dapagliflozin. These data indicate that dapagliflozin directly reduced oxidative stress in diabetic kidney. To further investigate the effect of dapagliflozin on high-glucose-induced ROS production in kidney, we performed dichlorofluorescein diacetate staining and FACS analysis using cultured mProx24 cells. High-glucose medium increased ROS production in mProx24 cells, which was significantly attenuated by dapagliflozin treatment in a dose-dependent manner. To evaluate whether or not the suppressive effect of dapagliflozin depends on the inhibition of SGLT2, we performed RNAi against *Slc5a2* in mProx24 cells. Knockdown of *Slc5a2* also suppressed the expression of these inflammatory genes to similar levels as dapagliflozin did. These results show that dapagliflozin inhibited oxidative stress by inhibiting SGLT2 in proximal tubular epithelial cells.

Conclusion: In conclusion, our study demonstrated that inhibition of SGLT2 by dapagliflozin improved hyperglycemia and ameliorated diabetic nephropathy directly by inhibiting oxidative stress in Akita mice.

The effect of SGLT-2 inhibitor, tofogliflozin on the urinary albumin excretion rate by the degree of albuminuria in Japanese type 2 diabetesK. Nuno¹, Y. Sato¹, K. Kaku², H. Suganami³;¹Division of Endocrinology & Metabolism, St.Mary's Hospital, Kurume,²Department of Internal Medicine, Kawasaki Medical School, Okayama,³Clinical Data Science Dept., Kowa Co.,Ltd., Tokyo, Japan.

Background and aims: Diabetic nephropathy is a major microvascular complication of diabetes characterized by albuminuria and progressive loss of kidney function. The renal sodium glucose transporter-2 (SGLT2) is specifically expressed on the proximal tubule as well as on the mesangial cells in the literature. However, there were a few reports that showed that SGLT2 inhibitors improved albuminuria. The aim of this study was to investigate the effect of the SGLT2 inhibitor, tofogliflozin (TOFO), on the urinary albumin excretion rate (UACR) by the degree of albuminuria in not so obese Japanese type 2 diabetic patients from TOFO phase 3 studies.

Materials and methods: Total number of subjects was 1044 type 2 diabetics (male:698, female:346, age:mean 58.3 years, duration of DM:6.9 years, BMI:25.6 kg/m²) who were rolled from TOFO phase 3 four studies except two subjects with eGFR less than 30. They were divided into three groups by the degree of UACR. Normal albuminuria group (G1:UACR<30 mg/gCr) was 701 subjects (placebo:40, TOFO:661). Microalbuminuria group (G2:UACR;30 to <300) was 290 subjects (placebo:12, TOFO:278). Macroalbuminuria group (G3:UACR≥300) was 53 subjects (placebo:4, TOFO:49). Glucose and physiological parameters were followed with urinary indexes (UACR, urinary beta-2 microglobulin to creatinine ratio [u-MG] and urinary N-acetyl-beta-D-glucosaminidase to creatinine ratio [u-NAG]). The changes of variables from baseline to week 24 (last observation carried forward [LOCF] procedure) were analyzed by Wilcoxon sign rank test. Urinary indexes were log-transformed in the correlation analysis.

Results: TOFO made significant reduction in HbA1c (mean:-0.76 to -0.89%) and weight (-2.72 to -2.85 kg) similarly in the three groups. A little reduction in UACR (median) was observed in G1 (-0.60 mg/gCr, $p < .05$ vs baseline), but its clinical significance was obscure. On the contrary, clinical significant reduction in UACR was observed in G2 (-26.10, $p < .0001$) and G3 (-323.30, $p < .0001$). UACR reduction was positively correlated with the changes in fasting plasma glucose ($r=0.30$), u-MG ($r=0.28$), u-NAG ($r=0.27$), weight ($r=0.19$) and diastolic blood pressure ($r=0.17$) in G2. On the contrast, UACR reduction in G3 was prominent and correlated only with urinary indexes, u-MG ($r=0.60$) and u-NAG ($r=0.32$).

Conclusion: SGLT2 inhibitor, TOFO, reduced UACR in Japanese type 2 diabetic patients preserved renal function with micro- and macroalbuminuria. Although UACR reduction might be attributed to improvement of glucose and physiological parameters by SGLT2 inhibition in microalbuminuric stage, other direct mechanism, for example, inhibition of SGLT2 on tubule or mesangial cells was considered in the cases with macroalbuminuria.

165

Linagliptin decreases the growth of immortalised human podocytes through the SDF-1-CXCR4/CXCR7 axisG. Miglio¹, G. Vitarelli¹, R. Fantozzi¹, T. Klein², E. Benetti¹;¹Dipartimento di Scienza e Tecnologia del Farmaco, University of Turin,Italy, ²Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

Background and aims: Linagliptin is a potent and selective dipeptidyl peptidase (DPP)-4 inhibitor, approved as an oral treatment for patients with type 2 diabetes mellitus. In contrast to its effects on glucose

homeostasis, the effects of linagliptin on diabetic nephropathy have been less well investigated, although mounting data indicate a therapeutic potential. Stromal cell-derived factor (SDF)-1 is a physiological substrate of DPP-4, and has been postulated to mediate the effects of DPP-4 inhibitors. However, due to complex interactions involving two chemokine receptors (CXCR4 and CXCR7), the role of SDF-1 remains controversial. The aims of this study were to evaluate whether linagliptin exerts direct effects on human glomerular cells, and determine the role of the SDF-1-CXCR4/CXCR7 axis in mediating these effects.

Materials and methods: Expression of DPP-4, SDF-1 α , CXCR4, and CXCR7 was evaluated in human immortalised podocytes and mesangial cells at the mRNA (RT-PCR analysis) and protein levels (western blot and ELISA). DPP-4 activity was assessed in cell extracts by measuring the cleavage of the DPP-4 substrate H-Ala-Pro-7-amido-4-trifluoromethylcoumarin. Cell growth was measured using an MTT assay. The role of SDF-1-CXCR4/CXCR7 signalling pathways was investigated by analysing the effects of the bicyclam AMD3100, which is a non-peptide CXCR4 competitive antagonist and CXCR7 allosteric modulator.

Results: Compared with mesangial cells, the expression and activity of DPP-4 was significantly higher in podocytes ($p < 0.001$). The DPP-4 activity in podocyte extracts was abolished by linagliptin (0.01–100 nM; $pIC_{50}=8.9$). Moreover, podocyte growth, which is a pathophysiological feature of activated podocytes, was decreased by linagliptin in a time- and concentration-dependent manner; maximal effect (mean \pm SEM) at 5 days was $25.1 \pm 1.6\%$ ($p < 0.01$ vs cells exposed to vehicle alone, and $pEC_{50}=8.8$). CXCR4 and CXCR7 were expressed in podocytes, and mean \pm SEM levels of SDF-1 α increased from 0.82 ± 0.18 ng/ml (day 0) to 7.76 ± 0.17 ng/ml (day 5; $p < 0.001$). The effects of linagliptin on podocyte growth were mimicked by AMD3100, and a synergistic interaction was observed when linagliptin and AMD3100 were combined.

Conclusion: Our *in vitro* data suggest that linagliptin could exert direct effects on human podocytes. In particular, it may promote the maintenance of a more favourable quiescent phenotype of this cell type, which is essential for preserving the integrity of the glomerular filtration barrier. These effects may depend on inhibiting DPP-4-mediated processing of SDF-1.

Comparable effectiveness of real-world dual combination therapies across different levels of renal function in patients with type 2 diabetesM.C. Thomas¹, P.M. Paldanius²;¹Baker IDI Heart and Diabetes Institute, Melbourne, Australia, ²Novartis Pharma AG, Basel, Switzerland.

Background and aims: Dipeptidyl Peptidase-4 (DPP-4) inhibitors are widely used in the management of type 2 diabetes mellitus (T2DM). They have demonstrated utility in patients with normal renal function, but have additional advantages for patients with renal impairment (RI). These include reduced need for complex dose titration and lack of increased risk of hypoglycaemia. Another advantage may be comparable efficacy across all levels of renal function, ages and duration of diabetes that may not be seen with other drug classes, and especially in comparison vs. sulphonylureas (SUs). To further explore this hypothesis in a 'real-world' setting, we compared the effectiveness and glycaemic response of a DPP-4 inhibitor, vildagliptin vs. SUs as add-on second-line dual therapy in patients with different degrees of RI enrolled in an observational, non-interventional study, EDGE, which included T2DM patients with failing antidiabetes monotherapy, worldwide.

Materials and methods: In this exploratory post-hoc analysis we used descriptive statistics and adjusted multivariate analysis to assess the effectiveness by the absolute change in HbA1c and the proportion of patients responding to treatment (HbA1c <7%) without tolerability issues

such as weight gain ($\geq 3\%$) or hypoglycaemia for 12 months. The estimated glomerular filtration rate (eGFR) values were available for a subset of EDGE patients (optional as per original study protocol) in whom vildagliptin or SU for treatment intensification was chosen by the investigators based on clinical judgment.

Results: MDRD-eGFR values were available for 20,822 patients; 2,532 of whom (1,649 in vildagliptin vs. 883 in SU group) had an eGFR value < 60 ml/min/1.73 m² denoting the presence of RI. Participants with RI were older (65 vs. 57 years), had a lower BMI or absolute body weight and had a longer duration of diabetes (7 vs. 5 years) than those with an eGFR > 60 ml/min/1.73 m². In multivariate analysis, the change in HbA1c in response to add-on therapy was associated with baseline HbA1c, weight, and assignment to receive vildagliptin (all $p < 0.001$). However, the HbA1c response to either vildagliptin or SUs was not significantly influenced by the presence or absence of renal impairment ($p = 0.7$). Overall, patients treated with vildagliptin reached their glycaemic targets more often without weight gain or hypoglycaemia vs. those treated with SUs (OR 1.766, 95%CI 1.646, 1.896, $p < 0.001$). The response rates (HbA1c $< 7\%$ without tolerability issues) were modestly lower in those patients with an eGFR < 60 vs. those with an eGFR > 60 ml/min/1.73 m² in both patients receiving vildagliptin (36 vs. 38%) vs. SUs (22 vs. 26%), respectively. In patients with an eGFR < 60 ml/min/1.73 m², weight gain appeared to be the main reason for the reduced tolerability ($p = 0.002$), and this issue was greater with SU add-on therapy.

Conclusion: Diabetes management is complicated and costly in an ever increasing number of patients with RI. This exploratory analysis from EDGE suggests that, DPP-4 inhibitors may have the potential to retain and simplify glycaemic control even in a heterogeneous, ‘real-life’ setting, without tolerability issues such as hypoglycaemia.

LEADER-6: variation of renal function status and risk markers across geographic origin, race and ethnicity in a high CV risk type 2 diabetic population: baseline results of the trial

I. Satman, on behalf of the LEADER investigators;

Div. Endocrinology and Metabolism, Dept. Internal Medicine, Istanbul University, Turkey.

Background and aims: Cardiovascular disease (CVD) correlates with the risk of chronic kidney disease (CKD) in patients with type 2 diabetes (T2D) but it is not clear whether ‘prior CVD’ or having multiple risk factors for CVD increase the risk of CKD, i.e. the direction of causality is unclear. Also ethnic, racial, geographical or demographic differences of CKD have not been extensively studied. Our objective was to examine prevalent CKD and potential risk factors in a study designed to evaluate the long-term cardiovascular safety of liraglutide in a multi-racial and multi-ethnic T2D population with high CVD risk.

Materials and methods: The Liraglutide Effect and Action in Diabetes: Evaluation of cardiovascular outcome Results (LEADER) trial included 9,340 participants with T2D from 32 countries. The majority of the participants (81.3%, $n = 7,592$) had ‘prior CVD’. In this group, CKD at baseline was estimated by calculation of glomerular filtration rate (eGFR) using the MDRD formula and CKD was defined as eGFR < 60 mL/min/1.73 m² and/or an albumin-to-creatinine ratio (ACR) > 2.0 mg/mmol. We used descriptive statistics and the association of baseline characteristics with prevalent CKD was examined using multivariable logistic regression analysis.

Results: Of the LEADER participants with prior CVD, 34.5% had normal renal function (eGFR ≥ 90 mL/min/1.73 m²). For the remaining participants with renal impairment, there were 38.8%, 24.4%, and 2.3% with mild (eGFR 89–60 mL/min/1.73 m²), moderate (eGFR 59–30 mL/min/1.73 m²), and severe (eGFR < 30 mL/min/1.73 m²), respectively. The prevalence of CKD differed between regions and was highest in participants from Asia (80%), lowest in patients from Europe or the Middle East

(47.5% and 47.6%, respectively) and 60% in participants from Australia and the Americas. In multivariate logistic regression analysis, the prevalence of CKD in participants with prior CVD was associated with increasing age (OR per SD: 1.40, $p < 0.0001$), increasing HbA1c (1.30, $p < 0.0001$), diabetes duration (1.23, $p < 0.0001$), systolic BP (1.34, $p < 0.0001$), heart rate (1.10, $p = 0.0290$) and serum triglycerides level (1.21, $p < 0.0001$). Furthermore, number of antihypertensive medications (1.54, $p < 0.0001$); region of living being Asia (4.78, $p < 0.0001$), N. America (1.50, $p < 0.0001$), Australia (1.48, $p = 0.0211$), Africa (1.47, $p = 0.0176$) and S. America (1.40, $p = 0.0004$) were associated with CKD at baseline (reference region Europe). In addition, male gender (1.28, $p = 0.0001$), current smoking (1.33, $p = 0.0010$), being on insulin only (1.71, $p = 0.0002$), no history of angina (1.71, $p < 0.0001$), myocardial infarction (1.41, $p < 0.0001$), and stroke (1.39, $p < 0.0001$) were factors that increased the likelihood of having CKD at baseline. In contrast, diastolic BP (0.91, $p = 0.0121$) and no diuretic treatment (0.75, $p < 0.0001$) was associated with a reduced likelihood of prevalent CKD.

Conclusion: The prevalence of CKD is high among T2D patients with ‘prior CVD’. Particularly, Asian patients are at highest risk. Age, diabetes control, comorbidities and medications used are the most important factors associated with prevalence of CVD. However, these data do not infer causality. Nonetheless, screening for CKD in T2D patients with prior CVD or high risk of CVD and priority inclusion of patients at high risk of CKD into preventive programs may be of great importance.

Albumin creatinine ratio and cardiovascular outcomes in the SAVOR-TIMI 53 trial

O. Mosenzon¹, A. Cahn¹, B. Hirshberg², M. Sjöstrand³, R.C. Ma⁴, G. Jermendy⁵, R.G. Bretzel⁶, I. Yanuv¹, A. Rozenberg¹, C. Wei⁷, B.M. Scirica⁸, D.L. Bhatt⁸, I. Raz¹;

¹The Diabetes Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel, ²CVMD, AstraZeneca, Gaithersburg, USA, ³CVMD GMed, AstraZeneca R&D Molndal, Gothenburg, Sweden, ⁴Department of Medicine and Therapeutics, The Chinese University of Hong Kong, China, ⁵Medical Department, Bajcsy-Zsilinszky Hospital, Budapest, Hungary, ⁶St. Josefs Hospital Baiserische Stiftung, Giessen, Germany, ⁷Biometrics & Information Sciences, AstraZeneca Pharmaceuticals, Gaithersburg, ⁸Brigham and Women's Hospital, Boston, USA.

Background and aims: Amongst type 2 diabetic patients (pts) albumin creatinine ratio (ACR) is an important marker both for the risk of renal function deterioration and for cardiovascular adverse (CV) events. However, the exact threshold of ACR at which CV risk is increased is unknown.

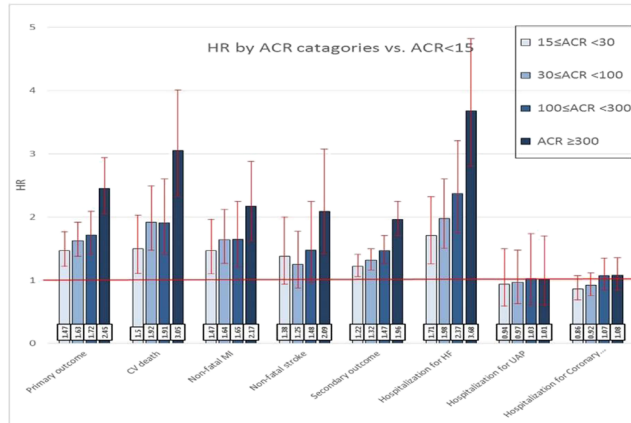

Materials and methods: We studied the CV outcomes of the 9,696 (58.8%) pts with ACR < 30 mg/G, 4,426 (26.8%) pts with microalbuminuria ($30 \leq \text{ACR} < 300$ mg/g) and 1,638 (9.9%) pts with macroalbuminuria ($\text{ACR} \geq 300$ mg/g) at baseline that participated in the SAVOR-TIMI 53 trial. We further subdivided ACR groups into ACR < 15 [$N = 7,445$ (45.1%)], $15 \leq \text{ACR} < 30$ [$N = 2,251$ (13.7%)], $30 \leq \text{ACR} < 100$ [$N = 2,893$ (17.5%)] and $100 \leq \text{ACR} < 300$ [$N = 1,533$ (9.3%)] mg/g. Pts. were followed prospectively for a median of 2.1 years. Cox proportional hazard ratio for time to first CV event was calculated with stratification for baseline eGFR and CV risk group and for treatment arm, ACR category, sex, age, diabetes duration, smoking, hypertension, hyperlipidemia, BMI and HbA1c as model terms.

Results: ACR > 15 mg/g was associated with increased risk for most adverse CV events (figure). In the ACR ≤ 15 mg/g group, every increase in ACR by 1 mg/g was associated with increased HR_{adj} for the primary composite endpoint (1.06 (95% CI 1.02–1.09)) and its components: CV death (1.05 (95% CI 1.00–1.11)) and myocardial infarction (1.05 (95% CI

1.00–1.10)) ($p < 0.05$). Such an association could not be demonstrated in the $15 \leq \text{ACR} < 30$ mg/G group.

Conclusion: Within the normoalbuminuric range, higher ACR is associated with increased CV risk. The risk for CV events increases rapidly in the $\text{ACR} \leq 15$ mg/dl range and continues to increase gradually thereafter.

Multivariable cox proportional hazard ratio for the association of ACR categories with time to first CV event: primary and secondary composite endpoints and their components

Stimulation of insulin secretion by cannabinoid ligands LH-21 and Abn-CBD in mouse and human islets: evaluation of the role of GPR55

I. Ruz Maldonado^{1,2}, A. Pingitore², B. Liu², G.C. Huang², D. Baker³, F.J. Bermúdez-Silva¹, S.J. Persaud²;

¹Unidad de Gestión Clínica Intercentros de Endocrinología y Nutrición, Instituto de Investigación Biomédica de Málaga (IBIMA), Hospital Regional Universitario de Málaga, Spain, ²Division of Diabetes & Nutritional Sciences, Diabetes Research Group, King's College London, ³Blizard Institute, Barts and The London School of Medicine and Dentistry, London, UK.

Background and aims: The cannabinoid receptors CB1 and GPR55 belong to the highly specialised G-protein coupled receptor (GPCR) family, and we and others have reported that ligands for these receptors regulate insulin secretion from islet beta cells. This study aims to investigate the effect on insulin secretion of the CB1 neutral antagonist LH-21 and the GPR55-selective agonist Abn-CBD to gain new insights into the signaling pathways operating downstream of CB1 and GPR55 in human and mouse islets.

Materials and methods: Islets isolated from WT C57BL/6J and GPR55 KO mice and from human pancreas were perfused with a physiological salt solution supplemented with 2 mM glucose followed by 20 mM glucose in the absence or presence of LH-21 or Abn-CBD at 37°C, and insulin secretion was quantified by radioimmunoassay. For assessment of downstream signalling mouse and human islets and MIN6 beta-cells were treated with Abn-CBD and/or LH-21 (0.1–10 μM) at 20 mM glucose for 30 min, after which phosphoCREB, total CREB and β-actin expression were evaluated by electrophoresis and western blotting with specific antibodies.

Results: Abn-CBD (1 μM) had no significant effect on glucose-stimulated insulin secretion from WT mouse islets, but it unexpectedly increased insulin secretion from GPR55 KO mice islets (control: 8 ± 1.5 pg/islet/min, Abn-CBD: 14 ± 0.9 , $n = 3-4$, $p < 0.0001$). In contrast, LH-21 at 0.1 and 1 μM increased insulin secretion from WT mouse islets, but no changes in secretion were observed with 10 μM LH-21 (control: 9 ± 1.7 pg/islet/min; 0.1 μM LH-21: 25 ± 5.6 , $p < 0.0001$; 1 μM LH-21: 15 ± 0.2 , $p < 0.01$; 10 μM LH-21: 10 ± 2.1 , $p > 0.2$). The stimulatory effects of 0.1 μM LH-21 on insulin secretion were abolished in islets from GPR55 KO mice (WT: 27 ± 5.4 pg/islet/min, KO: 11.4 ± 7.4 , $n = 3-4$, $p < 0.01$). 1 μM LH-21 also potentiated glucose-induced insulin secretion from isolated human islets (188 ± 16.7 pg/islet/min vs 124 ± 9.3 pg/islet/min at 20 mM glucose, $n = 3-4$, $p < 0.0001$) as did 0.1 and 1 μM Abn-CBD (225 ± 14.1 and 230 ± 8.7 pg/islet/min, respectively, $p < 0.0001$ vs 20 mM glucose alone). 10 μM Abn-CBD increased CREB phosphorylation by 20% in WT mouse islets and in MIN6 beta-cells, as revealed by densitometry analysis of the western blot signals, but it did not alter phosphoCREB expression in human islets. 0.1 μM LH-21 also promoted CREB phosphorylation in MIN6 beta-cells.

Conclusion: Our results indicate that LH-21 potentiates glucose-stimulated insulin secretion from mouse and human islets and the data obtained using islets from GPR55 KO mice imply that it exerts these stimulatory effects by activating GPR55. In contrast, the apparently selective GPR55 agonist Abn-CBD stimulated insulin secretion in a GPR55-independent manner. Both ligands were capable of inducing small increases in CREB phosphorylation, suggesting a potential role in beta-cell mass expansion. A broader knowledge of these novel mechanisms of action of LH-21 and Abn-CBD might offer new approaches to treat type 2 diabetes.

Diet-derived short chain free fatty acids stimulate insulin secretion from mouse and human islets

A. Pingitore, T. Hill, J.E. Bove, G.C. Huang, S.J. Persaud;
Diabetes Research Group, Division of Diabetes&Nutritional Sciences,
King's College London, UK.

Background and aims: Short chain fatty acids (ScFA) are saturated 2-6 carbon fatty acids originating from fermentation of undigested carbohydrates and fibre by gut microbiota, which act as endogenous ligands of G-protein coupled receptors FFA2 and FFA3. Diets rich in fermentable carbohydrates improve glucose homeostasis, but it is not known if direct action of ScFA at islets via FFA2 and FFA3 contributes to this. FFA2 couples to Gi and Gq, while FFA3 is Gi-coupled.

Materials and methods: We have studied the effects of sodium acetate (SA; C2) and sodium propionate (SP; C3), the main circulating ScFAs, on insulin secretion from human (HI) and mouse islets (MI) via dynamic insulin profiling, with quantification of secreted insulin by radioimmunoassay. Changes in intracellular Ca²⁺ in Fura-2-loaded islet cells following ScFA treatment were measured by single cell calcium microfluorimetry.

Results: Perfused human islets (HI) responded with a significant and reversible increase in insulin secretion upon exposure to SA (0.1–1 mM) in the presence of 20 mM glucose, with 0.1 mM being as effective as 1 mM (20 mM glucose: 25.9±3.4 pg/islet/min; +0.1 mM SA: 110.7±25; +1 mM SA: 118.0±12.9, n=5, p<0.001). Insulin secretion from human islets was also potentiated by 1 mM SP, albeit to a lesser extent than with 1 mM SA (20 mM glucose: 24.8±1.9 pg/islet/min; +1 mM SP: 40.3±6.4, n=5, p<0.05). Potentiation of glucose-induced insulin secretion was also observed in response to SA and SP in perfusion experiments using mouse islets (MI), although the magnitude of response was lower than that seen in human islets (20 mM glucose: 8.0±0.7 pg/islet/min; +1 mM SA: 11.5±1.6, n=3, p<0.01; +1 mM SP: 25.2±4.8, n=4 p<0.001). Despite the reversible potentiation of insulin secretion observed upon exposure to SA and SP in perfused human and mouse islets, neither ScFA significantly affected insulin secretion during one hour static incubation experiments of both HI and MI (HI, 20 mM glucose: 1.8±0.2 ng/islet/h; +1 mM SP: 1.9±0.2, n=8, P>0.2; MI, 20 mM glucose: 1.0±0.3 ng/islet/h; +1 mM SP: 1.0±0.1, n=8, P>0.2). Dispersed MI loaded with Fura-2 responded with reversible increases in free intracellular Ca²⁺ concentrations in the presence of 20 mM glucose upon exposure to SA or SP (SA basal to peak difference 0.069±0.025 n=10, p<0.05; SP basal to peak difference 0.033±0.015, n=12 p<0.05)

Conclusion: Despite reports of an inhibitory role for ScFAs on insulin secretion via FFAs, our dynamic insulin and calcium profiling experiments depict a different picture, with a stimulatory role of SA and SP, possibly acting via the Gq-coupled FFA2. These data implicate the ScFA receptor system as a potential pharmacological target in the treatment of type 2 diabetes.

Potentiation of glucose-stimulated insulin secretion by GPR40-PLC-TRPC pathway in pancreatic beta cells

H. Yamada¹, M. Yoshida¹, K. Ito¹, K. Dezaki², M. Kawakami¹, S.-E. Ishikawa¹, T. Yada², M. Kakei¹;

¹First Department of Comprehensive Medicine, Jichi Medical University Saitama Medical Center, ²Department of Physiology, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Background and aims: G-protein coupled receptors (GPCRs) are expressed in pancreatic beta cells. G protein-coupled receptor 40 (GPR40) contributes to medium- or long-chain fatty acids-induced amplification of glucose-stimulated insulin secretion (GSIS). Thus, its agonists are promising therapeutic target in type 2 diabetes. Recently we demonstrated that GLP-1, a ligand of pancreatic GPCR, activates a class

of nonselective cation channel (NSCC) and enhances GSIS. The aim of the current study is to determine whether GPR40 signal interacts to NSCCs and to identify what type of channel is related to the NSCC.

Materials and methods: Islets of Langerhans were isolated by collagenase digestion from male Wistar rats. Measurement of insulin secretion was performed with static incubations. Perforated whole-cell clamped currents were recorded at the holding potential of -70 mV in the presence of 100 μM tolbutamide or at -80 mV without tolbutamide. The latter potential was used to exclude the influence of KATP-channel current on NSCC-current changes induced by GPR40 agonist.

Results: GPR40 agonist (fasiglifam 10 μM) potentiated GSIS at 16.7 mM glucose (control vs. fasiglifam 10 μM; 19±0.3 vs. 26.2±0.8 ng/mL/10 islets/hour), but not at 2.8 mM glucose (5.0±0.1 vs. 6.1±0.2). NSCC current was activated by fasiglifam at 5.6 mM glucose with 100 μM tolbutamide at the holding potential of -70 mV (control vs. fasiglifam 10 μM; -1.8±0.3 pA/pF vs. -3.8±1.2 pA/pF, p=0.016, n=6) and the consistent results were obtained at 5.6 mM glucose without tolbutamide at -80 mV. The current increase was prevented by the presence of 2-APB (a nonspecific NSCCs blocker) or BTP2 (transient receptor potential canonical; a TRPC channel blocker). Then we examined the relationship between GPR40 stimulation and phospholipase C (PLC) downstream of the GPR40 signal. A PLC inhibitor U73122 inhibited the increase in GSIS of 16.7 mM glucose (fasiglifam vs. fasiglifam+U73122; 29.7±1.7 vs. 22.9±0.7 ng/mL/10 islets/hour, p<0.05) and the NSCC-current (fasiglifam vs. fasiglifam+U73122; -1.4±0.3 pA/pF vs. -1.4±0.9 pA/pF, p=0.99). Fasiglifam did not increase cytosolic cyclic adenosine 3',5'-monophosphate (cAMP) concentration of islets. Protein kinase A inhibitor H89 did not affect the potentiation of GSIS by fasiglifam at 16.7 mM glucose.

Conclusion: The present study demonstrates a novel mechanism underlying potentiation of GSIS by GPR40 in pancreatic beta-cells. Stimulation of GPR40-PLC-TRPC channel pathway potentiates GSIS by depolarization of the beta-cell plasma membrane.

172

Extracellular ATP affects stimulus-secretion coupling of mouse pancreatic beta cells by activating Ca²⁺-dependent K⁺ channels

C. Bauer¹, P. Krippeit-Drews¹, M. Düfer², G. Drews¹;

¹Pharmacology, University of Tuebingen, ²Pharmacology, University of Muenster, Germany.

Background and aims: ATP acts as an autocrine signal in beta-cells which affects stimulus-secretion coupling. The signalling cascade downstream the activation of purinergic receptors that modulates electrical activity and the cytosolic Ca²⁺ concentration ([Ca²⁺]_i) as well as the consequences for insulin secretion are still a matter of debate.

Materials and methods: Membrane potential (V_m) and Ca²⁺ currents (I_{Ca}) were measured using the perforated patch-clamp technique; [Ca²⁺]_i was determined by fluorescence technique. Experiments were carried out with clusters of beta-cells from C57Bl/6N wild type and BK knockout mice.

Results: In 10 mM glucose ATP (100 μM) led to a hyperpolarization of V_m (Δ-24±4 mV, n=7, p≤0.05) which was reduced by blocking SK₄ channels or knock-out of BK channels (Δ-12±1 mV, n=5 and Δ-10±1 mV, n=9, respectively, p≤0.05). ATP caused a transient peak in [Ca²⁺]_i after blocking L-type Ca²⁺ channels with D600 (100 μM) (Δ24±2 nM, n=31, p≤0.05). This transient Ca²⁺ release was inhibited by either the P2_U antagonist suramin (200 μM) or emptying Ca²⁺ stores of the endoplasmic reticulum with thapsigargin (1 μM). Surprisingly, ATP (100 μM) only transiently decreased glucose-induced (10 mM) Ca²⁺ oscillations for (235±32 sec, n=24, p≤0.05) to basal values. This effect was not altered by preincubation with thapsigargin (1 μM). The time interval of the transient decrease was reduced by blocking SK₄ channels or knock-out of BK channels (149±21 sec, n=17, 128±

21 sec, $n=37$, respectively, $p \leq 0.05$). Moreover, ATP induced a decline in the maximum amplitude of the Ca^{2+} oscillations ($[\text{Ca}^{2+}]_{\text{cMax}}$) ($\Delta-285 \pm 47$ nM, $n=24$, $p \leq 0.05$). Both ATP effects on $[\text{Ca}^{2+}]_{\text{c}}$ described above were blocked by suramin (400 μM) and the effect on $[\text{Ca}^{2+}]_{\text{cMax}}$ was mimicked by the $\text{P}_{2\text{X}}$ agonist α, β -Methylene ATP (100 μM) ($\Delta-340 \pm 34$ nM, $n=16$, $p \leq 0.05$). The reduction in $[\text{Ca}^{2+}]_{\text{c}}$ is probably owing to an ATP-induced decrease in voltage-dependent Ca^{2+} currents (I_{Ca}) ($\Delta-13 \pm 4$ pA, $n=9$, $p < 0.05$) which were elicited by voltage steps from -70 mV to 0 mV.

Conclusion: ATP appears to act as a negative autocrine signal in beta-cells and seems to exert this effect through ionotropic purinergic $\text{P}_{2\text{X}}$ receptors. Obviously, this leads to activation of SK_4 and BK channels as well as a direct inhibition of I_{Ca} through L-Type Ca^{2+} channels culminating in changes of beta-cell electrical activity and $[\text{Ca}^{2+}]_{\text{c}}$.

The calcium sensor sorcin lowers G6PC2 expression to protect against obesity-induced beta cell failure

A.P. Marmugi, L. Carmichael, G.A. Rutter, I. Leclerc;
Department of Medicine, Imperial College London, UK.

Background and aims: Pancreatic beta cell dysfunction is central to the pathogenesis of Type 2 diabetes. We have recently reported that the calcium-sensor sorcin (SRI) prevents glucose-induced nuclear shuttling of the transcription factor ChREBP (Carbohydrate-responsive element-binding protein). Moreover, SRI overexpression in pancreatic beta cells in transgenic mice preserves whole body glucose homeostasis during high fat feeding, and alleviates endoplasmic reticulum (ER) stress. Here, we demonstrate a role in SRI signalling for *G6pc2* (Glucose-6-phosphatase 2), a regulator of fasting blood glucose in human.

Materials and methods: Transgenic male mice bearing one (SRI-1) or ten (SRI-10) copies of SRI cDNA, resulting in SRI overexpression specifically in beta cells, and their littermate controls (CTRL), were maintained on a high-fat diet (60%; HFD). Glucose-stimulated insulin secretion (GSIS) was assessed *in vivo* and *ex vivo*. Real-time intracellular calcium imaging was measured using Fura-2 for cytosolic calcium ($[\text{Ca}^{2+}]_{\text{cyt}}$) and D4ER for ER calcium ($[\text{Ca}^{2+}]_{\text{ER}}$), and changes in gene expression was assessed by quantitative RT-PCR on isolated islets.

Results: SRI-10 mice displayed enhanced GSIS *in vivo* (30 min plasma insulin (mmol/L): 0.60 ± 0.06 for SRI-10, 0.43 ± 0.04 for CTRL, $n=5-7$ mice, $p < 0.05$) and *ex vivo* (% secreted insulin, high glucose condition: 0.57 ± 0.06 for SRI-10, 0.37 ± 0.02 for CTRL, $n=3$ mice, $p < 0.01$). Concomitantly, SRI-1 and SRI-10 islets displayed higher $[\text{Ca}^{2+}]_{\text{cyt}}$ in response to high glucose than control islets (AUC (a.u.): 499.1 ± 7.3 for SRI-1, 471.4 ± 7.8 for CTRL, $n=3$ mice, $p < 0.05$; 165.6 ± 7.1 for SRI-10, 144.3 ± 5.4 for CTRL, $n=3$ mice, $p < 0.05$). Moreover, as assessed using acetylcholine to fully deplete the ER calcium stores, SRI-10 islets had a greater $[\text{Ca}^{2+}]_{\text{ER}}$ compared to controls (fall (%): -6.1 ± 0.5 for SRI-10, -4.2 ± 0.3 for CTRL, $n=3-4$ mice, $p < 0.01$). Furthermore, islets from both SRI-1 and SRI-10 mice showed lowered expression of *G6pc2* with respect to those from littermate controls (fold-change normalised to beta-actin: 0.6 ± 0.06 for SRI-1, $n=3$ mice, $p < 0.05$; 0.4 ± 0.05 for SRI-10, $n=5$ mice, $p < 0.01$). *G6PC2* is a negative regulator of GSIS whose inactivation in mice leads to increased $[\text{Ca}^{2+}]_{\text{cyt}}$ and decreased fasting blood glucose. Similar changes in fasting blood glucose were observed in our SRI-10 mice on a HFD (0 min glycaemia (mmol/L): 8.7 ± 0.4 for SRI-10, 10.9 ± 0.8 for CTRL, $n=9-11$ mice, 8-week-old, $p < 0.05$).

Conclusion: SRI appears to preserve beta cell function during high fat feeding at least in part by lowering *G6pc2* expression. This is likely to increase glucose 6-phosphate levels, elevate ER calcium, lower ER stress, and potentiate GSIS. Such changes may avert or delay the decline in insulin secretion which underlies progression towards Type 2 diabetes.

CAMTA1 - Calcium-Calmodulin Transcriptional Activator 1, a new player in the regulation of microRNAs and insulin secretion

I.G. Mollet, H.A. Malm, A. Wendt, M. Orho-Melander, L. Eliasson;
Clinical Sciences, Malmö, Lund University, Malmö, Sweden.

Background and aims: CAMTAs are calmodulin-binding transcriptional activators highly conserved across a wide range of multicellular eukaryotes, involved in cell differentiation in response to environmental stresses. Mammalian CAMTA1 and CAMTA2 came to our attention as putative transcription factors involved in miR-212/132 expression, a cluster which responds to glucose and cyclic AMP in rat insulin secreting β -cells and is upregulated in islets of the diabetic Goto-Kakizaki (GK) rat model. Our aim was to examine the role of CAMTAs in insulin secretion and the regulation of miR-212/132 expression in islets and the INS-1 832/13 insulin secreting beta-cells.

Materials and methods: Human and rat islets and INS-1 832/13 cells were conditioned for hours or days at various glucose concentrations, cyclic AMP stimulation and/or alpha-2 adrenergic stimulation. Insulin secretion was determined by radioimmunoassay. Gene knockdowns were performed with siRNA. Gene expression was determined by qPCR. Luciferase assay was performed using a construct containing the promoter of miR-212/132.

Results: In GK rat islets incubated for 24 h at 16.7 mM glucose or 6 days at 5 mM glucose CAMTA1 and CAMTA2 expression was markedly reduced compared to Wistar control: 24 h at 16.7 mM glucose ($n=4$), CAMTA1 ($p=6.7E-4$), CAMTA2 ($p=6.9E-3$); six days at 5 mM glucose ($n=4$), CAMTA1 ($p=5.4E-4$), CAMTA2 ($p=0.028$). In human islets CAMTA1 and CAMTA2 are both upregulated after 72 h at 16.7 mM glucose compared to 5 mM glucose ($n=7$): CAMTA1 ($p=4.0E-4$); CAMTA2 ($p=0.023$). Knockdown of CAMTA1 reduced insulin secretion ($p=9.0E-3$, $n=3$) in INS-1 832/13 cells and upregulated miR-132 ($p=0.032$, $N=3$). Luciferase expression from miR-212/132 promoter was upregulated after knockdown of CAMTA1 ($p=7.0E-4$, $n=3$). In INS-1 832/13 cells expression of CAMTA1 was reduced after 2 h in Forskolin/IBMX ($p=9.8E-3$, $n=3$) and after 48 h of 50 nM clonidine ($p=4.1E-3$, $n=3$).

Conclusion: This data show that CAMTA1 expression is modulated not only by glucose and cyclic AMP in beta-cells but also by alpha-2 adrenergic stimulation and is involved in the regulation of insulin secretion and expression from the miR-212/132 promoter. We believe that CAMTA1 is therefore a new player involved in the pathways that lead to reduced insulin secretion in the diabetic GK model.

OP 30 The genetic landscape of diabetes in high resolution

175

Elucidating the role of protein-coding variants in type 2 diabetes susceptibility

A. Mahajan, on behalf of ExT2D Exome Chip Consortium, for PROMIS, CHARGE and T2D-GENES/GoT2D; Wellcome Trust Centre for Human Genetics, Oxford, UK.

Background and aims: Changes in protein-coding sequence have been hypothesised to be particularly enriched for variants of large-effect on complex human diseases. Such variants are more likely to have functional impact and support more direct biological interpretation than non-coding alleles. To evaluate the contribution of coding variants to type 2 diabetes (T2D) risk, we combined exome array data from 208,465 individuals (50,760 cases and 157,705 controls) in 39 studies from five ancestry groups: European (78.1%), South Asian (11.7%), African American (5.6%), Hispanic (3.0%), and East Asian (1.5%).

Materials and methods: Within each study, we tested single variants for association with T2D, with/without body-mass index (BMI) adjustment, using a linear mixed model to account for relatedness and population structure. We combined association summary statistics across studies in a fixed-effects z-score effective sample size weighted meta-analysis. In established genome-wide association study (GWAS) loci, we investigated the relationship between coding variants and previously reported lead SNPs (where available on the exome array) through approximate conditional analyses implemented in RareMetal.

Results: A total of 36 coding variants, mapping to 22 loci, were associated with T2D at exome-wide significance ($P < 5 \times 10^{-7}$) in European only or trans-ethnic meta-analysis. All but three were common, with minor allele frequency (MAF) $> 5\%$ in the ancestry driving the association. Eleven variants were located outside established T2D GWAS loci. These included common variants in ZZEF1 (L1972P, $P = 4.6 \times 10^{-9}$ and I2014V, $P = 1.3 \times 10^{-8}$), POC5 (H36R, $P = 3.4 \times 10^{-7}$), PNPLA3 (I148M, $P = 5.7 \times 10^{-8}$), and a low-frequency variant (MAF=1%) in FAM63A (Y285N, $P = 6.1 \times 10^{-8}$). Of these, POC5 maps to a known BMI GWAS locus and the PNPLA3 variant has been implicated in fatty liver disease. The other 25 variants mapped to established T2D susceptibility loci. These included nine variants in SLC30A8, MACF1, GCKR, PPARG, KCNJ11-ABCC8, and PAM-PP1P5K2, which were confirmatory of previously-reported coding alleles that drive GWAS association signals. However, the 16 remaining variants have not previously been directly implicated in T2D susceptibility, and not reported to drive the non-coding association signal. Amongst novel variants that were distinct from the GWAS signal was GIPR E354Q, for which T2D association observed only after BMI adjustment ($P = 2.4 \times 10^{-8}$), but which was not eliminated after conditioning on the previously reported inter-genic lead SNP ($P_{\text{cond}} = 3.6 \times 10^{-6}$). Conversely, at the CILP2 locus, a coding variant in TM6SF2 (E167K, $P = 1.0 \times 10^{-10}$) was indistinguishable from the previously reported lead SNP ($P_{\text{cond}} = 0.11$), suggesting that the GWAS signal is mediated through this gene.

Conclusion: Our results indicate that low-frequency and rare coding variants of large effect do not make a major contribution to T2D risk. However, these analyses implicate several novel genes in T2D pathogenesis, and provide direct insight into the underlying biology of the disease.

176

A meta-analysis of Japanese genome-wide association studies identified seven novel susceptibility loci to type 2 diabetes

M. Imamura¹, S. Maeda^{1,2}, T. Yamauchi³, K. Hara⁴, M. Iwata⁵, H. Hirose⁶, K. Yasuda⁷, H. Watada⁸, H. Maegawa⁹, C. Ito¹⁰, Y. Tanaka¹¹, K. Tobe⁵, K. Kaku¹², R. Kawamori⁸, T. Kadowaki³;

¹Laboratory for Endocrinology, Metabolism and Kidney Disease, RIKEN Center for Integrative Medical Sciences, Yokohama, ²University of the Ryukyus, Nakagami-gun, ³The University of Tokyo, ⁴Tokyo Medical University, ⁵University of Toyama, ⁶Keio University, Tokyo, ⁷National Center for Global Health and Medicine, Tokyo, ⁸Juntendo University, ⁹Shiga University of Medical Science, Otsu, ¹⁰Grand Tower Medical Court, Hiroshima, ¹¹St. Marianna University School of Medicine, Kawasaki, ¹²Kawasaki Medical School, Kurashiki, Japan.

Background and aims: Genome-wide association studies (GWAS) have been extensively performed in diverse ethnic groups, and have identified over 80 loci for susceptibility to type 2 diabetes; ~50 loci from European GWAS and ~30 loci from non-European or trans-ethnic GWAS meta-analysis. Although many loci have been shown to be common loci for conferring susceptibility to type 2 diabetes across different ethnic groups, the joint effects of these variants could explain only less than 10% of the heritability for type 2 diabetes. To identify novel genetic loci associated with susceptibility to type 2 diabetes further, we expanded Japanese GWAS by combining a new Japanese GWAS data (Stage-1; 9,817 cases and 6,763 controls, BioBank Japan) with a GWAS data in previously reported case-control samples (Stage-2; 5,646 cases and 19,420 controls, BioBank Japan).

Materials and methods: We analyzed ~7.5 million single nucleotide polymorphisms (SNPs) data obtained from genotype imputation performed by mini-mac using directly genotyped data (Study-1; Omni-express exome, Study-2; Illumina 610 K SNP array) and reference data in the 1000 genomes (JPT+CHB+CHS, $n = 275$), and combined the results of the 2 GWAS with a meta-analysis using the inverse variance method. As a result, we have identified 17 novel loci showing suggestive evidences for the association with type 2 diabetes ($p < 1 \times 10^{-6}$) in Japanese populations. These loci were further evaluated in an independent Japanese case-control study (Stage-3; 7,936 cases and 6,478 controls, multi-center) using *de novo* genotyping data obtained by the multiplex PCR-invasader assay.

Results: After combining all the association data (Stage-1, Stage-2 and Stage-3) for the 17 loci by a meta-analysis, the association of 7 loci reached to a genome-wide significant level ($p < 5 \times 10^{-8}$); rs1116357 on chromosome (Ch) 2: $p = 9.20 \times 10^{-11}$, OR (95%CI)=1.10 (1.07-1.13), rs147538848 on Ch12: $p = 2.96 \times 10^{-10}$, OR (95%CI)=1.11 (1.08-1.15), rs1575972 on Ch9: $p = 1.14 \times 10^{-9}$, OR (95%CI)=1.19 (1.13-1.26), rs67839313 on Ch15: $p = 2.05 \times 10^{-9}$, OR (95%CI)=1.09 (1.06-1.13), rs9309245 on Ch2: $p = 4.21 \times 10^{-9}$, OR (95%CI) = 1.11 (1.07-1.14), rs7107784 on Ch11: $p = 5.97 \times 10^{-9}$, OR (95%CI)=1.15 (1.10-1.20), rs67156297 on Ch1: $p = 4.30 \times 10^{-8}$, OR (95%CI)=1.13 (1.08-1.18). The effect sizes (odds ratio) of these 7 SNPs were similar before and after adjusting for age, sex, and BMI.

Conclusion: By performing the largest Japanese GWAS meta-analysis, we have identified 7 new loci associated with susceptibility to type 2 diabetes in the Japanese population.

High-density imputation and trans-ethnic association analysis reveals a novel locus for type 2 diabetes susceptibility

A.P. Morris;

Department of Biostatistics, University of Liverpool, UK.

Background and aims: The Resource for Genetic Epidemiology Research on Adult Health and Aging (GERA) is a large multi-ethnic

population-based cohort, created for investigating the genetic and environmental basis of common age-related diseases, including type 2 diabetes (T2D). Participants were genotyped using one of four custom arrays, designed to maximise coverage of common and low-frequency variants in non-Hispanic white, East Asian, African-American and Latino ethnicities. With these data, this study aimed to discover loci for T2D susceptibility through high-density imputation and trans-ethnic association analysis and to evaluate the evidence for heterogeneity in allelic effects on the disease between ancestry groups.

Materials and methods: After quality control, 71,604 unrelated participants, including 9,747 T2D cases, were retained for analysis and imputed up to the multi-ethnic reference panel (Phase 3, October 2014 release) from the 1000 Genomes Project Consortium. High-quality imputed variants were tested for association with T2D in a logistic regression model, after adjustment for sex and eigenvectors from principal components analysis to account for trans-ethnic and ancestry-specific population structure.

Results: Common lead SNPs at ten loci attained genome-wide significant evidence ($p < 5 \times 10^{-8}$) of association with T2D, including a novel signal mapping to *TOMM40* ($p = 2.8 \times 10^{-9}$). This gene has been previously implicated in Wolfram Syndrome, a neurodegenerative disorder characterised by diabetes mellitus. Across lead SNPs for the ten loci, nominal evidence of heterogeneity in allelic effects between ethnicities was observed only at *TCF7L2* ($p_{\text{HET}} = 0.012$), where the risk allele had the lowest T2D odds-ratio for participants of East Asian ancestry.

Conclusion: This study provides further evidence for the homogeneity of allelic effects of common T2D risk variants across diverse populations, and highlights the benefits of trans-ethnic analysis for the discovery of novel loci associated with the disease.

Genome-wide association study imputed to 1000 Genomes Project reference panels reveals 17 novel associations with type 2 diabetes

R. Mägi¹, R.A. Scott², A.P. Morris³, L. Marullo⁴, K. Galton⁵, M. Boehnke⁶, J. Dupuis⁷, M.I. McCarthy⁵, L.J. Scott⁶, I. Prokopenko⁸, DI-GRAM consortium;

¹Estonian Genome Center, Tartu, Estonia, ²MRC Epidemiology Unit, University of Cambridge School of Clinical Medicine, ³Department of Biostatistics, University of Liverpool, UK, ⁴Department of Life Sciences and Biotechnology, University of Ferrara, Italy, ⁵Wellcome Trust Centre for Human Genetics, Oxford, UK, ⁶Center for Statistical Genetics and Dept of Biostatistics, University of Michigan, Ann Arbor, ⁷Department of Biostatistics, Boston University School of Public Health, USA, ⁸Genomics of Common Disease, Imperial College London, UK.

Background and aims: Genome-wide association studies (GWAS) using imputation based on the HapMap 2 reference panel (analysis of 2.5 M single nucleotide variants (SNVs)), have identified more than 70 loci associated with type 2 diabetes (T2D). These loci are exclusively common, with minor allele frequency (MAF) > 5%. The aim of current work was to detect additional common (MAF ≥ 5%) and low-frequency (0.5% ≤ MAF < 5%) T2D associated loci using the denser 1000 Genomes (1000G) Project imputation reference panel.

Materials and methods: We performed imputation using the March 2012 release of the 1000G “all ancestries” reference panel in 26,676 T2D cases and 132,532 controls from 18 European GWAS. The 1000G panel provides more comprehensive coverage than HapMap for imputation of both common and low frequency variants. Amongst more than 12 million SNVs in meta-analysis of which 2.9 M were low frequency, we followed up those achieving $p < 5 \times 10^{-5}$ in an additional 14,545 cases and 38,994 controls of European ancestry genotyped with Metabochip.

Results: In combined meta-analysis, we identified 17 novel loci achieving genome-wide significant ($p < 5 \times 10^{-8}$) associations with T2D. All lead SNVs were common with MAF > 10%, including loci mapping to/near *PLEKHA1* ($p = 1.8 \times 10^{-12}$), *APOE* ($p = 1.5 \times 10^{-10}$), and *CENPW* ($p = 5.9 \times 10^{-10}$). On the

basis of the meta-analysis, we defined 99% credible sets of variants that were most likely to drive the association signal in established and novel loci. The 99% credible set contained fewer than 20 SNVs at 17 loci. Within these 17 credible sets, we were able to find coding variants for three genes (*HNF1A*, *CTRB2*, *ADCY5*), which were not present in HapMap2.

Conclusion: Our results highlight the potential for the identification of novel T2D loci through imputation up to 1000G reference panels, and highlight functional mechanisms driving association signals at three loci through coding variants that were not present in HapMap2.

Genome-wide association studies on kidney complications in patients with type 1 diabetes

N. Sandholm^{1,2}, E. Ahlqvist³, H. Deshmukh⁴, N. Van Zuydam⁵, N.W. Rayner⁵, V. Harjutsalo^{1,6}, M.L. Marcovecchio⁷, J. Cooper⁷, A.J. McKnight⁸, R.M. Salem⁹, M. Lajer¹⁰, D. Tregouet¹¹, L.T. Hiraki¹², M. Pezzolesi¹³, C. Forsblom^{1,2};

¹Folkhälsan Institute of Genetics, Folkhälsan Research Center, ²Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, ³Skåne University Hospital, Lund University, Malmö, Sweden, ⁴University of Dundee, ⁵Wellcome Trust Centre for Human Genetics, Oxford, UK, ⁶National Institute for Health and Welfare, Helsinki, Finland, ⁷University of Cambridge, ⁸Queen's University of Belfast, UK, ⁹Broad Institute, Cambridge, USA, ¹⁰Steno Diabetes Center, Gentofte, Denmark, ¹¹INSERM UMR S 1166, Paris, France, ¹²Hospital for Sick Children, Toronto, Canada, ¹³Joslin Diabetes Center, Boston, USA.

Background and aims: Diabetic nephropathy is a common and serious complication of type 1 diabetes (T1D), but few genetic risk factors have been identified. Our aim was to detect genetic risk factors by performing genome-wide association studies (GWAS) on a variety of renal phenotypes in four European studies with 5,156 T1D patients from the SUMMIT Consortium.

Materials and methods: We employed seven different case-control definitions based on the severity of diabetic nephropathy (DN; micro-/macro-albuminuria and/or end stage renal disease (ESRD)), chronic kidney disease (CKD; estimated glomerular filtration rate (eGFR) < 60 ml/min), or a combination. The proportion of phenotypic variance explained by the GWAS SNPs, the narrow-sense heritability, was estimated in 3,415 Finnish patients (GCTA). Genotype imputation with the 1000 Genomes (March 2012) resulted in 8,578,867 variants (minor allele frequency ≥ 0.01) found in at least two studies. Association analysis with an additive model was adjusted for sex, diabetes duration, age at diabetes onset, and kinship matrix (EMMAX). Meta-analyses were performed using a sample size weighted method (METAL). Associations with $p < 5 \times 10^{-6}$ were *in silico* replicated in six additional GWAS with 7,041 T1D patients and data on renal complications.

Results: Heritability of DN was estimated to be 35% ($p = 0.006$), or 50% after adjusting for sex, duration of T1D, and age at T1D onset ($p = 2.5 \times 10^{-4}$). Strongest heritability was estimated for the combined CKD and DN vs. no CKD and normal AER phenotype (59%, $p = 0.0011$). A total of 101 loci reached $p < 5 \times 10^{-6}$ in GWAS meta-analyses. After joint meta-analysis with the *in silico* studies, no locus reached genome-wide significance, but three reached a suggestive $p < 10^{-6}$: on chromosome (chr) 7q36.1 near *CNTNAP2* for the combination of DN and CKD ($p = 6 \times 10^{-7}$); on chr4q21.3 near *PTPN13* for ESRD ($p = 6 \times 10^{-8}$); and on chr2q11.2 in *AFF3* for ESRD ($p = 3 \times 10^{-7}$). In a look-up from the SUMMIT meta-analysis of 5,717 patients with type 2 diabetes (T2D), only the *AFF3* signal showed any corroboration for kidney phenotypes (CKD+DN: T2D $p = 0.002$, T1D+T2D $p = 2 \times 10^{-7}$). These three SNPs, and a SNP near *NRG3* with $p < 0.05$ for DN in replication, were further genotyped in up to 1,800 T1D patients. However, the associations were not significant and did not improve the overall p-values.

Conclusion: Although no locus was robustly associated with renal complications in T1D, these analyses support the role of *AFF3*, and suggest a notable genetic contribution, especially for the more extreme phenotypes. Synergistic effect of genetic susceptibility and poor glycaemic control on renal decline in patients with type 1 diabetes and proteinuria

J. Skupien^{1,2}, A.M. Smiles², A.T. Galecki³, J.C. Mychaleckyj⁴, M.G. Pezzolesi², A.S. Krolewski²;

¹Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland, ²Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, ³University of Michigan, Ann Arbor, ⁴University of Virginia, Charlottesville, USA.

Background and aims: The key phenotype of diabetic nephropathy, the renal decline, is a progressive loss of glomerular filtration rate that eventually leads to end-stage renal disease (ESRD). Its genetic background is not well understood. Glycemic control may be an important modifier of genetic susceptibility to renal decline.

Materials and methods: As a part of search for genes determining time to onset of ESRD in type 1 diabetes (T1D) patients with proteinuria we sought for common genetic variants associated with renal decline, whose effect on the slope of renal decline is modified by glycemic control. We examined 544 patients with T1D and proteinuria, followed for up to 24 years. Serial serum creatinine determinations were obtained during the follow-up. We used a joint longitudinal-survival model, which accounts for informative censoring in those who rapidly progress to ESRD. We tested for an interaction with HbA_{1c} in strata below and above values of 8.0% or 63.9 mmol/mol (1st quartile), 9.1% or 76.0 mmol/mol (median) and 10.5% or 91.3 mmol/mol (3rd quartile). The patients were genotyped with the Illumina HumanCoreExome Beadarray 1.0.

Results: We identified two variants associated with renal decline with genome-wide significant effect modification by HbA_{1c}. A minor allele of rs10997250 polymorphism (minor allele frequency 7.2%) in patients with fair glycaemic control (HbA_{1c}<10.5%) was not associated with a significant change in the slope of renal decline (1.0 ml/min/1.73 m²/year less decline per one additional minor allele, p=0.24), while in patients with poor glycaemic control (HbA_{1c}≥10.5%) an additional minor allele was associated with a 9.1 ml/min/1.73 m²/year steeper renal decline than in those with fair glycaemic control (p=2.2×10⁻⁸ for the interaction). Similarly, a minor allele of rs12877579 (minor allele frequency 14.8%) in patients with fair glycaemic control was associated with 0.8 ml/min/1.73 m²/year less decline (p=0.20), but in patients with poor glycaemic control an additional minor allele resulted in a 6.9 ml/min/1.73 m²/year steeper renal decline than in the patients with fair glycaemic control (p=4.2×10⁻⁸ for the interaction). This gene-environment interaction can be also presented as estimated mean slopes for each genotype and HbA_{1c} stratum. For the variant rs10997250 the mean slopes of renal decline in patients with fair glycaemic control in major homozygotes, heterozygotes and minor homozygotes were -5.7, -4.5 and -7.5 ml/min/1.73 m²/year, respectively. In those with poor glycaemic control they were -8.9, -17.2 and -23.8 ml/min/1.73 m²/year. The respective means for the rs12877579 variant were -5.8, -4.7, -5.7 and -8.3, -15.0, -17.7 ml/min/1.73 m²/year. No significant interactions were found for HbA_{1c} strata formed by thresholds 8.0% and 9.1%.

Conclusion: The minor alleles of variants rs10997250 on chromosome 10 and rs12877579 on chromosome 13 have strong deleterious effect on renal decline only in patients with poor glycaemic control. Genetic susceptibility and poor glycaemic control seem to have synergistic effect on the risk of renal decline. This phenomenon should be accounted for in studies of genetics of diabetic nephropathy.

Empagliflozin reduces HbA_{1c} with lower insulin doses in patients with type 1 diabetes: a 4-week placebo-controlled trial (EASE-1)

T.R. Pieber¹, S. Famulla², J. Eilbrach³, J. Cescutti⁴, N. Soleymanlou⁵, O. Johansen⁶, H.J. Woerle⁷, U.C. Broedl⁷, S. Kaspers⁷;

¹Medical University of Graz, Austria, ²Profil, Neuss, ³Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany, ⁴Boehringer Ingelheim France, Reims, France, ⁵Boehringer Ingelheim Canada Ltd./Ltee, Burlington, Canada, ⁶Boehringer Ingelheim Norway K.S, Asker, Norway, ⁷Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany.

Background and aims: In the EASE-1 study, we investigated the pharmacodynamics, efficacy and safety of empagliflozin (EMPA) as adjunct to insulin in patients with type 1 diabetes.

Materials and methods: In this Phase II, double-blind trial, patients with type 1 diabetes were randomized to placebo (PBO; n=19), EMPA 2.5 mg (n=19), EMPA 10 mg (n=19) or EMPA 25 mg (n=18) as adjunct to insulin (multiple daily injections) for 28 days. Insulin dose was to be kept as stable as possible for 7 days and was freely adjustable thereafter. The primary exploratory endpoint was change from baseline in 24-h urinary glucose excretion (UGE) at day 7.

Results: EMPA significantly increased 24-h UGE vs PBO at days 7 and 28. At day 28, EMPA significantly reduced HbA_{1c} vs PBO, with reductions in fasting plasma glucose, and a significant reduction in recorded total daily insulin use. EMPA significantly reduced weight vs PBO at day 28. Adverse events (AEs) were reported in 94.7%, 89.5%, 78.9% and 100.0% of patients on PBO, EMPA 2.5 mg, 10 mg and 25 mg, respectively. AEs consistent with urinary tract infection were reported in one patient (on EMPA 25 mg). No AEs consistent with genital infection were reported. In PBO, EMPA 2.5 mg, 10 mg and 25 mg groups, respectively, 19, 8, 10, and 13 symptomatic hypoglycemic episodes with glucose ≤54 mg/dL not requiring assistance were reported. One hypoglycemic episode requiring assistance was reported (on PBO).

Conclusion: In patients with type 1 diabetes, EMPA for 28 days as adjunct to insulin increased UGE, improved HbA_{1c} and reduced weight with lower insulin doses vs PBO and was well tolerated. EMPA is not yet approved for use in patients with type 1 diabetes.

		PBO (n=19)	EMPA 2.5 mg (n=19)	EMPA 10 mg (n=19)	EMPA 25 mg (n=18)

Sotagliflozin, a dual SGLT1 and SGLT2 inhibitor, improves glycaemic control in type 1 diabetes mellitus in a randomised, placebo-controlled, double-blind study

W. Cefalu¹, A.T. Sands², J. Rosenstock³, P. Lapuerta², B.W. Bode⁴, S.K. Garg⁵, J.B. Buse⁶, P. Banks², R. Heptulla⁷, M. Rendell⁸, B. Zambrowicz², P.S. Strumph²;

¹Pennington Biomedical Research Center, Baton Rouge, ²Lexicon Pharmaceuticals, Inc., The Woodlands, ³Dallas Diabetes and Endocrine Center, ⁴Atlanta Diabetes Association, ⁵University of Colorado Denver/Barbara Davis Center for Childhood Diabetes, Aurora, ⁶University of North Carolina Diabetes Care Center, Chapel Hill, ⁷Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, ⁸Creighton Diabetes Center, Omaha, USA.

Background and aims: Dual inhibition of both SGLT1 and SGLT2 may provide additional benefit above that achieved with SGLT2 inhibition alone when used as adjunctive therapy to insulin in T1DM. Sotagliflozin (LX4211) is a dual inhibitor of sodium-glucose cotransporters SGLT1 and SGLT2. In T1D we hypothesized that inhibition of SGLT1, the major intestinal glucose transporter, would reduce glucose absorption in the gastrointestinal tract, with an increase in incretins. SGLT2 inhibition reduces renal glucose reabsorption.

Materials and methods: This 29-day study evaluated 33 subjects with T1D (ages 21–57 years, duration of diabetes 3–42 years) with screening A1C of 7.0%–9.0%, treated with insulin pump or multiple daily injection therapy who were randomized to double-blind treatment with sotagliflozin 400 mg or placebo once daily.

Results: All participants completed the study. Raw means are displayed; p-values for change from baseline and between group effects are based on least squares means, unless otherwise noted.

Conclusion: Sotagliflozin a next generation SGLT inhibitor, significantly reduced A1C levels, daily bolus and total daily insulin dose, postprandial blood glucose, and body weight, and increased PYY in T1D with no increase in hypoglycemia risk. Larger studies of a longer duration are needed to confirm these findings.

Dapagliflozin modulates SGLT1 and GLUT2 expression and glucagon secretion in a SGLT2-independent manner in murine alpha cells

A. Solini¹, L. Nigri², E. Santini¹, G. Sebastiani², B. Astiarraga¹, C. Rossi¹, F. Dotta²;

¹Dept of Clinical and Experimental Medicine, University of Pisa, ²Department of Medicine, Surgery and Neuroscience, University of Siena, Italy.

Background and aims: SGLT2 inhibitors reduce plasma glucose levels via a forced glycosuria through inhibition of glucose uptake by the kidney, with a fully insulin-independent mechanism. However, recent studies show increased glucagon concentrations after acute or chronic administration of SGLT2 inhibitors. Whether or not such effect is consequence of a series of systemic metabolic variations rather than due to a direct effect on pancreatic α -cells is unclear.

Materials and methods: We tested this hypothesis by treating for different times (30, 45, 60 min and 12 h) murine pancreatic α -cell line (alpha-TC1) with 100 ng/ml dapagliflozin (Dapa), and measuring its effect on the expression of glucose transporters, molecular mediators of hormone secretion and glucagon and GLP-1 release.

Results: SGLT2 was not detectable in these cells even by digital PCR technique. SGLT1, was quite abundantly represented and was significantly increased by Dapa at 30' and 45' (+65±21% and +16±3% vs untreated, p<0.001 and 0.05, respectively). GLUT1 expression was substantially unaffected by Dapa (-5% at 30' and -7% at 45'), while GLUT2 was down-regulated (-24±60% at 30' and -19±23% at 45', both p<0.005). At 12 h, the expression of both glucose transporters returned to baseline levels. Similarly, Dapa did not induce variations in the expression of several molecules involved in the modulation of glucagon release or α -cell phenotype (fold induction at Dapa 30' vs untreated=CHGA: 1.10±0.17; PAX6 1.13±0.14; PCSK2: 1.20±0.18; PCSK1: 0.99±0.18; SYP: 1.14±0.23, all p=ns). Moreover, GLP-1 receptor expression did not differ in α -cells treated or untreated with Dapa. Accordingly, glucagon release minimally changed in cells pretreated with Dapa (at 30': 822±76 vs 828±85; at 45': 1198±127 vs 1515±112 pg/ml/μg protein, both p=ns). Of note, at 12 h, glucagon release was significantly lower in Dapa-treated cells (3524±254 vs 2446±157 pg/ml/μg protein, p<0.005). GLP-1 did not significantly change after Dapa (at 30': 610±76 vs 640±52; at 45': 842±96 vs 1000±118 pmol/ml/μg protein, both p=ns). At 12 h, GLP-1 was 3533±216 in untreated cells and 3604±270 pmol/ml/μg in Dapa-treated cells (p=ns). Low (5.5 mM) or high (25 mM) glucose pulses did not affect SGLT1, GLUT1 or GLUT2 expression, while glucagon (2210±125 vs 1725±117 pg/ml/μg protein, p<0.05) and GLP-1 release (2671±139 vs 2090±154 pmol/ml/μg protein, p<0.01) secretion were slightly but significantly reduced by high glucose.

Conclusion: Dapa acutely upregulates SGLT1 and downregulates GLUT2 expression in pancreatic α -cells, while SGLT2 was not detectable in these cells. In addition, glucagon release was significantly reduced after long-term (12 h) treatment with Dapa. These data suggest that the glucagon raise reported in type 2 diabetes patients treated with Dapa does not reflect the direct action of this molecule on pancreatic α -cells.

Dapagliflozin potentiates glucagon secretion at high glucose: experimental findings and mathematical simulation

I. Ahlstedt¹, M. Gram Pedersen², E.-M. Andersson¹, S.O. Göpel¹;

¹Bioscience, AstrazenecaR&D, Mölndal, Sweden, ²Information Engineering, Univ. Padua, Italy.

Background and aims: Inhibiting glucose re-absorption in the kidney by blocking the Na⁺/glc co-transporters SGLT has been proven to be a safe and effective treatment for diabetes. However, recently it was discovered that SGLT inhibition raises hepatic glucose output and plasma glucagon

levels. It is plausible that the former is caused by the latter and we thus attempted to investigate the direct effect of the SGLT2 blocker Dapagliflozin on glucagon secretion from pancreatic islets. α -cells respond to low glucose levels with increased glucagon secretion which is directly regulated by the electrical activity of the cell. The current generated by the electrogenic SGLT-transporters is thus expected to affect glucagon secretion by changes of the membrane potential. We constructed a mathematical model of α -cell electrical activity based on data from human α -cells which is able to explain our experimental findings.

Materials and methods: Mice islets were prepared by pancreas collagenase digestion and for human islets assay ready 3D InSight™ plates were used. Islets were kept for 1 h under the indicated conditions and glucagon levels determined using ELISA-kits from Meroctodia. For each preparation secretion was measured in 6–8 wells and median secretion calculated. Values were normalized to secretion at 1 mM glc and data are presented as average from indicated number of preparations. A Hodgkin-Huxley type model of electrical activity was constructed including KATP, Nav, T-, L- and P/Q-type Cav, A-type and delay-rectifier Kv-channels based on published human A-cell electrophysiological data. A previously published 6-state model of SGLT Na⁺/glc co-transport was included to analyze the effect of SGLT currents on α -cell electrophysiology. Simulations were performed in XPPAUT using the cvoid solver.

Results: In mouse islets raising the glucose concentration to 11 mM glc reduced glucagon secretion to 17 ± 2.6% (n=16) compared to 1 mM glc. Dapagliflozin (10 nM) had no effects at 1 mM glc but increased secretion from 17% to 59.1 ± 22% (n=13) at high glucose. In human islets Dapagliflozin had similar effects (19.2 ± 3.5% at 11 mM glc, 32.7 ± 7.3% with 11 mM glc + Dapagliflozin n=5). We then simulated the effects of glucose and Dapagliflozin on the membrane potential. High (11 mM) and low (1 mM) glucose was simulated by changing the extracellular glucose concentration (Go) in the SGLT submodel and varying the KATP-channel conductance (G-KATP) between 0.19 nS and 0.17 nS, which resulted in action potentials reaching 10 mV and -12 mV, respectively. Inhibition of SGLT2 at Go and G-KATP corresponding to low glucose had almost no effect whereas at high glucose it increased action potential peaks from -12 mV to 15 mV.

Conclusion: Our α -cell model reproduces the effects of glucose on action potential firing seen in membrane potential recordings in rodent α -cells. Dapagliflozin directly stimulates glucagon secretion from pancreatic islets at high glucose. Since glucagon secretion is strongly dependent on the maximal depolarization reached during an action potential, the increased action potential height upon SGLT2 inhibition in our model fits well to our secretion data. These findings potentially explain the observation that diabetic subjects treated with SGLT-blockers experience elevated glucagon levels and increased hepatic glucose output.

Dapagliflozin reduces albuminuria on top of renin-angiotensin system blockade in hypersensitive patients with diabetes

H. J. Lambers Heerspink¹, E. Johnsson², I. Gause-Nilsson², C. Sjöström²;

¹Dept of Clinical Pharmacology, University Medical Center Groningen, Netherlands, ²AstraZeneca, Mölndal, Sweden.

Background and aims: Hypertension (HTN) and albuminuria are risk factors for cardiovascular (CV) and renal disease in patients with type 2 diabetes mellitus (T2DM). Glycaemic, blood pressure (BP) and albuminuria control are critical to reducing CV and renal risk. Dapagliflozin (DAPA) reduces HbA1c and BP in patients with T2DM. The aim of the study was to characterise the effect of DAPA on albuminuria and estimated glomerular filtration rate (eGFR).

Materials and methods: Data was pooled from 2 studies for patients with T2DM, micro- or macroalbuminuria and HTN, who were assigned to DAPA 5 mg (n=87), 10 mg (n=167) or placebo (PBO; n=189). All

patients were on stable angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy.

Results: At 12 weeks, DAPA resulted in greater reductions from baseline vs PBO in albuminuria (as assessed by albumin:creatinine ratio [ACR]). Reductions in HbA1c and systolic BP (SBP) vs PBO were also observed (Table). There was a decrease in eGFR with DAPA vs PBO, which was readily reversed 1 week after the last dose. DAPA's ACR-reducing effect was also present after adjusting for changes in HbA1c, SBP and eGFR. There were no increases in serum creatinine $\geq 1.5 \times$ baseline for DAPA 5 or 10 mg vs PBO (0%, 1.2%, 1.1%, respectively). Potassium ≥ 6 mEq/L values were also similar for DAPA 5 or 10 mg vs PBO (1.2%, 2.4%, 2.2%, respectively). There were no serious renal-related adverse events (AEs) in any group.

Conclusion: DAPA reduces ACR in T2DM patients with HTN using renin-angiotensin system blockade without increasing serious renal AEs.

Canagliflozin reduces both HbA1c and body weight in patients with type 2 diabetes on background dipeptidyl peptidase-4 inhibitors or glucagon-like peptide-1 agonists

V. Woo¹, C. Wysham², C. Mathieu³, F. Vercauteren⁴, G. Capuano⁵, G. Fulcher⁶;

¹Endocrinology Section, Department of Internal Medicine, University of Manitoba, Winnipeg, Canada, ²Washington State University, Spokane, USA, ³Laboratory of Experimental Medicine and Endocrinology, KU Leuven, ⁴Janssen Research & Development, Beerse, Belgium, ⁵Janssen Research & Development, LLC, Raritan, USA, ⁶The Royal North Shore Hospital and University of Sydney, Australia.

Background and aims: Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor approved for the treatment of type 2 diabetes mellitus (T2DM), has been shown to provide reductions in HbA1c and body weight (BW) compared with placebo (PBO) over 18 weeks in subgroups of patients on background dipeptidyl peptidase-4 (DPP-4) inhibitors or glucagon-like peptide-1 (GLP-1) agonists from the CANagliflozin cardiovascular Assessment Study (CANVAS), an ongoing, randomised, double-blind, study in patients with T2DM and a history or high risk of cardiovascular disease; this post hoc analysis evaluated the proportion of patients who had decreases in both HbA1c and BW with CANA versus PBO at Week 18.

Materials and methods: Of the 4,330 patients enrolled in CANVAS, 316 patients were taking DPP-4 inhibitors (mean baseline HbA1c, 8.1%; BW, 90.7 kg) and 95 were taking GLP-1 agonists (mean baseline HbA1c, 8.1%; BW, 108.8 kg). Patients were randomised to receive CANA 100 or 300 mg or PBO. Using individual patient data, the proportion of patients achieving both change from baseline in HbA1c <0% and BW <0 kg was assessed at Week 18.

Results: At Week 18, least squares (LS) mean changes in HbA1c with CANA 100 and 300 mg and PBO were -0.46%, -0.64%, and 0.10%, respectively, in patients taking DPP-4 inhibitors; LS mean percent

changes in BW were -3.2%, -3.9%, and -0.9%, respectively. In patients taking GLP-1 agonists, LS mean changes in HbA1c at Week 18 with CANA 100 and 300 mg and PBO were -0.83%, -0.89%, and 0.17%, respectively; LS mean percent changes in BW were -3.0%, -3.7%, and -0.4%, respectively. In the DPP-4 inhibitor subgroup, a greater proportion of patients had reductions in both HbA1c and BW at Week 18 with CANA 100 and 300 mg versus PBO (65.3%, 78.1%, and 29.2%, respectively; PBO-subtracted differences [95% confidence interval (CI)] of 36.2% [22.2, 50.2] and 48.9% [35.9, 62.0]). A greater proportion of patients in the GLP-1 agonist subgroup also had reductions in both HbA1c and BW at Week 18 with CANA 100 and 300 mg versus PBO (82.4%, 85.7%, and 24.1%, respectively; PBO-subtracted differences [95% confidence interval (CI)] of 58.2% [34.9, 81.6] and 61.6% [37.8, 85.3]). CANA was generally well tolerated in both subgroups with a safety profile similar to that seen in previous Phase 3 studies of CANA.

Conclusion: CANA provided greater attainment of reduction in both HbA1c and BW versus PBO at Week 18 and was generally well tolerated in patients with T2DM as add-on to DPP-4 inhibitors or GLP-1 agonists.

Is access to the outdoors associated with childhood overweight and obesity?

B.C. van der Zwaard^{1,2}, A. Schalkwijk^{1,2}, P.J.M. Elders^{1,2}, G. Nijpels^{1,2}, L. Platt³;

¹General practice and elderly care medicine, VU medical center,

²EMGO+ Institute for Health and Care research, Amsterdam, Netherlands, ³Social Policy, London School of Economics and Political Science, London, UK.

Background and aims: Overweight and obese children are at increased risk of becoming overweight and obese adults and therefore an important risk factor for developing type 2 diabetes. Being overweight or obese is associated with environmental, parental and socioeconomic status (SES) characteristics. The aims of this study were to assess the association of environmental characteristics during ages 3-5 on being overweight or obese at age 7. Furthermore we assessed if parental behaviors moderate or mediate this influence. In the final stage of our analysis we assessed if the influence of SES on the derived model the previous aims was assessed.

Materials and methods: The analysis used the Millennium Cohort Study; a nationally representative study of around 19,000 children born in the UK between 2000-2001 who are followed over time. We use measures from the surveys carried out at age 9 months, 3 years, 5 years and 7 years. Logistic regression was used to test the initial association between the outcome measure overweight/obese (according to the age specific Cole criteria) and determinants: amount of green space in the neighborhood, having access to a garden and the condition (i.e. shabbiness) of the neighborhood. Subsequently, parental determinants consisting of variables summarizing: food consumption, physical activity, rules and regularity were evaluated as moderators or mediators of the initial association. Lastly SES related variables, namely education level, housing tenure and poverty were tested as moderators or mediators of the associations.

Results: Statistically significant associations ($p \leq 0.05$) were found between low levels green space, not having access to a garden, shabbiness of the neighborhood and childhood obesity (OR (95% CI) respectively: 1,14 (1,02-1,27), 1,35 (1,16-1,58), 1,22 (1,05-1,42)). Parental determinants were related to the environmental determinants and childhood overweight/obese but did not moderate or mediate the association between the latter two. Therefore no parental variables were left in the model. For SES, the highest level of education in the household did diminish the magnitude of the associations found between the environmental determinants and being overweight/obese. In the final model the remaining significant associations with childhood overweight/obese were no garden access for lower educated households and shabbiness of the neighborhood for higher educated households (OR (95% CI) respectively: 1,41 (1,09-1,84), 1,38 (1,12-1,70)).

Conclusion: Not having access to a garden at age 3 - 5 for lower educated households increased childhood overweight/obesity at age 7. Also the combination of a more dilapidated neighborhood and higher education increased childhood overweight/obesity. To conclude, we showed that limits on access to outdoors space is associated with future childhood overweight/obesity although moderated by education level. More research is needed to see how we can deploy these findings in the prevention of type 2 diabetes.

Body mass index during early adulthood in relation to risk of diabetes in later life among Chinese men and women

H. Du¹, L. Li², D. Bennett¹, Y. Guo³, M. Holmes¹, Z. Bian⁴, A. Iona¹, L. Yang¹, I. Millwood¹, Y. Chen¹, R. Collins¹, R. Peto¹, Z. Chen¹;
¹CTSU, University of Oxford, UK, ²Peking University, Beijing, ³Chinese Academy of Medical Sciences, ⁴Chinese Academy of Medical Sciences, Beijing, China.

Background and aims: Although adiposity has been established as a strong risk factor for diabetes, the independent effects of body mass index (BMI) in early adulthood on risk of diabetes in middle and older age remains unclear, particularly in China.

Materials and methods: The study population includes 430,074 participants (57% women, mean baseline age 51 years) enrolled into the China Kadoorie Biobank between 2004–8 from 10 diverse localities across China, for whom self-reported data on weight at 25 years old (weight25) were available. Information on socio-demographics, lifestyle and personal & family disease history was collected using an electronic questionnaire. Data on diabetes incidence was collected through electronic linkage with mortality and morbidity registries and the national health insurance system. Height at 25 years old (height25, in meters) was estimated according to the age trend of baseline measured height, and body mass index (BMI) at 25 years (BMI25) was calculated using the standard formula. The Pearson correlation coefficient of weight25 recalled at baseline and at resurvey (~3 years after baseline, n=14,452) was calculated to assess its reproducibility. Cox regression models were used to yield hazard ratios (HRs) relating BMI25 to risk of incident diabetes (between 35–79 years of age), adjusting for age, sex, region, smoking, alcohol consumption, education, income, baseline values of BMI and waist circumference, and family history of diabetes.

Results: The correlation coefficient of weight25 reported at baseline and resurvey was 0.80. Mean (SD) BMI25 was ~2.5 kg/m² lower [21.4 (2.5) kg/m²] than BMI at baseline [23.8 (3.4) kg/m²] and the correlation coefficient between the two was 0.32. During approximately 7-years of follow-up, 17,105 incident diabetes cases were documented. A J-shaped association was observed between BMI25 and diabetes, with risk lowest at BMI25 around 20 (19.5–20.5) kg/m². Between 20 and 25 kg/m², diabetes risk increased by 3–6% per unit BMI25 increase. However, at BMI25 > 25 kg/m² the HR of diabetes increased substantially to 1.61 (95% CI: 1.54–1.68) (Figure). BMI25 lower than 19.5 was also associated with a 6–9% elevated risk of diabetes. Although a similar J-shaped association was observed in both genders and different age groups, stronger associations were observed in men than in women, and in younger than in older people.

Conclusion: Among Chinese, overweight in early adulthood is associated with a greatly elevated risk of diabetes in late adulthood. This association is independent of family history of diabetes and adulthood adiposity, highlighting the importance of lifelong body weight control.

Objectively measured sedentary behaviour patterns according to diabetes status: The Maastricht Study

J.D. van der Berg¹, C.D.A. Stehouwer^{2,3}, H. Bosma¹, J.H.P. van der Velde^{4,3}, P.J.B. Willems⁴, H.H.C. Savelberg⁴, M.T. Schram^{2,3}, S.J.S. Sep^{2,3}, C.J.H. van der Kallen^{2,3}, R.M.A. Henry^{2,3}, P.C. Dagnelie^{5,6}, N.C. Schaper^{3,5}, A. Koster¹;

¹Social Medicine/CAPHRI School for Public Health & Primary Care, ²Cardiovascular Research Institute Maastricht (CARIM), ³Department of Internal Medicine, ⁴Dep Human Movement Sciences; School for Nutrition and Translational Research in Metabolism (NUTRIM), ⁵CAPHRI School for Public Health & Primary Care; Cardiovascular Research Institute Maastricht (CARIM), ⁶Department of Epidemiology, Maastricht University, Netherlands.

Background and aims: Studies have shown that physical activity (PA) plays a role in the development and management of type 2 diabetes mellitus (T2DM). Next to the role of PA, there has been growing interest in the role of sedentary behaviour. However, large-scale studies with objectively measured sedentary behaviour in a population with T2DM are scarce. Therefore, we examined differences in objectively assessed sedentary behaviour patterns between participants with T2DM, with pre-diabetes (impaired glucose metabolism) and without T2DM.

Materials and methods: We included 2,529 participants (aged 40–76 years) of The Maastricht Study who wore an activPAL accelerometer 24 h/day for 7 consecutive days on the front right thigh. We calculated percentage sedentary time (ST) of waking time, mean number of breaks in ST per day (≥1 minute of ST followed by ≥1 minute activity), and mean step frequency per day (measure for PA). To determine glucose metabolism status, all participants underwent an oral glucose tolerance

test. Associations between glucose metabolism status and percentage ST were examined using linear regression analysis.

Results: 726 participants (28.7%) had T2DM, 391 (15.5%) had prediabetes, and 1,412 (55.8%) had no T2DM. Participants provided on average 6.4 valid days (defined as ≥ 14 h of monitoring), and 91% wore the device 6 or more days. Participants with T2DM spent on average (mean \pm SD) 10.2 ± 1.8 hours per day sedentary, as compared to on average 9.5 ± 1.8 in participants with prediabetes and 9.1 ± 1.6 in participants without T2DM ($P < 0.001$). Mean number of sedentary breaks per day was 35.8 ± 9.3 among participants with T2DM, and 37.4 ± 8.8 and 38.0 ± 8.5 among participants with prediabetes and participants without T2DM ($P < 0.001$). After adjustment for demographic factors (sex, age, level of education), health factors (smoking status, body mass index, mobility limitation, history of cardiovascular diseases and chronic obstructive pulmonary disease), and mean step frequency, participants with T2DM had on average 22.5 minutes more ST per day (95%CI=16.8 - 28.2; $P < 0.001$) compared to those without T2DM.

Conclusion: Having T2DM was significantly associated with on average 22.5 sedentary minutes more per day. The results suggest that next to PA, sedentary behaviour could be an important determinant of the development and management of T2DM.

Overall dietary characteristics of individuals with high consumption of beverages previously associated with risk of type 2 diabetes

L. Brunkwall, S. Hellstrand, M. Orho-Melander, U. Ericson; Diabetes and Cardiovascular Disease, Genetic Epidemiology, Lund University, Clinical Sciences, Malmö, Sweden.

Background and aims: Consumption of several beverages has been associated with risk of type 2 diabetes; high coffee and tea consumption has been associated with a decreased risk and high consumption of sugar-sweetened beverages (SSB) with an increased risk. Regarding juice and artificially sweetened beverages (ASB), the results are inconclusive. As beverages are part of our overall diet and lifestyle we hypothesized that high consumption of these beverages (SSB, ASB, juice, coffee and tea) may be associated with certain characteristics of the overall diet that could be difficult to take into account when analysing associations between beverage consumption and disease.

Materials and methods: Analyses were performed among 25 112 individuals (60% women, 45-74 years, mean BMI=25.6) without prevalent diabetes, cardiovascular disease or cancer from the population based Swedish Malmö Diet and Cancer Cohort. Intake of beverages, macronutrients and 24 food groups were obtained from a modified diet history method including a 7-day food record and a 168-item questionnaire. To examine food intakes across five intake groups of the different beverages, we used linear regression adjusted for age, sex, season, method, BMI, leisure time physical activity, total energy intake, smoking, education and alcohol intake. Bonferroni correction was applied to handle multiple testing and therefore statistical significance was assumed at $p < 0.002$ ($0.05/28 = 0.002$).

Results: We observed a high consumption of SSBs to be significantly associated with lower intakes of foods generally perceived as healthy; the largest intake differences between high and low consumers of SSBs were seen for fruits, vegetables, yoghurt, breakfast cereals, fiber rich bread and fish (all p -values for trend < 0.002). In contrast, high consumption of both tea and juice was significantly associated with higher intakes of foods perceived as healthy; largest differences were seen for fruits, vegetables and yoghurt (all p -values for trend < 0.002). High consumption of ASBs was significantly associated with higher intakes of low fat products; low fat milk and margarines (both p -values for trend < 0.002). High consumption of coffee associated with higher intakes of meat and high fat margarine and a lower intake of breakfast cereals (all p -values for trend < 0.002).

Conclusion: We observed that high consumption of beverages that have previously been associated with risk of type 2 diabetes strongly associates with characteristics of the overall diet. This might be of importance when interpreting future studies investigating beverage-disease associations.

Maternal smoking during pregnancy is associated with poorer aerobic fitness of offspring in young adulthood

M.P. Hagnäs^{1,2}, I. Mikkola², J. Jokelainen¹, H. Cederberg³, U. Rajala¹, S. Keinänen-Kiukaanniemi¹;

¹Department of Medicine, Center for Life Course Epidemiology and Systems Medicine, Oulu, ²Rovaniemi Health Centre, ³Department of Medicine, Kuopio University Hospital, Finland.

Background and aims: In Finland pregnant women are offered a cost-free health care at municipal maternity welfare clinics and health counselling is being given incl. adequate/excessive gestational weight gain (GWG) and maternal smoking. Our aim was to investigate the association of maternal pre-pregnancy body mass index (BMI), GWG and maternal smoking with aerobic fitness and weight in young men aged 19-28.

Materials and methods: Data consisted of 508 mothers and their offspring in the Northern Finland Birth Cohort (NFBC 1986) who entered military service at the Sodankylä Jaeger Brigade in 2005. The associations of weight, 12-minute running test result (Cooper test), smoking among offspring on entry to military service were evaluated with antenatal factors including maternal smoking, pre-pregnancy BMI and GWG in this prospective cohort study. Physical activity at the 15-16 years age was evaluated from questionnaires.

Results: Weight of conscripts whose mothers were overweight and gained excessive weight during pregnancy was higher (84.4 kg, SD 18.1) than those of overweight mothers whose weight gain was considered appropriate (73.5 kg, SD 12.5) ($p = 0.005$). Offspring of mothers who smoked > 10 cigarettes / day during pregnancy also had a lower Cooper test result (2237 m, 95% CI 1930-2544) compared to the offspring of mothers did not smoke during pregnancy (2537 m, 95% CI 2499-2574). Multivariate linear regression analysis showed that maternal smoking, low level of physical activity at 15-16 years age, conscripts own smoking and own BMI, however not maternal pre-pregnancy BMI or GWG, were independently associated with worsening of Cooper test result. According to mediation analysis, conscript's own BMI mediated the association of maternal pre-pregnancy BMI and GWG with the Cooper test result. Direct effect of maternal pre-pregnancy BMI on the Cooper test result of the offspring was 28% (regression coefficient of direct effect - 4.07, $p = 0.394$) and that of GWG was 60% (regression coefficient of direct effect - 5.51, $p = 0.092$). No association of birth weight and the Cooper test result was observed.

Conclusion: Maternal smoking during pregnancy had a long-term negative impact on the aerobic fitness of the offspring, observed during a 19-year follow-up. This study highlights the need of health-counsel for pregnant women concerning non-smoking and appropriate weight gain during pregnancy. Supervised exercise and smoking cessation groups for pregnant women via maternity clinics could be one way for attaining beneficial circumstances for pregnancy.

Table 1. Association of maternal pre-pregnancy body mass index, excessive gestational weight gain, maternal smoking, physical activity of offspring at 15–16 years age, conscript's body mass index and smoking with the change in the Cooper test result.

Variable	B (SE)	β	p

The association between sleep duration and insulin sensitivity: the EGIR-RISC study

F. Rutters¹, H. Besson², M. Walker³, A. Mari⁴, B. Balkau⁵, J.M. Dekker¹, on behalf of the EGIR-RISC Study group;

¹Department of Epidemiology and Biostatistics, VUmc, Amsterdam, ²PHARMO Institute for Drug Outcome Research, Utrecht, Netherlands, ³Medical School Newcastle University, UK, ⁴Institute of Biomedical Engineering, Padova, Italy, ⁵EpReC: Renal and Cardiovascular Epidemiology UVSO, Inserm U1081 Centre for Research in Epidemiology and Population Health, Villejuif, France.

Background and aims: In the past 10 years, over three-dozen studies reported a relationship between short sleep and disturbed glucose metabolism. Studies with insulin sensitivity assessed according to the gold standard hyperinsulinemic-euglycemic clamp are however still missing. We therefore aimed to evaluate the cross-sectional association between sleep duration and insulin sensitivity in the European Relationship between Insulin Sensitivity and Cardiovascular Disease (EGIR-RISC) study.

Materials and methods: We used data from the baseline measurements of the European, multi-centre EGIR-RISC study, which included 1259 clinically healthy men and women. Sleep and physical activity were measured objectively using a single-axis accelerometer, which was worn for at least 3 days and up to 8 days. Insulin sensitivity was measured by hyperinsulinemic-euglycemic clamp (M/I). Other markers of metabolic syndrome included levels of fasting plasma glucose, insulin, 2-h plasma glucose and insulin as well as BMI, waist circumference and blood pressure.

Results: In our current analysis, we included 797 participants (57% women, age 44±8 years). A weak U-shaped association between hours of sleep and M/I was observed: after adjustment for age and sex, M/I was 10.7 (-

4.4- 25.9), 3.6 (-10.2-17.4), -0.8 (-15.9-14.3) and 4.7 (-14.3-23.9) $\mu\text{molmin}^{-1}\text{kgffm}^{-1}\text{nM}^{-1}$ higher for the 6–7 hour group, 7–8 hour group, 8–9 and the >9 hour group, respectively, compared to the <6 h group. Additionally, we observed a J-shaped association for basal glucose: after adjustment for age and sex, glucose levels were 0.13 (0.02–0.24), 0.12 (0.02–0.22), 0.16 (0.05–0.27) and 0.19 (0.05–0.33) mmol/l higher for the 6–7 hour group, 7–8 hour group, 8–9 and the >9 hour group, respectively, compared to the <6 h group. Similar J-shaped associations were observed for basal insulin levels and 2-h glucose and insulin levels. No associations were observed for BMI, waist circumference or blood pressure.

Conclusion: Short and long sleep duration are weakly associated with insulin sensitivity and markers of glucose homeostasis in a healthy population. Prospective studies are needed to study the temporal associations in a healthy population.

Six year follow-up after CSII initiation: HbA_{1c} is significantly reduced without weight gain

H.U. Andersen, S. Hangaard, E.E. Hommel, M. Ridderstråle;
Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Meta analyses show that treatment with continuous subcutaneous insulin infusion (CSII) lowers HbA_{1c} by 0.3% compared to multiple daily injections (MDI) in adult populations. The longest observation period in the included RCTs was one year. An observational study included 331 patients that were observed for 5.5 years in ten clinics. In CSII treated patients, HbA_{1c} decreased 0.42% after 1 and 2 years, but only 0.2% after 5 years, when compared to time-matched MDI patients. In our clinic, we have previously found that the HbA_{1c} of 505 patients was reduced by 0.7% (females) and 0.5% (males) one year after CSII initiation. In the present study, our aim was to investigate the long term effect of shift from MDI to CSII on HbA_{1c} and weight.

Materials and methods: All patients were analysed for age, T1D duration, weight (kg), and HbA_{1c} (IFCC mmol/mol and DCCT %) four years before and six years after initiation of CSII. Data are mean±standard deviation. A *p*-value below 0.05 was considered statistically significant.

Results: Since 2002, 856 patient initiated CSII at our center. Mean age and T1D duration at CSII initiation were 39±14 years and 21±13 years. 622 patients that had data two years before CSII were included in the analysis. There was no significant change in weight or in HbA_{1c} prior to minus 2 years (Fig. 1). HbA_{1c} decreased by 1.6 mmol/mol during the ensuing period prior to initiation (1.1 mmol/mol between minus 2 years and minus 1 year (*p*<0.0002), and 0.5 mmol/mol between minus 1 year and initiation (*p*<0.02)). This reduction was concomitant to the patients receiving education on carbohydrate counting. The total reduction in HbA_{1c} from minus 2 years to one year after initiation was 8.3 mmol/mol (*p*<0.0001). The reduction in HbA_{1c} from initiation to six years after was 7.8 mmol/mol (*n*=183, *p*<0.0001). There was no significant rise or decline in HbA_{1c} between one and six years after CSII initiation.

Conclusion: Our one year data show a significant HbA_{1c} reduction after CSII initiation which is comparable, or better, than results from RCTs. Previous studies have suggested a diminishing effect of CSII on HbA_{1c} over time. By contrast, here we found a stable reduction of HbA_{1c} in the six year follow-up period after CSII initiation. Importantly, contrasting the effect of most other effective glucose-lowering strategies the effect was obtained without an increase in body weight.

Figure 1. HbA_{1c} (mmol/mol) and total body weight (kg) development over time in adult subjects transferring from multiple daily injection therapy to continuous subcutaneous insulin infusion. Patients with HbA_{1c} data available two years prior to pump initiation were included (*n*=622). Number of patients for each data point is given below the graph. Year "0" represents the HbA_{1c} closest to initiation (-13±26 days); the others represent averages of all data available for each patient during that year.

194

Effects on glycaemic variability and glyco-metabolic control of an insulin pump integrated with continuous glucose monitoring system in type 1 diabetic patients

P. Maffioli, D. Romano, A. D'Angelo, G. Derosa;
Internal Medicine and Therapeutics, University of Pavia, IRCCS Policlinico S.Matteo, Italy.

Background and aims: Often, insulin pump therapy is not enough to reach an adequate glycaemic control; this is particularly true in type 1 diabetic patients, where glycaemic fluctuations are very high. For this reason, in the latest years, continuous glucose monitoring system (CGMS) has become available. The aim of this study was to evaluate the effects of an insulin pump integrated with continuous glucose monitoring system (CGMS) compared to insulin pump alone on glycaemic control, and blood glucose variability in type 1 diabetic patients, in a case-control clinical trial. We also evaluated the degree of patients' satisfaction to treatment.

Materials and methods: We enrolled 38 type 1 diabetic subjects, with an inadequate glycaemic control (glycated hemoglobin >7.5%), with an insulin pump from at least three months. At baseline, patients were instructed to use a CGMS able to communicate with an insulin pump in an integrated system. The function of suspension of insulin delivery, in case of hypoglycemia, was activated. We evaluated: anthropometric measurements, glycated hemoglobin, fasting plasma glucose (FPG), postprandial glucose (PPG). These parameters were recorded at baseline, at 3 and 6 months after the placement of the device. Diabetes Treatment Satisfaction Questionnaire (DTSQ) was used to assess patients' satisfaction toward treatment. The primary analyzed variable was glucose measured by CGMS and evaluated using area under curve. Percentage of time spent (based on CGMS records) in different ranges of glucose was also analyzed. These two variables were analyzed using Wilcoxon signed rank test, and stepdown Bonferroni (Holm's) correction of *p*-values was applied to adjust *p*-values for multiple testing. The following variables were analyzed using Wilcoxon signed rank test: M value, glycated hemoglobin, mean blood glucose, number of hypoglycemia during CGMS (blood glucose ≤70 mg/dL), and standard deviation (SD) of glucose measured by CGMS. Mean amplitude of glycaemic excursions (MAGE) measured by CGMS was analyzed using *t*-test.

Results: After 6 months since the placement of the integrated system, there was a decrease of glycated hemoglobin, FPG and PPG compared to baseline (*p*<0.05 after 3 months, and *p*<0.01 after 6 months). The daily blood glucose variability, expressed as MAGE, was reduced after the placement of the integrated system. Mean blood glucose, as calculated from CGMS values, was significantly higher with insulin pump alone compared to insulin pump + CGMS (172.4±60.4 vs 153.1±51.3, *p*<0.05). M value with insulin pump + CGMS was lower compared to insulin pump alone between 7-8, 10-11, 17-18, and 23-24 h. The SD, and the MAGE values were significantly lower with insulin pump + CGMS compared to insulin pump alone (*p*<0.05). The MODD value at 7-8, and 10-11 h was lower with insulin pump + CGMS compared to insulin pump alone (*p*<0.05). Insulin pump + CGMS gave less time spent with glycemia <70 mg/dl and more time with glycemia between 70 and 180 mg/dL compared to insulin pump alone. There was a greater degree of satisfaction for the insulin pump integrated with CGMS according to the DTSQ.

Conclusion: The insulin pump integrated with CGMS better improved glycaemic control, glycaemic variability and patients' satisfaction in type 1 diabetic patients compared to insulin pump alone.

195

Medical imaging for performance characterisation of a novel continuous subcutaneous insulin infusion set

R.J. Pettis¹, N.G. Bolick¹, D.E. Sutter², B. Pflug³, B.W. Bode⁴, L.J. Hirsch³;

¹Parenteral & Translational Sciences, ²Corporate Clinical Development, BD Technologies, Research Triangle Park, ³Medical Affairs, BD, Franklin Lakes, ⁴Atlanta Diabetes Associates, USA.

Background and aims: Insulin pump therapy for Continuous Subcutaneous Insulin infusion (CSII) is a highly effective method of glycaemic control for diabetic patients. However, CSII set performance is often characterized as the “Achilles heel” of an otherwise sophisticated control system. An investigational flow-stabilizing infusion set with 28G, 6 mm side-ported polymer catheter has been designed to reduce infusion delivery pressures, stabilize flow performance, and minimize insulin flow stoppages that may occur without triggering pump alarms (e.g. “silent occlusions”). Medical imaging can be highly informational but is not a routine testing procedure for delivery devices. The objective of this study was to utilize various imaging techniques to characterize the *in vivo* flow and deposition performance of the investigational CSII set against control 6 mm and 9 mm commercial polymer sets in both animal and human studies.

Materials and methods: *In vivo* fluoroscopy was performed using both static and dynamic imaging during bolus (10U) infusion of iodinated contrast media on anesthetized swine from the investigational set and commercial controls. Images were analyzed for location of device placement in the tissue, bolus depot patterning, and occurrence of delivery faults such as incomplete insertion and leakage. A corollary human MRI study with saline placebo was performed in 8 non-diabetic subjects across multiple bolus volumes (2–20U) and various routine insulin infusion sites (arm, thigh, abdomen, and gluteus). The addition of MR contrast enhancers was not required for effective depot visualization.

Results: For each imaging modality, contrast-filled polymer catheters were visible *in situ*. Depots were clearly visible after bolus administration, even at low bolus volumes. The investigational ported set typically exhibited more diffuse subcutaneous (SC) depot patterns in contrast to denser more localized depots observed from marketed sets. Side-port flow was typically most readily observed during stepwise boluses of increasing volume (Figure 1). The investigational set demonstrated effective SC placement and placebo delivery at all anatomical sites tested sites during the human trial.

Conclusion: Both fluoroscopic and MR imaging techniques provide effective characterization of CSII set insertion and bolus delivery performance at relevant anatomical sites and may enable better comparative device performance assessment. The investigational catheter set porting appears to create an auxiliary tissue flow pathway that may reduce occlusion and stabilize flow.

Figure 1. Human MR transverse images of SC infusion from 6mm CSII sets (A, C ported investigational sets; B commercial device) in upper gluteal region at increasing bolus volumes (2, 10, 20U). Arrow highlights side-port delivery on device A. Investigational sets show increased depot diffusion.

196

Effect of sensor augmented pump treatment on fear of hypoglycaemia and quality of life in subjects with dysregulated type 1 diabetes

H.-C. Andersen, H. Andersen, E. Hommel, M. Ridderstråle; Steno Diabetes Center, Gentofte, Denmark.

Background and aims: To investigate the one year effect of sensor augmented pump (SAP) treatment on glycaemic control and quality of

life of subjects with dysregulated type 1 diabetes (DT1D) and/or problematic hypoglycaemia.

Materials and methods: As part of quality assurance we studied 64 patients on insulin pump (32 male and 32 female) with DT1D (HbA1c >69 mmol/mol for >12 months), or problematic hypoglycaemia (unawareness or ≥one severe episode during the preceding year) who were offered SAP. Primary endpoints were decrease in HbA1c and effect on quality of life as evaluated by the Hypo Fear Scale (HFS), Problem Areas in Diabetes (PAID), and WHO5. Non-parametric statistical analyses were used to compare responses before and one year after SAP was initiated. Data are expressed as mean±sem.

Results: The average age was 44±1.7 years. Baseline HbA1c was 75.3±1.5 mmol/mol ($n=64$), HFS 38±3 ($n=53$), PAID 26.6±2.6 ($n=54$); 19.4±2.7 and 35.0±4.1 for males ($n=29$) and females ($n=25$), respectively ($p=0.004$), and WHO5 15.1±0.7 ($n=59$). More than five episodes of severe hypoglycaemia had been experienced by 33%. Any degree of hypoglycaemia unawareness was significantly more common in this group ($p=0.02$). After one year 48 patients (75%) were still using SAP. These were significantly older than those who stopped (45±2 vs. 39±3, $p=0.04$) but there was no difference in duration of diabetes or time on pump. Average sensor use was 9.0±0.6 out of 12 months; 34 patients (71%) reporting a use greater than 2/3 of the time. HbA1c decreased in both SAP users and in those who stopped using SAP (from 73.8±1.6 to 66.1±1.7 [$n=48$; $p<0.0001$] and 80.3±3.5 to 72.9±3.2 [$n=14$; $p=0.001$], in users and non-users, respectively). There was no correlation between time on SAP and HbA1c lowering. By 12 months HFS had decreased significantly (from 38.1±3.2 to 28.9±3.4; $n=39$, $p=0.001$), as had PAID (from 25.2±2.6 to 20.9±2.6; $n=41$, $p=0.007$), whereas there was no difference in WHO5. PAID>30, a level indicating high diabetes related distress, was found in 62% of those who stopped using sensor, compared to 31% for the SAP users, ($p=0.047$). The influence of SAP on the top three PAID score questions at baseline are shown in Table 1. WHO5 score<13, indicating declined wellbeing, was found in 16% of the SAP users and 43% of patients who stopped using sensor ($p=0.035$).

Conclusion: Additional to a significant improvement in HbA1c, SAP seems to offer specific support concerning the fear of hypoglycaemia and diabetes related distress to subjects with T1D who are prone to hypoglycaemia with no negative impact on overall wellbeing of the patients from the use of sensors.

Which of the following diabetes issues is currently a problem for you?	Baseline	12 mth	P
9. Worrying about low blood sugar reactions? ($n = 44$)	1,47	0,93	0,004
12. Worrying about the future and the possibility of serious complications? ($n = 46$)	2,15	1,82	0,01
20. Feeling "burned out" by constant effort needed to manage diabetes? ($n=46$)	1,37	1,05	0,03

Table 1. Top three PAID score questions at baseline.

HbA_{1c} improvement with less hypoglycaemia in patients with type 1 diabetes wearing an artificial pancreas for two months from dinner to breakfast

J.H. DeVries¹, J. Place², J. Kroppf¹, S. del Favero³, F. di Palma⁴, G. Lanzola⁴, A. Farret², F. Boscari², A. Avogaro⁵, S. Galasso⁵, D. Bruttomesso⁵, E. Renard², C. Cobelli³, L. Magni⁴, AP@home consortium;

¹Internal Medicine F4-222, Academic Medical Center, Amsterdam, Netherlands, ²Endocrinology, Diabetes, Nutrition, Montpellier University Hospital, France, ³Information Engineering, University of Padova, ⁴Civil Engineering and Architecture, University of Pavia, ⁵Internal Medicine, University of Padova, Italy.

Background and aims: Wearable artificial pancreas (AP) at home from dinner to breakfast appears a safe concept for first routine use in patients

with Type 1 diabetes (T1D). We explored this concept in the first AP trial with sufficient length to assess HbA_{1c}.

Materials and methods: Thirty-five adult T1D patients with insulin pumps and an HbA_{1c} between 7.5 and 10% were enrolled in a randomized crossover trial comparing AP use from dinner to wake-up time and sensor augmented pump (SAP) during day-time vs. all day SAP under free-living conditions. The design included a run-in of 2 weeks with SAP and a wash-out of 4 weeks between 2 periods of 2 months. AP was achieved by connecting a continuous glucose monitor (CGM) and insulin pump to a smart-phone which ran a Model Predictive Control algorithm. CGM data from the last 6 weeks of each period were analyzed on an intention-to-treat basis with % time in target [70–180 mg/dL] from 20:00 to 08:00 as primary endpoint. HbA_{1c} change was analysed with an ANOVA model with patient, period and treatment as factors.

Results: Three patients dropped out, 1 before and 2 shortly after randomization, due to poor system acceptance. 18 (56%) of 32 analysed patients were female, HbA_{1c} was 8.2±0.6% and age 47.0±11.2 years. From 20:00 to 08:00, time in target was higher with AP: 67.0 vs. 57.8% (paired difference 8.2%, IQR 5.0–14.4, p<0.0001), through a reduction in %time both >180 mg/dL and <70 mg/dL: 31.8 vs. 38.6% (paired difference 6.7%, 95%CI 3.7–9.8, p<0.0001) and 1.7 vs. 3.0% (paired difference 1.3%, IQR 0.5–3.0, p<0.0001). Also over 24 hrs, higher time in target was seen with AP (63.7 vs. 58.9%, paired difference 5.0%, IQR 1.7–7.8, p=0.00017), again through a reduction in %time both >180 mg/dL (33.5 vs. 36.9% paired difference 4.3% IQR 0.7–7.4, p=0.00179) and <70 mg/dL (2.2 vs. 3.0%, paired difference 1.0% IQR 0.3–1.7, p=0.00013). HbA_{1c} was reduced 0.18% more on AP (95%CI 0.00 to 0.36, p=0.047).

Conclusion: AP from dinner to wake-up time increases % time in target range during this time period and also over 24 hours, due to a decrease in time both above and below target and with a significant decrease in HbA_{1c}. These results support AP from dinner to breakfast as a safe and beneficial option for moving to the market.

Delivery of exenatide by subdermal placement of ITCA 650 in a nonclinical model demonstrates 1 year of continuous exposure and tolerability

D.T. Zane¹, L. Thorner¹, M. Baron², M. Charan¹, T. Zoetis³, R. Fielding⁴, C. Papagiannis⁵, T. Alessi¹;

¹Product Development, Intarcia Therapeutics, Hayward, ²Clinical Research, Intarcia Therapeutics, Boston, ³SciLucent, Herndon, ⁴Biologistic Services, Boulder, ⁵MPI Research, Mattawan, USA.

Background and aims: ITCA 650 is a mini osmotic pump designed to deliver exenatide as a continuous zero-order subdermal infusion. In an ongoing 2-year carcinogenicity study, rats received ITCA 650 at exenatide doses of 0, 3, 10 (females), 20 (males) and 40 mcg/d. The low and high doses were selected to provide approximately 4-fold and 25-fold exposure multiples of the anticipated clinical dose (60 mcg/d).

Materials and methods: On Day 1, an ITCA 650 osmotic minipump or placebo was placed subdermally in each rat. At 6-month intervals, devices were removed and replaced with another of the same dose at the same site to provide continuous exposure during the 2-year study. Plasma exenatide was measured by a validated ECL assay in toxicokinetic group animals on Day 365/366.

Results: There was no evidence of systemic toxicity and survival was not adversely affected by treatment. As expected from the pharmacology of exenatide, a decrease in body weight gain (up to 40% vs control) was noted in ITCA 650-treated groups. Macroscopic evaluation of tissues local to the placement site revealed a minimal tissue response to the device. Despite repeated removal and replacement of devices during the study, microscopic observations were minimal to mild in all groups, with minimal inflammation in some animals. Exenatide exposures increased as

the dose increased from 3 mcg/d to 40 mcg/d. Comparing Day 365 AUC_{24h} with human AUCs at the clinical dose (60 mcg/d) showed that this study achieved exposure multiples of at least 7.3-fold at the mid dose and 18.1-fold at the high dose.

Conclusion: These results are relevant to the human experience as prolonged exposure and repeat minipump placements did not result in any local or systemic toxicologic differences between the active and control groups.

OP 34 Biomarkers of beta cell autoimmunity

199

Non-invasive determination of the beta cell mass with ¹¹¹In-exendin-3 in rodent models for spontaneous type 1 diabetes

L. Joosten¹, M. Brom¹, D. Bos¹, C. Frielink¹, H. Peeters², E. Himpe³, L. Bouwens³, O.C. Boerman¹, M. Gotthardt¹;

¹Department of Radiology and Nuclear Medicine, Radboud university medical center, Nijmegen, ²Radiation Oncology, GROW munc, Maastricht, Netherlands, ³Cell differentiation, Vrije Universiteit, Brussel, Belgium.

Background and aims: The beta cell mass (BCM) plays a key role in the development and progression of diabetes, but the onset of beta cell loss and the relationship between loss of beta cell mass and beta cell function still needs to be unraveled. A non-invasive method to determine the BCM *in vivo* allows measurement of the BCM over time during the development and progression of type 1 and 2 diabetes. Exendin-3 is a stable analogue of glucagon-like peptide 1 (GLP-1) and has high affinity for the GLP-1 receptor, which is specifically expressed on beta cells. Recently, targeting of the GLP-1 receptor on beta cells was proven to be a successful method to determine the beta cell mass *in vivo* in a rat model of chemically induced beta cell loss. Furthermore, in a first clinical proof-of-principle study these preclinical data were confirmed. In this study we investigated the potential of ¹¹¹In-exendin-3 to determine the BCM *in vivo* in a mouse and rat model that closely mimic the development of type 1 diabetes in humans: Non-obese Diabetic (NOD) mice and BioBreeding Diabetes Prone (BBDP) rats. In these models the potential of SPECT, the relationship between the BCM, exendin uptake in the pancreas and insulinitis were investigated.

Materials and methods: NOD mice (n=78) of 7-21 weeks old and BBDP rats (n=45) of 4-18 weeks of age were injected intravenously with 15 MBq ¹¹¹In-exendin-3. SPECT/CT Images were acquired 1 h p.i. and the animals were euthanized after SPECT/CT acquisition. The pancreas and relevant organs were dissected, weighed and the radioactivity in the organs was measured in a gamma counter. The pancreas was fixed in formalin, embedded in paraffin and sections were used for histology, determination of the beta cell mass by morphometric analysis and degree of insulinitis.

Results: With SPECT the pancreas in both rats and mice was visualized. Biodistribution showed high uptake of ¹¹¹In-exendin in the pancreas in healthy mice of 7 weeks of age (15.1±2.5%ID/g) and a significantly reduced uptake in diabetic mice of 21 weeks old (10.1±3.8%ID/g, p=0,0379). In BBDP rats a reduction in pancreatic uptake of more than ninety percent was found. In BBDP rats and NOD mice the correlation (Pearson) between the BCM (mg) and pancreatic uptake (%ID) was 0.80 (p<0,0001) and 0.42 (p<0,0002), respectively. *Ex vivo* autoradiography showed high uptake in the exocrine pancreas in mice, but not in rats, which might explain the difference in correlation between BCM and uptake between both models. In severely diabetic rats, with no insulin-positive cells, the pancreas was undetectable by autoradiography. Furthermore, insulinitis did not have an influence on the uptake of exendin in the pancreas.

Conclusion: In conclusion, the BCM can be determined after injection of ¹¹¹In-exendin-3 in a mouse and rat model for type 1 diabetes, closely mimicking the human development of type 1 diabetes. Furthermore, the pancreas can be visualized with SPECT in both models. These results indicate that ¹¹¹In-exendin-3 is a promising tracer to determine the BCM during the development of type 1 diabetes, without interference of severe insulinitis or insulin treatment. However, due to exocrine uptake of exendin in mice, rat models would be more suitable than mouse models when studying the GLP-1R in diabetes.

Immune subsets profile through disease onset, remission phase and final establishment in type 1 diabetic children

C. Martins¹, A.L. Fitas², G. Nunes¹, R. Pina², L. Lopes², S. Lenzen³, L.M. Borrego¹, C. Limbert²;

¹CEDOC-NMS, ²HDE - CHLC, Lisbon, Portugal, ³MHH, Hannover, Germany.

Background and aims: Type 1 diabetes (T1D) is an autoimmune disease with regulatory/effector T cell imbalance. Its autoinflammatory nature makes it possible to develop new therapies based on immune-modulatory strategies. Immunologic characterization along the natural history of the disease (onset, remission and established T1D) is essential for better targeting the immune treatment and to identify key immunological markers that will allow monitoring future interventions towards immune balance restoration. The aim of this study was to evaluate the dynamics of T cell subsets from T1D onset to final establishment, in children.

Materials and methods: T1D children (n=24) were followed along 3 time points of the disease (t1 - onset, t2 - remission, t3 - establishment). Peripheral blood (PB) samples from patients and matched controls were analyzed by flow cytometry. Treg were identified as the CD4+CD25+CD127dim subset within CD3+T cells. Th1, Th17, Tc1 and Tc17 cells were identified through the production of IFN-γ and IL17 within CD4 and CD8 T cells, after a 5 h stimulation with PMA+Ionomycin, at 37°C, 5% CO₂.

Results: Compared to controls, in t1, T1D children presented a tendency for lower % of Treg, recovering in t2. At t3, Treg % and absolute counts were significantly impaired, also compared to t1 and t2 (p<0.05). Again in t1, a significantly lower % of IFN-γ secreting cells (Th1 and Tc1) was observed (p<0.05) compared to t2 and t3. Despite this tendency for higher values in the final t2 and t3 evaluations, none of the time points significantly differ from controls. In contrast, compared to controls, Th17 cells were significantly impaired in all time points (p<0.05), in particular t1. Tc17 present the same profile, but their % recover to levels similar to controls in t3.

Conclusion: To our knowledge, this is the first study evaluating the immune profile throughout T1D stages. Our data points to a more pro-inflammatory profile as the disease evolves, with loss of Treg, and increasing IFN-g, as well as IL-17, producing T cells. Although the status of Treg in T1D onset is controversial, our study shows a significant Treg imbalance only after disease establishment. The normal values of Treg in remission may be related to the apparent control of the immune response at this stage. The increasing Th1/Tc1 compartments observed in T1D establishment are in accordance with the less effective presence of suppressive Treg. Also, remission corresponds to regeneration of β-cells and normalization of glycaemia, which can lead to new inflammatory events with subsequent Th1/Tc1 differentiation and activation. A more prominent Th17 response in T1D has been suggested. We report lower circulating Th17 cells in T1D patients, though recovering at established disease. Accordingly, recent studies report increased Th17 cells in pancreatic lymph nodes (PLN), but not in PB, speculating the migration of Th17 to target organs later in the disease. In our study, circulating Th17 and Tc17 were impaired in early stages of T1D, when massive destruction of pancreatic tissue occurs, which suggests an early migration of Th17 into target tissues, associated with tissue damage events. The chemotactic capacity of Th17 towards neutrophils can reinforce our data, as PB neutrophils were impaired in T1D patients, mostly in t1 and t2. PLN immune profile evaluation would help the interpretation of our data on the quest for immune markers and therapeutic targets for T1D.

Relationship between islet specific autoantibodies at the diagnosis and the first autoantibody marking initiation of the autoimmune process in children with type 1 diabetes

J. Ilonen¹, J. Lempainen², A. Hammais², T. Härkönen³, J. Toppari¹, R. Veijola⁴, M. Knip³;

¹University of Turku, ²Immunogenetics Laboratory, University of Turku, ³University of Helsinki, ⁴University of Oulu, Finland.

Background and aims: Serum autoantibodies specific for islet antigens characterize the onset of type 1 diabetes and also predict development of the disease. Demographic and genetic associations with the presence of specific autoantibodies have been described suggesting immunological heterogeneity in the immunology of the disease. Prospective follow-up studies collecting samples from children at genetic risk starting from birth on have recently made it possible in many cases to detect the first islet autoantibody to appear. This has revealed patterns associated with the specificity of this autoantibody. In the present study we aimed to compare islet autoantibodies detected at the diagnosis of overt diabetes with the first autoantibodies initiating the diabetes associated autoimmunity.

Materials and methods: Antibody data from the children participating in the follow-up cohort of the Finnish Diabetes Prediction and Prevention (DIPP) study who had developed clinical type 1 diabetes were analysed. A single first islet autoantibody out of three (IAA, GADA and IA-2A) could be identified in 135 of 233 (57.9%) children who had developed type 1 diabetes.

Results: The results are summarized in the Table. The most common initialising autoantibody was IAA followed by GADA and IA-2. However, when the presence of various antibodies was compared at diagnosis, IA-2A was the autoantibody most often detected followed by IAA and GADA.

Conclusion: These results can be used to estimate to what extent the presence of various autoantibodies at diagnosis reflects the initiating autoantibody. Because of antigen spreading and disappearance of some autoantibodies (especially in the case of IAA), during the prediabetic period autoantibody status at diagnosis gives limited information on the development of islet autoimmunity. In addition antibody status at diagnosis is largely affected by the variable proportion of different first autoantibodies at various ages.

Table. Autoantibodies present at diagnosis divided according to the first autoantibody initialising the autoimmunity and first antibody to appear in children positive for different autoantibodies at diagnosis

First autoantibody to appear	Autoantibodies present at diagnosis					
	IAA		GADA		IA2-A	
	N	%	N	%	N	%
IAA (N=82)	60	73.2	36	43.9	61	74.4
GADA (N=37)	16	43.2	33	89.2	29	78.4
IA-2A (N=16)	7	43.8	4	25	16	100

Autoantibody present at diagnosis	First autoantibody to appear					
	IAA		GADA		IA2-A	
	N	%	N	%	N	%
IAA (N=83)	60	72.3	16	19.3	7	8.4
GADA (N=73)	36	49.3	33	45.2	4	5.8
IA-2A (N=106)	61	57.5	29	27.4	16	15.1

Functional defects of regulatory T cells and the influence of age in naïve and memory T cells in new-onset type 1 diabetes and first degree relatives

G. Treiber¹, B. Prietl¹, E. Fröhlich-Reiterer², M. Tauschmann², A. Ribitsch¹, E. Lechner¹, W. Graninger³, T.R. Pieber¹;

¹Division of Endocrinology and Metabolism, ²Division of Diabetes and Endocrinology, ³Division of Rheumatology and Immunology, Medical University Graz, Austria.

Background and aims: T cells are key mediators of autoimmune diseases like type 1 diabetes (T1D) and regulatory T cells (Tregs) are a critical subset that plays an indispensable role in maintaining immunotolerance. In the present study, we aimed to assess number and function of Tregs as well as naïve and memory T cell population in children and adults with new-onset T1D compared to first degree relatives (FDR) and healthy controls and we evaluated age effects on T cell subsets.

Materials and methods: Peripheral blood cells from 14 adult T1D (age: 35±12ys), 29 juvenile T1D patients (age: 12±4ys), age matched FDR (20 children, 38 adults) and healthy controls (17 children, 55 adults) were quantified by a multi-parameter FACS analysis. Apoptosis and suppressive capacity of Tregs were measured in vitro with FACS sorted Tregs and stimulated autologous effector T cells.

Results: The suppressive capacity of Tregs was decreased in children with T1D (mean±SEM; 20.6±6.6% vs 39.4±4.2% vs 43.8±6.4% p=0.024) and adult T1D patients (7.5±8.1% vs 34.5±3.6% vs 39.7±2.0% p<0.001) in comparison to FDR and healthy. Apoptosis of Tregs was only significantly increased in children with T1D (2.83±0.68% vs 1.24±0.31% vs 0.67±0.19%, p=0.026) but apoptosis of effector T cells were increased (p=0.001) in adults with T1D. Number and function of Tregs did not change with age within the group of new onset T1D, FDR or healthy controls but naïve CD4⁺CD25^{hi} decreased and memory CD4⁺CD25^{hi} T cells increased with age in each group.

Conclusion: Our data show that Tregs function is impaired in juvenile and adult new-onset T1D, which is already seen in FDR. Furthermore age influences the frequencies of naïve and memory CD4⁺CD25^{hi} T cells and the functional differences in peripheral Tregs suggest an age dependent defect of Tregs function in the pathogenesis of T1D.

Autoantibodies to posttranslationally modified insulin in type 1 diabetes

R. Strollo^{1,2}, C. Vinci¹, M.H. Arshad¹, D. Perrett³, C. Tiberti⁴, F. Chiarelli⁵, N. Napoli², P. Pozzilli^{2,6}, A. Nissim¹;

¹Centre for Biochemical Pharmacology, Queen Mary University of London, UK, ²Endocrinology & Diabetes, University Campus Bio-Medico, Rome, Italy, ³BioAnalytical Science, Queen Mary University of London, , ⁴Department of Experimental Medicine, Sapienza University of Rome, Italy, ⁵Department of Pediatrics, University of Chieti, Italy, ⁶Centre for Diabetes, Queen Mary University of London, London, UK.

Background and aims: Insulin is the most specific antigen for pancreatic beta-cells and a primary potential autoantigen in type 1 diabetes. Although insulin autoantibodies (IAA) are the earliest marker of beta-cell autoimmunity only half of children with newly-diagnosed type 1 diabetes and fewer patients diagnosed in adult age are positive to IAA. The aim of this investigation was to determine if insulin, posttranslationally modified by reactive oxidants (oxPTM) present within the inflamed beta-cells microenvironment, could generate neoantigenic epitopes.

Materials and methods: oxPTM of insulin were induced by incubation with reactive oxidants such as ribose and various reactive oxygen species (ROS). Modifications were analysed by polyacrylamide gel electrophoresis, 3-dimensional fluorescence and mass spectrometry. Reactivity to posttranslationally modified insulin by ROS (oxPTM-INS)

was measured by ELISA, radioimmunoassay and Western blotting, using sera from 114 patients with newly-diagnosed type 1 diabetes and 113 healthy controls.

Results: Mass spectrometry mapped oxPTM of insulin to chlorination of Tyr16 and 26; oxidation of His5, Cys6 and Phe24 and glycation of Lys29 and Phe1 in B-chain. Significantly higher binding to oxPTM-INS vs native-insulin was observed in type 1 diabetic individuals ($P<0.0001$). oxPTM-INS autoantibodies showed better sensitivity than IAA (79 vs. 60% with the same 99% specificity) and were able to detect 31% of IAA-negative patients. The combined measurement of IAA and oxPTM-INS autoantibodies raised the detection of insulin autoimmunity to 91% of subjects with new-onset type 1 diabetes. Binding to oxPTM-INS did not correlate with blood glucose or age and was directed toward oxPTM-INS fragments with slower mobility than native insulin.

Conclusion: These data suggest that oxPTM-INS is an autoantigen in type 1 diabetes and that antibodies to oxPTM-insulin are present in the large majority of new-onset type 1 diabetes patients. Overall, over 90% of individuals with new-onset type 1 diabetes presented autoimmunity to insulin, either IAA or oxPTM-INS autoantibodies.

(sRAGE) isoform is thought to bind RAGE ligands within the circulation. We aimed to reduce AGEs early in life in the NOD mouse model by delivering a short pulse of recombinant human sRAGE, and to determine the therapeutic effect on diabetes incidence, beta cell function and immune cell infiltration.

Materials and methods: Groups of female NOD mice were randomized to either vehicle (PBS) or recombinant human sRAGE (25 μ g twice daily) via intraperitoneal injection from day 50–64 of life. To determine the effect of sRAGE therapy on the immune system, glucose homeostasis and diabetes incidence, mice were followed until 0 ($n=6$), 2 ($n=14$) or 22 ($n=15$) weeks post-treatment, respectively.

Results: Two weeks of sRAGE therapy afforded protection from diabetes at day 221 of life compared to mice given the vehicle control only (13% vs 53%; $p=0.01$). This reduction in diabetes associated with a progressive decrease in non-fasted ($p<0.0001$) and fasted blood glucose levels ($p=0.02$) after 22 weeks post sRAGE treatment compared to vehicle control. Although oral glucose tolerance tests revealed no change in the area under the glucose curve between groups (835 vs 899 mmol/L.120 min; $p=0.19$), there was an increase in the area under the insulin curve demonstrating an increase in insulin secretion (29.8 vs 37.1 ng/mL.120 min; $p=0.02$). Flow cytometry analysis confirmed an increase in splenic numbers of CD11b⁺CD11c⁺CD8⁺RAGE⁺ dendritic cells (2.7-fold; $p=0.008$), as well as classical (F4/80⁺CD11c⁺Ly6C⁺; 2-fold; $p=0.04$) and non-classical (F4/80⁺CD11c⁺Ly6C⁻; 1.9-fold; $p=0.02$) macrophages directly after sRAGE therapy compared to vehicle alone.

Conclusion: These results demonstrate for the first time that short-term, recombinant human sRAGE therapy prediabetes, has long lasting effects that improve insulin secretion and autoimmune diabetes incidence. The mechanism responsible for these improvements by sRAGE remain to be elucidated, but may involve changes to antigen presenting cells such as macrophages and dendritic cells.

Delivery of recombinant human soluble receptor for advanced glycation end products delays autoimmune diabetes in the NOD mouse model

D.J. Borg¹, S. Leung^{1,2}, A. Zhuang¹, A. Fotheringham¹, D. McCarthy¹, J. Di Trapani², P.-H. Groop³, M. Knip³, J. Forbes^{1,4},

¹Mater Research Institute- University of Queensland, Brisbane, ²School of Natural Sciences, Griffith University, Brisbane, Australia, ³University of Helsinki, Helsinki, Finland, ⁴Mater Clinical School, The University of Queensland, Brisbane, Australia.

Background and aims: Like other autoimmune diseases in developed nations, the risk of developing type 1 diabetes (T1D) is increasing, which remains unexplained, and is postulated to occur as a result of environmental triggers. Recently, circulating advanced glycation end products (AGEs) and their receptor, receptor for AGEs (RAGE), have been shown to be altered in children prior to T1D diagnosis. The soluble RAGE

OP 35 Assembling adiposity: building fat tissue

Intrinsic depot-specific differences in the angiogenic potential of ASC
M. Azorin-Ortuño, B. Oñate, G. Vilahur, L. Badimon;
 Cardiovascular Research Center, CSIC-ICCC, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Background and aims: Fat body distribution is known to be an important factor for the development of metabolic and cardiovascular diseases. Regional differences include variation in the residing cell populations and the vasculature. Fat cell progenitors (adipose-derived stem cells, ASC) are considered one of the most abundant (15–50% of total cells) and important cellular population within adipose tissue (AT) because their active role in the modulation of tissue expansion and homeostasis, producing paracrine factors and metabolic signals. The expansion of AT is closely associated with the development of its vasculature and the regulation of AT angiogenesis is emerging as a promising therapeutic target in obesity. Our objective was to explore the role of ASC isolated from the two main adipose depots, subcutaneous and omental visceral fat, in the modulation of AT angiogenesis.

Materials and methods: ASC were isolated from omental (omASC) and subcutaneous (subASC) fat paired samples obtained from metabolically-healthy morbidly obese (ob, n=13, 6 M/7 F, BMI=43.3±5.1 kg/m², age: 33.4±9.5 years) and metabolically-healthy control individuals (n-ob, n=6, 5 M/1 F, BMI=28.7±2.7 kg/m², age: 43.7±10.5 years). ASC were in vitro expanded, and gene expression and protein levels were evaluated by real-time PCR and WB, respectively.

Results: The gene expression level of a set of pro-angiogenic and anti-angiogenic molecules was analyzed: VEGFA, VEGFB, VEGFC, TSP1, and TGFβ1. The genes encoding for VEGFB, TSP1 and TGFβ1 showed a similar expression pattern and expression levels in ob and n-ob individuals, being significantly up-regulated in subASC compared with omASC, with fold-changes ranging from 2 to 3 for VEGFB and TGFβ1, and reaching 10-fold up-regulation for TSP1, further confirmed at protein level. For VEGFA and VEGFC, we only observed depot-specific differences in ob individuals. The expression of VEGFA in subASC was 2.4-fold higher than in omASC, and 2-fold higher than in the counterpart from n-ob individuals. Moreover, correlation analysis revealed that the expression levels of VEGFA in omASC, but not in subASC, negatively correlated with serum cholesterol levels ($r=-0.454$, $p=0.05$). VEGFC was the only angiogenic factor with higher expression in omASC than in subASC, showing a slight (1.2-fold up-regulation) but significant ($p=0.012$) differential expression. A range of endothelial cell (EC) markers (CD105, vWF, VEGFR1, and VEGFR2) was explored. We did not find depot-specific differences in the expression of CD105 and vWF. Interestingly, high significant differences, and opposite pattern, were observed in the expression of VEGFR1 and VEGFR2, in both ob and n-ob. The expression of VEGFR1 was higher in subASC compared with omASC (2.55±1.96 arbitrary units (AU) vs 0.22±0.18 AU, $p<0.001$, ob; 1.33±0.57 AU vs 0.29±0.22 AU, $p<0.01$, n-ob), whereas VEGFR2 showed the opposite trend, moderate gene expression in omASC (1.76±1.40 AU, ob; 1.45±1.39 AU, n-ob) and almost undetectable expression in subASC, further confirmed at protein level. Unexpectedly, omASC did not show in vitro EC differentiation capacity.

Conclusion: The results show a more active role of subASC producing pro and anti-angiogenic paracrine factors than omASC. VEGFA and VEGFC appear as important factors in obesity. Due to the differential expression of VEGFR2 and VEGFR1, there is a depot-specific role for VEGFA in ASC that is independent of EC differentiation potential.

The role of BMP2 in the pathophysiology of obesity

M. Unthan¹, E. Guiu- Jurado², T. Wohland¹, D. Schleinitz¹, K. Ruschke³, M. Kern⁴, B. Gutsmann¹, N. Klötting¹, A. Tönjes⁴, M. Stumvoll^{1,4}, M. Scholz^{5,6}, M. Blüher^{1,4}, P. Kovacs¹;

¹IFB Adiposity Diseases, University of Leipzig, Germany, ²Department of Medicine and Surgery, University Rovira i Virgili, Tarragona, Spain, ³Institute for Chemistry and Biochemistry, Freie Universität Berlin, ⁴Department of Medicine, University of Leipzig, ⁵Institute of Medical Informatics, Statistics and Epidemiology, University of Leipzig, ⁶LIFE Research Center, University of Leipzig, Germany.

Background and aims: Besides its known functions in the embryonic development the Bone Morphogenetic Protein 2 (BMP2) may affect adipogenesis. Our aim was to investigate the potential role of BMP2 in the pathophysiology of obesity and related traits and to uncover genetic variants determining the variability in circulating BMP2 levels.

Materials and methods: Circulating BMP2 levels were measured by commercially available ELISA in serum samples from subjects derived from two phenotypically well characterized cohorts: the Sorbs (n=638) and the Leipzig cohort (n=489). We measured *BMP2* mRNA expression by qRT-PCR in 632 paired samples of human subcutaneous and visceral adipose tissue. We also conducted a Genome Wide Association Study (GWAS) for circulating BMP2 in the Sorbs using the GenABEL Package of R for HapMap imputed genotypes generated by Affymetrix Gene chip arrays (500 K and 6.0) (n=580).

Results: BMP2 serum levels were significantly lower in obese (BMI>30 kg/m², n=248) compared to lean subjects (BMI<25 kg/m², n=250; $p<0.05$ adjusted for age and sex). Consistently, they correlated negatively with waist circumference, Waist- to Hip- Ratio (WHR) and Waist- to-Height- Ratio (WHtR) (adj. $p<0.05$). Furthermore, *BMP2* mRNA expression in visceral and subcutaneous adipose tissue correlated positively with BMI (n=620; adj. $p<0.001$) and related traits like waist circumference (adj. $p<0.001$) and circulating blood lipids (n=110; adj. $p<0.05$). After adjusting for sex, age, BMI and inflation factor, 45 single nucleotide polymorphisms (SNPs) showed association with circulating BMP2 at $p<1\times 10^{-5}$, including rs918604 ($p=1.77\times 10^{-7}$) in RGS7BP (Regulator of G-Protein Signalling 7 Binding Protein), rs17111592 ($p=6.5\times 10^{-7}$) in USP24 (Ubiquitin Specific Peptidase 24) and rs7799603 ($p=1.75\times 10^{-6}$) in CNTNAP2 (Contactin-associated Protein-like 2) locus.

Conclusion: Our data suggests that BMP2 is related to the pathophysiology of obesity and highlights the role of genetic variation in the regulation of circulating BMP2 levels.

Reduced SIRT1 and SIRT2 expression in visceral adipose stem cells may promote visceral fat expansion in human obesity

S. Perrini, P. Nigro, S. Porro, A. Cignarelli, C. Caccioppoli, A. Natalicchio, R. Ficarella, L. Laviola, F. Giorgino;
 Endocrinology & Metabolic Diseases, University of Bari, Italy.

Background and aims: Adipose tissue expands as a consequence of hypertrophy of preexisting fat cells and hyperplasia by recruitment of adipose stem cells (ASC) into the adipogenic program. SIRT1 and SIRT2 have been involved in regulation of adipocyte differentiation in rodent cells. In this study, we investigated the role of SIRT1 and SIRT2 in human adipocyte differentiation in obesity.

Materials and methods: Subcutaneous (Sc)- and visceral (V)-ASC were isolated from fat biopsies of 30 obese (Ob) and 30 non-obese (n-Ob) donors and differentiated in vitro. Cell cultures were analyzed by immunofluorescence with Nile Red/DAPI to quantify triglyceride-containing cells (adipogenesis) and Oil-Red-O staining followed by spectrophotometry to measure accumulated triglycerides (lipogenesis). mRNA

expression of marker genes for early (PPAR γ , SREBP1c, C/EBP α) and terminal (FAS and adiponectin) phases of adipogenesis was evaluated after selective overexpression of SIRT1 or SIRT2 by adenoviral-mediated gene transfer in V-ASC. Assessment of SIRT1 and SIRT2 mRNA levels in human Sc and V fat biopsies from 149 donors with a wide BMI range was also carried out.

Results: No differences in either adipogenesis or lipogenesis were found in Sc-ASC from Ob vs. n-Ob donors. By contrast, both the number of triglyceride-containing cells and extent of triglyceride accumulation were ~2.0-fold higher in V-ASC from Ob compared to n-Ob donors ($p < 0.05$). These cellular phenotypes correlated with changes in SIRT1 and SIRT2 mRNA and protein levels, which were not different in Sc-ASC from n-Ob and Ob, and 50% lower in V-ASC from Ob compared to n-Ob subjects ($p < 0.05$). Noteworthy, the selective overexpression of SIRT1 or SIRT2 in Ob V-ASC resulted in downregulation of genes involved in early adipogenesis, such as PPAR γ , SREBP1c, C/EBP α ($p < 0.05$), as well as genes marking terminal adipocyte differentiation, such as FAS and adiponectin ($p < 0.05$), and in a significant 45% decrease in both lipogenesis and adipogenesis ($p < 0.05$). Finally, assessment of SIRT1 and SIRT2 mRNA levels in human Sc and V fat biopsies from 149 donors with a wide BMI range showed a significant negative relationship between SIRT1/SIRT2 expression in V fat and BMI, both in males ($R = -0.448$, $p < 0.05$) and females ($R = -0.535$, $p < 0.05$), while no correlation was found between SIRT1/SIRT2 expression in Sc fat and BMI.

Conclusion: Reduced SIRT1 and SIRT2 expression in V-ASC from obese individuals promotes enhanced lipogenesis and adipogenesis, representing a new mechanism for expansion of V fat in human obesity.

TMEM18 is a regulator of adipogenesis and involved in PPAR γ signalling in vivo

K. Landgraf^{1,2}, J.T. Schwartz¹, D. Rockstroh¹, W. Kiess¹, A. Kömer^{1,2}; Center for Pediatric Research Leipzig (CPL), ²Medical Center AdiposityDiseases (IFB), Leipzig, Germany.

Background and aims: Polymorphisms in *TMEM18* are associated with obesity in children and adults. We have reported previously that *TMEM18* is a regulator of human adipogenesis *in vitro*. The aim of this study was to investigate the role of *TMEM18* during adipose tissue (AT) accumulation *in vivo*.

Materials and methods: We used the zebrafish as an *in vivo* model for AT development. In addition, we analysed *TMEM18* expression in whole AT samples, isolated adipocytes and cells of the stroma-vascular fraction (SVF) from lean and obese children of our Leipzig Childhood AT cohort, and addressed associations with *PPARG* expression and measures of obesity and glucose homeostasis.

Results: Using whole mount *in situ* hybridisation on 9 day old zebrafish larvae, we showed co-expression of *tmem18* and *pparg* in a visceral region where also first adipocytes are detectable by Nile red staining. Morpholino-mediated inhibition of *tmem18* expression resulted in a reduction in the number of visceral adipocytes but did not affect zebrafish development *per se*. There was no effect of *tmem18* knockdown on eating behaviour suggesting that the inhibition of adipocyte formation was not mediated by a central effect. *Tmem18*-mediated inhibition of adipogenesis was accompanied by a significant down-regulation in *pparg* expression. Using luciferase reporter assays in 3 T3-L1 cells, we detected a significant activation of the *PPARG* promoter in presence of *Tmem18* indicating that *Tmem18* is an upstream regulator of *PPARG* signalling. In line with these data, *TMEM18* expression correlated with *PPARG* expression in whole AT and isolated adipocytes but not in SVF cells of children included in our Leipzig AT cohort. Similar to *PPARG*, *TMEM18* expression was down-regulated in adipocytes of obese children compared to lean children and correlated with adipocyte diameter, macrophage infiltration, serum adiponectin levels and HOMA-IR as a measure of insulin resistance.

Conclusion: Our findings may indicate a potential role of *TMEM18* as a regulator of *PPARG*-driven adipogenesis and obesity progression *in vivo*. *Clinical Trial Registration Number: NCT02208141*

The impact of birth weight on epigenetic and transcriptional regulation of adipose-derived stem cells

A.H. Olsson¹, C. Broholm¹, A. Perflyev², N.S. Hansen¹, A. Ali³, B. Mortensen⁴, S.W. Jørgensen^{1,4}, C. Ling², A. Vaag^{1,4};

¹Department of Endocrinology, Diabetes and Metabolism, Rigshospitalet, Copenhagen, Denmark, ²Department of Clinical Sciences, Epigenetics and Diabetes, ³Department of Clinical Sciences, Genetic and Molecular Epidemiology, Lund University, Malmö, Sweden, ⁴Steno Diabetes Center A/S, Gentofte, Denmark.

Background and aims: Low birth weight (LBW) is associated with dysfunctions of adipose tissue contributing to an elevated risk of developing metabolic diseases in adulthood. We hypothesized that altered epigenetic and transcriptional regulation of adipose-derived stem cells (ADSCs) could play a role in programming adipose tissue dysfunctions in LBW subjects.

Materials and methods: ADSCs were isolated from adipose tissue of 13 normal birth weight (NBW) and 13 LBW adult males. Global DNA methylation and gene expression patterns were analysed in cultured ADSCs during proliferation and after differentiation into mature adipocytes.

Results: Immature ADSC from LBW subjects exhibit differential expression of 506 gene transcripts after correction for multiple testing, including genes involved in spliceosomal function and cell cycle regulation. Principal component analyses confirmed that the transcriptional and epigenetic profiles differed more between the birth weight (BW) groups in the immature ADSC compared with only subtle differences in the mature adipocytes. Although differentiation of ADSCs into mature adipocytes was associated with multiple and within the BW groups converging changes in gene expression and DNA methylation, the dynamics of specific gene groups varied. Construction of gene interaction networks suggest a key role for the transcription factor CCNT2 in the diverse gene regulation patterns seen between BW groups during adipocyte differentiation.

Conclusion: Our findings support the notion that the differential epigenetic and transcriptional changes in LBW subjects are most pronounced in immature ADSCs that in turn may program more permanent structural and physiological characteristics of the mature adipocytes influencing risk of metabolic diseases.

Increased brown fat and insulin sensitivity in obese mice overexpressing WISP2 in the adipose tissue

J.R. Grünberg¹, J.M. Hoffmann¹, S. Hedjazifar¹, A. Nerstedt¹, L. Jenndahl¹, J. Castellot², L. Wei³, S. Movérare Skrtic⁴, F. Bäckhed¹, I. Syed⁵, A. Saghetelian⁶, B. Kahn⁵, A. Hammarstedt¹, U. Smith¹;

¹Molecular and Clinical Medicine/Diabetes, Medicine, Göteborg, Sweden, ²Department of Integrative Physiology and Pathobiology, Tufts University School of Medicine, ³Massachusetts General Hospital, ⁴Medicine, Göteborg, Sweden, ⁵Harvard Medical School, Boston, ⁶Salk Institute, San Diego, USA.

Background and aims: WISP2 is highly expressed in, and secreted by, mesenchymal precursor cells. It is an important early regulator of mesenchymal precursor cell commitment to the adipogenic lineage through dual effects; by forming a BMP4-regulated complex with the PPAR γ

transcriptional activator ZFP423 in the cytosol preventing its nuclear translocation and; as a secreted protein activating the canonical WNT pathway and inhibiting differentiation of the precursor cells. To examine the in vivo effect of secreted WISP2 by the adipose tissue we generated a transgenic (Tg) mouse overexpressing WISP2 under an α P2 promoter.

Materials and methods: The mice were fed a control or high fat diet (HFD) for 17 weeks. Metabolic phenotyping included hyperinsulinemic euglycemic clamps combined with [14 C] 2-deoxyglucose uptake and body composition analysis with DEXA. Samples were collected for blood chemistry and several tissues were analyzed with immunohistochemistry, protein and gene profiling. Conventional statistical methods were used to analyse results.

Results: Tg mice on HFD showed unchanged body weight compared to wildtype (wt) mice but had markedly increased and hypercellular brown adipose tissue (BAT) (weight increased \approx 100%, $p < 0.05$), hypercellular white adipose tissue with smaller cells (42% increase in number of cells; $p < 0.05$) and increased lean body mass (\approx 8% $p < 0.05$). In spite of same body weight, Tg mice were markedly more insulin-sensitive, verified by hyperinsulinemic euglycemic clamps (GIR +237% at steady-state, $p < 0.01$) and had increased glucose uptake by the adipose tissue and skeletal muscle, increased adipose tissue adiponectin mRNA and circulating levels (150%, $p < 0.01$) and increased GLUT4 in both adipose tissue and skeletal muscles (\approx 140% $p < 0.05$). Insulin-stimulated glucose uptake ex vivo was also increased in adipose cells and skeletal muscle (\approx 160%, $p < 0.05$). Interestingly, de novo lipogenesis, known to be elevated when GLUT4 is increased in the adipose tissue, and serum levels of the novel fatty acid-hydroxy fatty acids (FAHFAs) were also increased in Tg compared to wt mice on HFD (\approx 175% $p < 0.05$). The mesenchymal tissue hypercellularity suggests that WISP2 increases mesenchymal precursor cell growth and this was also verified in vivo in BAT. Furthermore, serum from Tg mice increased the proliferation of both BAT precursor cells and the mesenchymal stem-like CH3T101/2 cells and this effect was inhibited by adding specific anti-WISP2 monoclonal antibodies to the serum.

Conclusion: WISP2 is a novel circulating adipokine which targets mesenchymal precursor cells leading to increased lean body mass, hypercellular BAT and hyperplastic healthy white adipose tissue with increased GLUT4 and circulating levels of adiponectin. Lipogenesis is increased leading to higher serum levels of the novel FAHFAs and improved insulin sensitivity. Thus WISP2 is a promising target to prevent obesity-related complications and Type 2 diabetes.

A multi-national normative dataset for corneal nerve morphological parameters with using corneal confocal microscopy for early diagnosing diabetic neuropathy

M. Tavakoli¹, M. Ferdousi¹, I. Petropoulos¹, J. Morris², N. Pritchard³, A. Zhivov⁴, D. Ziegler⁵, D. Pacaud⁶, K. Romanchuk⁶, B. Perkins⁷, V. Bril⁷, G. Smith⁸, A. Boulton¹, N. Efron⁹, R. Malik¹;

¹Center for Endocrinology and Diabetes, University of Manchester, ²University of Manchester, Manchester, UK, ³Institute of Health Biomedical Innovation, QUT, Brisbane, Australia, ⁴University of Rostock, ⁵University Hospital, Düsseldorf, Germany, ⁶University of Calgary, Canada, ⁷University of Toronto, Canada, ⁸University of Utah, Salt Lake City, USA, ⁹QUT, Brisbane, Australia.

Background and aims: Corneal confocal microscopy (CCM) is a novel diagnostic technique for the detection of nerve damage and repair in a range of peripheral neuropathies, in particular diabetic neuropathy. To enable clinical translation and wider use of this technique, normative reference values need to be defined. We have therefore undertaken a multicenter collaboration to provide worldwide age adjusted normative values of corneal nerve fibre parameters.

Materials and methods: 1965 corneal nerve images from 343 healthy volunteers were pooled from six clinical academic centers across the world (Manchester, Brisbane, Calgary, Düsseldorf, Utah and Toronto). All subjects underwent examination with the Heidelberg Retina Tomograph corneal confocal microscope. Images of the sub-basal nerve plexus were acquired by each centre using a standard protocol and analyzed by manually with using Semi-automated software (CCMetrics) and also by automated software (ACCMetrics). Age-trends were established using simple linear regression, and normative corneal nerve fiber density (CNFD), corneal nerve fiber branch density (CNBD), corneal nerve fiber length (CNFL) reference values were calculated using quantile regression analysis for each method of measurements.

Results: There was a significant linear age-dependent decrease in CNFD (-0.164 no/mm² per year for men, $P < 0.01$ and -0.161 no/mm² per year for women, $P < 0.01$) that determined with both analysing systems. There was no change with age in CNBD (+0.192 no/mm² per year for men, $P = 0.26$ and -0.050 no/mm² per year for women; $P = 0.78$). CNFL decreased in men (-0.045 mm/mm² per year, $P = 0.07$) and women (-0.060 mm/mm² per year, $P = 0.02$). Height, weight and BMI did not influence the 5th percentile normative values for any corneal nerve parameter. Significant correlations for CNFL, CNBD, CNFL were observed between 2 methods of measurements.

Conclusion: This study provides robust worldwide normative reference values for corneal nerve parameters to be used in research and clinical practice in the study of diabetic and other peripheral neuropathies.

Obesity related neuropathy and the effects of bariatric surgery

S. Azmi¹, M. Ferdousi¹, G. Ponirakis², I. Petropoulos², J. Schofield¹, H. Fadavi¹, M. Tavakoli¹, H. Soran¹, R.A. Malik^{1,2};

¹Diabetes and Endocrinology, University of Manchester, UK, ²Weill Cornell Medical College in Qatar, Doha, Qatar.

Background and aims: Obese subjects have risk factors for the development of neuropathy. Bariatric surgery normalises these risk factors, however its benefits on neuropathy have not been assessed.

Materials and methods: 50 morbidly obese subjects and 30 age-matched controls underwent assessment of: sural nerve conduction velocity (SNCV) and amplitude (SNAP), peroneal nerve conduction velocity (PMNCV) and amplitude (PNA), Vibration Perception Threshold (VPT), cold (CT) and warm (WT) threshold, corneal nerve fibre density (CNFD), branch density (CNBD) and fibre length (CNFL). 19 subjects were re-assessed 6 months post-bariatric surgery

Results: Obese subjects had a higher BMI (50.5 ± 2.2 v 27.9 ± 1.9 , $P < 0.000$), HbA1c (55.1 ± 4.4 v 38.5 ± 0.8 , $P = 0.002$) with no difference in blood pressure (mmHg) ($133.2 \pm 4.7/73.0 \pm 2.6$ v $125.8 \pm 2.9/74.1 \pm 2.4$, $P = 0.69/0.37$). They had a significant reduction in SNAP (mV) (11.4 ± 1.4 v 20.5 ± 1.9 , $P < 0.001$), PNA (mV) (3.65 ± 0.3 v 5.5 ± 0.42 , $P < 0.001$), PMNCV (m/s) (45.7 ± 0.8 v 47.8 ± 2.0 , $P = 0.005$) and CT (OC) (24.1 ± 1.4 v 28.7 ± 0.3 , $p = 0.02$) with an increase in WT (OC) (40.0 ± 0.7 v 36.7 ± 0.79 , $P = 0.02$). CNFD (no/mm²) (23.3 ± 1.3 v 37.7 ± 2.0 , $p < 0.000$), CNBD (no/mm²) (32.0 ± 3.1 v 37.9 ± 2.6 , $p < 0.000$) and CNFL (mm/mm²) (14.2 ± 0.6 v 26.9 ± 2.0 , $p < 0.000$) were significantly reduced. Paradoxically, CNBD (38.5 ± 5.7 v 23.9 ± 2.8 , $p = 0.03$) and CNFL (15.1 ± 1.1 v 13.2 ± 0.5 , $p = 0.05$) were significantly lower in the non-diabetic ($n = 35$) compared to the diabetic ($n = 14$) group. In the 19 subjects assessed post-operatively at 6 months, BMI (52.2 ± 3.5 v 34.6 ± 2.1 , $P = 0.004$), BP ($112 \pm 2.3/71.5 \pm 0.4$, $P = 0.03$), CIP (7.3 ± 1.6 v 16.5 ± 4.0 , $P = 0.05$) and CNFD (23.0 ± 1.6 v 25.3 ± 0.9 , $P = 0.05$) and (CNFL (14.3 ± 1.0 v 16.0 ± 1.0 , $P = 0.005$) improved with no change in other parameters

Conclusion: Obese subjects have large and small fibre neuropathy. Paradoxically those with diabetes have less severe small fibre damage, presumably driven by factors other than hyperglycaemia. Bariatric surgery improves small fibre neuropathy as shown by CCM within 6 months.

Disrupted resting-state attentional networks in type 2 diabetes mellitus patients

W. Xia^{1,2}, S. Wang¹, H. Rao², A. Spaeth², P. Wang¹, Y. Yang¹, R. Huang¹, H. Sun¹;

¹affiliated Zhongda Hospital of Southeast University, Nanjing, China, ²Center for functional Neuroimaging, University of Pennsylvania, Philadelphia, USA.

Background and aims: Although Type 2 diabetes mellitus (T2DM) is a well-recognized risk factor for dementia, the neural mechanisms that underlie cognitive impairment in T2DM remain unclear. In addition to memory deficits, attention is compromised in patients with T2DM. Our study aims to examine attentional network alterations in T2DM patients and their relationships to impaired cognitive performance using resting-state functional magnetic resonance imaging (fMRI).

Materials and methods: For the first time, data-driven independent component analysis was applied to resting-state fMRI data from 38 T2DM patients and 32 healthy controls to identify the dorsal attention network (DAN) and ventral attention network (VAN). Correlations were then determined among the resting-state functional connectivity (rsFC), clinical data, and neuropsychological scores.

Results: Typical significant spatial patterns of the DAN and VAN in both the controls and T2DM patients were revealed ($p < 0.01$, corrected; figure). When compared with the healthy controls, the T2DM patients exhibited decreased rsFC in the left middle frontal gyrus (MFG) and bilateral inferior parietal lobe (IPL) of the DAN, as well as the left IPL and right MFG/IFG of the VAN. In addition, the rsFC of the left MFG was inversely correlated with the Trail Making Test-B scores ($r = -0.533$, $p = 0.001$); the rsFC of the left IPL was positively correlated with the Digit Span Test scores but negatively correlated with HbA1c ($r = 0.403$, $p = 0.012$; $r = -0.370$, $p = 0.022$, respectively).

Conclusion: T2DM patients exhibit disrupted functional integration within attention-related brain networks. Several core regions in the DAN, especially the IPL, likely underlie the attentional deficits in T2DM patients. We suggest T2DM affects resting-state attentional networks, which may be related to reduced attention and a hyperglycemic state. Our data may potentially support resting-state fMRI as a promising tool to detect attentional changes in T2DM and provide new insights into the neural deficits present in T2DM patients.

Thalamic neuronal dysfunction and patterns of sensory loss in diabetic neuropathy: a proton magnetic resonance spectroscopy study

M. Greig^{1,2}, D. Selvarajah^{1,2}, P. Shillo^{1,2}, G. Rao², I.D. Wilkinson¹, S. Tesfaye²;

¹University of Sheffield, ²Sheffield Teaching Hospitals, UK.

Background and aims: Although we have previously demonstrated thalamic neuronal dysfunction in diabetic neuropathy (DN) using proton magnetic resonance spectroscopy (1H-MRS), the relationship between quantitative sensory testing of large and small fibre function (QST) and thalamic neuronal dysfunction is not known.

Materials and methods: 37 subjects with T1DM (12 No-DN and 25 DN) and 14 healthy volunteers (HV) underwent QST using the German DFNS protocol. All subjects were right handed and aged between 45 and 60 years (with no significant difference between the groups). 1H-MRS examination was performed at 3 T (Ingenia, Phillips Netherlands). Single

voxel spectra were obtained from a 2.25 cm³ (15×10×15mm) cubic volume of interest within the L. thalamus. TE=135 ms, TR=1600 ms, NSA=256 using point resolved (PRESS) technique. Fitted metabolite area ratios were calculated for choline (Cho) at 3.2 ppm, Creatine (Cr) at 3.0 ppm, and N-Acetyl Aspartate (NAA) at 2.02 ppm, and mean area under the curve values were compared. ANOVA was performed for group means and correlations between QST parameters and 1H-MRS ratios were calculated using Pearson's correlation.

Results: Subjects with DN had significantly lower NAA:Cr [1.74(0.22)] compared to HV [1.96(0.3)] and No-DN [1.90(0.26); ANOVA $p=0.036$]. There was a significant negative correlation between NAA:Cr and small fibre assessments of heat pain threshold $r=-0.287$ ($p=0.04$) and warm detection threshold $r=-0.289$ ($p=0.043$). There was no significant correlations between assessments of large fibre dysfunction and NAA:Cr.

Conclusion: The thalamus plays an important role in processing ascending somatosensory inputs to the cerebral cortex. Reduction in NAA:Cr as assessed using 1H-MRS indicates abnormal thalamic neuronal function in DN. In this preliminary study we have demonstrated that thalamic neuronal dysfunction relates to abnormalities of small fibre function on detailed QST. NAA ratios associated with changes in the thalamus may be linked to specific patterns of sensory abnormalities. Further investigation of the relationship between these findings and underlying structural and perfusion abnormalities, may provide a physiological mechanism for this novel finding.

Vibration sensitivity violation evaluation for diabetic distal polyneuropathy early diagnosis in patients with type 2 diabetes

A.P. Shepelkevich¹, I.K. Bilodid¹, A.V. Sosedkova¹, S.S. Korytko², L.M. Pedchenec³, L.P. Kovshik⁴, M.I. Tylypova⁵, N.V. Karlovich⁶, A.S. Grigorovich⁷, O.G. Zaleskaya⁸, V.N. Selivanov⁹;

¹Belarusian state medical university, ²Centre for Medical Rehabilitation and Balneotherapy, Minsk, ³Vitebsk Regional Endocrinological Dispensary, ⁴Grodno Regional Endocrinological Dispensary, ⁵Gomel Regional Endocrinological Dispensary, ⁶City Endocrinological Dispensary of Minsk, ⁷Brest Regional Endocrinological Dispensary, Brest, ⁸Minsk Regional Clinical Hospital of the Order of the Red Banner of Labour, Minsk, ⁹Mogilyov Regional Diagnostic and Treatment Centre, Mogilyov, Belarus.

Background and aims: Distal sensorimotor polyneuropathy (DSPN) is a severe complication of type 2 diabetes. According to the German National Disease Management Guidelines for neuropathy adults with type 2 diabetes mellitus (T2DM) should be screened for distal sensorimotor polyneuropathy (DSPN) at diagnosis set up and yearly thereafter. This study aimed to assess the prevalence of vibration sensitivity disorders in T2DM patients using Vibratip device which can be used as an alternative test for vibration sensation evaluation for DSPN early diagnosis.

Materials and methods: 4303 patients with T2DM (2757 women, 1546 men, average age: 59.2±10.4 years, average body mass index (BMI) 32.2±5.6 kg / m²) were examined. The study was conducted within the framework of the campaign "Approach Optimization in Diabetic polyneuropathy Early Diagnostics and Prevention Improvement". All participants with inclusion criteria (T2DM duration≤1 year with average duration of DM: 0.8±0.3 years) had a clinical examination and were examined with Vibratip on both feet. Vibratip is new device using standardized vibration for DSPN detection. Vibratip is applied to the patients feet, testing 2 sites on both feet (1st metatarsal head on the plantar surface and hallux pump)-once whilst non-vibrating and once whilst vibrating and the patient (with their eyes closed) is asked to indicate when they feel the vibration. Vibration sensitivity disorder was defined in condition when patients were answering twice "yes" to the question, "Are you able to feel vibration on any site of both feet during the test?"

Results: Clinical symptoms of DSPN were prevalent in 3781 (88%) participants with T2DM, 775 (18%) of whom were suffered from pain, 706 (16.4%) - from burning, 1144 (26.6%) - numbness, 921 (21.4%) - feeling of pins and needles, 235 (5.5%) - feeling of electric shock. Patients with clinical symptoms such as numbness (26.6%) and feeling of pins and needles (21.4%) had the highest prevalence of clinical impairment of feet. Vibration sensitivity disorders feet were found in 24,1% (1036) of diabetic patients: 15,3% (656) women, 8,8% (380) men using Vibratip device.

Conclusion: Our findings showed a high prevalence of vibration sensitivity disorders among patients with T2DM with disease duration≤1 year using Vibratip device, suggesting inadequate attention to diabetic foot prevention practice.

216

Oxidative and carbonyl stress in relation to polyneuropathy in subjects with recently diagnosed type 1 and type 2 diabetes

D. Ziegler¹, A. Strom¹, K. Kaul¹, I. Rokitta¹, T.H. Fleming², S. Püttgen¹, J. Brüggemann¹, I. Ziegler¹, B. Ringel¹, J. Szendrödi¹, P.P. Nawroth², M. Roden¹, for the German Diabetes Study Group;

¹Institute for Clinical Diabetology, German Diabetes Center at Heinrich Heine University, Düsseldorf, ²Department of Medicine I and Clinical Chemistry, University of Heidelberg, Germany.

Background and aims: Oxidative stress resulting from enhanced free-radical formation, reduced antioxidative defense, and reactive carbonyls which react with proteins to form advanced glycation endproducts (AGEs) have been implicated in the pathogenesis of diabetic neuropathy. We sought to determine whether biomarkers of systemic oxidative stress, defective antioxidative defense, and carbonyl stress are altered in relation to diabetic sensorimotor polyneuropathy (DSPN) in recently diagnosed diabetes patients.

Materials and methods: We assessed serum concentrations of thiobarbituric acid reactive substances (TBARS) as a marker of oxidative stress, extracellular superoxide dismutase (SOD3) and reduced glutathione (GSH) as markers of antioxidative defense, and methylglyoxal as a marker of carbonyl stress in 111 type 1 and 223 type 2 diabetic subjects from the baseline cohort of the German Diabetes Study (GDS) (type 1/type 2 diabetes (T1D/T2D): age: 34.3±13.0/52.8±11.0 [SD] years; male: 57/65%; BMI: 24.6±4.1/31.7±6.0 kg/m², diabetes duration: 7.2±3.2/6.1±3.0 months; HbA1c: 6.8±1.4/6.5±1.0% [50.5±15.2/47.3±10.4 mmol/mol]) and 52 healthy control subjects (age: 40.3±16.4 years; male: 56%). Neurophysiological and clinical measures included motor and sensory nerve conduction velocity (MNCV, SNCV), Neuropathy Symptom Score (NSS), and Neuropathy Disability Score (NDS). DSPN was defined by electrophysiological and clinical criteria (Toronto Consensus, 2011). All comparisons were adjusted for sex, age, and BMI.

Results: TBARS levels were higher in T1D (3.1±2.0 μM) and T2D (3.2±1.8 μM) than in controls (0.9±0.3 μM) as was methylglyoxal (T1D: 404±150, T2D: 412±160, controls: 154±69 nM, while SOD3 concentrations were reduced in T1D (38.9±14.9 ng/ml) and T2D (32.7±16.3 ng/ml) compared to controls (52.4±16.6 ng/ml) as was GSH (T1D: 1.6±0.6, T2D: 1.7±0.8, controls: 2.7±1.2 μM) ($P<0.0001$ for T1D and T2D vs controls for all markers). Subclinical and clinical DSPN confirmed by nerve conduction studies were present in 21% of subjects with T1D and 29% of those with T2D. Multiple linear regression analysis revealed that low SOD3 levels were associated with the presence of DSPN in both T1D subjects ($\beta=-0.319$, $P=0.002$) and those with T2D ($\beta=-0.151$, $P=0.030$), while low methylglyoxal concentrations were associated with DSPN in T2D subjects ($\beta=-0.153$, $P<0.022$). No association with DSPN was noted for TBARS and GSH.

Conclusion: Patients with recently diagnosed T1D and T2D show evidence of systemic oxidative and carbonyl stress despite good glycaemic control, but only lower SOD3 concentrations in both T1D and T2D and lower methylglyoxal levels in T2D were linked to the presence of polyneuropathy. The predictive value of these markers for the development and progression of diabetic neuropathy remains to be determined in prospective studies.

Sulfonylurea is still useful in type 2 diabetic patients with sulfonylurea failure

T. Kunavisarut, R. Lertwattanarak, S. Sriussadaporn;
Mahidol University, Bangkok, Thailand.

Background and aims: A large number of type 2 diabetic patients cannot achieve good glycaemic control with maximum dosage of sulfonylurea (SU), so called sulfonylurea failure (SUF). Some guidelines suggest to continue SU whereas some suggest to stop SU once insulin therapy is started in patients with SUF. This study was aimed to evaluate whether SU is still useful in patients with SUF.

Materials and methods: Type 2 diabetic patients who had $A1c \geq 8\%$ while receiving recommended maximum dosage of SU and metformin were studied. Beta-cell function and insulin resistance status were assessed by plasma glucose and insulin response to oral glucose tolerance (OGTT) method. OGTT were performed 3 times including while receiving maximum dose of SU (max-SU), after discontinuation of SU for 4 weeks (discont-SU), and at 2 weeks after restarting the same SU at 25% of max-SU (25%-SU). During each OGTT, plasma insulin and glucose levels were measured at 0, 30, 60, 90 and 120 minutes. Beta-cell function was assessed by area under the curve (AUC) of plasma insulin divided by AUC of plasma glucose. Insulin sensitivity and insulin resistance were assessed by Matsuda index and HOMA-IR, respectively. The patients were assigned to continue the same dosage of metformin throughout the study and to measure fasting capillary blood glucose at home (CBG) at least 3 times per week to assess glycaemic control and for safety monitoring during the intervals between OGTT.

Results: Twenty-five patients with SUF were recruited. Median duration of diabetes was 12 years (range, 4-38). Beta-cell function during max-SU (median 0.1, range 0.02-0.56) was significantly higher than that of during discont-SU (0.06, range 0.01-0.22), ($p < 0.001$) and also higher but not significant ($p = 0.269$) than that of during 25%-SU (0.09, range 0.01-0.32). Beta-cell function was also higher during 25%-SU (0.09, range 0.01-0.32) compared with during discont-SU (0.06, range 0.01-0.22), ($p < 0.001$), suggesting that SU is still able to stimulate insulin secretion in SUF in dose dependent manner. Among the 3 OGTT, there was no significant difference in Matsuda index (OGTT-1 1.97 ± 1.14 , OGTT-2 1.93 ± 1.1 and OGTT-3 1.98 ± 1.31 , $p = 0.759$) and HOMA-IR (OGTT-1 11.48 ± 8.17 , OGTT-2 12.13 ± 6.7 and OGTT-3 11.24 ± 7.42 , $p = 0.179$), suggesting that SU has no significant effect on insulin sensitivity or insulin resistance. For the glycaemic control, the mean CBG measured during max-SU and 25%-SU were lower than that of during discont-SU (186.2 ± 43.5 vs. 222.3 ± 60.6 vs. 256.1 ± 66.7 mg/dL, respectively, $p < 0.05$).

Conclusion: Discontinuation of SU results in a decrease in insulin secretion and worsening glycaemic control. The findings lead to the clinical implication that SU is still useful and should be continued, if not contraindicated, in diabetic patients with SUF who need insulin therapy.

The OCT1 reduced-function polymorphisms are associated with common metformin-induced gastrointestinal side-effects

T. Dujic¹, A. Causevic¹, T. Bego¹, M. Malenica¹, Z. Velija-Asimi², E.R. Pearson³, S. Semiz^{4,1};

¹Department of Biochemistry and Clinical Analysis, Faculty of Pharmacy, University of Sarajevo, ²Clinic for Endocrinology, Diabetes and Metabolism Diseases, University Clinical Centre of Sarajevo, Bosnia and Herzegovina, ³Division of Cardiovascular & Diabetes Medicine, Medical Research Institute, University of Dundee, UK, ⁴Faculty of Engineering and Natural Sciences, International University of Sarajevo, Bosnia and Herzegovina.

Background and aims: Metformin is the first-line drug for treatment of type 2 diabetes, and the most widely used antidiabetic agent. However, 20–30% patients treated with metformin develop gastrointestinal (GI) side-effects, which may result in suboptimal drug dosage and non-adherence. About 5% of patients are not able to tolerate metformin due to severity of these GI symptoms. The mechanism of GI side-effects, as well as their considerable interindividual variability, is unknown. We have recently shown that organic cation transporter 1 (OCT1) polymorphisms are associated with severe intolerance to metformin, namely the discontinuation of metformin and switching to another oral hypoglycaemic agent in the first months of metformin treatment. The aim of this study was to examine the association OCT1 reduced-function alleles with common metformin-induced GI adverse effects in T2D patients.

Materials and methods: This prospective observational study included 92 newly diagnosed T2D patients who were prescribed metformin as their initial hypoglycaemic therapy. Patients were monitored during the first six months of metformin treatment for development of adverse GI outcomes. Two common loss-of-function variants in the OCT1 gene (*SLC22A1*), R61C (rs12208357) and M420del (rs72552763) were genotyped using TaqMan genotyping assays. The association of OCT1 reduced-function diplotypes with GI side-effects was analysed using logistic regression. Age, gender, weight, and the concomitant use of medications known to inhibit OCT1 activity, were added as covariates.

Results: A total of 43 patients (47%) experienced GI side-effects during first six months of metformin treatment. The effects were ranging from mild/moderate to severe GI symptoms. The most frequent symptom was diarrhoea. Female gender and lower weight showed a trend of association with the presence of adverse effects. Interestingly, the number of OCT1 reduced-function alleles was significantly associated with over two-fold higher odds of metformin-induced GI side-effects (OR=2.31, 95% CI 1.07–5.01, $p=0.034$).

Conclusion: In this study we showed for the first time the association of OCT1 reduced-function variants with the incidence of common metformin-induced GI side-effects in T2D patients. Our results confirm the recent findings related to the severe cases of metformin intolerance, and suggest that a high interindividual variability seen in mild to moderate, as well as severe GI intolerance, share common underlying mechanism, despite considerably different intensity and duration of GI symptoms. Importantly, our data could lead to more personalised and safer treatment with metformin.

The acute glucose-lowering effect of metformin in patients with type 2 diabetes is partly glucagon-like peptide-1-dependent

M. Hansen^{1,2}, E. Bahne¹, D.P. Sonne^{1,2}, J.F. Rehfeld³, J.J. Holst², T. Vilsbøll¹, F.K. Knop^{1,2};

¹Center for Diabetes Research, Gentofte Hospital, Hellerup, ²NNF Center for Basic Metabolic Research and Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University Copenhagen, ³Department of Clinical Biochemistry, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Metformin has been suggested to increase glucagon-like peptide-1 (GLP-1) secretion. By the use of the GLP-1 receptor antagonist exendin 9-39 (Ex9-39), we evaluated whether the acute effect of metformin on postprandial glucose excursions is GLP-1-dependent.

Materials and methods: Twelve patients with type 2 diabetes (age: 60.8 ± 8.8 years (mean \pm SD); BMI: 29.8 ± 3.0 kg/m²; HbA_{1c}: $6.5 \pm 0.5\%$ (48 ± 6 mmol/mol)) were included in this placebo-controlled, double-blinded study. On 4 separate days, after 1-week washout of antidiabetic drugs, the patients received metformin (1.5 g) or placebo suspended in a 302-kcal liquid meal with 1.5 g paracetamol (for evaluation of gastric emptying) with i.v. infusion of Ex9-39 (450 pmol \times kg body weight⁻¹ \times min⁻¹) or saline. At baseline and during 240 min blood was sampled, gallbladder volume was evaluated by ultrasound and appetite was evaluated by visual analogue scale. At the end of each day ad libitum food intake was measured.

Results: On the 2 days of Ex9-39 infusion, mean basal concentrations of plasma glucose were higher compared with the 2 days of saline infusion (9.8 ± 0.58 mmol/l vs. 8.7 ± 0.52 mmol/l, $p < 0.05$). Metformin + saline increased plasma GLP-1 incremental AUC (iAUC) compared with placebo + saline (1985 ± 365 pmol/l \times min vs. 1156 ± 244 pmol/l \times min, $p < 0.05$). Ex9-39 increased GLP-1 iAUC after both metformin and placebo, but GLP-1 iAUC remained significantly higher with metformin compared to placebo (3218 ± 563 pmol/l \times min vs. 1798 ± 333 pmol/l \times min, $p < 0.05$). Metformin + saline reduced the postprandial plasma glucose iAUC by 58% vs. placebo + saline (145 ± 68 mmol/l \times min vs. 350 ± 73 mmol/l \times min, $p < 0.05$), and while the difference was still significant, metformin + Ex9-39 only reduced iAUC by 25% vs. saline + Ex9-39 (467 ± 112 mmol/l \times min vs. 614 ± 124 mmol/l \times min, $p < 0.05$). C-peptide:glucose ratios were significantly higher after metformin + saline vs. placebo + saline (18225 ± 2703 pmol/mmol \times min vs. 12345 ± 1766 pmol/mmol \times min, $p < 0.05$) whereas the difference was no longer significant with Ex9-39 infusions (13233 ± 3243 pmol/mmol \times min vs. 9863 ± 2505 pmol/mmol \times min, $p = 0.07$). Metformin did not affect gastric emptying, plasma cholecystokinin concentrations and gallbladder contraction vs. placebo, irrespective of Ex9-39. None of the interventions affected appetite perceptions or ad libitum food intake.

Conclusion: We show that acute administration of metformin increases plasma GLP-1 secretion and reduces postprandial plasma glucose excursions vs. placebo, and that a substantial part of the glucose-lowering effect appears to be GLP-1-dependent.

Clinical Trial Registration Number: NCT02050074

Metformin, methylmalonic acid and the risk of neuropathy: a randomised placebo-controlled trial

M. Out^{1,2}, A. Kooy^{1,2}, P. Leher³, C.G. Schalkwijk⁴, C.D.A. Stehouwer⁵;

¹Internal Medicine, location Bethesda, Treant Care Group, ²Bethesda Diabetes Research Center, Hoogeveen, Netherlands, ³Faculty of Economics, Louvain Academy, Belgium, ⁴Faculty of Health, Medicine and Life Sciences, Maastricht University Medical Center, ⁵Internal Medicine, Maastricht University Medical Center, Netherlands.

Background and aims: Metformin lowers serum vitamin B12 (B12) and increases serum methylmalonic acid (MMA), the gold standard

biomarker for tissue B12 deficiency. However, the clinical relevance of metformin-associated decreases in B12 is still controversial, since relevant clinical outcomes are lacking. Current guidelines mention B12 deficiency as a disadvantage of metformin, but do not yet give recommendations on the detection and prevention of B12 deficiency, waiting for more clinical evidence. Therefore, we studied whether the increase in MMA was associated with the onset or deterioration of neuropathy.

Materials and methods: In the HOME trial, 390 insulin-treated patients with type 2 diabetes were treated with 850 mg metformin or placebo up to three times daily for 52 months. We analyzed the association between metformin and changes in HbA1c, MMA and the Valk Score, a validated neuropathy score. We used structural equation modeling (SEM) analysis to estimate the mediation effects of MMA and HbA1c in the total effect of metformin on neuropathy score. We excluded patients with B12 deficiency at baseline or with B12 supplementation (n=15).

Results: In mixed model analysis, metformin, as compared to placebo, was associated with an increase of MMA at the end of the study (0.04 $\mu\text{mol/L}$, 95%CI 0.02 - 0.06, $p=0.001$). There was no significant difference in neuropathy score after 52 months between placebo (increase from 0.8 ± 2.2 to 2.2 ± 1.6) and metformin (1.1 ± 2.1 to 3.7 ± 1.3 ; ANCOVA: 0.03; 95% CI -0.03 - 0.08, $p=0.41$). However, SEM analysis showed that the effect of metformin on the neuropathy score consisted of a beneficial effect through lowering HbA1c (-0.02 per gram year of metformin) and an adverse effect through increasing MMA (0.04 per gram year). The model satisfied the goodness-of-fit test ($\chi^2=4.0$; $df=2$, $p=0.13$; normed fit index=0.98). In addition, during the study, MMA did not differ significantly between treatment groups when stratified for B12 concentration, showing that metformin did not affect the biological relation between B12 and MMA.

Conclusion: Metformin not only reduces B12, but also progressively increases MMA. The increase of MMA in metformin users was associated with significant worsening of the neuropathy score. Furthermore, metformin did not affect the biological relation between B12 and MMA. These results indicate that metformin-related B12 deficiency is clinically relevant. Monitoring of B12 and, when available, MMA, in users of metformin should be considered.

Differential adaptation of human gut microbiota to weight loss and diabetes remission achieved by gastric bypass versus sleeve gastrectomy

R. Murphy¹, P. Tsai², L. Plank³, M. Booth⁴;

¹Department of Medicine, ²Bioinformatics Institute, ³Department of Surgery, University of Auckland, Auckland, ⁴Department of Surgery, Waitemata District Health Board, Auckland, New Zealand.

Background and aims: Bariatric surgery achieves weight loss and remission of type 2 diabetes through many mechanisms, potentially including modification of gut microbiota. By comparing human gut microbiota changes after two types of bariatric surgery: gastric bypass (GBP) and sleeve gastrectomy (SG), with similar metabolic outcomes and food intake at 1 year, we aim to examine the gut microbiota changes which differ by type of surgery and those that correlate with diabetes remission status achieved by both surgeries.

Materials and methods: Whole-metagenome shotgun (WMS) sequencing of genomic DNA fragments using Illumina HiSeq2000 was obtained from stool samples collected from 14 obese patients with type 2 diabetes pre-operatively and 1 year after either SG (n=7) or GBP (n=7) as part of a randomised, blinded clinical trial in which metabolic outcomes, including body composition, resting energy expenditure (REE), glycaemia, inflammatory markers, and food diaries were collected. Post-operative diabetes status was defined as partial remission (PR) or complete remission (CR) if HbA1c was ≤ 48 mmol/mol or ≤ 38 mmol/mol respectively and off glucose lowering therapy. Resulting shotgun reads were annotated with Kyo-to Encyclopaedia of Genes and Genomes (KEGG).

Results: There were similar reductions in body weight (27.4 kg [SEM 5.3] v 23.5 kg [SEM 5.4], $p=0.48$), BMI (9.9 [SEM 1.8] v 7.6 [SEM 1.6], $p=0.29$) and REE (240 kcal [SEM 44] v 198 kcal [SEM 72], $p=0.57$) after GBP compared to SG. Estimated caloric intake and dietary components (fibre, fat, carbohydrate, protein) were similar between GBP and SG at baseline and 1 year. Diabetes remission occurred to a greater extent after GBP (4 CR, 1 PR) than after SG (1 CR, 4 PR). A greater change in taxonomy of gut microbiota was observed after GBP (3 major phyla differences) than after SG (no major phyla difference, only increase in *Bacteroidia* species). A significant increase in *Roseburia* species was found among those achieving diabetes remission after both GBP and SG. Functional analysis of gut microbiota metabolism by KEGG Orthology revealed a greater number of significant changes in KEGG gene function among those achieving diabetes remission after GBP (15 higher and 13 lower) than after SG (9 lower and 9 higher), and similarly for KEGG pathways (9 altered after GBP and 4 altered after SG). There were no common KEGG gene functions or pathways that were significantly altered among those achieving diabetes remission after both SG and GBP.

Conclusion: A greater proportion of gut microbiota are altered following GBP than SG surgery, likely reflecting the greater alteration to the gut ecological system achieved by GBP. The association of greater *Roseburia* species among those achieving diabetes remission after both GBP and SG supports a causal link with metabolic benefits.

Does experimental metabolic endotoxaemia worsen high-fat diet-induced insulin resistance and obesity?

L. Lebrun¹, S. Mandard¹, N. Le Guem¹, J.-P. Pais de Barros¹, J. Petot¹, V. Deckert¹, D.J. Drucker², L. Lagrost^{1,3}, J. Grober¹;

¹Faculté de médecine, INSERM UMR866, Dijon, France, ²Department of Medicine, Samuel Lunenfeld Research Institute, Toronto, Canada, ³Centre Hospitalier Universitaire, Dijon, France.

Background and aims: Obesity and type 2 diabetes are metabolic diseases which have reached epidemic proportions worldwide. According to World Health Organization, about 347 million adults have diabetes and around 1.6 billion are overweight (400 million of them are obese). These metabolic disorders are associated with a low grade inflammation whose molecular origin is still unknown. Previous studies have highlighted the involvement of the gut microbiota and lipopolysaccharides (LPS), which are components of the cell wall of Gram (-) bacteria. It has been shown that a slight increase of LPS plasma levels, metabolic endotoxemia, could mimic the effect of a very high-fat diet and initiate insulin resistance and obesity. We have recently shown that LPS increase glucagon-like peptide 1 (GLP-1) plasma levels, a hormone which is known to stimulate insulin secretion. Our present work deals with i) the molecular mechanisms involved in this newly described pathway and ii) the physiological consequences of this LPS/GLP-1/Insulin cascade during an obesogenic diet.

Materials and methods: Molecular mechanisms are investigated through in vivo, ex vivo and in vitro experiments to study the effects of LPS on synthesis/secretion/degradation of GLP-1. The long-term outcomes of the induced metabolic endotoxemia are explored by a continuous infusion of LPS (300 µg/kg/day). Osmotic pumps are implanted intraperitoneally in high-fat fed mice for one or two months.

Results: In vivo, measurements of total and active GLP-1 plasma levels show that the increase of GLP-1 upon LPS stimulation is due to enhanced secretion (x3.91 compared to NaCl control group, $p < 0.001$) rather than inhibition of its degradation. Stimulation of ileum explants or enteroendocrine cultured cells by LPS leads to an increased GLP-1 secretion suggesting a direct effect of LPS. This effect is mediated through toll-like receptor 4 (TLR4). Indeed, pharmacological (TLR4 antagonist) and genetical (TLR2/TLR4 KO mice) experiments suppress GLP-1 secretion. Very surprisingly, experimental metabolic endotoxemia induced by a continuous infusion of LPS for 30 days leads to improved metabolic consequences of an obesogenic diet. Compared to NaCl control mice, LPS-infused mice show a significant reduced fat mass measured by EchoMRI® (NaCl: 16.9%±1.3%; LPS: 9.7%±0.8%, $p < 0.001$). Hepatic lipid content estimated by Oil Red O staining indicate a significant decrease in LPS-treated mice ($p < 0.001$). Finally, glucose metabolism and insulin sensitivity are also improved in LPS-treated mice as shown by an oral glucose tolerance test (area under curve: NaCl: 819.7±22.2; LPS: 698.6±39.5, $p < 0.01$) and an insulin tolerance test (area under curve: NaCl: 216.5±10.1; LPS: 184±7.3, $p < 0.05$).

Conclusion: We demonstrate for the first time that LPS modulate the secretion of GLP-1 through a direct regulation of enteroendocrine cells by a TLR4 pathway. In addition, our data suggest that 30 days of experimental metabolic endotoxemia does not worsen high-fat diet-induced insulin resistance and obesity but rather seem to improve it. Nevertheless further experiments are currently ongoing to test the effect of a longer infusion of LPS (60 days) and pharmacological approaches will define the specific involvement of GLP-1.

Clc-5-deficient mice, a novel murine model for investigating the role of gut microbiota in obesity and metabolic syndrome

Y. Dong, H. Zhai, S. Jin, J.E. Maria, X. Li;

Medicine, Johns Hopkins University School of Medicine, Baltimore, USA.

Background and aims: Clc-5 (chloride channel 5) functions primarily as an electrogenic 2Cl⁻/1H⁺-exchanger. Mice deficient in Clc-5 exhibit a phenotype strikingly similar to human Dent's disease. We have identified Clc-5 knockout (Clc-5KO) mice as a completely novel animal model of obesity and metabolic syndromes. The aim of this study is to characterize this new phenotype and identify the molecular mechanisms involved.

Materials and methods: We extensively characterized the obesity phenotype and molecular features of Clc-5KO mice using various technologies including QNMR, MRI, PCR, ELISA, and Western blot.

Results: We have identified a previously unrecognized and highly unique phenotype of Clc-5KO mice: they are all (100%) markedly obese on regular chow diet, with a body weight 25-35% higher than that of age-matched WT mice. QNMR analysis showed that Clc-5KO mice were constituted of 21% of total body fat compared to only 7% in WT controls. MRI analysis indicated a dramatic increase in both subcutaneous and visceral (abdominal) fats. All Clc-5KO exhibited glucose intolerance and 3-4-fold elevated levels of systemic proinflammatory IL-6 and MCP-1 (than WT), remarkably similar to those in human obesity. Moreover, the Clc-5KO mice exhibit a 3- to 10-fold increase in the expression of a panel of diabetes/obesity-related genes in the liver, including PPARγ, LXRα, RXRα, CD36 (a lipoprotein scavenger receptor), SRA (class A scavenger receptor), leptin-R, SREBP2, AMPKβ, and GHRP-R, all of which are the hallmarks of metabolic syndrome. More surprisingly, Clc-5KO mice had similar food assumption as the age-matched WT mice, suggesting that Clc-5KO mice acquire a more efficient dietary energy harvesting mechanism. We found a weakened bacterial killing capacity of the Clc-5KO macrophages compared to WT macrophages. Co-caging littermate WT with Clc-5KO mice led to a marked improvement of glucose intolerance and decreased body fats in Clc-5KO mice while impaired glucose intolerance in WT.

Conclusion: Our data clearly indicate that it is the altered intestinal flora that enable the Clc-5KO mice a higher energy-harvesting efficiency from dietary foods, while the WT microbiota can diminish this efficiency. We conclude that Clc-5 plays a critical and previously unrecognized role in lipid and glucose metabolism via modulating gut flora, and Clc-5KO mice can be used as a novel model of obesity, diabetes or metabolic syndromes.

Diet interacts with host NOD2 genotype to control blood glucose and the gut microbiota

K.P. Foley, E. Denou, T.C. Lau, J.F. Cavallari, B.D. Henriksbo, B.M. Duggan, Y.E. Li, J.D. Schertzer;

Biochemistry and Biomedical Sciences, McMaster University, Hamilton, Canada.

Background and aims: Obesity is associated with inflammation, which is critical in causing insulin resistance. Sensing of bacterial components via Pattern Recognition Receptors (PPRs) contribute to this metabolic inflammation during obesity. The gut microbiome has also emerged as a mediator of metabolic inflammation and insulin resistance during obesity. However, familial transmission of microbiota during long term breeding can confound associations between immunity and taxonomy of the microbiota. Recently, our lab showed that deletion of Nucleotide Oligomerization Domain 2 (NOD2) in mice promotes diet-induced inflammation, dysbiosis, and insulin resistance. The dysbiosis caused by NOD2 deletion was an independent factor that transmits insulin resistance. Here

we aim to circumvent issues associated with familial transmission of microbiota by generating WT and NOD2 KO littermates and tracking changes in metabolism, inflammation, and microbiome across the first 3 generations of breeding. We hypothesized that the dysbiosis phenotype of NOD2 deletion would first manifest in F2 generation NOD2 KO mice and that inflammation and insulin resistance would be exacerbated in these mice when compared to F1 generation mice.

Materials and methods: See Fig. 1

Results: We confirmed that after 14 weeks of HFD Fx generation NOD2 KO mice (2556±/105) were glucose intolerant relative to WT mice (2005±/112) as measured by GTT AUC ($p<0.01$). In contrast, F1 generation WT (2265±/113) and NOD2 KO (2150±/145) littermates did not differ in GTT AUC ($p=0.55$). The role of NOD2 in regulating glucose during a HFD emerged in the F2 generation, with NOD2 KO mice (3168±/115) being significantly more glucose intolerant than F2 WT mice (2596±/115) on HFD ($p<0.01$). F2 NOD2 mice also trended towards having higher fasting blood glucose (FBG) ($p=0.069$, 12.7 vs 14.2 mM). F2 generation WT and NOD2 KO mice were then used as donors for microbiota transfer to germ-free WT mice. After 4 weeks of colonization while on HFD NOD2 KO recipient germ-free mice had significantly higher FBG than WT recipient germ-free counterparts ($p<0.01$, 11.6 vs 14.0 mM). Glucose intolerance (WT=1991±/132 vs NOD2 KO=2688±/142, $p<0.01$) and increased FBG (WT=10.8 vs NOD2 KO=12.3, $p=0.096$) characteristics persisted in F3 generation mice. Chow-fed WT versus NOD2 KO mice did not have altered glucose tolerance in any generation.

Conclusion: Our data shows an interaction between deletion of host NOD2 and lipid content in the diet that alters blood glucose. The gut microbes that thrive in the absence of NOD2 during a HFD promote hyperglycemia independent of host genetics. Data from F2 generation mice demonstrate that the divergence in microbiota between WT and NOD2 KO mice that drives glucose intolerance is not due to prolonged familial transmission during successive breeding of mice. Ongoing analysis will determine taxonomic microbial markers and effects of the diet-microbiome interaction on inflammation in the gut and metabolic tissues.

Figure 1: Materials and Methods. Mice from each generation were placed on a chow or 45% high fat diet (HFD) and glucose tolerance tests (GTT) were completed after 14 weeks. These data were compared with that of Fx generation WT and NOD2 KO mice – long term continuously bred colonies. Liver, adipose tissue, and cecums from each generation were harvested after 16 weeks HFD for measure of inflammatory markers and sequencing of the microbiome.

OP 39 Diabetes in the elderly

225

Frailty and the relationship between HbA_{1c} and mortality in elderly patients with type 2 diabetes

L.C. Hartog¹, H. van Hateren¹, K.H. Groenier², H. Bilo¹, N. Kleefstra¹; ¹Diabetes Centre, Isala, Zwolle, ²General Practice, University, Medical Center Groningen, Netherlands.

Background and aims: In patients with type 2 diabetes mellitus, poor glycemic control is associated with an increased risk of all-cause and cardiovascular mortality. Frailty influences the relationship between blood pressure and mortality in old age. We hypothesized that the relationship between HbA_{1c} and mortality may also be influenced by the level of frailty.

Materials and methods: Patients with type 2 diabetes mellitus participating in a prospective observational cohort study in the Netherlands were included. Patients aged 60 years and older were selected from this cohort of primary care treated patients. Frailty was defined as a score less than 80 on the subscale ‘physical functioning’ of the RAND-36 questionnaire. After median follow-up for 14 years, multivariate Cox regression analyses were performed to evaluate the association between HbA_{1c} and mortality, adjusted for age, sex, BMI, duration of diabetes, systolic blood pressure, serum creatinine level, total cholesterol-HDL ratio, macrovascular complications, albuminuria, and the use of insulin. Analyses were performed in strata according to the frailty level (‘physical functioning’ score <80 and ≥80) and diabetes duration.

Results: Approximately 60% of our study population was female. Median age (interquartile range) at baseline was 72 (67-77) years and median diabetes duration was 6 (3-12) years. Frailty was highly prevalent in our study population: 629 out of 858 patients (73%). Hazard ratios (95% confidence interval) of an increase in HbA_{1c} for all-cause and cardiovascular mortality in frail patients were 1.11 (1.02-1.21) and 1.19 (1.05-1.34), respectively (table 1). For the non-frail patients no significant associations were observed. When stratified according to diabetes duration, all confidence intervals were comparable between frail and non-frail patients, except for non-frail patients with a diabetes duration <5 years. Within this group no significant association was observed.

Conclusion: Higher HbA_{1c} was significantly related to increased all-cause and cardiovascular mortality in frail patients but outcomes were more or less comparable to the non-significant relationships in the non-frail population. Therefore, we conclude that frailty does not modify the relationship between HbA_{1c} and mortality in elderly patients with type 2 diabetes mellitus very much. Within non-frail patients with a diabetes duration less than 5 years, HbA_{1c} was not significantly related to mortality. Perhaps the positive relationships in frail patients with short diabetes duration reflect underlying morbidity.

Table 1. Hazard ratios and their 95% confidence intervals of HbA_{1c} for all-cause and cardiovascular disease (CVD) mortality. Analyses were stratified according to frailty.

	Diabetes duration	All-cause mortality	Number of events	CVD mortality	Number of events
Total group		1.12 (1.04-1.21)		1.16 (1.04-1.31)	
	< 5 years	1.09 (0.94-1.26)	199	1.13 (0.89-1.43)	76
	≥ 5 years	1.15 (1.05-1.26)	356	1.19 (1.05-1.36)	159
Non-frail subjects		1.18 (0.99-1.39)		1.06 (0.80-1.41)	
	< 5 years	0.90 (0.63-1.29)	47	0.78 (0.41-1.46)	16
	≥ 5 years	1.33 (1.10-1.62)	61	1.24 (0.88-1.74)	27
Frail subjects		1.11 (1.03-1.21)		1.19 (1.05-1.34)	
	< 5 years	1.21 (1.02-1.44)	152	1.26 (0.96-1.64)	60
	≥ 5 years	1.10 (0.99-1.22)	295	1.19 (1.03-1.38)	132

Adjusted for age, sex, BMI, duration of diabetes, systolic blood pressure, serum creatinine level, total cholesterol-HDL ratio, macrovascular complications, albuminuria, and the use of insulin were selected for their possible confounding effect.

226

Optimum level of glycaemic control for the lowest mortality in very old adults with type 2 diabetes mellitus

T. Wongviriyawong, A. Sriwijitkamol, V. Srinonprasert; Medicine, Faculty of medicine, Siriraj hospital, Bangkok, Thailand.

Background and aims: The complexity of care for diabetes patients increases substantially with age. Older adults with diabetes have higher rates of major diabetic complication and mortality. There are few studies conducted in the very old (age \geq 75 years) diabetic patients to investigate on optimal care for the very old adults, particularly glycemic target for this group of population. The aims of this study were to primarily explore which level of HbA_{1c} is associated with the lowest mortality and secondly for HbA_{1c} level with lowest diabetic-related complications in the very old diabetic patients.

Materials and methods: We conducted a retrospective cohort study of 1,000 participants with T2DM age \geq 75 years being treated in a university hospital during January 2007 to December 2013. Data collected were baseline characteristics including HbA_{1c} level, and geriatric syndromes such as dementia and frailty, a progressive decline in multiple organ systems and function which leads to vulnerability to complications and mortality. Primary outcome was analyzed in using Cox proportional hazard models and binary logistic regression for secondary outcomes.

Results: Included population had median age of 77(75-100) years with median HbA_{1c} of 7.0 (4.3-17.3) % and diabetic microvascular complications of 24.8%. Median follow-up time was 5.0(1.6-7.0) years. Overall mortality rate was 47.5/1000 person-year. HbA_{1c} had a U-shaped relationship with mortality; the lowest mortality was at HbA_{1c} of 6.0-6.9% and the highest at \geq 8.0% (hazard ratio [HR] 1.59; 95% confidence interval [CI] 1.04-2.45; P=0.034). Other factors influencing mortality were; GFR $<$ 30 mL/min/1.73 m² (HR 3.52; 95% CI 2.05-6.04; P $<$ 0.001), age \geq 85 year (HR 2.91; 95% CI 1.91-4.43; P $<$ 0.001), frailty (HR 2.52; 95% CI 1.76-3.61; P $<$ 0.001), presence of coronary artery disease (CAD) (HR 2.02; 95% CI 1.39-2.93; P $<$ 0.001), male sex (HR 1.82; 95% CI 1.27-2.61; P=0.001), having both diabetic nephropathy and retinopathy (HR 1.95; 95% CI 1.10-3.43; P=0.021). While attending a special clinic (DM or geriatric) was a protective factor (HR 0.56; 95% CI 0.39-0.79; P=0.001). Higher level of HbA_{1c} was related to more hypoglycemia especially in patients using insulin and having impaired renal function; and also more stroke events when HbA_{1c} \geq 8%. Moreover, frailty was significantly associated with stroke (odd ratio [OR] 2.92; 95% CI 1.58-5.38; P=0.001). Patients using beta blockers were more likely to develop CAD (OR 2.00; 95% CI 1.17-3.41; P=0.012) and heart failure (OR 2.28; 95% CI 1.20-4.31; P=0.011).

Conclusion: Optimum level of HbA_{1c} in the very old adults aimed for the lowest mortality should be less than 8%. However, attention should be drawn to other risk factors, such as reduced renal function, extreme age and frailty, which appeared to show more influence on mortality in older diabetic patients. In order to provide good care of diabetes for the very old, optimal goal should not focus only on glycemic level.

Serum levels of advanced glycation end products and their receptor in the elderly diabetic patients with mild cognitive impairment

M. Gorska-Ciebiada¹, M. Saryusz-Wolska¹, A. Borkowska¹, M. Ciebiada², J. Loba¹;

¹Department of Internal Medicine and Diabetology, ²Department of General and Oncological Pneumology, Medical University of Lodz, Poland.

Background and aims: Type 2 diabetes (T2DM) is a risk factor for Alzheimer's disease and mild cognitive impairment (MCI) in the elderly. The cause of cognitive impairment in diabetes is unknown, but it is most likely multi-factorial. Advanced glycation end products (AGEs) and their receptor (RAGE) play crucial roles in the pathogenesis of T2DM and

associated complications, but RAGE is also an important cell-signaling receptor involved in cognitive impairment. The aim of the study was to evaluate serum levels of AGEs, RAGE and C-reactive protein (CRP) in elderly patients with T2DM with and without MCI and to determine the predictors (including AGEs, RAGE and CRP levels) of having MCI in elderly patients with T2DM.

Materials and methods: According to the criteria proposed by the MCI Working Group of the European Consortium on Alzheimer's Disease 276 elderly subjects with T2DM were screened for MCI (using the Montreal Cognitive Assessment: MoCA score) and selected into groups: 87 patients with MCI and 189 patients without MCI as a control. Data of biochemical parameters and biomarkers were collected. The serum levels of AGEs, RAGE and CRP were assessed using ELISA kit.

Results: In MCI patients serum levels of AGEs (2.19 \pm 1.12 ng/ml), RAGE (4.24 \pm 1.89 ng/ml) and CRP (7.6 \pm 2.7 mg/L) were significantly increased compared to controls (AGEs 1.04 \pm 0.82 ng/ml; RAGE 1.94 \pm 0.91 ng/ml; CRP 3.9 \pm 2.0 mg/L; p $<$ 0.001). In group of subjects with MCI serum RAGE level was positively correlated with AGEs level (r=0.85; p $<$ 0.001) and with CRP level (r=0.54; p $<$ 0.001). RAGE, AGEs and CRP concentrations were positively correlated with HbA_{1c} levels (RAGE: r=0.78, p $<$ 0.001; AGEs: r=0.71, p $<$ 0.001; CRP: r=0.63, p $<$ 0.001) and negatively correlated with MoCA score (RAGE: r=-0.61, p $<$ 0.001; AGEs: r=-0.5, p $<$ 0.001; CRP: r=-0.37, p $<$ 0.001). The univariate logistic regression models revealed that variables which increased the likelihood of diagnosis of MCI in elderly patients with T2DM were: higher levels of HbA_{1c}, RAGE, AGEs, CRP, triglycerides, lower level of HDL cholesterol, previous cardiovascular disease (CVD), hypertension (HA) or use of antihypertensive drugs, hiperlipidaemia, retinopathy, nephropathy, increased number of co-morbidities, older age and less years of formal education. HA or use of anti-HA drugs (OR 3.48, 95% CI: 1.56-7.76, p=0.002), previous CVD (OR 3.34, 95% CI: 2.06-5.41, p $<$ 0.001), higher level of RAGE (OR 1.95, 95% CI: 1.24-3.06, p=0.004), and CRP (OR 1.55, 95% CI: 1.21-1.99, p=0.001), older age (OR 1.11, 95% CI: 1.0-1.23, p=0.039), and less years of formal education (OR 0.64, 95% CI: 0.5-0.82, p $<$ 0.001), are the factors increasing the likelihood of having MCI in elderly patients with T2DM in multivariable analysis.

Conclusion: In summary, serum levels of AGEs, RAGE and CRP are increased in MCI elderly diabetic patients compared to controls. A larger population-based prospective study needs to be performed to further confirm the relationship between AGEs, RAGE and the cognitive decline or progress to dementia. As an option, targeting the AGEs-RAGE system in diabetes especially with cognitive impairments through specific pharmacologic interventions might result in a clinical benefit for these patients.

Protection from diabetic retinopathy, but not nephropathy

K.A. Hillary¹, M. Khamaisi¹, L.J. Tinsley¹, S.M. Hastings¹, S. D'Eon¹, D. Pober¹, J.K. Sun², G.L. King¹;

¹Vascular Cell Biology, ²Beetham Eye Institute, Joslin Diabetes Center, Boston, USA.

Background and aims: Diabetic patients with nephropathy (DN) most often develop retinopathy (DR) as well, but those with DR frequently do not have DN suggesting that causal and protective factors may differ. Amongst the Joslin 50-Year Medalist we identified a cohort with DN, but not DR, providing the unique opportunity to characterize this unusual phenotype and possibly identify protective factors.

Materials and methods: This is a cross-sectional study of individuals with 50 or more years of type 1 diabetes, the Joslin 50-Year Medalists. The cohort was grouped into four categories by DN (eGFR Lt 45 mL/min/1.73 m²) and proliferative DR (PDR, ETDRS gt 53) status. We compared groups of Medalists with DN and PDR (+DN/+PDR; n=63), DN and no PDR (+DN/-PDR; n=30), no DN and with PDR (-DN/+PDR; n=345), and no DN and no DR (-DN/-PDR; n=326).

Results: Of those with DN (+DN/-PDR and +DN/+PDR) the mean eGFR, serum creatinine and ACR in the groups were 37.5 ± 8.5 v 33.9 ± 8.8 mL/min/1.73 m², 1.7 ± 0.5 v 1.9 ± 0.7 mg/dL, median [Q1, Q3] were 18.8 [8.0, 57.9] v 49.7 [14.0, 127.1] mcg/mg, respectively. Post-mortem pathology in +DN/-PDR (n=4) confirmed classic clinical DN with mesangial expansion and advanced glomerulosclerosis (DN class IIB and III). Those in the +DN/-PDR group were older at diagnosis (15.0 ± 7.5 , 10.4 ± 5.5 , 11.6 ± 6.6 , 10.5 ± 5.9 years, $p < 0.01$) and at study participation (72.1 ± 7.2 , 66.3 ± 6.8 , 66.1 ± 7.3 , 64.6 ± 7.0 years, $p < 0.01$). Surprisingly, those in the +DN/-PDR group had lower rates of cardiovascular disease (CVD) than expected for those with renal disease, 34.5% in the +DN/-PDR compared to 71.0% in the +DN/+PDR, 43.8% in -DN/+PDR, and 29.3% in -DN/ -PDR, $p < 0.05$. Interestingly, the highest proportion of detectable c-peptide was in the +DN/ -PDR group (56.7% v. 30.7% +DN/+PDR, 37.4% -DN/-PDR, 32.2% -DN/+PDR, $p = 0.03$). In addition, vascular endothelial growth factor (VEGF) response to stimulation (insulin and hypoxia) in fibroblasts was almost twice as high amongst those +DN/ -PDR (n=4) compared to those +DN/+PDR (n=6) (insulin 29% v 15%; hypoxia 40% v 29%). Those without DN or PDR (n=6) had the highest response to stimulation (insulin 94% and hypoxia 128%) over baseline. The VEGF response to stimulation mirrored the prevalence of CVD across the four DN/DR groups.

Conclusion: Among Medalists, the absence of PDR with DN is associated with a relative decreased prevalence of CVD, retention of beta cell function and higher VEGF response compared to the other +DN group indicating possible common protective factors against hyperglycemic toxicity for CVD and PDR.

Effects of quiescent and activated mesenchymal stromal cells on islet secretory functions

A.A. Arzouni, A.E. Vargas, P.K. Dhadda, A. King, P.M. Jones; Diabetes Research group, Division of Diabetes and Nutritional Sciences, King's College London, UK.

Background and aims: Pre-culturing of islets in a direct co-culture with mesenchymal stromal cells (MSCs) has been shown to enhance islet function *in vitro* and to the outcome of islet transplantation *in vivo*. This study aimed to determine whether activation of MSCs by exposure to pro-inflammatory cytokines affects their ability to influence islet function.

Materials and methods: Adipose-derived MSCs and pancreatic islets were isolated from C57B1/6 and ICR mice. To determine the optimum time of co-culture required for MSCs to improve islet function, islets were co-cultured with quiescent MSCs in a direct-contact configuration and islets function was assessed by measuring glucose-stimulated insulin secretion (20 mmol/l; GSIS) at 24, 48 and 72 hours. Activation of MSCs was achieved by incubation (37C, 8 h) in the presence of the inflammatory cytokines TNF- α and IFN- γ (20 ng/ml each), and confirmed by measuring the relative expression of mRNAs for nitric oxide synthase-2 (NOS2) and chemokine C-X-C motif ligand 9 (CXCL9). Islets were cultured alone or in a direct-contact configuration with either quiescent or activated MSCs for 48 hrs before assessment of GSIS.

Results: *Co-culture incubation time:* GSIS measured from islets alone vs. islets co-cultured on MSCs at different time points revealed that a minimum of 48 hrs incubation time was needed for the MSCs to exert their beneficial effect on islets: islets-MSCs (2 mmol/l: 0.91 ± 0.08 ng/islet/h; 20 mmol/l: 6.20 ± 0.50) vs. islets-alone (2 mmol/l: 0.333 ± 0.05 ng/islet/h; 20 mmol/l: 2.08 ± 0.30 , $p < 0.001$, $n = 3$ experiments, each of 10 observations). *Activation of MSCs:* Culturing MSCs for 8 h in the presence of TNF- α and IFN- γ was sufficient to activate MSCs as assessed by increased mRNA expression levels of NOS2 (quiescent MSCs 0.0001 vs. activated MSCs 0.1 relative expression) and CXCL9 (quiescent MSCs 3.4×10^{-5} vs. activated MSCs 0.6 relative expression). The activation of MSCs was maintained for 72 hours after removal of cytokines. Islets cultured alone (IA) for 48 hours responded to a stimulatory concentration of glucose with increased insulin secretion (2 mmol/l: 0.07 ± 0.05 ng/islet/h; 20 mmol/l: 0.73 ± 0.14). Glucose-induced insulin secretion was potentiated from islets that had been co-cultured with quiescent or activated MSCs compared to IA (quiescent-MSCs 20 mmol/l 4.99 ± 1.1 , activated MSCs 20 mmol/l 3.50 ± 0.82 $p < 0.05$). However, activated MSCs did not further enhance insulin secretion above that induced by co-culture of islets with quiescent MSCs.

Conclusion: Both quiescent and activated MSCs enhanced glucose-induced insulin secretion from islets when co-cultured in a direct co-culture configuration *in vitro*. MSCs activation by cytokine treatment did not further enhance insulin secretion above that induced by quiescent MSCs, but activated MSCs may also influence islet cell survival.

Activation of pancreatic progenitors during isolation of porcine neonatal pancreatic cell clusters

J.-H. Juang¹, C.-Y. Chen¹, W.-J. Chang², C.-Y. Chen², C.-H. Kuo³, W.-C. Li²;

¹Division of Endocrinology and Metabolism, Department of Internal Medicine, Chang Gung Memorial Hospital, Taoyuan, ²Institute of Oral Biology, School of Dentistry, Taipei, ³Biomedical Technology and Device Research Laboratories, Industrial Technology Research Institute of Taiwan, Hsinchu, Taiwan.

Background and aims: Generation of β cells *ex vivo* that are suitable for transplantation paves the way to correct beta-cell deficit in diabetic patients. While multiple step-wise protocols to differentiate human stem cells into functional β cells were proposed and early commitment of pluripotent cells into pancreatic progenitors is fairly efficient, the β cell maturation triggers are still largely unknown. Previous studies showed that *in vitro* cultivated porcine neonatal pancreatic cell clusters (NPCCs) exhibited primarily epithelial progenitor-like phenotype *in vitro* and could successfully ameliorate hyperglycemia in diabetic mice revealing a useful tool to explore islet maturation promoters.

Materials and methods: Current study sought to identify molecular profile of NPCCs upon isolation to better define their cellular properties. The NPCCs from 1-3 day new-born pigs were isolated using collagenase-based protocol and maintained *in vitro* for up to 4 days after dissociation. The mRNA and protein expression for insulin, glucagon, exocrine enzymes amylase and carboxypeptidase B, proliferation indicator Ki67 as well as the progenitor markers Pdx1 and Sox9 in time-course NPCC cultures were examined using semi-quantitative RT-PCR and immunofluorescence staining analysis, respectively.

Results: Histological analysis showed 3.4%, 7.6%, 8.6% and 11.4% of NPCCs are insulin+ in 1-, 2-, 3- and 4-day cultures, respectively, whereas semi-quantitative RT-PCR detected increased insulin and decreased exocrine enzyme carboxypeptidase B (CPB) mRNA expression over 4-day cultivation implying gradual enrichment of β cell population in culture. Strikingly, highly proliferating (30.1% Ki67+ cells in first 4-day cultures compared to 16.1% Ki67+ cells in 1-day old pig pancreas) pancreatic progenitors stained for Pdx1 (83.7%, 72.7%, 77.3% and 77.1% in 1-, 2-, 3- and 4-day cultures, respectively, compared to 51.9% in 1-day old pig pancreas) and Sox9 (respect 78.0%, 79.7%, 80.0% and 81.3% in 1-, 2-, 3- and 4-day cultures compared to 6.8% in 1-day old pig pancreas) were quickly induced after isolation indicating the pancreatic precursors could be propagated *in vitro*.

Conclusion: In summary, our results showed that islet precursors could be simply activated during NPCC isolation. NPCC-derived progenitors maintain their pluripotency in culture providing a useful platform to examine insulinotropic and maturation-promoting effects of candidate molecules to direct human pluripotent cells into functional β cells.

A small molecule that facilitates the differentiation into pancreatic endocrine cells from human ES/iPS cells

Y. Kondo^{1,2}, T. Toyoda¹, M. Funato¹, Y. Hosokawa¹, T. Sudo¹, X. Zhuang², A. Ohta¹, N. Inagaki², K. Osafune¹;

¹Center for iPS Cell Research and Application (CiRA), ²Department of Diabetes, Endocrinology and Nutrition, Kyoto University, Japan.

Background and aims: Type 1 diabetes is an autoimmune disease characterized by the destruction of β -cells in the pancreas, absolute insulin deficiency and persistent high levels of blood glucose. Cases with difficult blood glucose control exist even using intensive insulin therapy. Although pancreas and pancreatic islet transplantation is established as the radical treatment of type 1 diabetes, problems of the transplantation

therapies include shortage of donors and immune rejection. Generation of pancreatic β cells from embryonic stem (ES) cells or induced pluripotent stem (iPS) cells would lead to the development of a promising replacement therapy for insulin-dependent diabetes, such as type 1 diabetes. Researchers have aimed to differentiate pancreatic β cells from stem or progenitor cells for the goal. However, the induction efficiency of insulin-producing (INS(+)) cells from human ES/iPS cells has been low (less than 10%) in most reports. Aims: To establish an efficient differentiation method of INS(+) cells from human ES/iPS cells by identifying novel small molecule inducers.

Materials and methods: Based on the previously-reported differentiation protocol (Kunisada Y et al, 2012), human iPS cells were first induced into PDX1(+) pancreatic progenitors through SOX17(+) definitive endoderm, and then 4 factors (Nicotinamide, Forskolin, Dexamethasone and ALK5 inhibitor; 4Fs) and/or small molecules were added on the PDX1(+) cells. We used High-Throughput Screening (HTS) system to examine thousands of compounds from various libraries. Anti-insulin immunostaining was performed and the induction rate of INS(+) cells was quantitatively evaluated. Small molecules that more efficiently induce INS(+) cells than the previous protocol with 4Fs were defined as primary hits. Then, we evaluated the insulin secretory function of the INS(+) cells generated with the hit compounds. Finally, we established the INSULIN-GFP human iPSC reporter line to monitor and isolate the INS(+) cells and evaluated the function and gene expression of INS(+) cells differentiated from human iPSCs.

Results: Out of about 1,250 small molecules that we screened, one hit compound (compound SC) was identified. When the compound SC was combined with the previously-reported protocol with 4Fs, the induction rate of INS(+) cells was increased up to 15-20%. We found that compound SC facilitates the differentiation of endocrine cells including INS(+) cells both *in vitro* and *ex vivo* by expanding the NEUROG3(+) endocrine precursor cells. The INS(+) cells generated with compound SC showed the ability to secrete C-peptide *in vitro*. We then successfully established the INSULIN-GFP human iPSC reporter line, and are currently examining the mechanisms of action of compound SC to induce the pancreatic endocrine differentiation, based on the information of its target molecules and by gene expression analyses of purified INS(+) cells generated with compound SC.

Conclusion: We have identified one small molecule that facilitates the differentiation of human iPS/ES cells into pancreatic endocrine cells including insulin-producing β -like cells *in vitro*.

Endocrine cell plasticity in human islets of Langerhans in type 2 diabetes

C. Perego¹, S. Moretti¹, C. Santi¹, S. LaRosa², F. Bertuzzi³, F. Folli⁴, E.S. Di Cairano⁵;

¹DiSFB Dept of Pharmacological and Biomolecular Sciences, University of Milano, ²Ospedale di Circolo, Varese, ³Niguarda Cà Granda Hospital, Milano, Italy, ⁴University of Texas Health Science Center, San Antonio, USA, ⁵DiSFeB Dept of Pharmacological and Biomolecular Sciences, University of Milano, Italy.

Background and aims: Studies in the last years indicate that the adult pancreas has an inherent regenerative capacity to produce new β -cells in response to increased metabolic demand or injury. Different mechanisms of beta cell regeneration in the adult pancreas have been proposed: 1) replication from endogenous β -cell, 2) neogenesis from non- β -cells precursors and 3) β -cell formation by transdifferentiation. The last mechanism consists in the conversion of one endocrine non-beta cell into beta by lineage reprogramming. It has been clearly identified in animal models; its existence and relevance in humans has never been demonstrated. Aim of this study was to examine the islet composition and architecture in control and diabetic subjects and to verify the existence of a transdifferentiation process in diabetic islets.

Materials and methods: We collected human pancreatic sections from 12 normal (7 M/5 F; mean age 69 ± 7 years) and 14 diabetic donors (8 M/6 F; mean age 66.4 ± 10.3 years). Sections were double/triple stained with antibodies directed against hormones (insulin, glucagon, somatostatin) and samples were analysed by confocal microscopy. Total islet area, $\beta/\alpha/\delta$ -cell area, frequency of heterologous/homologous contacts among different endocrine populations, and the % of endocrine cells co-expressing insulin and glucagon (indicative of transdifferentiation) were quantitatively analyzed with the image-Pro 3D analyser software.

Results: In pancreatic sections derived from diabetic subjects there is a significant decrease of the total islet area ($27\pm 5\%$ reduction; $p=0.01$) and cell density ($15\pm 7.9\%$ reduction) compared to healthy controls, due to b-cell death and amyloid accumulation. In particular, we detected a $49\pm 7\%$ ($p<0.0001$) reduction in b-cell area of T2D subjects compared to healthy controls (particularly evident in the islet core). No significant modification of a-cell area was observed. The overlap coefficient between insulin and glucagon stainings (co-localization index) was significantly increased in diabetic subjects compared to controls (T2D 0.36 ± 0.03 ; CTR 0.20 ± 0.04 ; $p<0.05$), suggesting a transdifferentiation process. No correlation was found between the overlap coefficient and subjects' age, sex, diabetes duration, islet area. Interestingly, subjects with the highest overlap coefficient were under insulin treatment, suggesting that the phenomenon correlates with severe islet dysfunction.

Conclusion: The validation of transdifferentiation as an alternative mechanism occurring in adult diabetic pancreases and the understanding of how this event can be manipulated may lead to the design of new treatments aimed at promoting the survival of residual β -cell and preventing diabetes progression.

OP 41 Eye on retinopathy

233

Cumulative excess HbA_{1c} index may substantially predict retinopathy in type 1 diabetes patients, if we use HbA_{1c} data of total diabetes duration - a DCCT/EDIC subgroup analysis

A. Hirose¹, A. Goto², N. Yamaguchi², S. Kitano¹, Y. Uchigata³;

¹Diabetic Ophthalmology, Diabetes Center, ²Public Health, ³Diabetes Center, Tokyo Women's Medical University, Japan.

Background and aims: We found that an index, cumulative excess HbA_{1c} value (CueA1C), may substantially predict retinopathy, if we use HbA_{1c} data covering total diabetes duration, which may reflect the whole effect of metabolic memory in our type 1 diabetes mellitus (T1DM) patients who had only a short period (≤ 12 months) between diabetes onset and the beginning of observation. We also found that the longer the period without HbA_{1c} data following onset, the lower the capacity for prediction in our cohort. To confirm these results, we examined the public data of DCCT/Epidemiology of Diabetes Interventions and Complications (EDIC).

Materials and methods: To examine only selected cases of DCCT/EDIC, those who had HbA_{1c} data during nearly their entire period of hyperglycemia, we included 55 T1DM patients of primary prevention with the shortest diabetes duration (≤ 12 months) at DCCT baseline. We developed a window which we named 'half-yearly visit (HV)' to integrate HbA_{1c} data and retinopathy steps of the final Early Treatment Diabetic Retinopathy Study (ETDRS) severity scale for persons. HV00 was DCCT baseline, and HV24 was at DCCT year 12. During DCCT, HbA_{1c} values of an even number of quarterly visits (QVs) were applied to those of HVs: for example, the value of QV00 (DCCT baseline) was applied to HV00, QV02 to HV01, and so on. During EDIC, HbA_{1c} values were applied to the corresponding HVs according to their data collection dates from DCCT baseline: for example, $11.75 \leq X < 12.25$ years' data to HV24. Missing values were estimated by time-weighted averaging from the HbA_{1c} values of preceding and succeeding HVs. CueA1C was calculated by adding the values of $(\text{HbA}_{1c} - 6.5)(\%) \times 1/2(\text{year})$ of all the HVs from onset to a given HV, supposing each case had one-year duration at HV00, keeping the same HbA_{1c} value during that period. Simulated 3-, 6- and 9-year masked CueA1Cs were calculated in the same way but masking HbA_{1c} data for 3, 6 and 9 years following onset respectively. Retinopathy was defined as DR+ at ETDRS step ≥ 4 , otherwise as DR- at a given HV. The prediction capacities of CueA1Cs for retinopathy between HV16 and HV24 (DCCT years 8 and 12, respectively) were examined by receiver operating characteristic (ROC) analysis and were compared by the method of DeLong. $P < 0.05$ was considered significant.

Results: Of the 132 HVs which had retinopathy data between HV16 and HV24, 36 were DR+ and 96 were DR-. The area under the curve (AUC) for retinopathy was 0.885, 0.875, 0.777 and 0.653 in CueA1C, 3-, 6- and 9-year masked CueA1Cs respectively. The difference of AUC compared to CueA1C was not significant for 3-year masked CueA1C ($P=0.39$), but it was significant for 6-year ($P=0.0002$) and 9-year ($P<0.0001$) CueA1Cs. It seemed that CueA1C had a substantial capacity to predict retinopathy, and that the longer the period without A1C data, the lower the capacity for retinopathy prediction. The results in our previous study of Japanese patients seemed to be confirmed in the patients of the current DCCT/EDIC subgroup.

Conclusion: CueA1C index may have a substantial capacity to predict retinopathy in T1DM, if we use HbA_{1c} data of total diabetes duration insofar as possible. We should consider information from the entire duration of diabetes in order to study the relation between hyperglycemia and retinopathy accurately.

234

Cardiac autonomic function in relation to diabetic retinopathy development and progression in type 1 diabetic patients: a prospective observational study

K. Blaslov^{1,2}, S. Vučković Rebrina¹, M. Tomić¹, L. Duvnjak^{1,2};

¹University hospital Merkur, ²School of Medicine, University of Zagreb, Zagreb, Croatia.

Background and aims: Denervation of the cardiovascular system is one of the earliest manifestations of diabetic autonomic neuropathy (DAN). Various studies have shown that it is strongly associated with microvascular complications of diabetes, microalbuminuria and diabetic retinopathy (DR). In this longitudinal observational study we aimed to determine whether cardiac autonomic function contributes to risk of DR development and progression in normoalbuminuric type 1 diabetic (T1DM) without symptomatic DAN.

Materials and methods: One hundred fifty four normoalbuminuric T1DM patients were included in the study. Urine albumin excretion (UAE) was measured from two 24-h urine samples and determined as the mean of 24-h urine collections to minimize variability. Photodocumented retinopathy status was made according to EURODIAB protocol. Normoalbuminuria was defined as a UAE < 30 mg/24 h. The battery of cardiovascular autonomic function (AFT) tests included: heart rate variation at rest (HRV-CV), HRV-CV during deep breathing (dbHRV-CV), Valsalva manoeuvre and active orthostatic test and blood pressure response to standing. In the frequency domain we measured high-frequency power (HF), and low frequency power (LF) using a fast Fourier transformation in order to calculate the power spectral density curve. Participants were reexamined after 18 months to update their glycaemic control, UAE and retinopathy status.

Results: The results of AFT in T1DM patients with NPDR and 107 free of DR are given in Table 1. Patients with NPDR showed significantly lower HRV at rest, HRV during deep breathing as well as deep breathing E/I ratio compared to group of patients without DR. There was a significant attenuation for both LF and HF Power in the NPDR group. In-between groups diabetes duration was significantly different although long-term glycaemic control assessed by glycated haemoglobin A1c (HbA1c) was similar. Six (3.89%) patients developed albuminuria during 18 months follow up period while 21 (13.36%) developed NPDR or progressed from NPDR to PDR. A Cox regression model adjusted for age, gender, disease duration, HbA1c, hypertension prevalence, ACE inhibitor use and smoking status showed that higher HRV-CV, dbHRV-CV as well as LF Power reduce the risk of DR incidence and progression (HR 0.664 (0.514 to 0.866), $p=0.002$; 0.873 (0.784 to 0.972), $p=0.013$ and 0.909 (0.892 to 0.964), $p=0.014$, respectively).

Conclusion: In this prospective, longitudinal, observational cohort study, we demonstrated that AFT results might serve as an independent prognostic factor for the future development or progression of DR in T1DM patients even in the DAN absence.

Table 1. Clinical, laboratory data and cardiac autonomic function tests

Variable	Patients without retinopathy (N=107)	Patients with retinopathy (N=47)	p value
Age (yrs)	37(34-39)	39.5 (36-42.5)	0.279
Gender (N, %)	Female	28 (59.6)	0.211

Effects of baseline haemoglobin A_{1c} and on-treatment blood pressure on outcomes in the VIVID-DME and VISTA-DME studies

M. Evans¹, T.A. Katz², M. Crane², VIVID-DME and VISTA-DME Study Investigators;

¹Diabetes Resource Centre, Llandough Hospital, Cardiff, UK, ²Bayer HealthCare Pharmaceuticals, Whippany, USA.

Background and aims: The VIVID-DME and VISTA-DME studies evaluated intravitreal aflibercept (IVT-AFL) vs. laser for diabetic macular edema (DME). The current subanalyses analyse associations between haemoglobin A1c (HbA1c) and blood pressure (BP) and visual and anatomical outcomes in these studies.

Materials and methods: In the VIVID-DME and VISTA-DME studies, 865 patients with diabetic macular edema (DME) were treated with IVT-AFL (2 mg every 4 weeks [2q4] or 2 mg every 8 weeks following 5 monthly doses [2q8]) or laser. In the current subanalyses, data from both studies have been integrated. The IVT-AFL treatment arms were pooled to increase the power of the analysis. HbA1c quartiles were defined using all available baseline data. On-treatment BP was calculated as ((mean systolic BP+mean diastolic BP)/2) using the average of measurements obtained every 4 weeks from baseline to week 52. Values were then divided into quartiles.

Results: Mean changes in best corrected visual acuity (BCVA) and central retinal thickness (CRT) by mean baseline HbA1c quartiles and by mean on-treatment BP quartiles are shown in the table. The most frequent ocular serious adverse event in a pooled analysis of VIVID-DME and VISTA-DME was cataract (2.4% and 1.0% vs. 0.3% for 2q4 and 2q8 vs. laser).

Conclusion: In the laser group but not the IVT-AFL group, visual and CRT improvements were less with increasing baseline HbA1c. There was no apparent correlation between increasing on-treatment BP and vision or CRT in either group. Visual benefits were consistently greater with IVT-AFL vs. laser, regardless of baseline HbA1c or on-treatment BP.

Quartiles	Mean change in BCVA (letters)		Mean change in CRT (μm)	
	IVT-AFL	Laser	IVT-AFL	Laser
Q1: HbA1c 4.5%–6.7%	11.7	4.1	-200.9	-101.9
Q2: HbA1c 6.7%–7.4%	11.9	1.9	-196.5	-83.1
Q3: HbA1c 7.4%–8.6%	11.7	0.8	-195.5	-68.9
Q4: HbA1c 8.6%–14.7%	11.1	-0.3	-187.7	-43.3
Q1: BP 78.0–99.7 mmHg	10.5	1.0	-137.8	-84.0

Topical administration of GLP-1 receptor agonists prevents retinal neurodegeneration in experimental diabetes

R. Simó¹, P. Bogdanov¹, L. Corraliza¹, C. Solà-Adell¹, A.I. Arroba¹, A.M. Valverde², C. Hernández¹;

¹Diabetes and Research Unit, Institut de Recerca Hospital Universitari Vall d'Hebron and CIBERDEM, Barcelona, ²Instituto de Investigaciones Biomédicas Alberto Sols and CIBERDEM, Madrid, Spain.

Background and aims: Retinal neurodegeneration is an early event in the pathogenesis of diabetic retinopathy (DR). Since glucagon-like peptide-1 (GLP-1) exerts neuroprotective effects in the central nervous system and the retina is ontogenically a brain-derived tissue. The aims of the present study were: 1) To examine the expression and content of GLP-1R in human and db/db mice retinas. 2) To determine the retinal neuroprotective effects of systemic and topical administration (eye drops) of GLP-1R agonists in db/db mice. 3) To examine the underlying neuroprotective mechanisms.

Materials and methods: Human study: retinas were obtained from the Tissue Bank of our Centre. A total of 8 diabetic donors and 8 non-diabetic donors matched by age and gender were included in the study. GLP-1R expression and content were analyzed by RT-PCR, Western-blot and immunohistochemistry. Animal studies: after 15 days of treatment by using subcutaneous or topical GLP-1R agonists the neurodegenerative features were examined. Functional abnormalities were assessed by electroretinography and neurodegeneration was assessed by measuring glial activation and the apoptotic rate. In addition, several representative mediators of apoptotic (Fas/FasL, caspase 8, Bax, p53), anti-apoptotic (BclxL), neuroinflammatory (iNOS), and insulin signaling (pAKT/AKT) pathways were also analyzed by Western blot. Glutamate (HPLC) and its main transporter GLAST (glutamate/aspartate transporter) were also determined.

Results: We have found abundant expression of GLP-1R in the human retina and retinas from db/db mice. Moreover, we have demonstrated that systemic administration of a GLP-1R agonist (liraglutide) prevents retinal neurodegeneration (glial activation, neural apoptosis and electroretinographical abnormalities). This effect can be attributed to a significant reduction of extracellular glutamate due to the prevention of the down-regulation of GLAST induced by diabetes. In addition, an increase of prosurvival signaling pathways was observed. We have found a similar neuroprotective effect using topical administration of native GLP-1 and several GLP-1R agonists (liraglutide, lixisenatide and exenatide). Notably, this neuroprotective action was observed without any reduction in blood glucose levels.

Conclusion: These results suggest that GLP-1R activation itself prevents retinal neurodegeneration. Our results should open up a new approach in the treatment of the early stages of DR.

OP 42 Liver metabolism: from fat to facts

237

Bioactive lipids dissociate steatosis and insulin resistance in the human liver in non-alcoholic fatty liver disease

P. Luukkonen^{1,2}, Y. Zhou¹, S. Sädevirta^{1,2}, M. Leivonen³, J. Arola⁴, M. Oresic⁵, T. Hyötyläinen⁵, H. Yki-Järvinen^{1,2};

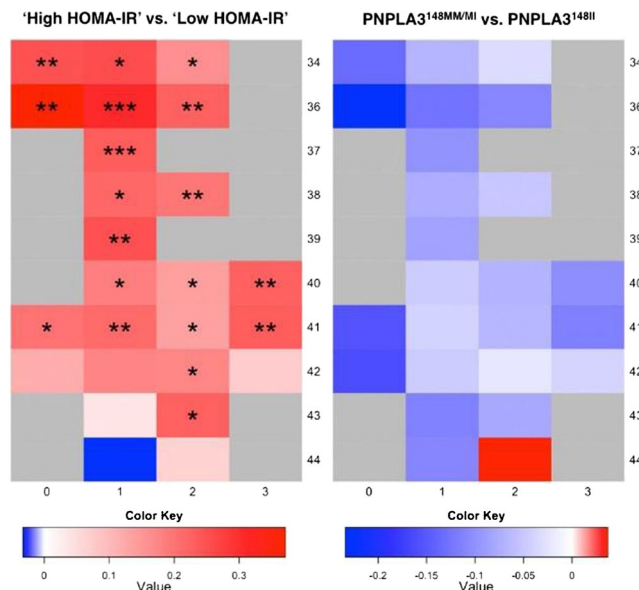

¹Minerva Foundation Institute for Medical Research, ²Department of Medicine, University of Helsinki, ³Department of Surgery, University of Helsinki, ⁴Department of Pathology, University of Helsinki, Helsinki, Finland, ⁵Steno Diabetes Center, Gentofte, Denmark.

Background and aims: ‘Metabolic NAFLD’ is characterized by hepatic insulin resistance (IR) and the features of metabolic syndrome, while NAFLD due to the common (40% of Europeans) PNPLA3 I148M gene variant at rs738409 (‘PNPLA3 NAFLD’) is not. We used these two models to determine in the human liver whether i) NEFA or triglyceride (TG) composition; ii) bioactive lipids; iii) pathways of ceramide synthesis differ between ‘Metabolic NAFLD’ and ‘PNPLA3 NAFLD’. The latter is of interest as recent studies in mice have identified 16:0-ceramide formed via the de novo ceramide synthetic pathway as the key mediator of hepatic insulin resistance.

Materials and methods: Liver biopsies from 125 subjects, characterized with respect to metabolic features and PNPLA3 genotype, were taken for profiling of molecular lipids using UHPLC-MS and liver histology. Subjects were divided into groups based on median HOMA-IR (‘High HOMA-IR’, n=62, vs. ‘Low HOMA-IR’, n=63) and the PNPLA3 genotype (PNPLA3148MM/MI, n=61 vs. PNPLA3148II, n=64). The groups were similar with respect to BMI and gender.

Results: Histologic liver fat was similarly 3-fold increased in ‘High HOMA-IR’ (15 [5 - 33]) vs. ‘Low HOMA-IR’ (5 [0 - 20], p<0.002) group, and in ‘PNPLA3148MM/MI (15 [5 - 30]) vs. the ‘PNPLA3148II’ (5 [0 - 28], p<0.04) group. By definition, the ‘High HOMA-IR’ group was insulin-resistant vs. the ‘Low HOMA-IR’ group (HOMA-IR 4.8 [3.9-5.8] vs. 1.8 [1.3-2.7], p<0.0001), and also had decreased serum adiponectin (6.0 [4.0-8.7] vs. 9.5 [6.1-12.1] ng/ml, p<0.0001), while no changes were observed in PNPLA3148MM/MI vs. PNPLA3148II group (HOMA-IR 3.2 [1.7-5.1] vs. 3.2 [1.9-4.5], NS). The liver in ‘High HOMA-IR’ vs. ‘Low HOMA-IR’ was markedly enriched in saturated and monounsaturated TGs, dihydroceramides (34:0 and 36:0, reflecting de novo ceramide synthesis from 16:0 palmitate and 18:0 stearate, Figure), other ceramides (Figure) and in 16:0 and 18:0 but not 18:2 or 20:4 intrahepatic NEFA. Markers of other ceramide synthetic pathways were unchanged. In PNPLA3148MM/MI vs. PNPLA3148II, the increase in liver fat was due to polyunsaturated TGs while other TGs, diacylglycerols, ceramides (Figure) and intrahepatic NEFA were unchanged.

Conclusion: Equal increases in liver fat due to ‘Metabolic NAFLD’ and ‘PNPLA3 NAFLD’ are characterized by strikingly different hepatic lipidomes. Bioactive IR causing lipids, particularly ceramides from de novo synthesis from saturated fatty acids, are increased in ‘Metabolic NAFLD’ but not ‘PNPLA3 NAFLD’. These differences imply measurement of liver fat allows diagnosis of NAFLD but not insulin resistance or its metabolic consequences.

Fold change of hepatic dihydroceramides and ceramides between the groups. The color code indicates the log of the ratio between means of the groups for an individual species. The y-axes denote the number of carbons and the x-axes the number of double bonds. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

Gene therapy with insulin receptor isoform a as an approach for the treatment of type 2 diabetes

S. Diaz-Castroverde^{1,2}, O. Escribano^{1,2}, M. Luque¹, A. Gómez-Hernández^{1,3}, S. Fernández^{1,3}, G. García-Gómez^{1,3}, G. González-Aseguinolaza⁴, M. Di Scala⁴, N. Beneit¹, L. Perdomo¹, M. Benito^{1,2}; ¹Biochemistry and Molecular Biology II, Complutense University of Madrid, ²Mechanism of Insulin Resistance Consortium, ³Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, Madrid, ⁴Center for applied medical research, University of Navarra, Pamplona, Spain.

Background and aims: Type 2 diabetes mellitus is a complex metabolic disease and its pathogenesis involves abnormalities in both peripheral insulin action and insulin secretion by pancreatic beta cells. There are many proteins involved in insulin resistance and one of the most important is the insulin receptor (IR). Our laboratory has generated iLIRKO mice (inducible Liver Insulin Receptor KnockOut) that develops Type 2 diabetes in a very similar way to what happens in humans. Moreover, previous experiments in our laboratory found that IRA isoform, but not IRB, plays a direct role in the regulation of basal glucose uptake/transport through its specific association with endogenous glucose transporters (GLUT1 and GLUT2) in murine hepatocytes. With this background, we hypothesized that the expression of IRA in iLIRKO mice using AAVs (Adenoassociated virus) as a gene therapy approach could be a good option in order to reverse the diabetic phenotype. Thus, reconstitution of iLIRKO with IRA in the liver might increase glucose consumption, ameliorate hyperglycaemia and therefore impair the compensatory mechanisms through beta cell hyperplasia/hypertrophy that finally lead to beta cell failure.

Materials and methods: Recombinant hepatospecific AAV vectors (serotype 8) were constructed with a transgene cassette encoding either the IRA or IRB or the reporter gene GFP. Twenty-week-old mice were injected intravenously with the AAV viruses. Glucose and insulin tolerance tests were performed to evaluate insulin sensitivity and glucose

clearance and follow the diabetic phenotype. In addition, insulin plasma levels were also measured by ELISA.

Results: The physiological effects of the disruption of insulin signaling in liver in iLIRKO mice were apparent 5 weeks after the induction of the IR deletion. By 3 months of age, male iLIRKO displayed pronounced glucose intolerance and insulin resistance. The expression of IRA in 20-week-old mice, but not IRB, was able to restore glucose tolerance and reverted insulin resistance about 8 weeks after the treatment. Moreover, plasma insulin levels were recovered in injected IRA iLIRKO mice as compared with IRB-injected or reporter gene-injected mice.

Conclusion: Our data demonstrate that the expression of IRA by gene therapy improves hyperglycemia by promoting an increased glucose uptake by the liver. The decrease on glucose plasma levels ameliorates the compensatory hyperinsulinemia that finally lead to beta cell failure and overt diabetes. Therefore, hepatic expression of IRA could be a therapeutic approach for Type 2 diabetes treatment.

Metabolic reprogramming in male offspring in a non-dietary model of liver insulin resistance

D.F. De Jesus^{1,2}, R.N. Kulkarni¹;

¹Islet Cell and Regenerative Biology, Joslin Diabetes Center, Harvard Medical School, Boston, USA, ²GABBA - Graduate Program in Areas of Basic and Applied Biology, Abel Salazar Biomedical Sciences Institute, University of Porto, Portugal.

Background and aims: Several studies have focused on investigating the effects of early nutritional insults that increase the likelihood of developing type 2 diabetes in the offspring. Virtually none include the use non-dietary models manifesting hyperglycemia and hyperinsulinemia. We aimed to determine the effects of paternal versus maternal liver insulin resistance on the developmental programming in the offspring of the liver-specific insulin receptor knockout (LIRKO) mice.

Materials and methods: Male control offspring from 12 weeks of age LIRKO father (LF) and control mother, LIRKO mother (LM) and control father, and control mothers and fathers (C) were weaned at 3 weeks of age on a chow (21%) or high-fat diet (HFD) (60%) and followed for 12 weeks. Body weights and blood glucose levels were measure weekly. Insulin sensitivity, glucose tolerance, in vivo glucose-stimulated insulin secretion was assessed between 9 and 12 weeks of age in randomly selected mice from a least 3 different offsprings in each group. Mice were sacrificed at 15 weeks of age, blood, pancreases and liver were harvested for further analysis.

Results: As previously reported, 8 week-old LIRKO males and females exhibited insulin resistance and glucose intolerance compared to their respective controls. On a chow diet, LF (LF: 14.1 ± 0.5 ; C: 17.5 ± 0.5 g; LF vs C: $p < 0.001$, 4 weeks of age): and LM (LM: 15.1 ± 0.5 ; C: 17.5 ± 0.5 g; LM vs C: $p < 0.001$; 4 weeks of age) exhibited lower body weights until 9 weeks of age and compensated by gaining weight with age compared to controls. After 3 weeks on HFD, LM (LM: 27.7 ± 1.0 ; C: 23.7 ± 0.7 g; LM vs C: $p < 0.01$; 6 weeks of age) but not LF gained more weight compared to C. LF and LM exhibited insulin resistance compared with C on both chow (LF vs C: $p(\text{area under the curve} - \text{AUC}) < 0.01$ and LM vs C: $p(\text{AUC}) < 0.01$; $n = 5-8$) and HFD (LF vs C: $p(\text{AUC}) < 0.05$ and LM vs C: $p(\text{AUC}) < 0.01$, $n = 4-5$) cohorts at 9 weeks of age. LF and LM maintained insulin resistance with age and after 8 weeks on HFD became hyperglycemic (LF, 110.2 ± 6.2 ; LM, 107.2 ± 4.1 ; C, 78.3 ± 6.9 mg/dL; LF vs C and LM vs C: $p < 0.01$; $n = 4$) and LM hyperinsulinemic (LM, 2.63 ± 0.66 ; LF, 1.62 ± 0.67 ; C, 0.52 ± 0.11 ng/ml; LM vs C: $p < 0.05$; $n = 4$) during fasting. LF and LM presented an augmented acute insulin secretion response to glucose (LF: 374.95 ± 4.4 ; LM: 502.41 ± 39.5 ; C: $223.65 \pm 36.4\%$ of initial insulin levels; LF vs C: $p < 0.001$; LM vs C: $p < 0.001$; $n = 3$; 2 minutes after stimulation) on chow. On HFD this response was abrogated in both groups. LF and LM had increased beta-cell

proliferation (LF: 0.42 ± 0.06 ; LM: 0.44 ± 0.02 ; C: $0.23 \pm 0.04\%$ KI67+/Insulin+ cells; LF vs C: $p < 0.05$; LM vs C: $p < 0.01$; $n = 3-4$) on chow comparing with C. After 12 weeks of HFD, LF and LM presented prominent hepatic steatosis. Analysis of genes involved in the regulation of liver glucose and fatty acid metabolism revealed LM and LF on chow diet exhibited downregulation of Glut2, Gpase, Cpt1, CD36, Elovl2, PPAR α and PPAR γ genes while the same groups on HFD showed upregulation of CD36, PPAR α , PPAR γ , Fas and Scd1.

Conclusion: Together these data suggest that prenatal hyperinsulinemia and hyperglycemia have detrimental effects on beta-cell adaptation and transcriptional regulation of hepatic metabolism in the offspring that may contribute to their impaired growth and metabolic response to dietary challenges.

Liver insulin sensitivity is linked with resting sympathetic nervous activity in non-diabetic obese men

D.L.T. Chen¹, D. Chisholm¹, R. Brown², V. Macefield², D. Samocha-Bonet^{1,3}, J. Greenfield^{1,4};

¹Garvan Institute of Medical Research, ²Integrative Physiology School of Medicine, University of Western Sydney, ³School of Medical Sciences, University of New South Wales, ⁴Department of Endocrinology and Diabetes Center, St. Vincent's Hospital, Sydney, Australia.

Background and aims: Sympathetic nervous system activity may play a role in the aetiology of insulin resistance in humans. Obesity is associated with peripheral and hepatic insulin resistance and with basal sympathetic nervous hyperactivation. However, whether sympathetic nervous activation is more closely aligned with peripheral or hepatic insulin resistance in obesity remains unclear. We aimed to compare resting muscle sympathetic nervous activity (MSNA) between non-diabetic obese insulin-sensitive and insulin-resistant subjects stratified by liver and muscle insulin sensitivity.

Materials and methods: Forty-five non-diabetic obese subjects (22 men, 23 women) aged 51 ± 11 years were studied. Two-step (low-dose [15] and high-dose [80] mU/m²/min) hyperinsulinaemic-euglycaemic clamps with deuterated glucose were performed. Subjects in the top tertile of endogenous glucose production (EGP) suppression were deemed Liverres; those in the bottom two tertiles were deemed Liverless. Subjects in the top tertile of glucose infusion rate (GIR) during the high-dose insulin clamp were deemed Musclesen; the bottom two tertiles were deemed Muscleres. Clinical and metabolic parameters were assessed. MSNA was measured by microneurography.

Results: MSNA did not differ between insulin-sensitive and insulin-resistant groups stratified by either liver or muscle insulin sensitivity. However, when men and women data were analysed separately, Liverres men had lower MSNA burst frequency compared to Liverless men (27 ± 14 vs. 38 ± 7 units; $P = 0.03$). Musclesen men had lower MSNA burst frequency compared to Muscleres men ($24 \pm 9 \pm 12.0$ vs. 38 ± 9 units; $P = 0.004$). No differences in MSNA were observed in parallel analyses in women. MSNA burst incidence correlated positively with age ($r = 0.48$, $P < 0.01$) and visceral fat ($r = 0.3$, $P = 0.05$) in total cohort. In men, MSNA burst frequency correlated with the hepatokines high-sensitivity C-reactive protein (hsCRP) and fibroblast growth factor (FGF)19 ($r = 0.57$, $P = 0.006$; $r = -0.47$, $P = 0.03$ respectively) and correlated negatively with liver insulin sensitivity (EGP suppression, $r = -0.53$, $P = 0.02$).

Conclusion: MSNA burst frequency is lower in obese insulin-sensitive men compared to their insulin-resistant counterparts, when stratified by either muscle or liver insulin-sensitivity. Basal sympathetic nervous activity is related to liver insulin sensitivity and circulating hepatokines, suggesting a potential hepato-endocrine-sympathetic axis. Future studies are needed to clarify the influence of sympathetic nervous activity on liver insulin sensitivity in men.

OP 43 From beta to alpha: shifting the diabetes paradigm

241

Non-invasive in vivo monitoring of pancreatic beta cell insulin resistance

M. Paschen, T. Moede, B. Leibiger, S. Jacob, G. Bryzgalova, I.B. Leibiger, P.-O. Berggren; Karolinska Institutet, Stockholm, Sweden.

Background and aims: Pancreatic β -cell dysfunction is central to the development of type 2 diabetes (T2DM) which has reached epidemic proportions. Because the pancreatic β -cell itself is a target for insulin action, β -cell insulin resistance can contribute to β -cell dysfunction. While *in vivo* tests are available to measure overall body or liver insulin resistance, there is currently no test to evaluate insulin resistance at the pancreatic islet/ β -cell level in the living organism. In the present study we present a technique to report on insulin resistance in pancreatic β -cells *in vivo*.

Materials and methods: We transplant pancreatic islets into the anterior chamber of the eye (ACE) that express a fluorescent biosensor in their β -cells and monitor insulin resistance non-invasively and longitudinally by fluorescence microscopy at single-cell resolution in the living mouse. The biosensor is based on the different subcellular localization of FoxO1-GFP, i.e. cytosolic in insulin responsive cells and nuclear at insulin resistance.

Results: *In vitro* experiments in MIN6 cells and islets of Langerhans were performed to validate the function of the biosensor. In these experiments we monitored insulin resistance induced by pharmacological inhibitors as well as by the free fatty acid palmitate. The leptin deficient ob/ob mouse was used to validate the biosensor *in vivo*. At 3 and 10 months of age, lean control mice did not develop either whole-body insulin resistance (AUC (3 months) = 845 ± 56 ; AUC (10 months) = 907 ± 67) or β -cell insulin resistance (3 months of age: $1.1 \pm 0.6\%$ insulin-resistant β -cells; 10 months of age: $1.8 \pm 0.9\%$ insulin-resistant β -cells). In contrast, ob/ob mice were β -cell insulin resistant at 3 months of age ($12.1 \pm 2.8\%$ insulin-resistant β -cells, $p < 0.001$ compared to ob-control (3 months) and $p < 0.01$ compared to ob/ob (10 months)) and insulin responsive at old age ($3.7 \pm 1.4\%$ insulin-resistant β -cells). The β -cell insulin resistance was paralleling the whole-body insulin resistance (AUC (3 months) = 1914 ± 72 ; AUC (10 months) = 827 ± 89 ; $p < 0.001$: 3 months compared to 10 months old ob/ob; $p < 0.001$: 3 months old ob/ob compared to 3 months old ob-control). The *in vivo* imaging data were complemented with and confirmed by data from immunohistochemistry and Western blot analysis of *in situ* pancreatic islets.

Conclusion: Our technique will allow monitoring longitudinally and non-invasively at single cell resolution the dynamics of pancreatic β -cell insulin sensitivity/resistance in the context of overall insulin resistance, hepatic insulin resistance and glucose tolerance during progression and intervention of experimental T2DM in a 'personalized' medicine approach.

Glucagon is a key factor in circadian glucose rhythm and clock gene regulation

S. Malmgren, B. Åhrén; Department of Clinical Sciences in Lund, Lund University, Sweden.

Background and aims: Metabolic regulation of glucose homeostasis is partly controlled by oscillations in the transcription of concurrent CLOCK genes. On the tissue level, these transcription patterns are strongly affected by nutritional intake and subsequent hormone release. Shift

work and/or an altered sleeping pattern are lifestyle factors that increase the risk of diabetes and other disturbances in glucose metabolism. Since dysregulation of glucagon accompanies disrupted insulin secretion in type 2 diabetes, we asked if glucagon signalling is involved in the circadian rhythm of clock genes and glucose homeostasis and whether glucagon secretion is regulated by circadian rhythm.

Materials and methods: To assess the effects of disrupted glucagon signalling on circadian glucose rhythm, we performed oral challenges using a mixed meal (60/20/20E% Glucose/Protein/Lipid) in wt and glucagon receptor knock-out mice (GCGR^{-/-}) and measured glucose and insulin in plasma at *zeitgeber* times (ZT) 3 (3 h after start of 12 h/12 h light/dark cycle; light phase) and ZT15 (dark phase). To assess the effect of disrupted glucagon signalling on molecular clocks we analysed core clock gene expression in islets at ZT 3, 9, 15 and 21 using qPCR. To further examine circadian rhythm in glucagon dynamics, glucagon response following a meal challenge or a hyperinsulinaemic, hypoglycaemic clamp was measured in wt mice.

Results: During light phase (ZT3), we found a marked difference in basal (4.2 ± 0.2 vs. 7.4 ± 0.3 mmol/l, $p < 0.0001$) and peak glucose (8.0 ± 0.4 vs. 13.5 ± 0.6 mmol/l, $p < 0.0001$), and glucose-stimulated insulin peak (837 ± 174 vs. 2250 ± 347 pmol/l, $p < 0.0001$) in GCGR^{-/-} compared to wt animals. In contrast, there was little difference in glucose levels and no difference in insulin levels between groups at the dark phase (ZT15). When applying the quantitative insulin sensitivity check index (QUICKI), we found that GCGR^{-/-} differ greatly from wt in insulin sensitivity at ZT3 (0.90 ± 0.07 vs. 0.51 ± 0.02 , $p < 0.0001$) but not at ZT15. GCGR^{-/-} mice displayed disrupted expression of clock genes *Bmal1*, *Clock*, *Rev-Erba* and *Per1* at the mRNA level compared to wt. The glucagon response to a meal challenge did not differ between the ZT:s, however, the glucagon response to hypoglycaemia (4.8 ± 1.2 vs. 1.9 ± 0.5 , $p = 0.035$) and the insulin sensitivity measured using clamp (4.8 ± 0.9 vs. 1.5 ± 0.2 , $p = 0.0034$) was greater at ZT15 in wt animals.

Conclusion: In conclusion, this study shows that glucagon signalling is important for circadian glucose rhythm, as is highlighted by the fact that GCGR^{-/-} mice differs in insulin dynamics from wt animals only during the light phase. This is further emphasized by the concurrent altered expression pattern of core clock genes in GCGR^{-/-} mouse islets that suggests that altered glucagon signalling disrupts islet clock gene transcription.

Hyperglucagonaemia after oral glucose and suppression of glucagon following i.v. glucose in totally pancreatectomised patients

A. Lund^{1,2}, J.I. Bagger^{1,2}, M. Christensen¹, M. Grøndahl¹, N.W. Albrechtsen², E.R. Mathiesen³, C.P. Hansen⁴, J.H. Storkholm⁴, G.V. Hall⁵, S. Larsen¹, J.J. Holst², T. Vilsbøll¹, F.K. Knop^{1,2};

¹Center for Diabetes Research, Gentofte Hospital, ²NNF Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, ³Center for Pregnant Women with Diabetes, Department of Endocrinology, Rigshospitalet, ⁴Department of Gastrointestinal surgery, Rigshospitalet, ⁵Clinical Metabolomics Core Facility, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Glucagon is believed to be a pancreas-specific hormone and postabsorptive hyperglucagonaemia is thought to contribute to the hyperglycaemic state of patients with diabetes. This hyperglucagonaemia has been thought to arise as a consequence of alpha cell insensitivity to the glucagon suppressive effects of glucose and insulin combined with reduced insulin secretion. We hypothesised that postabsorptive hyperglucagonaemia represents a gut-dependent phenomenon occurring independently of plasma glucose and insulin concentrations. Therefore, we evaluated plasma levels of glucagon during OGTT and isoglycaemic i.v. glucose infusion (IIGI) - bypassing the gastrointestinal tract - in totally pancreatectomised patients.

Materials and methods: Ten totally pancreatectomised patients (PX) (age: 59.8 ± 3.1 years [mean \pm SEM]; BMI: 21.5 ± 1.3 kg/m²; HbA_{1c}: 67.3 ± 3.5 mmol/mol) and 10 healthy control subjects (CTRL) (age: 58.4 ± 1.6 years; BMI: 22.9 ± 0.8 kg/m²; HbA_{1c}: 34.6 ± 2.0 mmol/mol) underwent a 75 g-OGTT and a corresponding IIGI on two separate days. Analysis of plasma glucagon was carried out using a newly developed sandwich ELISA specific for fully processed human 29-amino acid glucagon.

Results: Significantly larger amounts of glucose were needed during the IIGI (in order to copy the 75 g-OGTT plasma glucose curve) in the PX group than in the CTRL group (83 ± 3 g vs. 28 ± 2 g, $p < 0.001$). The PX group tended to have lower fasting levels of plasma glucagon compared to the CTRL group (5.4 ± 0.2 pmol/l vs. 8.3 ± 1.5 pmol/l, $p = 0.064$), but exhibited a significant hyperglucagonaemic response during OGTT (Fig. 1). In contrast, IIGI suppressed plasma glucagon levels in both groups.

Conclusion: We demonstrate that fully processed 29-amino acid glucagon circulates in patients without a pancreas and that glucose stimulation of the gastrointestinal tract elicits significant hyperglucagonaemia whereas i.v. glucose administration results in suppression of plasma glucagon levels. These findings emphasise that gut-derived glucagon may play an important role in diabetic pathophysiology - also in diabetes secondary to total pancreatectomy. *Figure 1.* Time courses of plasma glucagon [mean \pm SEM] following OGTT and isoglycaemic i.v. glucose infusion (IIGI) in totally pancreatectomised patients (PX) and healthy control subjects (CTRL).

A role for glucokinase in pancreatic alpha cell stimulus-secretion coupling

T. Moede, B. Leibiger, P. Vaca Sanchez, E. Daré, M. Köhler, T.P. Muhandiramlage, P.-O. Berggren, I.B. Leibiger; Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: One of the remaining controversial issues of glucose-regulated glucagon secretion is the identity of the glucose sensor linking glucose metabolism to hormone secretion. To strengthen the argument that glucokinase (GK) is this sensor in pancreatic alpha cells we decided on the following two aims: 1. Which hexokinases are expressed in pancreatic alpha cells? 2. Does manipulation of GK activity by inhibitors, activators or knockdown lead to a change in stimulus-secretion coupling in alpha cells?

Materials and methods: Primary pancreatic alpha cells were purified by FACS sorting from islets of 3 months old Wistar rats. Single cells RT-

PCR was performed for ca. 100 cells using primer sets for insulin, glucagon, somatostatin and pancreatic polypeptide to verify cell identity and to determine the expression patterns of glucose phosphorylating enzymes (GK and hexokinase I to III). 5' race combined with cloning and sequencing was performed to identify the isoforms of glucokinase mRNAs present in pancreatic alpha cells. For glucagon secretion studies the cells were seeded onto 25 mm cover glasses and transduced with an adenovirus expressing glucagon-pHluorin under the control of the glucagon promoter. 72 h after transduction the cover glasses were moved to a ZEISS Axiovert TIRF microscope and glucagon release events were imaged, analyzed and quantified. GK inhibitors and a GK activator were used acutely while knockdown of GK expression was achieved by treatment with siRNA. To verify the glucagon release measurements performed by TIRF microscopy, glucagon secretion from isolated primary alpha cells was measured by glucagon RIA.

Results: Single cell RT-PCR showed that >90% of analyzed pancreatic alpha cells were positive for glucokinase mRNA (>90 analyzed cells). All analyzed cells were negative for hexokinase I-III. 5' Race and sequence analysis revealed that 63% of the analyzed mRNAs (45/71) were the full length neuroendocrine GK form, resulting in a functional protein while 37% had deletions resulting in non-functional proteins. Primary alpha cells show a twofold difference in glucagon release at 3 mM vs 4 mM glucose (22.4±6 release events/minute and 100 μm² (RE) vs. 11.2±2 RE; *p*<0.001). The same difference in release at these two glucose concentrations was observable using RIA (3%±0.5 of content released at 3 mM glucose vs 1.5%±0.1 at 4 mM; *p*<0.05). Treatment with glucokinase inhibitors 5-thioglucoase and deoxyglucose led to an increased release at 4 mM glucose concentration (22±3 RE or 24±4 RE respectively; *P*<0.001 vs 4 mM glucose) while treatment with the activator RO0281675 led to a decreased release at 3 mM glucose (9,68±2RE; *p*<0.001 vs 3 mM glucose). 80% knockdown of glucokinase mRNA, which was verified by RT-PCR, led to a loss of glucose sensitivity resulting an increased release at 4 mM glucose (14.4±0.9 RE) and a decreased release at 3 mM glucose (16.2±1 RE).

Conclusion: Rat alpha cells express the functional neuroendocrine form of glucokinase. Single rat alpha cells respond to an increase of glucose concentration with a decrease in glucagon release with a set point between 3 and 4 mM glucose. Activation of glucokinase lowers this set point while inhibition of Glucokinase raises it. Knockdown of glucokinase leads to a loss of glucose responsiveness. Taken together these data indicate that glucokinase is indeed the glucose sensor linking glucose concentration to glucagon secretion in pancreatic alpha cells.

A systematic review of educational, psychosocial, behavioural and health service organisational interventions to improve outcomes for young adults with type 1 diabetes

M. O'Hara^{1,2}, L. Hynes³, M. O'Donnell¹, N. Nery¹, M. Byrne³, S.F. Dinneen^{1,2}, for the Irish Type 1 Diabetes Young Adult Study Group; ¹School of Medicine, NUI Galway, ²Endocrinology and Diabetes Centre, Galway University Hospitals, ³School of Psychology, NUI Galway, Ireland.

Background and aims: Many young adults (YA) with type 1 diabetes (T1D) experience poor outcomes as a result of their condition. Reasons may include poor knowledge and self management skills, poor clinic attendance, poor adherence with treatment recommendations and engaging in high risk behaviours. The aim of this systematic review was to identify, describe and synthesise the evidence regarding the effectiveness of any educational, psychosocial, behavioural and health service organisational interventions to improve outcomes for YA with T1D.

Materials and methods: Five electronic databases were searched between June and September 2014. Expert groups were contacted to identify relevant grey literature. Any studies that addressed interventions related to patient education and/ or support, behaviour, lifestyle change, or health service organisational change for YA between 15-30 years old with T1D were included. Interventions which aimed to improve outcomes by purely pharmacological or physiological means were excluded. A narrative synthesis of all relevant studies was undertaken.

Results: Papers (*n*=1,700) were screened by 2 authors (a 3rd author screened if there were discrepancies), 19 quantitative studies published between 1991 and 2013 met the inclusion criteria. Four major categories were identified; Health Services Organisation (*n*=4), Technology (*n*=9), Support (*n*=2) and Education (*n*=4). Quality of the studies was variable, 1 randomised controlled trial (RCT), 3 retrospective, 7 feasibility/ acceptability studies and 8 studies with a pre/ post design were identified. All the studies were of relatively short duration (3 days - 12 months, 1 study was 36 months), 12 had convenience/ opportunistic samples (often with small sample sizes) and 10 had no/ inappropriate controls. Outcome measures included HbA_{1c} (*n*=14), frequency of episodes of hypoglycaemia/ diabetic ketoacidosis, diabetes knowledge, clinic attendance, telephone contact time with diabetes nurse, insulin administration, treatment satisfaction, self care activities, attitudes and behaviours towards intervention, number of blood glucose (BG) tests, BG cue awareness and compliance. The majority reported weak evidence for the intervention improving the outcomes of interest and where significance was reported, it often deteriorated over time. The use of E-health (text messaging and internet), newer insulin administration devices and smarter BG self monitoring devices in the review highlighted the importance of Technology. Papers in the Health Services Organisation category mainly aimed at impacting on diabetes management/ engagement by the introduction of a structured/ coordinated approach to transition, some incorporated educational elements (*n*=2), and technology (*n*=1). Papers in both the Education and Support categories aimed to improve management of diabetes, specifically glycemic control and 2 aimed to enhance awareness of BG cues.

Conclusion: This systematic review and narrative synthesis has highlighted a lack of well designed and well described interventions, in particular RCTs, aimed at improving health outcomes for YA with T1D. Further high quality research is warranted in this area.

Patients education focusing on physical activity - impact on habitual activity levels, exercise tolerance, metabolic control and life quality

A.V. Petrov, L.G. Strongin, D.V. Shokareva;

Dpt. of Endocrinology and internal medicine, Nizhny Novgorod State Medical Academy, Russian Federation.

Background and aims: The aim of study was to evaluate physical activity changes in T2DM patients after standard education and educational program with specific target of its increase and influence on metabolic control and patients life quality.

Materials and methods: Prospective randomized unblinded study was performed with 79 T2DM patients randomized to standard educational program consisting of 5 sessions and similar program with addition of 15 minute simple physical exercises during each session, use of pedometer (“standard” and “active” education groups correspondingly). Physical activity was evaluated by IPAQ questionnaire and average number of steps per day by pedometer. 6-minute walk test (6-MWT) distance was used for assessment of exercise tolerance, SF-12 v.2 questionnaire for life quality. HbA1c and body weight changes characterized metabolic control. Patients were observed for 6 months after finishing education program. Data are presented as M(SD) format, Mann-Whitney U-test was used for statistical analysis.

Results: 39 patients were randomized to standard and 38 to active group. At baseline groups were comparable for age, diabetes duration, HbA1c, BMI, IPAQ score, 6-MWT distance, number of steps per day and physical component score of SF-12 (see Table). For mental component score of SF-12 there was statistically significant difference in favor of standard group. As it is shown in data table, in 6 months patients of active group had increase in physical activity and 6-MWT distance, increase in number of steps per day compared to standard education. Also they had significantly larger decrease of HbA1c, improvement of PCS and trend for improvement of MCS scores of SF-12. Then both standard and active group were evaluated together higher self-reported activity (METs/wk >1500) was associated with significantly more weight loss compared to baseline (-1.9(2.4) vs. -0.7(2.7) kg p=0.04), larger 6-MWT distance (460(62) vs. 415(81) m p=0.01), better life quality on physical component score (42(7.2) vs. 37(7.9) p=0.006).

Conclusion: In T2DM patients education can lead to significant increase in physical activity together with improvement of metabolic control and life quality. Its effectiveness was significantly enhanced by introducing practical physical exercises and patients’ participation in physical activities together with use of pedometers with minimal additional time and costs. Not only daily patients activities but also their tolerance to physical exercise was increased which can improve patients’ attitude and capacity for habitual exercise. Higher habitual exercise levels were associated with better weight control and life quality thus improving health care for diabetic patients.

Standard and active groups characteristics at baseline and 6 months after therapeutic education.

Study on efficacy of long-term education for achieving compensation of type 1 diabetes mellitus in children and adolescentsA.B. Tashmanova^{1,2}, S.I. Ismailov^{3,4}, G.N. Rakhimova^{3,5};¹Diabetology, Center for the Scientific and Clinical Study of Endocrinology, ²Endocrinology, Tashkent Pediatric Medical Institute, ³Center for the Scientific and Clinical Study of Endocrinology, ⁴Tashkent Pediatric Medical Institute, ⁵Tashkent Institute of Physicians’ Post-Graduate Study, Uzbekistan.

Background and aims: Today education is a basic component in therapy of patients with diabetes mellitus in most countries. It was interesting to assess achievement of compensation in children and adolescents with type 1 diabetes mellitus within a 5-year period after training. The work was initiated to assess level of knowledge and compensation degree in children and adolescents with type 1 diabetes mellitus in “Type 1 Diabetes School”.

Materials and methods: A five-day training course was conducted in “Type 1 Diabetes School” at our Center. The training was conducted by means of a structured program containing all appropriate sections. Before and after training course all participants were tested with a questionnaire containing 30 key questions for self-control. On the basis of the findings children and adolescents with type 1 diabetes mellitus were divided into groups, trained and untrained. 54 of 80 children and 38 of 57 adolescents were preliminary trained, 26 children and 19 adolescents got no training. DS5 Glycomat (USA) was used to measure glycated hemoglobin (HbA1c) by means of high pH anion-exchange liquid chromatography. Certified by the National Glycohemoglobin Standardization Program this method became the reference one. It helps demonstrate the predicting role of HbA1c level as a criterion for assessment of compensation.

Results: Before training children gave right answers to 20% of questions only. In 5 years they could give right answers to 85% of questions, mean HbA1c in trained and untrained children was 7.8% and 10.8%, respectively. Children who got no training, those with low level of knowledge and motivation both in them and their parents were hospitalized at the intensive care units more frequently both before and after training. Within follow-up period they gave right answers to 15% of questions only. The trained adolescents with type 1 diabetes mellitus initially could give right answers to 30% of questions, in 5 years there were 70% of right answers. In the untrained adolescents, level of knowledge remained as low as it was before and after 5-year follow-up, mean HbA1c level was 8.1% and 10.1% in the trained and untrained adolescents, respectively.

Conclusion: In the group of children trained for 5 years HbA1c mean level was 7.8%, in those untrained it was 10.8%. In the groups of trained and untrained adolescents mean HbA1c was 8.1% and 10.1%, respectively. Better compensation and level of knowledge in children as compared with those among adolescents confirm the role of family in the type 1 diabetes mellitus control.

Effectiveness of nurse-led telecoaching in optimising diabetes control: results of a randomised controlled trial in patients with type 2 diabetesI. Odnoletkova¹, G. Goderis¹, F. Nobels², B. Aertgeerts¹, L. Annemans³, D. Ramaekers¹;¹Public Health and Primary Care, University of Leuven, Brussel, ²Endocrinology, OLV Hospital Aalst, ³Public Health, Ghent University, Belgium.

Background and aims: About a half of people with type 2 diabetes do not reach their treatment targets, increasing the risk of future complications. Patient education has been shown to contribute to a better glycaemic control. Diabetes education by phone may improve patient inclusion and increase efficiency, however the effectiveness of telephone

education in type 2 diabetes is uncertain. The objective was to study the effect of “The COACH Program”, a well-established Australian telecoaching program for patients with chronic conditions, on glycohemoglobin and other modifiable risk factors in patients with type 2 diabetes in primary care.

Materials and methods: Randomized controlled trial in Belgium where in people between 18 and 75 years were selected on hypoglycaemic agent consumption, recruited by their sickness fund and randomized to telecoaching or usual care. The intervention was delivered by diabetes nurse educators and consisted of five telephone sessions spread over 6 months, aimed at achievement of guideline-recommended diabetes treatment targets. The primary outcome was change in HbA1c at 6 months in the entire study group and the subgroup with HbA1c \geq 7% at baseline (further “subgroup”). The secondary outcomes were: total cholesterol (TC), LDL, HDL, triglycerides, BP and BMI at 6 and 18 months follow-up. The measurements were performed by trial nurses and the blood samples analyzed in a single lab. Linear mixed-effect model was used to compare the change in outcomes within and between groups.

Results: 574 eligible patients were randomized to the telecoaching (N=287) or the control group (N=287). Their median age was 64 years, 62% were men, 86% on oral antidiabetics therapy. The mean (SD) baseline HbA1c,% was 7.0 (1.0) and 7.9 (0.9) in the subgroup, TC: 176 (38) mg/dl, BP: 133 (17)/75 (10) mmHg, BMI: 30 (5) kg/m². 85% of patients in the telecoaching group attended the intervention as planned. The attrition rate was 11% and 16% in the intervention group and 9% and 14% in the control group at 6 months and 18 months respectively. At 6 months, the reduction in HbA1c,% (95% CI) in the intervention group was -0.2 (-0.3 to -0.1, p=.000) and in the subgroup -0.5 (-0.7 to -0.3, p=.000); in the control group 0.0 (-0.1 to 0.1, p=.703) and -0.1 (-0.3 to 0.1, p=.411) in the respective subgroup. The between-group difference in HbA1c was 0.2 (0.1 to 0.3, p=.003) and 0.4 (0.1 to 0.7, p=.002) in the subgroup. Other between group differences at 6 months were observed only in BMI (kg/m²): 0.4 (0.1 to 0.7, p=.003) and TC (mg/dl): 6 (2 to 11, p=.011), in favor of the intervention. At 18 months, the sustained between-group difference in HbA1c was 0.1 (0.0 to 0.3, p=.065) and 0.3 (0.0 to 0.6, p=.033) in the subgroup. No between-group difference in other outcomes was observed at 18 months.

Conclusion: The COACH Program improved the glycaemic control, total cholesterol and body mass index at 6 months in people with type 2 diabetes in Belgian primary care. Overall, the differences between groups did not sustain at 18 months. In patients with HbA1c \geq 7% at baseline, the clinically relevant difference in glycaemic control slightly declined but stayed significant at 18 months follow-up. Nurse-led telecoaching in type 2 diabetes is an effective alternative to face-to-face patient education.

The effect of a short-term high-fat overfeeding on plasma levels of acylcarnitines in young, healthy men with low or normal birth weight
A. Ribel-Madsen^{1,2}, R. Ribel-Madsen^{2,3}, C. Brøns², C.B. Newgard⁴, A.A. Vaag², L.I. Hellgren¹;

¹Department of Systems Biology, Technical University of Denmark, Kongens Lyngby, ²Department of Endocrinology, Copenhagen University Hospital, ³Danish Diabetes Academy, Odense, ⁴Sarah W. Stedman Nutrition and Metabolism Center, Duke University, Durham, USA.

Background and aims: Low birth weight (LBW) subjects have an increased risk of developing type 2 diabetes later in life compared with normal birth weight (NBW) subjects. Also, an impaired oxidation of fatty acids and a subsequent accumulation of lipid species have been implicated in the pathogenesis of type 2 diabetes. Acylcarnitines are markers of an incomplete beta-oxidation in mitochondria. Here, we investigated whether LBW and NBW subjects had different plasma levels of acylcarnitines after a control diet and a high-fat, high-calorie diet and whether they changed these levels in response to overfeeding. Also, we examined whether the levels were related to insulin secretion and/or sensitivity.

Materials and methods: Twenty LBW (0-10th percentile) and twenty-six NBW (50-90th percentile) young, healthy men were in a random order given a three-day control diet and a five-day high-fat, high-calorie diet. After these challenges, we measured fasting plasma levels of forty-five acylcarnitine species by tandem mass spectrometry and assessed differences in these levels between birth weight groups or diets by unpaired or paired t-tests, respectively, or Wilcoxon signed rank tests. Also, we performed intravenous glucose tolerance tests and hyperinsulinaemic euglycaemic clamps to assess insulin secretion and sensitivity and evaluated associations between levels of acylcarnitines and these measures by regression analyses adjusted for age, body mass index, and birth weight.

Results: LBW subjects had higher plasma levels of eight acylcarnitine species, of these five hydroxyl- (OH)/dicarboxyl- (DC) species, as well as of total acylcarnitines and total OH-/DC-acylcarnitines after the control diet compared to NBW subjects, but no differences were seen after the high-fat, high-calorie diet. Furthermore, LBW and NBW subjects decreased levels of twelve species and increased levels of three or four species, respectively, and additionally decreased the level of total acylcarnitines in response to overfeeding. Also, the level of total OH-/DC-acylcarnitines was inversely associated to the serum level of insulin and hepatic insulin resistance after the control diet.

Conclusion: LBW subjects had a higher plasma level of total acylcarnitines after the control diet compared to NBW subjects, which indicates that they have an incomplete beta-oxidation of fatty acids in mitochondria. Also, their higher level of total OH-/DC-acylcarnitines suggests that they have a higher omega-oxidation of fatty acids in endoplasmic reticulum and/or an incomplete beta-oxidation of OH-/DC-fatty acids. LBW and NBW subjects decreased the level of total acylcarnitines in response to overfeeding, which may be a normal response to an acute overfeeding followed by an overnight fast with a minor release and oxidation of fatty acids in this less fasted state. Acylcarnitines do not seem to adversely affect insulin secretion or action. On the contrary, the level of total OH-/DC-acylcarnitines was inversely associated to insulin resistance, which suggests that omega-oxidation may be a scavenger pathway for oxidation of fatty acids that could accumulate as lipid species that impair insulin signalling.

Suppression of plasma free fatty acids similarly reduces myocardial lipid content and left ventricular systolic function in type 2 diabetic patients as in controls

P. Wolf¹, Y. Winhofer¹, S. Smajis¹, J. Harreiter¹, L. Kosi-Trebotic¹, C. Fürsinn¹, C. Anderwald¹, S. Baumgartner-Parzer¹, S. Trattnig², A. Lugger¹, M. Krssak¹, M. Krebs¹;

¹Internal Medicine III, Medical University of Vienna, ²Biomedical Imaging and Image-guided Therapy, Centre of Excellence - High Field MR, Medical University of Vienna, Austria.

Background and aims: Type 2 diabetes (T2DM) is closely associated with the development of heart failure, which could in part be due to impaired substrate metabolism and accumulation of myocardial lipids (MYCL). To better understand substrate metabolism of the diabetic heart, this study investigated the impact of an acute pharmacological inhibition of adipose tissue lipolysis leading to reduced availability of circulating FFA on MYCL and heart function in T2DM.

Materials and methods: 8 T2DM (Age: 56±11a; BMI: 28±3.5 kg/m²; HbA1c: 7.29±0.88%) were investigated on two study days in random order, following administration of Acipimox /Placebo and compared to previously assessed data in healthy controls. MYCL and heart function was measured by 1H-magnetic-resonance-spectroscopy and tomography at baseline, at 2 and at 6 hours.

Results: Acipimox reduced MYCL by -39±41% as well as systolic heart function significantly (Ejection Fraction (EF): -13±8 and cardiac index: -16±15% compared to baseline) to the same extent than in healthy controls., FFA strongly correlated with changes in MYCL Δ MYCLMR1 vs MR3: $r=0.707$; $p=0.002$ and EF (Δ EFMR1 vs MR3: $r=0.651$; $p=0.006$). Diastolic heart function remained unchanged.

Conclusion: Inhibition of adipose tissue lipolysis is associated with a rapid depletion of MYCL-stores and reduced systolic heart function in T2DM. These changes were comparable to those previously found in insulin sensitive controls. MYCL thus likely serves as a readily available energy source to cope with short-time changes in FFA availability in the diabetic state.

Clinical Trial Registration Number: NCT01980524

Saturated fatty acids increase intramuscular lipid by activation of lipogenic pathways dependent on SREBP-1c with no modification of fatty acid transport or lipid oxidation

E. Rubio-Martín¹, R. Monastero¹, N. Colomo¹, J. Gomez-Zumaquero², S. Garcia-Serrano¹, A. Lago-Sampedro¹, E. Garcia-Fuentes¹, G. Rojo-Martinez¹, E. Garcia-Escobar¹;

¹UGC Endocrinología y Nutrición. IBIMA, ²ECAI de Genómica IBIMA, Malaga. Spain.

Background and aims: Dietary saturated fatty acids induce insulin resistance in muscle with the increment in intramuscular lipid accumulation (IMLA). The mechanism by which dietary fatty acids modulate IMLA are not clear. The aim of this study is evaluate the mechanism that could be regulating the IMLA under different dietary fatty acid composition.

Materials and methods: A group of rats was assigned to an isoenergetic and normocaloric diet, each with a significantly different composition of saturated (SD), monounsaturated (MD) and polyunsaturated (PD) fatty acids and they were feed for a month. Samples of muscle tissue were taken to determine tissue lipid accumulation and to study the gene expression levels of fatty acids transports FATP1, FATP4, FAT/CD36 and FABPpm, muscle lipid oxidation marker CPT1 and the lipogenic markers SREBP-1c, ACC1 and SCD1. Additionally, L6 cells were differentiated and then treated with Palmitic, Oleic, and Linoleic fatty acid for 24 h. Fatty acid cytotoxicity was evaluated by the gene expression levels of BCL2, P53 and Casp3.

After treatment lipid accumulation and the same genetic markers as in muscle tissue samples were studied. Analysis of differences between groups was performed using Kruskal-Wallis or U of Mann-Witney test. Associations between variables were evaluated by Spearman correlation test. A P value <0.05 was considered statistically significant.

Results: Animal weights did not vary according to diets. Muscle lipid accumulation were significantly higher in animals feed with CD ($p=0.01$). The expression levels of CPT1 and fatty acid transport proteins FATP1, FATP4, FAT/CD36 were no different between diets, however FABPpm gene expression levels were significantly lower in animals fed with SD ($p<0.01$), with an inverse correlation with the IMLA ($r=-0.59$, $p<0.01$). SD raised muscle lipogenic markers with the increment of SREBP-1c, ACC1 and SCD1 gene expression levels ($p<0.01$, $p=0.05$ and $p=0.03$ respectively); a direct association between these gene expression levels and the IMLA was found ($r=0.54$, $p=0.02$; $r=0.59$; $p<0.01$ and $r=0.52$, $p=0.03$ respectively). Fatty acids did not induce apoptosis. L6 lipid content (CLC) was higher in cells treated with any of the fatty acids than in control group, with no differences between the fatty acid treatment. None of the measured gene expression levels were different according to the control group nor to fatty acids treatment. However, FATP1 and FABPpm gene expression were negative associated with the lipid content ($r=-0.64$, $p<0.01$ and $r=-0.62$, $p<0.01$ respectively), while lipogenic markers SREBP-1c, ACC1 and SCD1 gene expression levels were directly correlated with CLC ($r=0.44$, $p=0.04$; $r=0.46$, $p=0.03$ and $p=0.54$, $r=0.01$ respectively).

Conclusion: The elevated levels of IMLA in the presence of saturated fatty acids are associated with the induction of SREBP-1c gene expression and its regulated lipogenic pathways with the increment of ACC1 and SCD1 gene expression levels, rather than the modification in the fatty acid transport or the muscle lipid oxidation.

Role of Rab-GTPases in the regulation of fatty acid metabolism in skeletal muscle

T. Benninghoff^{1,2}, Z. Zhou^{1,2}, A. Chadt^{1,2}, H. Al-Hasani^{1,2};

¹Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center (DDZ), Leibniz-Center for Diabetes Research at the Heinrich-Heine University Düsseldorf, ²German Center for Diabetes Research (DZD e.V.), Partner Düsseldorf, Neuherberg, Germany.

Background and aims: Besides glucose, fatty acids play a central role in the energy metabolism of skeletal muscle. Deficiency of the Rab GTPase-activating protein (Rab-GAP) TBC1D1 leads to an increase of fatty acid uptake and fatty acid oxidation accompanied by a shift in skeletal muscle energy substrate preference from glucose towards fatty acids. It is the aim of this project to find the underlying mechanisms that drive the shift towards fatty acid metabolism under conditions of Tbc1d1-deficiency.

Materials and methods: Cell culture experiments were performed using differentiated C2C12 myoblasts. Selected Rab GTPases (Rab8a, 10, 14, 28) that function as potential substrates of TBC1D1 were silenced via siRNA technology. Subsequently, fatty acid uptake was determined measuring the incorporation of ³H-Palmitic acid. In addition, siRNA oligos for Rab-GTPase knock-down (KD) were transfected into Extensor digitorum longus (EDL) and Soleus muscle of 12 - 15 week old C57BL/6 males via in vivo Electrotransfection (IVE). Seven days after electrotransfection intact EDL and Soleus muscle were dissected and ³H-Palmitic Acid oxidation was measured.

Results: In cultured C2C12 myotubes the Knock-down (KD) of Tbc1d1 led to a significant increase in fatty acid uptake (+41%, SEM±21%). KD of Rab8a, Rab10 and Rab14 reduced fatty acid uptake (Rab8a: -43%, SEM±13%; Rab10: -41%, SEM±9%;

Rab14: -23%, SEM±20%). In contrast to this Rab28 KD did not affect fatty acid uptake in these cells. In both, glycolytic EDL and oxidative Soleus muscle the siRNA-mediated KD of Rab8a caused a significant reduction of fatty acid oxidation (EDL: -35%, SEM±9%; Soleus: -42%, SEM±8%). KD of Rab10, however, did not alter fatty acid oxidation in EDL or Soleus muscle.

Conclusion: We showed that Rab8a, Rab10 and Rab14 influence fatty acid uptake in cultured C2C12 myotubes in a similar fashion, while knock-down of Rab28 did not lead to changes in fatty acid uptake in these cells. Ex vivo experiments revealed that the siRNA-mediated KD of Rab8a led to a significant reduction of the ex vivo fatty acid oxidation of intact isolated EDL and Soleus muscle. In contrast to the cell culture experiments, KD of Rab10 did not affect ex vivo fatty acid oxidation in both, EDL and Soleus muscle.

OP 46 Watching the granule: novel regulators of beta cell exocytosis

Rabs and RIM are differentially involved in docking and tethering of insulin granules

N.R. Gandasi, S. Barg;

Institute of Medical cell biology, Box 571, Husargatan 3, Uppsala University, Sweden.

Background and aims: Glucose dependent insulin release is markedly reduced in the islets obtained from type 2 diabetic subjects. Insulin is released by regulated exocytosis and docking of insulin granules at the plasma membrane, followed by the assembly of the secretory machinery is a prerequisite for insulin release. We have recently shown that central elements of the secretory machinery assemble after granule docking, but it remains unclear whether granule docking sites can exist before arrival of a granule. Current models propose that docking of the granules occurs through binding to either raft-like clusters of SNARE proteins or to structural proteins such as RIM1, in all cases implying at least partial assembly of the secretory machinery prior to docking. However, direct evidence for this is lacking.

Materials and methods: Dual-color TIRF microscopy of INS1 cells 832/13 combined with quantitative image analysis was used to study the association of GFP-labeled proteins with granules labelled with NPY-mCherry at the plasma membrane.

Results: We show that the insulin granule transits to stably docked state from a loosely tethered state a few seconds after the arrival of the granule. This transition is induced by recruitment of syntaxin and munc18-1, and that recruitment of munc13 and SNAP25 was delayed further. Here we extend on this work and present quantification of several exocytosis proteins including rab3 and 27, rabphilin, granuphilin, RIM1, tagged with EGFP at the insulin granule release site during insulin granule docking, priming and exocytosis. We find that the Rab3 interacting protein RIM1 and Rabphilin were enriched at docking sites prior to granule tethering and docking. A slow but significant increase of RIM1 fluorescence was seen during granule maturation into the releasable pool (priming), suggesting roles for RIM1 in both docking and priming. None of the other proteins were present before granule arrival, but they were instead recruited during docking or even later during priming. Granules that docked successfully carried Rab3 and Rabphilin, whereas those that only temporarily tethered did not. In contrast, Rab27 and its effector Granuphilin were present on both types of granules.

Conclusion: We conclude that sites enriched with RIM1 at the plasma membrane act as tethers for incoming granules. The likely binding partners on the granule for this weak interaction are rab27/granuphilin. Conversion into the stably docked state that is required for exocytosis occurs only when rab3/rabphilin are also present on the granule. Successful docking coincides with acute clustering of syntaxin/munc18, and we propose that this cluster then nucleates assembly of the exocytosis machinery. It may thus underlie the docking defect observed with reduced expression of SNARE and accessory proteins during type 2 diabetes.

Clustering of L-type Ca²⁺-channels promotes exocytosis of individual secretory granules

P. Yin¹, N.R. Gandasi¹, M. Riz², G. Cortese³, M. Chibalina⁴, P. Rorsman⁴, A. Sherman⁵, M.G. Pedersen², S. Barg¹;

¹Institute of Medical cell biology, Box 571, Husargatan 3, Uppsala University, Sweden, ²Department of Information Engineering, ³Department of Statistics, University of Padua, Italy, ⁴Oxford center for diabetes, Endocrinology and Metabolism, University of Oxford, UK, ⁵NIDDK, NIH, Bethesda, USA.

Background and aims: Ca²⁺ entry through voltage gated L-type calcium channels triggers release of insulin-containing secretory granules, and is required for 1st phase insulin secretion. Indirect electrophysiological and biochemical evidence suggest that L-type channels functionally couple to the exocytosis machinery by binding of the $\alpha 1$ subunit of L-type channels to SNARE proteins through its synaptic protein interaction site (synprint). Clustering of L-type channels near docked granules is thought to facilitate exocytosis by generating local domains where Ca²⁺ is sufficiently elevated. However, direct evidence for channel clustering and localized Ca²⁺ influx near granules is lacking.

Materials and methods: EGFP-labeled Ca²⁺-channel subunits (Cav1.2) were imaged together with a granule marker in human islet cells and Ins1 cells using TIRF-microscopy. Local Ca²⁺ domains were visualized using Fluo 5 F-am or membrane-targeted lyn-R-GECO. Ca²⁺-currents were recorded using whole cell patch clamp.

Results: Cav1.2-EGFP formed clusters on a hazy background that partially colocalized with a subset of the docked granules. Image analysis indicated specific binding of Cav1.2-EGFP to granules, which was confirmed by single molecule imaging demonstrating reduced mobility of Cav1.2-EGFP near docked granules. This binding was not detectable when the synprint fragment was coexpressed, suggesting that the peptide competes with and uncouples Cav1.2 from the exocytosis machinery. Ca²⁺-channel clusters formed at granules at least 60 s after their arrival at the plasma membrane, and rapidly dispersed after exocytosis. In depolarized cells, docked granules that exocytosed (responders) carried significantly more Cav1.2-EGFP than those that failed to do so (failures). Endogenous Ca²⁺-channels were visualized functionally as Ca²⁺ microdomains; these measurements indicated localized and more rapid Ca²⁺-entry at responder granules compared with failures or random sites. Modeling of Ca²⁺-influx confirmed that the observed rates of Ca²⁺-entry and distribution are consistent with localized Ca²⁺-influx near granules. Statistical analysis indicates that the probability of exocytosis is at least 1000-fold higher when a channel is bound to the granule than when it is 500 nm away.

Conclusion: Using high resolution microscopy we identify in human and rat insulin secreting cells a granule pool where localized Ca²⁺ influx leads to exocytosis with high release probability and minimal latency, corresponding to the immediately releasable pool (IRP). Prior to exocytosis these granules slowly recruit on average L-type Ca²⁺-channels through an interaction that involves the channels' synprint site. When this interaction is interrupted by expression of exogenous synprint or when Ca²⁺ is raised by release from intracellular stores, rapid exocytosis is absent. This arrangement leads focal Ca²⁺ influx that supports rapid and selective exocytosis of the associated granules with minimal requirements for Ca²⁺-influx. Thus, IRP granules are docked at the plasma membrane and associated with L-type Ca²⁺-channels.

MiR-335 regulates exocytotic proteins and affects glucose-stimulated insulin secretion through decreased Ca²⁺-dependent exocytosis in beta cells

V.A. Salunkhe¹, J. Ofori¹, N.R. Gandasi², S.A. Salö^{1,3}, S. Hansson¹, M.E. Andersson¹, A. Wendt¹, S. Barg², J.L.S. Esguerra¹, L. Eliasson¹;

¹Islet Cell Exocytosis, Lund University Diabetes Centre, Clinical Research Centre Malmö, Lund University, Malmö, ²Department of Medical Cell Biology, BMC, Uppsala University, Sweden, ³Department of Science, Systems and Models, Roskilde University, Denmark.

Background and aims: Ca²⁺-induced exocytosis is essential for insulin to be secreted from beta-cells, and in islets from type-2 diabetic (T2D) donors the expression of several genes coding for exocytotic proteins is reduced. Largely this phenomenon cannot be explained by polymorphism; rather it is likely due to epigenetic factors like microRNAs (miRNAs). Indeed, previous studies have identified a number of miRNAs with differential expression in the islets from T2D donors and the Goto-Kakizaki (GK) rat. One of the upregulated miRNAs in the GK rat is miR-335, predicted to target several exocytotic genes amongst those *Stxbp1* is a validated target. Here we aim to investigate whether miR-335 regulates the expression of exocytotic genes and affects insulin secretion and exocytosis in beta-cells.

Materials and methods: Insulin secretion was measured by radio immuno assay. Exocytosis and docking of insulin granules was studied by capacitance measurements using the patch-clamp technique and by TIRF microscopy. Rat miR-335 was overexpressed using chemically-modified mature microRNA mimic in INS-1 832/13 beta-cells by transfection. Gene knockdown was performed with RNAi. Protein and mRNA levels were analysed with Western Blot and RT-qPCR, respectively.

Results: Overexpression of miR-335 (OE335) in INS-1 832/13 cells reduced insulin secretion at 16.7 mM glucose compared to control cells (SCR) (n=3; p<0.01). This was not due to reduced insulin content (n=3) or voltage-dependent Ca²⁺ currents (n=15-17) but rather a direct effect on second phase exocytosis; the measured increase in membrane capacitance was extensively decreased in OE335 cells (42±23 f. vs 128±18 fF; n=11-14; p<0.01). In agreement, exocytotic events measured by TIRF microscopy were reduced in OE335 cells (0.032±0.001 min⁻¹ μm⁻²; n=8) compared to SCR cells (0.049±0.003 min⁻¹ μm⁻²; n=8; p<0.001). However, TIRF microscopy revealed similar density of docked granules in both OE335 and SCR cells (n=51-53). The exocytotic genes coding for Snap25, Stxbp1 and Synaptotagmin 11 (Syt11), known to have reduced expression in T2D islets, are putative targets of miR-335. In accordance, protein levels of Snap25, Stxbp1 and Syt11 were decreased in OE335 cells compared to SCR cells (p≤0.05; n=4 for each protein). Snap25 and Stxbp1 have previously been proven essential in insulin exocytosis, but the role of Syt11 is still uncertain. Interestingly, Syt11 silencing in INS-1 832/13 cells resulted in decreased first phase exocytosis measured as increase in membrane capacitance (161±22 f. vs 251±34 f. in control cells; n=9-13; p<0.05).

Conclusion: We suggest that miR-335 is crucial in the regulation of glucose-stimulated insulin secretion. It functions by reducing the exocytotic proteins Snap25, Stxbp1 and Syt11 which modulates Ca²⁺ dependent exocytosis in beta-cells. The progression of T2D is facilitated by failure of beta-cell adaptations to secrete more insulin. We believe our study contributes with novel insights as to how single dysregulated miRNA may affect pancreatic beta-cell function.

Effects of high glucose and K⁺ depolarisation on secretion and insulin granule mobility in MIN6 cells and mouse beta cells

D. Brüning¹, K. Schumacher¹, M. Matz², K. Baumann², I. Rustenbeck¹;
¹Institute of Pharmacology, Toxicology and Clinical Pharmacy, ²Institute of Medicinal and Pharmaceutical Chemistry, University of Braunschweig, Germany.

Background and aims: To further characterize the differences between nutrient- and depolarization-induced insulin secretion, we compared insulin secretion and parameters of insulin granule mobility in MIN6 cells and MIN6 pseudo-islets and in normal mouse beta-cells and islets.

Materials and methods: Insulin granules were labeled by transient transfection with insulin-EGFP in MIN6 cells and by adenoviral transduction in primary mouse beta-cells. The granules present in the submembrane space of the cell footprint were imaged by TIRF microscopy. The cells were continuously perfused at 37°C with oxygenated medium containing the respective stimuli. The image files (1 sequence=200 images=25 seconds) were evaluated by an in-house written program to achieve an observer-independent quantification. The insulin secretion of MIN6 pseudo-islets and mouse islets was measured by perfusion with ELISA of the fractionated efflux.

Results: The perfused islets and pseudo-islets were stimulated by 40 mM K⁺ for 10 min and, after a wash-out period, by 30 mM glucose for 10 min. In MIN6 pseudo-islets 30 mM glucose was much less effective than 40 mM K⁺. When the K⁺ depolarization preceded the glucose stimulus, glucose was entirely ineffective. In mouse islets glucose was about equi-effective with K⁺ depolarization. When the K⁺ depolarization preceded the glucose stimulus, the glucose-induced secretion had a sluggish onset, but still reached the same maximal level. Under control condition, the number of granules in the first image of the sequences was 337 ±34 per MIN6 cell but only 68±15 per beta cell. In both cell types this parameter remained essentially stable during imaging. Due to continuous arrivals at and departures from the evanescent field the total number of granules under this condition were 6972±873 per sequence in MIN6 cells and 1439±281 in beta-cells. In MIN6 cells about 5720 granules per sequence were classified as short-term resident granules (residence time ≤1 s) and about 118 granules were long-term residents (residence time ≥25 s). The corresponding values for beta-cells were 1334±247 and 15±5, respectively. Apparently, the proportion of long-term resident granules is lower in beta cells than in MIN6 cells. The stimulation pattern in beta cells differed from that of MIN6 cells, in that only K⁺, but not glucose increased the number of arriving granules and diminished the number of long-term resident granules.

Conclusion: The insulinotropic efficacy of nutrient stimulation is much higher in beta-cells than in MIN6 cells, while both have comparable responses to K⁺ depolarization. This may be related to the proportionally lower number of tethered granules in beta-cells. Unexpectedly, the granule mobility in beta cells was less influenced by insulinotropic stimulation than that in MIN6 cells.

Lack of association between plasma PCSK9 and LDL-cholesterol in patients with controlled type 1 diabetes

S. Laugier-Robiolle¹, B. Verges², S. Hadjadj¹, B. Cariou³;
¹Médecine Interne, Endocrinologie, Maladies Métaboliques, C.H.U. Poitiers, ²Médecine Interne, Endocrinologie, Maladies Métaboliques, C.H.U. du Bocage, Dijon, ³Clinique d'Endocrinologie, Institut du thorax, C.H.U. de Nantes, France.

Background and aims: Pro-protein convertase subtilisin/kexin type 9 (PCSK9) is a post-transcriptional inhibitor of LDL-receptor (LDLR). PCSK9 impairs LDL clearance by promoting the LDLR degradation. PCSK9 is secreted by hepatocytes and binds to the extracellular domain of the LDLR, causing degradation in the lysosomes. Previous studies have shown that, in non-diabetic population, PCSK9 was positively correlated to the circulating plasma concentrations of total cholesterol and especially LDL cholesterol (LDL-C). In case of good glycemic control, lipid profile of patients with type 1 diabetes mellitus (T1DM) is different from what is observed in case of poor glycemic control; it can be observed an increase in plasma triglycerides and higher LDL-C levels in case of poor glycemic control. A previous study has shown that PCSK9-LDL association was lost in patients with type 2 diabetes mellitus with poor glycemic control. Here, we aimed to determine the relationship between circulating levels of PCSK9 and LDL-C in subjects with T1DM depending on glycemic control.

Materials and methods: A multicentric study of PCSK9 plasma levels was performed in 202 patients with T1DM whose diagnosis was made before age 40 and insulin treatment initiated within 12 months after diagnosis. They were free of any hypolipidemic agent. Fasting blood samples were obtained from a biological collection. Plasma concentrations of PCSK9 were measured using a sandwich ELISA assay (CycLex).

Results: The mean age was 38 years and diabetes duration 18 years. The mean HbA1c was 8.3%. Plasma PCSK9 concentrations ranged from 85 to 868 ng/ml (mean 314 ng/ml). A positive correlation was found between PCSK9 and age and systolic blood pressure. Plasma PCSK9 was positively correlated with total cholesterol, triglycerides, LDL-C, apoB (Table 1). There was a tendency for a positive association between PCSK9 and HbA1c. In multivariate analysis, PCSK9 (log) was independently associated with LDL-C (p=0,04) and HbA1c (p=0,03). However, the association between PCSK9 and LDLC seemed to be limited to the patients with "uncontrolled" diabetes: PCSK9 was still correlated with LDL-C (p=0.0004) in "uncontrolled" diabetics (HbA1c ≥8%) while this correlation was lost (p=0.52) in "controlled" diabetics. Plasma PCSK9 levels were significantly higher in "uncontrolled" diabetes subgroup than in "controlled" diabetics (p=0.001).

Conclusion: This first study evaluating PCSK9 in patients with T1DM shows a positive correlation between PCSK9 and total cholesterol, LDL and triglycerides; this correlation is lost in patients with good glycemic control in contrast to patients with poor glycemic control.

Dysfunctional endothelial progenitor cells in diabetes: establishing a link between epigenetics and metabolic memory

V. Bianchessi, M. Toia, M. Pesce, M. Vinci;

Unit of Cardiovascular Tissue Engineering, Centro Cardiologico Monzino IRCCS, Milan, Italy.

Background and aims: Endothelial progenitor cells (EPCs) have regenerative capacities and play an important role in vessel wall homeostasis by promoting angiogenesis and maintaining endothelial integrity. The EPCs dysfunction, observed in type I and II diabetes mellitus, contributes to the insurgen of vascular complications in diabetic patients. These complications persist and progress even after good long-term glycemic control, a phenomenon termed “metabolic memory”, suggesting that EPC dysfunction might also last even after glycemia normalization. We investigated whether the exposure to pathologic glucose concentrations affected human cord blood-derived CD34+ cell functions and whether these defects persisted after glucose normalization.

Materials and methods: CD34+ cells were purified from cord blood of healthy donors and expanded in normal-glucose (NG; with 30 mM mannitol for osmotic control) or high-glucose (HG; 30 mM) serum-free medium plus cytokines (FLT3 50 ng/ml, SCF 50 ng/ml, IL3 20 ng/ml and IL6 20 ng/ml) for up to 30 days. The proliferative capacity of CD34+ cells was assessed by producing a growth curve over 30 days and performing doubling time analyses. Telomere length was evaluated by quantitative real-time PCR. Migration ability toward stromal cell-derived factor-1 (SDF-1) was determined using a modified Boyden chamber. CXCR4 protein and mRNA expression were assessed by flow cytometry and quantitative real-time PCR, respectively. The methylation status of CXCR4 gene was assessed by methylation-sensitive restriction enzyme digestion followed by quantitative real-time PCR.

Results: We previously showed that after 20 days hyperglycemia dramatically impaired CD34+ cell proliferation, migration and differentiation into pro-angiogenic cells. Here we demonstrated that high glucose affected CD34+ proliferation by inducing cell senescence. Indeed, after 20 days HG-CD34+ cells presented a significant telomere shortening when compared to the NG-CD34+ cells ($p \leq 0.05$ vs NG). In addition, we also showed that the reduced migration toward SDF-1 in HG-CD34+ cells was associated to a down-regulation of CXCR4 receptor, both in terms of protein ($p \leq 0.001$ vs NG) and mRNA ($p \leq 0.05$ vs NG). Importantly, this defect was maintained even after 72 hours of relief from hyperglycemia ($p \leq 0.05$ HG and exHG vs NG). To address whether epigenetic regulation contributed to defective CXCR4 expression in HG-CD34+ cells, we investigated the methylation status of the CXCR4 gene using methylation-specific restriction enzymes. We found that after 20 days HG-CD34+ cells presented a significant ($p \leq 0.05$ vs NG) hypermethylation of CpG island I, IV and V of CXCR4 gene when compared to NG-CD34+ cells.

Conclusion: These data suggest that hyperglycemia negatively affects CD34+ stem cell function by promoting premature senescence and reducing migration ability towards SDF-1 via CXCR4 gene methylation. Interestingly, this latter defect, which persists after glucose normalization, provides the first evidence of an epigenetic contribution to the establishment of “metabolic memory” in CD34+ cells, paving the way to new pharmacological targets.

FDG-PET-CT assessed subclinical arterial inflammation is associated with glycaemic control, central obesity, and systolic blood pressure in type 2 diabetes patientsS.A. de Boer¹, M.C. de Boer², J.D. Lefrandt¹, A.J. Smit¹, H.L. Lutgers³, A.W.J. Glaudemans⁴, H.J. Lambers Heerspink⁵, R.H.J. Slart⁴, D.J. Mulder¹;

¹Vascular Medicine, University Medical Center, Groningen, ²Radiology & Nuclear Medicine, Meander Medical Center, Amersfoort, ³Endocrinology, ⁴Nuclear Medicine and Molecular Imaging, ⁵Department of Clinical Pharmacy and Pharmacology, University Medical Center, Groningen, Netherlands.

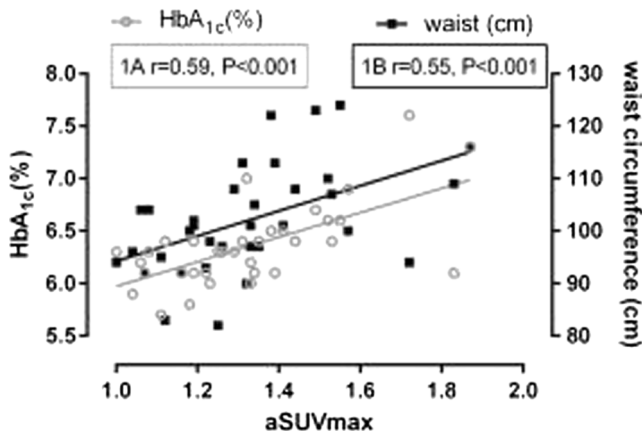

Background and aims: In type 2 diabetes mellitus (T2DM), subclinical atherosclerotic changes occur early in its course. We investigated the association of arterial inflammation and calcification assessed with ¹⁸Fluorodeoxyglucose positron emission tomography-computed tomography (FDG-PET-CT) with atherosclerotic risk factors, skin advanced glycation end products (AGEs), and microalbuminuria in early T2DM.

Materials and methods: 34 patients with treatment naïve T2DM, without cardiovascular disease, were studied (age 63 [IQR, 55–66] yrs, 65% male, BMI 31.5 [28.6–36.8] kg/m², HbA1c 6.4±0.4% (46±4.3 mmol/mol), 17% microalbuminuria). A whole body FDG-PET-CT scan was performed to assess arterial inflammation. Standardized uptake value (SUV)max was calculated according to EARL guidelines and CT was used to score arterial calcification (AC: visual score: 0(no calcification) to 4(>50% calcified plaque)). SUVmax and AC were measured in 4 segments (carotid arteries, ascending aorta and aortic arch, descending and abdominal aorta, and iliac and femoral arteries) and calculated for the total aortic tree (aSUVmax, mean of 4 segments). Clinic and 24-hour ambulatory blood pressure (ABPM) was assessed. Skin AGEs were measured as skin autofluorescence.

Results: aSUVmax and AC were not associated. aSUVmax was associated with BMI ($r=0.64$, $P<0.001$), HbA1c (figure 1A), waist circumference (1B), systolic BP(1C) and pulse pressure ($r=0.39$, $P=0.025$; comparable results for ABPM), urinary albumin/creatinine ratio ($r=0.38$, $P=0.031$), and not with SAF, age, gender, smoking, and lipids. After multivariate adjustment ($r^2=0.73$, $P<0.001$), only HbA1c, ($\beta=0.50$, $P<0.001$), waist circumference ($\beta=0.45$, $P<0.001$), and SBP ($\beta=0.40$, $P<0.001$) remained significant. AC was associated with male gender ($r=0.48$, $P=0.004$), age ($r=0.51$, $P=0.002$), BMI ($r=-0.43$, $P=0.011$), and SAF ($r=0.37$, $P=0.036$) and not with other mentioned risk factors. After multivariate adjustment ($r^2=0.39$, $P=0.001$) only male gender ($\beta=0.49$, $P=0.003$) and SAF ($\beta=0.34$, $P=0.033$) remained significant.

Conclusion: These results show that in treatment naïve T2DM, glycemic control, central obesity, and SBP are independent determinants of FDG-PET-CT assessed subclinical arterial inflammation. Interestingly, while the extent of arterial calcification did not show any relation with arterial inflammation, it was independently associated with skin AGEs, suggesting discordant pathways at different stages of atherosclerotic disease.

Association HbA_{1c} and waist with aSUVmax

RVX-208 acts via an epigenetic mechanism to lower Major Adverse Cardiovascular Events (MACE) in patients with atherosclerosis and especially in those with diabetes mellitus

N.C.W. Wong¹, E. Kulikowski¹, L. Tsujikawa¹, D. Gilham¹, S. Wasiak¹, C. Halliday¹, K. Lebioda¹, J.O. Johansson², M. Sweeney²;

¹Clinical Development, Resverlogix Corporation, Calgary, Canada,

²Clinical Development, Resverlogix Corporation, San Francisco, USA.

Background and aims: RVX-208 binds selectively to the second ligand domain of Bromodomain and Extra-Terminal (BET) proteins and inhibits their activity. Each BET protein has two bromodomains that bind acetylated lysines in histones. When a BET protein binds ligand, it recruits transcriptional machinery to DNA and thereby modifies gene activity. Analysis of pooled data from two phase 2b trials; SUSTAIN and ASSURE revealed a 55% relative risk reduction (RRR) of MACE in RVX-208 treated patients (n=331) vs. placebo (n=168). But in those with diabetes mellitus (DM) RVX-208 treatment lead to a 77% RRR of MACE vs. placebo. RVX-208 increased production of ApoA-I yielding more high-density lipoprotein (HDL) particles. While these effects should lower MACE, the magnitude was more than expected, prompting studies to identify properties of RVX-208 beyond its effects on ApoA-I/HDL.

Materials and methods: Plasma biomarkers from SUSTAIN and ASSURE trials were analyzed. Microarray data from RVX-208 treated primary human hepatocytes (PHH) or human whole blood (HWB) were used to identify differentially expressed genes, and guide measurements of specific proteins in clinical samples to confirm key findings.

Results: Biomarkers from the trials showed significant increases (p<0.05, unless specified) between RVX-208 vs. placebo in: HDL-c (+3 mg/dL), ApoA-I (+7.5 mg/dL), large HDL (+0.7 umol/L), HDL size (+0.1 nm), and total HDL particles (+1.8 umol/L, p<0.07). Glucose in all patients (n=499) or in those with DM (n=192) given RVX-208 or placebo was unchanged vs baseline. In patients with DM (n=119) and low HDL (<40 mg/dL), RVX-208 reduced glucose by -0.3 mmol/L but in placebo it increased +0.9 mmol/L. These modest changes do not predict the MACE reductions. Thus microarrays were used to survey PHH and HWB exposed to RVX-208. In PHH, RVX-208 decreased expression of genes in pathways for cholesterol & fatty acid synthesis, innate immunity and glucose processing. Most profound were effects on complement and coagulation pathways, where RVX-208 downregulated expression of 19/26 and 20/33 genes respectively. These data were confirmed by RT-PCR of key mRNAs. Furthermore, specific complement and coagulation proteins were found to be decreased in plasma from the trials (range 7-

12% vs. baseline). Microarrays from HWB exposed ex-vivo to RVX-208 identified pathways with known roles in atherogenesis including: pro-inflammatory signaling, cell-cell interactions and extracellular matrix organization. RVX-208 significantly downregulated several pro-atherogenic genes (43/56) but upregulated anti-atherogenic genes (9/17), that control monocyte recruitment, migration and activation, macrophage function, inflammatory signaling and plaque stability to suggest an overall anti-atherosclerotic benefit.

Conclusion: RVX-208 treatment is associated with marked MACE reductions in SUSTAIN and ASSURE patients and especially in those with DM. RVX-208 modifies cellular epigenetics to impact multiple biological processes that underlie CVD. Combined effects of RVX-208 on reverse cholesterol transport, vascular inflammation, innate immunity, atherosclerosis and thrombosis may explain its efficacy in reducing MACE.

A trans-ethnic meta-analysis of genome wide association studies reveals new loci associated with childhood obesity

J.P. Bradfield¹, J.F. Felix², V.W.V. Jaddoe², S.F.A. Grant¹, Early Growth Genetics Consortium;

¹Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, USA, ²The Generation R Study Group, Erasmus Medical Center, Rotterdam, Netherlands.

Background and aims: Childhood obesity has more than doubled in the last 30 years. Children who are obese are more likely to be obese as adults and are more at risk for several adult health problems such as type 2 diabetes and heart disease. To search for genetic variants that are associated with childhood obesity, we performed a trans-ethnic meta-analysis of 22 genome wide association studies with European, African, South American, and East Asian ancestry.

Materials and methods: The discovery stage of the meta-analysis has 10,668 cases, defined as greater than the 95th percentile of BMI between 2 and 18 years old, and 12,647 controls, defined as less than the 50th percentile all throughout childhood.

Results: Using the MANTRA algorithm, we meta-analyzed approximately 19 million SNPs, and found 14 loci that attained genome wide significance ($P < 5 \times 10^{-8}$). 10 of these loci (FTO, TMEM18, FAIM2, MC4R, SEC16B, ADCY3, TNNT3K, GNPDA2, FHIT, and TFAP2B) have been previously discovered, while 4 (PHLDA1, METTL15, RBMS3, and COTL1) are novel. More than 100 loci were found to be suggestive of association ($P < 5 \times 10^{-6}$), 7 of which (HOXB3, ADCY9, NEGR1, PTPB2, OLFM4, LINGO2 and SULT1A2) have previously been found to be associated with BMI or Obesity. All of these loci will be carried over into our replication effort, which will narrow down the list even more.

Conclusion: In summary, should these loci survive our replication effort, we will have implicated new pediatric obesity loci.

CReP loss-of-function causes beta cell failure and diabetes

B. Abdulkarim¹, M. Nicolino^{2,3}, M. Igoillo-Estève¹, M. Daures^{4,5}, S. Romero^{4,5}, A. Philippi^{4,5}, V. Senée^{4,5}, M. Lopes¹, D.A. Cunha¹, H.P. Harding⁶, N. Bendelac², A.T. Hattersley⁷, D. Ron⁶, M. Cnop¹, C. Julier^{4,5};

¹ULB Center for Diabetes Research, Université Libre de Bruxelles, Belgium, ²Hôpital Femme-Mère-Enfant, Division of Pediatric Endocrinology, Hospices Civils de Lyon, Lyon1 University, ³Inserm U870, Lyon, ⁴Inserm UMR-S 958, Faculté de Médecine Paris Diderot, ⁵University Paris 7 Denis-Diderot, France, ⁶Cambridge Institute for Medical Research (CIMR), Department of Medicine, University of Cambridge, ⁷University of Exeter Medical School, University of Exeter, UK.

Background and aims: A well balanced endoplasmic reticulum (ER) function is crucial for insulin release and survival of pancreatic β -cells. Deficient as well as excessive/prolonged ER stress can cause β -cell dysfunction/death and diabetes. Phosphorylation of the α subunit of eukaryotic translation initiation factor 2 (eIF2 α) is key for protein folding homeostasis in the ER. CReP is a cofactor for protein phosphatase 1 (PP1), which is required for eIF2 α de-phosphorylation. Here we report on the first mutation in PPP1R15B, encoding CReP, in two siblings with young-onset diabetes.

Materials and methods: Exome sequencing was performed in the index case. PP1 binding was examined in HEK293T cells expressing wild type

or mutant CReP. CReP, PUMA, DP5 and Bim were silenced by RNA interference in INS-1E and FACS-purified primary rat β -cells. Insulin secretion was measured by ELISA. eIF2 α phosphorylation was examined by Western blot and gene expression by qPCR. Apoptosis was assessed by Hoechst 33342/propidium iodide staining and by Western blot for caspases and cytochrome c release.

Results: Two siblings, born to unaffected parents, had early-onset insulin treated diabetes (autoantibody negative, with low but detectable C-peptide levels) diagnosed at 15 and 28 years. This was associated with short stature and microcephaly. Exome sequencing identified a homozygous R658C mutation in PPP1R15B in the index case, which was confirmed by Sanger sequencing in the two siblings. Introducing the R658C mutation in a CReP plasmid diminished the ability of CReP to bind PP1 in vitro and de-phosphorylate eIF2 α . CReP silencing in INS-1E cells increased eIF2 α phosphorylation. CReP-deficient β -cells had reduced insulin content and reduced glucose-induced insulin secretion. CReP silencing induced apoptosis in INS-1E cells ($14 \pm 3\%$ apoptosis with siCReP vs $4 \pm 0\%$ with control siCT, $p < 0.05$, $n = 4-5$) and primary β -cells (siCReP $22 \pm 3\%$ vs siCT $15 \pm 2\%$, $p < 0.05$, $n = 5$). CReP silencing induced caspase-9 cleavage and cytochrome c release from the mitochondria, indicating activation of the intrinsic pathway of apoptosis. CReP deficiency induced a 2-3-fold increase in mRNA expression of the proapoptotic BH3-only proteins PUMA and DP5 ($p < 0.05$, $n = 6$). Silencing of PUMA, DP5 and Bim partially protected CReP-deficient β -cells against apoptosis ($11-13\%$ apoptosis vs 16% , $p < 0.05$, $n = 3-4$).

Conclusion: We have identified a homozygous missense mutation in PPP1R15B leading to a syndrome that includes young-onset diabetes and microcephaly. The mutation diminishes the ability of CReP to bind PP1 and de-phosphorylate eIF2 α , leading to β -cell dysfunction and apoptosis. Our findings support the concept that dysregulated eIF2 α phosphorylation, decreased in Wolcott-Rallison syndrome or increased by the PPP1R15B mutation, is deleterious to β -cells and leads to diabetes.

Characterisation of rapid progressors to type 1 diabetes among children with HLA-conferred disease susceptibility

P.M. Pöllänen^{1,2}, H. Siljander^{1,3}, J. Lempainen⁴, A.-P. Laine⁴, R. Veijola⁵, J. Toppari^{6,7}, J. Ilonen^{4,8}, M. Knip^{1,2};

¹University of Helsinki and Helsinki University Hospital, Children's Hospital, ²Research Programs Unit, Diabetes and Obesity, Helsinki, ³Tampere University Hospital, Department of Paediatrics, ⁴University of Turku, Immunogenetics Laboratory, ⁵University of Oulu, Department of Paediatrics, PEDEGO Research Unit, MRC Oulu, ⁶University of Turku, Department of Paediatrics, ⁷University of Turku, Department of Physiology, ⁸University of Eastern Finland, Department of Clinical Microbiology, Kuopio, Finland.

Background and aims: To assess the characteristics of rapid progressors to type 1 diabetes (T1D) among children with HLA-conferred disease risk.

Materials and methods: We followed from birth 7410 children (52.6% males) with HLA-conferred disease risk for development of islet autoimmunity and progression to T1D over a median follow-up time of 13.2 years (range 0.9-18.2). Islet cell autoantibodies (ICA), autoantibodies to insulin (IAA), to glutamic acid decarboxylase (GADA), and islet antigen 2 (IA-2A) were analyzed for screening for β -cell autoimmunity. Disease progression was considered rapid when T1D was diagnosed within 1.5 years after the seroconversion to autoantibody positivity. We analyzed the association between rapid progression and 25 non-HLA single nucleotide polymorphisms (SNPs) predisposing to T1D.

Results: Among the 7410 children, 1563 (21.1%) tested positive for diabetic autoantibodies, and 221 (14.1%) of the seroconverted children progressed to T1D by the end of 2012. The median time from seroconversion to diagnosis was 0.35 (0.02-1.46) years in rapid progressors ($n =$

46, 20.8%) and 4.3 (1.5–15.8) years in slower progressors. Compared to slower progressors, rapid progressors had higher frequency of multipositivity (76 vs. 54%; $P=0.008$), higher titers of ICA (10.0 vs. 5.0 JDFU; $P=0.003$) and IAA (9.1 vs. 6.6 RU; $P=0.02$) at seroconversion, and higher prevalence of a single nucleotide polymorphism (SNP) in the FUT2 gene (major allele G homozygotes, 74 vs. 25%; $P<0.001$) among individuals carrying the high risk HLA genotype. Furthermore, rapid progressors carried more frequently a combination of ≥ 3 of these risk SNPs in comparison to slower progressors (74 vs. 57%; $P=0.04$). Compared to autoantibody-positive non-progressors, rapid progressors were younger at seroconversion (1.6 vs. 5.5 years; $P<0.001$), carried more often the high risk HLA-DQB1*02/*0302 genotype (48 vs. 26%; $P=0.001$), had higher frequency of IAA (80 vs. 13%; $P<0.001$), GADA (58 vs. 13%; $P<0.001$), and IA-2A positivity (31 vs. 3%; $P<0.001$), and higher titers of ICA (10.0 vs. 4.0 JDFU; $P<0.001$), IAA (9.1 vs. 0.3 RU; $P<0.001$), GADA (6.9 vs. 0.1 RU; $P<0.001$), and IA-2A (0.11 vs. 0.08 RU; $P<0.001$) at seroconversion. In comparison to autoantibody-positive non-progressors, rapid progressors with a high risk HLA genotype carried more often the predisposing SNP in the FUT2 gene (74 vs. 32%; $P=0.001$).

Conclusion: At seroconversion, individuals with rapid progression to T1D are characterized by young age, high-risk HLA genotype, higher autoantibody titers, positivity for multiple autoantibodies, higher prevalence of the predisposing SNP in the FUT2 gene and a higher number of risk SNPs per individual. Such children should be considered as a target for careful monitoring and aggressive intervention.

Prevalence of monogenic diabetes in the Norwegian childhood diabetes registry estimated by targeted deep sequencing

B.B. Johansson^{1,2}, H.U. Irgens^{1,3}, J. Molnes^{1,2}, P. Sztromwasser², O. Søvik^{1,3}, S. Levy⁴, I. Aukrust^{2,1}, D.E. Undlien⁵, T. Skrivarhaug⁶, G. Joner^{6,7}, A. Molven^{1,8}, P.R. Njølstad^{1,3}, S. Johansson^{1,2},

¹Department of Clinical Science, KG Jebsen Center for Diabetes Research, ²Center for Medical Genetics and Molecular Medicine, ³Department of Paediatrics, Bergen, Norway, ⁴Hudson Alpha Institute for Biotechnology, Huntsville, USA, ⁵Department of Medical Genetics, ⁶Department of Paediatrics, ⁷Institute of Health and Society, Oslo, ⁸Gade Laboratory for Pathology, Bergen, Norway.

Background and aims: 10–15% of children with diabetes do not have auto-antibodies at diagnosis, and it is unknown how many of these who have an underlying monogenic form of diabetes. We therefore screened all auto-antibody negative patients in the Norwegian Childhood Diabetes Registry for five monogenic diabetes genes. Our aim was to estimate the prevalence of common forms of monogenic diabetes in childhood diabetes in Norway.

Materials and methods: The Norwegian Childhood Diabetes Registry includes 95% of all children with newly diagnosed diabetes from 2002. By 17.03.2015, the registry contained clinical data (onset of diabetes, family history and treatment) for 3882 children, as well as serum and DNA samples. 469 negative as well as 469 GAD and IA-2 antibody positive individuals were screened for HNF1A, HNF4A, GCK, HNF1B, and INS sequence variants using TruSeq Custom Amplicon sequencing. Classification of DNA variant pathogenicity was performed blindly to auto-antibody status.

Results: Mean coverage was 488X with 97% of the target covered at $>20X$. We found 58 rare exonic and splice variants and classified them according to clinical criteria for pathogenicity (class 1–5). 6.7% of auto-antibody negative patients had a sequence variant classified from unknown to pathogenic (class 3–5) compared to 2.8% of the auto-antibody positive patients ($P=0.005$, $OR=2.51$). For the stricter classification (class 4–5), the corresponding numbers were 3.9% and 0.2%, respectively. Interestingly, 4.1% of the auto-antibody negative patients showed an enrichment of

HNF1A variants of pathogenicity class 3–5; compared to 0.8% of the auto-antibody positive patients ($P=0.001$, $OR=4.99$).

Conclusion: This is a population-based study screening all the auto-antibody negative patients for five monogenic diabetes genes. Our results suggest that the prevalence of monogenic diabetes in the Norwegian Childhood Diabetes Registry is in the range of 3.9–6.7% among GAD- and IA-2 antibody negative patients. Molecular screening in all auto-antibody negative patients should now be considered for routine diagnostics.

Gender difference in diabetes related excess risk of cardiovascular events: When does the 'risk window' open?

G. Seghieri¹, L. Policardo¹, R. Anichini², P. Francesconi¹;

¹Epidemiology, Agenzia Regionale Sanità, Florence, ²Epidemiology, Diabetes Unit, Ospedale S.Jacopo, Pistoia, Italy.

Background and aims: Diabetic women have a significantly higher excess risk of cardiovascular events than diabetic men, when compared with their respective non diabetic counterparts. However, whether this is evident along the entire period of life or whether this gender driven 'risk window' opens only in some life's periods, remains still uncertain. This study has retrospectively followed up, along a period of eight years (from 2005 to 2012) a cohort of diabetic patients living in Tuscany, a region of centre of Italy, comparing between genders the effect of age on diabetes related excess risk of hospitalization for acute myocardial infarction (AMI), ischemic stroke (IS), and congestive heart failure (CHF).

Materials and methods: The database used for this investigation was obtained from linking three datasets: the first concerning hospital discharges with main diagnosis of AMI (ICD-9-CM:410.xx), IS (ICD-9-CM:430.xx, 431.xx, 432.xx, 434.xx or 436.xx) or CHF (ICD-9-CM:402 to 428), from all Tuscan hospitals over the period 2005 to 2012, the second was the general population registry of all inhabitants of Tuscany and the third a dataset containing the registry of all known diabetic patients from Tuscany. The effect of diabetes, identified by hospital discharge with ICD-9-CM code: 250.xx, and/or by the presence in the regional diabetes registry, on hospitalization for AMI, IS, CHF, was separately measured in men and in women according to a Cox regression analysis model, along the entire period 1st January 2005 to 31st December 2012.

Results: On a total of 3,192,203 inhabitants aged more than 16 yr (47% males), we counted 24,605 hospitalizations for AMI (16,251 in men and 8,354 in women), 26,953 for IS (14,848 in men and 12,105 in women), 17,628 for CHF (8,403 in men and 9,225 in women). After adjusting for age, the diabetes related excess risk, expressed as hazard ratio (HR:95%CI), was, overall, significantly higher in women than in men hospitalized for AMI [2.629(2.484-2.781) vs. 1.963 (1.877-2.053); $p < 0.05$], but similar between genders for those hospitalized for IS [2.103(2.000-2.209) vs. 2.131(2.041-2.224); $p = ns$] and CHF [2.631(2.499-2.769) vs. 2.550(2.418-2.688); $p = ns$]. After stratifying the population by age decades, however, diabetic women hospitalized for AMI had a significantly higher excess risk than diabetic men, along the entire age interval between decade 45-54 yr up to age class 75-84 yr, with the highest difference found in age class 45-54 yr [5.827(4.299-7.720) in women vs. 2.879(2.493-3.304) in men; $p < 0.05$]. In patients hospitalized for IS and CHF diabetic women had an excess risk higher than men from age class 55-64 yr up to class 75-84 yr, with the highest difference in age decade 55-64 yr in both [4.139(3.594-4.745) vs. 3.044(2.769-3.339) and 6.828(5.683-8.156) vs. 4.109(3.611-4.663) respectively; $p < 0.05$ for both].

Conclusion: In this cohort of Tuscan population the excess risk of cardiovascular events linked with diabetes, is significantly different between genders. With respect to AMI, diabetic women are more disadvantaged, compared to diabetic men, with a gender driven 'risk window' which mostly opens in the perimenopausal age. As to IS and CHF, it opens later, in the postmenopausal age, and at a lesser extent. All this prompts attention to a timely, gender oriented, prevention of cardiovascular events in people with diabetes.

N-terminal prohormone of brain natriuretic peptide is a predictor of heart failure complicating type 2 diabetes: the Fremantle Diabetes Study Phase II

W.A. Davis¹, K.E. Peters¹, P. Chubb², D.G. Bruce¹, T.M.E. Davis¹;

¹School of Medicine and Pharmacology, University of Western Australia, Fremantle, ²Fiona Stanley Hospital, Department of Clinical Biochemistry, PathWest Laboratory Medicine WA, Murdoch, Australia.

Background and aims: N-terminal prohormone of brain natriuretic peptide (NT-proBNP) predicts incident heart failure in the general population but can be influenced by factors such as renal disease and obesity that are common in type 2 diabetes. The aim of this study was to determine the prognostic utility of NT-proBNP for hospitalisation or death due to heart failure in type 2 diabetes.

Materials and methods: We used baseline data and incident outcomes from the Fremantle Diabetes Study Phase II, a community-based longitudinal observational study. Patients were recruited between 2008 and 2011 and heart failure events were obtained from validated linked data up to end-June 2013. Plasma NT-pro BNP was measured by commercial assay with inter-day imprecision $\leq 4.0\%$ at concentrations up to 406 pg/mL and limit of detection 5 pg/mL. The optimum plasma NT-pro BNP cut-points for prevalent and incident heart failure were identified from the area under the receiver operating characteristic curve (AUC) and Youden's Index. Cox regression with age as time-scale identified independent predictors of heart failure.

Results: Of 1,551 type 2 diabetes participants (mean age 66 years, 52% male, median diabetes duration 9 years), 101 (6.5%) had a prior hospitalisation for heart failure. The geometric mean (SD range) NT-proBNP was greater in those with vs without prior heart failure (456 (99-2098) vs 75 (19-291) pg/mL, $P < 0.001$). In those < 75 years, the AUC for NT-proBNP for identifying prevalent heart failure was 0.83 (0.77-0.89) with an optimum cut-off of 122 pg/mL, and 0.74 (0.65-0.83), with an optimum cut-off of 275 pg/mL, in those ≥ 75 years. During a mean \pm SD 3.6 \pm 1.1 years' follow-up (5,153 patient-years), 80 (5.5%) of the remaining 1,450 patients were hospitalised with/died from heart failure, an unadjusted incidence of 15.5 (95% CI 12.3-19.3) per 1000 patient-years. NT-proBNP was greater in those with vs without incident heart failure (424 (107-1685) vs 68 (19-246) pg/mL, $P < 0.001$). The NT-proBNP AUC for incident heart failure was 0.79 (0.71-0.88) with an optimum cut-point of 114 pg/mL in those aged < 75 years (sensitivity, specificity, PPV and NPV: 72.4%, 76.4%, 8.3% and 98.9%), and 0.78 (0.71-0.85) and 282 pg/mL for those aged ≥ 75 years (sensitivity, specificity, PPV and NPV: 76.3%, 74.0%, 30.2% and 95.5%). Significant independent predictors of incident heart failure were longer diabetes duration, insulin use and $\ln(\text{NT-proBNP})$.

Conclusion: NT-proBNP cut-offs for predicting incident hospitalisation with/death from heart failure in our contemporary type 2 diabetes cohort were similar to those for defining prevalent heart failure. For those ≥ 75 years, NT-proBNP cut-offs for both prevalent and incident heart failure were lower than for diagnosis of heart failure in the general population (> 450 pg/mL).

Fructosamine is a risk factor for myocardial infarction and all-cause mortality: longitudinal experience from the AMORIS cohortH. Malmström¹, G. Walldius¹, V. Grill², I. Jungner^{1,3}, N. Hammar^{1,4},¹Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, ²Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, Trondheim, Norway, ³CALAB Research, Stockholm, ⁴Department of Epidemiology, AstraZeneca R&D, Mölndal, Sweden.

Background and aims: Glycation is linked to microvascular complications of diabetes and also to macrovascular events. Fructosamine is a biomarker of glycation but its associations to macrovascular complications are not well documented. The aim of this study was to evaluate fructosamine as a risk factor of myocardial infarction and all-cause mortality in a large population based cohort.

Materials and methods: Information on glucose and fructosamine was obtained from subjects of the large AMORIS cohort between 1985 and 1996 (n=338,443) who were followed for 19 years on average. None of the subjects were hospitalized at the time of blood sampling and samples were collected either at routine health check-ups or in primary care. Incident cases of myocardial infarction and death from any cause were identified from national patient and cause of death registers respectively with no loss to follow-up. Cox regression with censored data was used to estimate hazard ratios between relevant clinical groups of glycemic status.

Results: The incidence of myocardial infarction (n=21,526 cases) and all-cause mortality (n=73,458 deaths) increased at fructosamine levels above 2.30 mmol/L indicating prediabetes. For myocardial infarction, the sex- age- fasting- and entry period adjusted hazard ratio in subjects above 2.70 mmol/L vs reference subjects with normal glucose tolerance was 2.9 (95% CI: 2.7-3.1) (Figure 1). The corresponding hazard ratio for all-cause mortality was 2.3 (95% CI: 2.2-2.4). These associations remained basically unchanged after adjustment for total cholesterol, triglycerides, albumin and social class. When additional adjustment for glucose was performed the associations were attenuated but remained. Furthermore, the associations remained stable when smoking and hypertension were accounted for in a subset of the cohort (n=3,178). In a proportion of the subjects with simultaneous measurements of fructosamine, HbA1c and fasting glucose respectively (n=9,746), similar associations across the biomarkers were observed with somewhat lower hazard ratios for fasting glucose.

Conclusion: There is a strong association between increased fructosamine levels and myocardial infarction and death from any cause when major cardiovascular risk factors are accounted for. This association could only partly be explained by glucose levels and fructosamine may add or complement to risk assessment in this setting.

Single nucleotide polymorphisms at the Niemann-Pick C1-Like 1 gene locus significantly predict cardiovascular events in coronary patients with type 2 diabetesA. Muendlein¹, A. Leiberer¹, C.H. Saeely^{1,2}, E. Kinz^{1,3}, P. Rein^{1,4}, A. Vonbank^{1,4}, P. Fraunberger⁵, H. Drexel^{1,4},¹VIVIT Institute, ²Department of Medicine and Cardiology, Academic Teaching Hospital Feldkirch, Feldkirch, Austria, ³Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, ⁴Department of Medicine and Cardiology, Academic Teaching Hospital Feldkirch, ⁵Medical Central Laboratories, Feldkirch, Austria.

Background and aims: Niemann-PickC1-like1 (NPC1L1) protein is critically involved in intestinal cholesterol absorption. Recently, genetic variation at NPC1L1 locus has been linked with cardiovascular event risk. The association of NPC1L1 variants with cardiovascular events in patients with type 2 diabetes (T2DM) is unknown and is addressed in the present study.

Materials and methods: We prospectively investigated the impact of NPC1L1 tagging single nucleotide polymorphisms (SNPs) rs3187907, rs10264715, rs4720470, rs217420, rs17655652, and rs17725246 on the incidence of vascular events in 943 patients undergoing coronary angiography for the evaluation of stable coronary artery disease. Furthermore, variants rs217434, rs2072183 and rs41279633 were included based on previously published associations.

Results: As is shown in the table, variants rs3187907, rs10264715, rs217420, rs17725246 as well as rs217434, rs2072183 and rs41279633 significantly predicted cardiovascular events both in the total study population and specifically in patients with T2DM after multivariate adjustment including statin use. Tagging variants rs4720470 and rs17655652 neither in the total study population nor among T2DM patients predicted cardiovascular events.

Conclusion: We conclude that common NPC1L1 variants significantly predict cardiovascular events, particularly in patients with T2DM.

Table: NPC1L1 SNPs as predictors of future cardiovascular events

SNP	HR [95%CI] - all patients	p-value- all patients	HR [95%CI] - T2DM patients	p-value - T2DM patients
rs3187907	1.32 [1.02-1.69]	0.032	1.63 [1.05-2.55]	0.031
rs217434	1.31 [1.02-1.68]	0.033	1.54 [1.00-2.36]	0.049

Diabetes as a risk factor for acute coronary syndrome in women compared with men: a systematic review and meta-analysis

X. Dong, R. Cai, J. Sun, R. Huang, P. Wang, H. Sun, S. Tian, S. Wang; Department of Endocrinology, The Affiliated ZhongDa Hospital of Southeast University, Nanjing, China.

Background and aims: Diabetes mellitus is a significant cause of death and disability worldwide and is a strong risk factor for acute coronary syndrome. Whether diabetes confers the same excess risk of acute coronary syndrome between the sexes is unknown. Therefore, we undertook a systematic review and meta-analysis to estimate the relative risk for acute coronary syndrome associated with diabetes in men and women.

Materials and methods: We systematically searched PubMed, Embase, and Cochrane Library databases for both case-control and cohort studies published between Jan 1, 1966, and Dec 3, 2014. Studies were included if they reported sex-specific estimates of the relative risk (RR), hazard ratio (HR), or odds ratio (OR) for the association between diabetes and acute coronary syndrome, and its associated variability. We pooled the sex-specific RR and their ratio (RRR) between women and men, using a random-effects model with inverse-variance weighting.

Results: We included 9 case-control and 10 cohort studies with data for 10856279 individuals and at least 106703 fatal and non-fatal acute coronary syndrome events. The pooled maximum-adjusted RR of acute coronary syndrome associated with diabetes was 2.46(95%CI 1.92-3.17) in women and 1.68(95%CI 1.39-2.04) in men. In patients with diabetes compared with no diabetes, women therefore had a significantly greater risk of acute coronary syndrome—the pooled women-to-men RRR was 1.38(95%CI 1.25-1.52, $p < 0.001$), with no evidence of publication bias.

Conclusion: Women with diabetes have a roughly 40% greater excess risk of acute coronary syndrome, compared with men with diabetes.

270

Concordance of glucose based and of HbA_{1c} based diagnoses of diabetes in patients with established coronary atherosclerosis: a comparison between men and women

E. Kinz^{1,2}, C.H. Saely^{1,3}, D. Zanolin^{1,4}, P. Rein^{1,5}, A. Vonbank^{1,5}, A. Leihner¹, G. Naerr², A. Muendlein¹, H. Drexel^{1,5};

¹VIVIT Institute, Feldkirch, Austria, ²Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, ³Academic Teaching Hospital Feldkirch, Feldkirch, ⁴Private University of the Principality of Liechtenstein, Triesen, ⁵Department of Medicine and Cardiology, Academic Teaching Hospital Feldkirch, Austria.

Background and aims: Concordance between glucose based and HbA_{1c} based diagnoses of diabetes differ between populations. Here, we aimed at investigating their concordance in men and in women with stable coronary artery disease (CAD).

Materials and methods: We measured fasting glucose as well as HbA_{1c} and performed standard 75 g oral glucose tolerance tests in a consecutive series of 711 patients, 513 men and 198 women, who had angiographically proven coronary artery disease (CAD) but not previously diagnosed diabetes. Based on glucose values, diabetes was diagnosed with a fasting plasma glucose (FPG) ≥ 126 mg/dl or a postchallenge glucose ≥ 200 mg/dl 2 hours after the oral glucose load; based on HbA_{1c} values diabetes was diagnosed with an HbA_{1c} $\geq 6.5\%$.

Results: Among men, 33 had diabetes based on fasting or postchallenge glucose values, of whom 26 also had diabetes according to the HbA_{1c} criterion. Of the 480 men who did not have diabetes based on glucose values, 446 also did not have diabetes according to HbA_{1c} criteria; among women, 3 had diabetes based on glucose values, of whom 2 also had diabetes according to the HbA_{1c} criterion. Of the 195 women who did not have diabetes based on glucose values, 185 also did not have diabetes according to HbA_{1c} criteria. Concordance of Glucose and HbA_{1c} criteria was similar in men and women (92% and 94%; $p = 0.335$). Applying glucose criteria as a standard, sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) of the HbA_{1c} criterion for men were 78.8%, 92.9%, 43.3%, and 98.5%, respectively. For women, sensitivity, specificity, PPV and NPV of the HbA_{1c} criterion were 66.7%, 94.9%, 16.7%, and 99.5%, respectively.

Conclusion: We conclude that concordance of glucose and HbA_{1c} criteria among patients with stable CAD is high and is similar in men

and women with CAD. However, for both sexes the sensitivity of the HbA1c criterion is poor in this patient population.

271

Glycaemic control and excess mortality in patients with type 2 diabetes

M. Tancredi¹, A. Rosengren², A.-M. Svensson³, M. Kosiborod⁴, A. Pivodic⁵, S. Gudbjornsdottir², S. Dahlqvist⁶, H. Wedel⁷, M. Lind⁸; ¹Medicine, NU-Hospital Organization, Trollhattan, ²Medicine, University, ³Registercentrum, Gothenburg, Sweden, ⁴Heart Institute, University of Missouri, Kansas, USA, ⁵Statistiska Konsultgruppen, Gothenburg, ⁶NU hospital Organization, Uddevalla, ⁷Nordic School of Public Health, Gothenburg, ⁸Medicine, NU-Hospital Organization, Uddevalla, Sweden.

Background and aims: The excess risk of all-cause and cardiovascular mortality in individuals with type 2 diabetes and various levels of glycaemic control and renal complications has not been evaluated.

Materials and methods: Individuals with type 2 diabetes registered in the Swedish National Diabetes Registry after 1/1/1998 were included in this study. For each patient, 5 controls were randomly selected from the general population and matched by age, sex, and county. All were followed until 31/12/2011 through the Swedish cause-specific death registry.

Results: Over a mean follow-up of 4.6 and 4.8 years respectively, 77,117 (17.7%) of 435,369 patients with diabetes and 306,097 (14.5%) of 2,117,483 controls died; corresponding rates for cardiovascular mortality were 7.9% vs 6.1% (adjusted hazard ratio (HR) 1.15 (95% confidence interval (CI): 1.14-1.16) and 1.14 (1.13-1.15), respectively). The excess risk of all-cause and cardiovascular mortality increased with younger age, worse glycaemic control, and severity of renal complications. In patients younger than 55 years having hemoglobin A1c (HbA1c), $\leq 6.9\%$ (≤ 52 mmol/mol), the HR for all-cause mortality was 1.92 (1.75-2.11), which decreased to 0.95 (0.94-0.96) in those older than 75 years. If normoalbuminuria coexisted the corresponding hazard ratios were 1.60 (1.40-1.82) and 0.76 (0.75-0.78) respectively, with a significant risk reduction also in those 65-75 years old, hazard ratio 0.87 (0.84-0.91).

Conclusion: Although there is evidence suggesting that the overall excess risk of mortality among individuals with type 2 diabetes has dropped to historically low levels of around 15%, our study shows that remains high in certain patient groups, and is still substantially increased in individuals younger than 55 years even among those with glycaemic control within target ranges and normoalbuminuria. Our study highlights the important need to continue efforts to improve life expectancy in people with diabetes type 2. This appears to be particularly important for younger middle-aged people.

Evaluation of aldehyde dehydrogenase from human erythrocytes of patients with type 2 diabetes mellitus

A. Picazo¹, A.S. Jiménez-Osorio², J. Pedraza-Chaverri², E. Ramirez-Arellano³, A. Monroy⁴, D. Barrera-Oviedo¹; ¹Facultad de Medicina, UNAM, Mexico, ²Departamento de Biología, Facultad de Química, ³Hospital "Lic. Adolfo Lopez Mateos, UNAM, ⁴Hospital General de México, Mexico.

Background and aims: Type 2 diabetes (DM2) is a complex disease that is typically diagnosed in midlife and is characterized by progressive defects due to insulin secretion decreased or insulin action accompanied by changes in the metabolism of carbohydrates, lipids and proteins. There is evidence that oxidative stress (OS) plays a major role in the insulin resistance and in the pathogenesis of DM2, then the oxidative stress association has been described for several years. As one of the consequences of oxidative stress is lipid peroxidation (LP) levels increase where the

aldehyde dehydrogenase (ALDH) enzymes are involved in the detoxification of aldehydes formed during this LP increase.

Materials and methods: In this study one of the proposals was to evaluate, how the activity ALDH is changed in patients suffering from insulin resistance and DM2 as well, a full evaluation of anti-oxidant and oxidant systems in human erythrocytes was performed with the aim of analyzing their activity and association with DM2, via absorbance and fluorescence techniques. The study subjects consisted of a total of 542 patients, aged 35-88 years. Groups were classified based on HOMA-IR, the cut off was 2.6 being 232 subjects showed no insulin resistance, 133 subjects showed insulin resistance and 177 patients with DM2. The average time the patients were diabetes diagnosis was 9.2 ± 7.2 years. Also, the DM2 patients were categorized by glycaemic control DM2 CT (DM2-HbA1c 6.9 , $n=82$) and without control DM2 NCT (DM2-HbA1c 7 , $n=95$).

Results: Interestingly, increased ALDH activity was observed in the diabetic group, it seems to be associated with the severity of the disease and might be a compensatory effect against oxidative stress (noticed in controlled and uncontrolled patients). The antioxidant enzymes activity (SOD, CAT, GPx), bilirubin and stress oxidative markers levels (ROS, lipid and protein oxidation) are modified during the development of DM2. Previous studies have shown that this could probably occur during the beginning of a certain pathology causing the increase in the antioxidant capability to diminish the oxidative stress and finally the oxidative damage. Additionally, associations between phenotypic characteristics with the antioxidant and oxidant systems were noticed between age, gender, glucose, HbA1c and HOMA-IR, probably for the oxidative stress severity of the diabetes.

Conclusion: Our findings suggest that glycaemic control and insulin resistance have an influence on the oxidative stress in DM2. DM2 presented more oxidative stress than HOMA-IR > 2.6 and HOMA-IR < 2.7 . Therefore, our obtained data suggest that oxidative stress play a role in the DM2 pathology and the evaluation of these antioxidants enzymes as ALDH and oxidative markers could help in the severity of the type 2 diabetes and improving redox status.

Antioxidant enzymes activities and Oxidative stress markers and bilirubin levels in erythrocytes lysates.

A) ALDH, B) SOD, C) CAT and D) GPx, E) ROS, F) Lipid oxidation and G) Protein Oxidation H) Bilirubin. HOMA-IR < 2.6 , HOMA-IR > 2.7 , DM2: diabetes mellitus, DM2 CT: controlled diabetes mellitus HbA1c < 6.9 , DM2 NCT: uncontrolled diabetes mellitus HbA1c > 7 . Each bar represents mean \pm SD. Statistical significance: * $P < 0.05$ vs HOMA-IR < 2.6 , [†] $P < 0.05$ vs HOMA-IR > 2.7 , [‡] $P < 0.05$ vs DM2, and [§] $P < 0.05$ vs DM CT with a Kruskal-Wallis test followed by the multiple comparison test proposed by Dunn's Method.

PS 002 Complications in type 1 diabetes

273

The epidemiology of diabetes, diabetes related mortality, complications, obesity and target HbA_{1c} in Russian Federation: the national diabetes register

O.K. Vikulova, M.V. Shestakova, Y.I. Suntsov, I.I. Dedov;
Endocrinology Research Center, Moscow, Russian Federation.

Background and aims: Due to the progressive growth of diabetes mellitus (DM) and diabetic complications and the rising costs of their treatment the data of diabetes registers are important for planning of healthcare system. The aim of our study was to evaluate the trends in epidemiology of DM, DM-related mortality, complications, obesity and target HbA_{1c} in Russian Federation (RF).

Materials and methods: The study summarized the data of National diabetes register based on medical records of DM patients in more than 2000 clinics of primary care in 31 regions of RF. Primary care is provided by DM specialists (mostly) or general practitioners, the data entered manually in online diabetes register, powered by Microsoft Dynamics CRM platform let data export/import to/from MS Excel. Statistics was performed by IBM SPSS Statistics version 19.

Results: In 31 regions of RF in 2014 have been registered 1984791 DM patients compared with 1882483 in 2013 (+5.4%); type 2 (T2DM) 92.2%, type 1 (T1DM) 5.6%, other types 2.2%; 99.4% adults (≥18 yr.), 0.4% children, 0.2% adolescents; gender M/F T1DM 52.5/47.5%, T2DM 28.1/71.9%. The average prevalence of T1DM was 1.56 cases/1000 population, T2DM 25.72 cases/per 1000 population with the wide range of variability among regions from 0.19 to 2.66 and 6.47 to 34.97/1000 population, respectively. The incidence of DM: in 2014 registered 103277 new DM cases, 30.9% less compared to 2013 (T2DM 92.1%, T1DM 3.3%, other types 4.6%). In 2014 registered 26 450 DM-related deaths, the rate of mortality compared to 2013 also decreased by 27.7%. The leading cause was cardiovascular disease: cumulatively heart failure, stroke and myocardial infarction - 50.7% of deaths in T2DM and 34.5% in T1DM, the third leading cause in T1DM - kidney failure (7.9%), in T2DM - oncology (7.5%). Mortality rate due to diabetic coma remains fairly high in T1DM (2.1%). The most frequent complications in T1DM/T2DM: diabetic neuropathy 38.4/19.0%, retinopathy 34.7%/15.3%, hypertension 18.8/37.6%, nephropathy 20.2/4.9%, CKD as GFR <60 9/17%, macroangiopathy 16.7/8.3%. Only 9% of T2DM patients had normal body weight, 33.7% were overweight and 57% had obesity; in T1DM 51%, 26% and 11%, respectively. HbA_{1c} in 2014 T2DM: 35.8% of patients <7.0% and another 35.7% <8.0%, that in some T2DM cases can be considered as suboptimal target achieved; in T1DM the situation was somewhat poorer: 26.1% had HbA_{1c} <7.0% and 30.3% of patients <8.0% (2013: 38.0/37.4%; 24.2/33.7% for T1/T2DM, respectively).

Conclusion: The data of National diabetes register have shown increased DM prevalence in RF over 2013-14 years that is clearly in concordance with the global worldwide trends, but decrease in DM incidence. Apparently, we are dealing not with true reduction but rather with inappropriate registration of new DM cases in primary care. With the general trend of DM-related mortality decrease the cardiovascular pathology remain the main cause of death both in T1 and T2DM. The registered in primary care frequency of complications looks rather underestimated, especially compared with the data of epidemiology studies with active screening. The data demonstrated a very high level of overweight and obesity in DM population that raises the issue of crucial importance for preventive measures. Based on HbA_{1c} level, we consider the situation as fairly stable but need the further efforts for the better DM control.

274

Glycaemic control and prevalence of complications in adolescents and young adults with type 1 diabetes: longitudinal data from two Norwegian diabetes quality registers

S. Carlsen¹, J.G. Cooper^{1,2}, T. Skriverhaug³, G. Thue², S. Sandberg^{2,4};
¹Medical department, Stavanger University Hospital, ²The Norwegian Diabetes Register for Adults, Bergen, ³Norwegian Childhood Diabetes Registry, Oslo, ⁴Department of Public Health and Primary Health Care, Bergen, Norway.

Background and aims: Good glycaemic control delays the onset and progression of microvascular complications, but this can be difficult to achieve, particularly in young people with type 1 diabetes. The aim of this study was to assess glycaemic control and the prevalence of complications in a contemporary cohort of adolescents and young adults in Norway.

Materials and methods: Data was obtained by linking the Norwegian Diabetes Register for Adults and the Norwegian Childhood Diabetes Registry. We identified 874 patients with type 1 diabetes (diagnosed before age 14) who were aged between 18-30 in 2013. All available HbA_{1c} data from the age of 14 until the age of 30 were obtained from the two registers. We calculated updated median HbA_{1c} for each patient, together with median HbA_{1c} for each year (14-30). The patients were grouped according to glycaemic control. Good control was defined as HbA_{1c} <7.5% (58 mmol/mol) for patients <18 years of age and <7.0% (53 mmol/mol) for patients aged 18-30, and poor control as HbA_{1c} >9.0% (75 mmol/mol). The last available data on retinopathy, nephropathy, blood pressure, lipid profile, smoking habits, weight and insulin device was obtained from the adult register.

Results: Median age of the cohort was 23, median age at diabetes onset 9 years and diabetes duration was 15 years. 51% were males, 18% were ex-smokers or current smokers and 40% were treated with continuous subcutaneous insulin infusion. Median HbA_{1c} rose during adolescence to peak at 9.3% (78 mmol/mol) at age 17 in females and 9.1% (75 mmol/mol) at age 19 in males thereafter decreasing steadily in both genders. Females had a higher HbA_{1c} result compared to males at ages 16-18 years (p<0.01). The proportion of patients achieving good glycaemic control was worst at 18 years of age (3%) and only 18% of patients achieved good glycaemic control in their late twenties. 26% of the patients had retinopathy and/or nephropathy with no gender differences. 72% of patients with poor glycaemic control both as teenagers and young adults had complications. In a binary logistic GEE model updated median HbA_{1c}, smoking habits, diabetes duration and age at diagnosis predicted complications (p<0.05).

Conclusion: Longitudinal data from two Norwegian diabetes quality registers show that glycaemic control is still far from satisfactory in adolescents and young adults, females have higher HbA_{1c} than males in their middle teens. The prevalence of microvascular complications was 26% for both genders and 72% in the group with sustained poor glycaemic control.

275

Long-term trends in cardiovascular risk factors in type 1 diabetes: nationwide monitoring of 38,169 patients from 1996 to 2014

A. Rawshani¹, A.-M. Svensson¹, A. Rosengren¹, S. Franzén², B. Eliasson¹, S. Gudbjörnsdóttir¹;
¹Clinical and Molecular Medicine, Inst of Medicine, ²Västra Götalandsregionen, Centre of Registers, Gothenburg, Sweden.

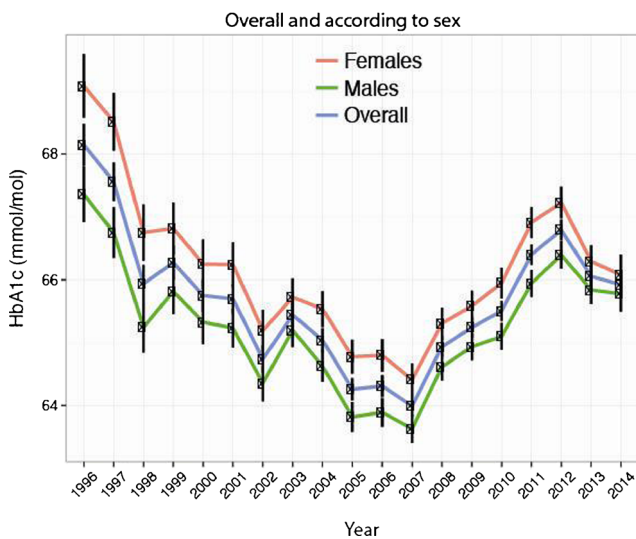

Background and aims: The last decades have witnessed remarkable advances in the management of type 1 diabetes. The risk of complications has presumably been reduced by intensive insulin therapy, improved insulin delivery and glucose monitoring, blood pressure control and lipid lowering therapy. Yet long-term trends in risk factor control has not been examined. We aimed to examine trends in six cardiovascular risk factors from 1996 to 2014, in the overall cohort and in relation to socioeconomic categories.

Materials and methods: We included all patients with type 1 diabetes entered in the Swedish National Diabetes Register from 1996 to 2014 ($n=38,169$ contributing 457,577 appointments). We calculated adjusted estimates of glycated haemoglobin (HbA1c), systolic blood pressure (SBP), LDL cholesterol (LDL-C), body mass index (BMI), physical activity and smoking.

Results: HbA1c declined from 68.1 mmol/mol to 64.0 mmol/mol from 1996 to 2007 and then reversed to 66.8 in 2012, declining slightly in the remaining two years. By the end of the study period there was no improvement in HbA1c since the turn of the millennium (Figure 1). Individuals with a college/university degree had 4 mmol/mol lower HbA1c than individuals with 9 years or less education and there was no trend towards reduced differences. Overall LDL-C declined from 2.85 in 2002 to 2.59 in 2014, which was, however, not significantly lower than LDL-C in 2006. Higher education, but not higher income, was associated with lower LDL-C. BMI increased linearly, from 24.7 kg/m² to 26.1 kg/m² from 1996 to 2014. SBP decreased from 131.2 mmHg in 1996 to 125.9 mmHg in 2014. Odds ratio for being a smoker in 2014, compared with 1999, was 0.75 (95% CI 0.69 to 0.82); there were staggering differences in relation socioeconomic status, with no tendencies towards reduced gaps. Smoking rates declined more in the background population than among persons with type 1 diabetes. Physical activity doubled between 2004 and 2007 and then remained unchanged for the remaining seven years. Odds ratio for being physically active in 2014, compared with 2001, was 5.25 (95% CI 5.05 to 5.45).

Conclusion: Blood pressure control has been successful. Smoking rates have declined but smoking cessation has been less successful among persons with type 1 diabetes, as compared with persons without diabetes. Promotion of physical activity has been successful. Less stable improvements are noted for HbA1c and LDL-C. BMI is increasing steadily. Socioeconomic differences are pronounced.

Long-Term Trends in Glycaemic Control (HbA1c)

276

Gender aspects in type 1 diabetes patients undergoing angiography: a registry report

C. Hero¹, V. Ritsinger^{2,3}, A.-M. Svensson⁴, N. Saleh², B. Lagerqvist⁵, A. Norhammar², K. Eeg-Olofsson¹;

¹Department of Medicine, Sahlgrenska University Hospital, University of Gothenburg, ²Department of Medicine, Karolinska Institute Cardiology unit, Karolinska University Hospital, Stockholm, ³Department of Research and Development, Region Kronoberg, ⁴Centre of Registers, The National Diabetes Register, Region of Västra Götaland, Gothenburg, ⁵Uppsala University Hospital, Department of Medical Sciences, Cardiology, Sweden.

Background and aims: In patients without diabetes, widespread coronary artery disease (CAD) is more common among men compared to women. This difference is often attenuated if diabetes is present. Few studies have addressed type 1 diabetes (T1D) in this context. The aim of this study was to describe angiographic findings and assess long term mortality also by affected coronary vessels in women and men with T1D.

Materials and methods: All patients undergoing coronary angiography in Sweden 2001–2012, included in the Swedish Coronary Angiography and Angioplasty Registry (SCAAR) and registered in the Swedish National Diabetes Registry (NDR) with T1D were included. T1D was defined both with an epidemiological definition and also using the clinicians' diagnosis and onset age before 50 years. Coronary angiogram was visually judged by the local coronary interventionist and divided into normal (including atheromatosis/stenosis <50%), one-, two-, three-, and left main-vessel disease. Patients were followed for mortality until 31 December 2012.

Results: We included 1180 women and 1664 men undergoing coronary angiography. Mean age 57.5±11 years in both women and men. Mean diabetes duration 37.0±14.1 years in women, vs. 33.5±14.0 years in men ($p<0.0001$). Mean HbA1c 67±14 vs. 66±14 mmol/mol ($p=0.26$), LDL 2.7±0.9 vs. 2.6±0.9 mmol/L ($p=0.83$), HDL 1.65±0.49 vs. 1.43±0.47 mmol/L ($p<0.0001$), systolic blood pressure 136±18 vs. 136±17 mmHg ($p=0.33$) in women and men respectively. Men had more albuminuria 51% vs. 42% ($p<0.0001$) and women more retinopathy 68% vs. 64% ($p<0.05$). Main indications for coronary angiography were stable coronary artery disease (CAD) 36 vs. 34%, unstable acute CAD 39 vs. 37% and ST-elevation myocardial infarction (STEMI) 9 vs. 12%, other indications 18 vs. 16% in women and men respectively. CAD findings by gender are presented in Figure 1. Normal angiography was more common in women (24% vs. 19%). The mean follow-up period was 7.2 (SD 2.2) years and total mortality did not differ (unadjusted) in women compared to men. In women diagnosed with 2- and 3-vessel disease crude mortality seemed higher compared to men.

Conclusion: In patients with T1D admitted for coronary angiography women more often had a normal angiogram whereas men more often had 3- vessel and left main vessel disease. Thus the advantage related to female gender seen in the general population is not completely attenuated by the presence of T1D. Despite less widespread angiographic findings in women, total mortality did not differ, which might be explained by longer diabetes duration in women.

Figure 1: Percentage of coronary artery disease findings on coronary angiogram by gender

What makes a survivor? Description of patients with very long duration of type 1 diabetes with and without a history of micro- or macrovascular complications

B. Eliasson¹, S. Adamsson Eryd², A.-M. Svensson², S. Franzén², P.M. Nilsson³, S. Gudbjörnsdóttir²;

¹University of Gothenburg, Department of Medicine, ²Region of Västra Götaland, The National Diabetes Register, Gothenburg, ³Lund University, Department of Clinical Medicine, Malmö, Sweden.

Background and aims: Type 1 diabetes (T1D) is associated with an increased risk of micro- and macrovascular disease. Some individuals with T1D develop such complications very early, while others may never experience them, despite long diabetes duration. The aim of this study was to describe the risk factor distribution in subjects with very long duration of T1D, with and without micro- and macrovascular complications.

Materials and methods: The study included individuals with T1D registered in the Swedish National Diabetes Registry (NDR) between 2002 and 2004. The distribution of biological, lifestyle- and socioeconomic factors were compared between subjects with and without a history of cardiovascular disease (CVD), and also between subjects with and without a history of renal impairment or severe retinopathy.

Results: Of those with a diabetes duration >50 years (n=583), 290 subjects had a history of CVD and 240 subjects had a history of kidney disease or severe retinopathy, while 180 individuals were free of these diagnoses. Detailed risk factor distributions in these groups are given in Table 1. Factors that differed significantly between subjects with and without CVD were age, HbA1c, body mass index (BMI), HDL-cholesterol, LDL-cholesterol, albuminuria, antihypertensive- as well as lipid-lowering medication, and income. The same factors differed significantly between subjects with and without history of renal impairment or severe retinopathy, except for BMI, HDL-cholesterol and income.

Conclusion: Individuals with T1D who have survived >50 years without either micro- or macrovascular complications have significantly lower age, HbA1c, and triglyceride levels compared to patients with a history of such complications. They also have higher LDL-cholesterol levels, less albuminuria and less antihypertensive and lipid-lowering medication. Although these differences in risk factor burden may contribute to explain the presence of diabetic complications, unknown protective factors may be present.

Table 1. Risk factor distribution for subjects with a diabetes duration >50 years

	History of cardiovascular disease			History of renal impairment or severe retinopathy		
	Yes	No	P-value	Yes	No	P-value
N	240	343		290	293	
Age, years	66.7 ± 7	63.9 ± 7	0.001	66.4 ± 8	63.7 ± 7	<0.001
Male sex (%)	54.2	51.0	0.45	53.1	51.5	0.70

Determinants of HbA_{1c} in patients with type 1 diabetes in seven Swedish county councils

M. Lilja¹, B. Julin², G. Andersson³, I.-L. Andersson⁴, M. Axelsen⁴, M. Ek⁵, R. Kristiansson⁶, J. Lekell⁷, A. Lindberg⁸, P. Lindgren², F. Löndahl⁹, K. Looström Muth¹⁰, A.-M. Svensson¹¹, T. Dahlström¹²;

¹Public Health and Clinical Medicine, Östersund unit, Umeå University, ²Ivbar, Stockholm, ³The Swedish Society of Diabetes Nursing, ⁴Swedish Association of Clinical Dietitians, ⁵Stockholm county council, ⁶Uppsala county council, Uppsala, ⁷Department of Medical Sciences, Uppsala University, ⁸Region Skåne, Malmö, ⁹Swedish Diabetes Association, Stockholm, ¹⁰Region Västra Götaland, Gothenburg, ¹¹Swedish National Diabetes Register, Gothenburg, ¹²Public Health and Caring Science, Uppsala University, Sweden.

Background and aims: In order to make fair comparisons between the results of different health care providers, proper consideration of the case-mix of the populations they serve is important. HbA_{1c} is often used as a metric to indicate the quality of diabetes care, it is therefore of value to determine what patient characteristics affect this outcome. As part of the ongoing National Collaboration for Value Based Reimbursement and Monitoring Systems, we therefore set out to investigate what factors are associated with HbA_{1c} in a large retrospective cohort of persons with type 1 diabetes.

Materials and methods: This was a retrospective register study where we analyzed persons 18 years or older, with a health care contact and a diagnosis of diabetes during 2010-11 in the administrative systems of seven Swedish county councils (Dalarna, Jämtland Härjedalen, Skåne, Stockholm, Uppsala, Västra Götaland and Östergötland), covering ~70% of the Swedish population and linked this data to data from the National Diabetes Register, socioeconomic data from Statistics Sweden and data on filled prescriptions from the Prescribed Drug Register. We estimated a random effect model on HbA_{1c} after one year of follow-up, including socioeconomic, demographic and clinical factors.

Results: Based on a complete case approach, 13 396 patients were analyzed. Women had on average higher HbA1c than men. Blood sugar control seemed to be better with higher age. Of the socioeconomic factors, higher education was associated with lower levels of HbA1c, as was being married. By contrast, we found no association between HbA1c and being born outside the EU. A history (previous 2 years) of diabetes related complications were associated with higher levels of HbA1c, which is likely due to high levels of HbA1c being an indicator of what is causing the complications in the first place. The exception to this pattern was patients with renal failure.

Conclusion: Apart from obvious demographic factors such as age and gender as well as disease history, educational and civil status are important factors to take into consideration when comparing obtained HbA1c levels between health care providers. This also raises the question of the need for additional focus on education directed towards these groups to facilitate improved diabetes management.

279

HbA_{1c} and incidence of micro- and macrovascular disease in patients with very long duration of type 1 diabetes

S. Adamsson Eryd¹, A. Rawshani², A.-M. Svensson¹, S. Franzén¹, B. Eliasson², P.M. Nilsson³, S. Gudbjörnsdottir¹;
¹Region of Västra Götaland, The National Diabetes Register, ²University of Gothenburg, Department of Medicine, Gothenburg, ³Lund University, Department of Clinical Medicine, Malmö, Sweden.

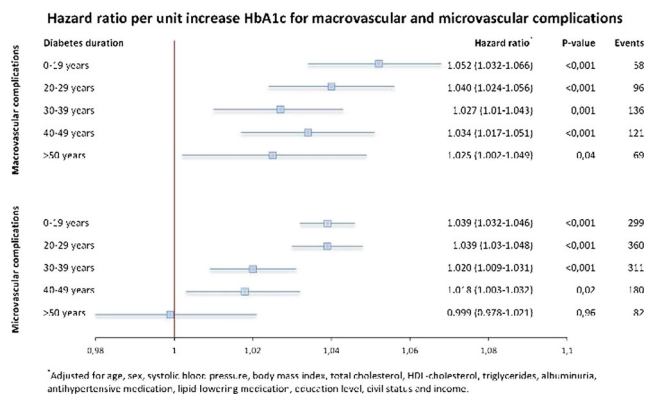

Background and aims: Type 1 diabetes (T1D) is associated with an increased risk of micro- and macrovascular disease. Glycemic control is

a strong predictor of these complications. The aim of this study was to explore whether HbA_{1c} is associated with incidence of micro- and macrovascular disease in subjects with very long duration of T1D.

Materials and methods: Individuals with T1D included in the Swedish National Diabetes Registry (NDR) between 2002 and 2004 without a history of cardiovascular disease (CVD) and albuminuria (n=7081) were followed until the first event of CVD, death or until December 31, 2012. Furthermore, subjects without a history of renal impairment, severe retinopathy and albuminuria (n=6577) were followed until the first event of renal impairment, severe retinopathy, death or until December 31, 2012. Cox proportional hazards regression was used to study the relation between HbA_{1c} and incidence of CVD, renal impairment and severe retinopathy. The models were adjusted for age, sex, systolic blood pressure, body mass index, total cholesterol, HDL-cholesterol, triglycerides, albuminuria, antihypertensive medication, lipid-lowering medication, education level, civil status and income. The analyses were stratified into five levels of diabetes duration: 0-19 years, 20-29 years, 30-39 years, 40-49 years, and >50 years.

Results: During a mean follow-up time of 9 years 480 individuals were diagnosed with CVD (7.3 per 1000 person-years). In addition, 1232 subjects were diagnosed with renal impairment or severe retinopathy (21.7 per 1000 person-years). After adjusting for potential confounding factors, incidence of CVD was significantly associated with HbA_{1c} levels in all duration strata (Figure 1). Hazard ratios decreased with longer diabetes duration. A similar relationship was observed with incidence of microvascular disease. HbA_{1c} levels were not associated with incidence of microvascular disease in patients with >50 years duration.

Conclusion: HbA_{1c} is a predictor of micro- and macrovascular disease independent of duration of T1D. The results suggest that HbA_{1c} is a weaker risk factor in persons with very long diabetes duration, indicating the importance of other known and unknown protective factors in this very selected group of patients.

280

Application of a validated prognostic model to identify type 1 diabetic patients at high risk for major outcomes

M. Garofolo, E. Russo, D. Lucchesi, L. Giusti, V. Sancho Bornez, R. Bellante, R. Miccoli, G. Penno, S. Del Prato;
 Clinical and Experimental Medicine, University of Pisa, Italy.

Background and aims: A prognostic model for assessing individual risk for major outcomes (CHD, stroke, ESRD, amputation, blindness and all-cause death) in type 1 diabetes (T1DM) has been developed from the EURODIAB PCS and tested in three other prospective cohorts. The model uses routinely available features: age, HbA_{1c}, waist-hip ratio, urinary ACR and HDL. It identifies three groups of T1DM at low- (LR, score lower than 16), intermediate- (IR, score 16-20) and high- (HR, score

higher than 20) absolute risk. This model has been applied to a cohort of 774 T1DM (367 F, 47%; 407 M, 53%) attending our outpatients clinic.

Materials and methods: Mean age and diabetes duration (DD) were 40.2±11.7 years and 19.3±12.2 years; HbA1c 7.8±1.2% (range 5.2–15.1%); urinary ACR (median) 0.49 mg/mmol (0.03–142.6); HDL 62.5±15.2 mg/dl (8–103 mg/dl), WHR 0.92±0.06 (0.74–1.14). Risk distribution was evaluated in the entire cohort and after exclusion of 41 T1DM subjects (5.3%) with major outcomes.

Results: Risk distribution was LR n. 466 (60.2%), IR n. 205 (26.5%) and HR n. 103 (13.3%) in the whole cohort, and LR n. 461 (62.9%), IR n. 195 (26.6%) and HR n. 77 (10.5%) after exclusion of T1DM with major outcomes. Major outcomes were more frequent in HR (26/103; 25.2%) and IR (10/205; 4.9%) than in LR (5/466; 1.1%; $p < 0.0001$). Mean absolute risk at 3, 5, 7 and 10 years in the 733 subjects with no previous outcomes were, respectively, 1.4, 2.4, 3.4 and 4.9% for LR; 3.8, 6.5, 9.2 and 13.1% for IR; 11.7, 18.9, 25.4 and 33.9% for HR. Distribution of risk was similar in M and F: LR 58.7 vs. 61.9%, IR 25.5 vs. 27.5% and HR 15.7 vs 10.6% ($p = 0.113$), but HR was more common in M ($p = 0.037$). IR and HR increased with quartiles of DD: DD lower than 9 years 16.6 and 1.6%; 10–18 years 24.8 and 4.9%; 19–28 years 24.7 and 13.9%; higher than 28 years 40.9 and 34.8% ($p < 0.0001$). By multiple regression, main factors associated with IR&HR were age ($r^2 = 0.801$), logACR ($\Delta r^2 = 0.097$) and HbA1c ($\Delta r^2 = 0.039$; $p < 0.0001$ for all). Other recognized prognostic factors (not included in the model because of weak additional effects) were strictly correlated with those included in the model; indeed, these risk factors increased from LR to HR: sBP 120±14, 132±17 and 145±20 mmHg; dBP 72±8, 75±9 and 75±10 mmHg; LDL cholesterol 113±29, 122±30 and 120±29 mg/dl; non-HDL cholesterol 120±32, 131±35 and 132±33 mg/dl; triglycerides 69 (55–91 IQR range), 82 (63–106) and 101 (69–137) mg/dl; fibrinogen 320±64, 353±63 and 376±67 mg/dl; uric acid 3.6±1.0, 3.8±1.9 and 4.8±4.7 mg/dl; on the other hand, eGFR (CKD-EPI) decreased progressively: 108±15, 99±13 and 83±20 ml/min/1.73 m² ($p < 0.001$ for all).

Conclusion: In our cohort of T1DM, 30–40% of subjects had high (about 10%) or intermediate risk (about 25%) for major outcomes. Subjects at IR and some at HR are also present among T1DM with short DD. This model allows to trace for each T1DM an exact risk profile to be used in the clinical practice with the aim of improving treatment for all risk factors.

SNP x SNP interactions in the VPS13C/C2CD4A/C2CD4B locus modulate diabetes risk

R. Wagner^{1,2}, M. Heni^{1,2}, J. Machann³, F. Schick⁴, E. Hatzigelaki⁵, F. Machicao^{1,2}, H. Staiger^{1,2}, H.-U. Häring^{1,2}, A. Fritsche^{1,2},

¹Division of Endocrinology, Diabetology, Nephrology, Vascular Disease and Clinical Chemistry, University Hospital of Tübingen, ²Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Centre Munich at the University of Tübingen (IDM), ³Department of Diagnostic and Interventional Radiology, Section on Experimental Radiology, University Hospital of Tübingen, ⁴Department of Diagnostic and Interventional Radiology, Section on Experimental Radiology, Eberhard Karls University Tübingen, Germany, ⁵2nd Department of Internal Medicine, Research Institute and Diabetes Center, University Medical School, “Attikon” University Hospital, Athens, Greece.

Background and aims: Single nucleotide polymorphisms (SNPs) in the VPS13C/C2CD4A/C2CD4B locus have been found to be associated with type 2 diabetes, fasting plasma glucose, 2-hour plasma glucose and insulin secretion in genome-wide association studies (GWAS). Some of the weakly linked SNPs demonstrate opposing effect directions. The functional impact of these genetic variants is unknown. Our objective was to examine a broad panel of intermediary traits in our extensively phenotyped cohort.

Materials and methods: We genotyped 21 tag SNPs in the locus. Metabolic traits from oral glucose tolerance tests conducted in 2273 participants and MR-based body fat distribution parameters in a subgroup were jointly examined using region-based analyses. Key variants were identified by iterative leave-one-out tests and single SNP association tests. Haplotype-association tests and linear regression tests with interaction models were conducted. Insulin secretion and insulin sensitivity were additionally examined in subgroups with hyperglycemic and hyperinsulinemic-euglycemic clamps, respectively.

Results: Joint tests confirmed the previously established association with post-challenge glucose and insulin secretion. After adjustment for sex, age and BMI, region-wide analysis indicated an association with insulin clearance ($p = 0.01$), fasting non-esterified fatty acids (NEFA, $p = 0.009$), glycerol ($p = 4 \cdot 10^{-4}$), and subcutaneous abdominal adipose tissue volume ($p = 10^{-5}$). For rs11629596 and rs1425270, a near genome-wide level of significance was detected for fasting glycerol and insulin clearance ($p = 4 \cdot 10^{-7}$ and $p = 7 \cdot 10^{-7}$, respectively). We demonstrated SNP x SNP interactions on metabolic traits centered around rs72752005. This SNP also augmented the association of the GWAS-SNP rs7172432 with diabetes (adjusted per-A-allele OR of rs7172432 on diabetes: 1.03 [CI 0.48–2.19], 1.44 [CI 0.98–2.11] and 2.63 [1.07–6.55] for strata of the A/A, A/G and G/G genotypes of rs72752005, respectively).

Conclusion: In the VPS13C/C2CD4A/C2CD4B locus, we demonstrate pleiotropic metabolic effects with strong SNP x SNP interactions affecting multiple metabolic traits and association with diabetes. Specific SNP combinations in this locus could bear a much higher diabetes risk than SNP effect estimates from GWAS that originally identified this genetic region.

282

Genome-wide multi-phenotype rare variant association analysis detects effect of *ZNF259* on fasting insulin and triglyceride levelsM. Kaakinen¹, R. Mägi², K. Fischer², M.-R. Järvelin^{1,3}, A.P. Morris⁴, I. Prokopenko¹;¹Imperial College London, UK, ²Estonian Genome Center, Tartu, Estonia, ³University of Oulu, Finland, ⁴University of Liverpool, UK.

Background and aims: Individuals with type 2 diabetes (T2D) have increased risk of coronary heart disease (CHD), suggesting shared pathogenesis. While adverse fasting insulin (FI) levels have a central role in T2D development, CHD is causally related to dyslipidaemia and triglycerides (TG), in particular. For common variants (minor allele frequency, MAF > 5%), single-trait analyses have shown an enrichment of FI associations among SNPs preselected on Metachip for TG and waist phenotypes. However, novel associations could be detected via i) multi-phenotype analysis by accounting for the correlation between traits, and ii) analysis of low-frequency and rare variants (MAF ≤ 5%, both denoted by RVs).

Materials and methods: We have developed a method and software tool for Multi-phenotype Analysis of RVs (MARV), and have applied it to jointly analyse FI, TG and WHR using data from 4788 individuals from the Northern Finland Birth Cohort 1966. Individuals were genotyped on the Illumina370CNV array and imputed to the 1000 Genomes Project all ancestries reference panel (March 2012). FI/TG/WHR were adjusted for sex, BMI and three principal components to control for population structure. The following transformations were applied: natural logarithm for FI and inverse normal for the residuals of TG and WHR.

Results: We identified RV associations, at genome-wide significance ($p < 1.7 \times 10^{-6}$, Bonferroni correction for 30,000 genes) in *ZNF259*, which maps to a common variant GWAS locus for TG and CHD. Based on BIC, the model with TG and FI provided the best fit ($p_{\text{model}} = 2.2 \times 10^{-9}$), and stronger associations than in univariate analyses ($p_{\text{TG}} = 1.1 \times 10^{-7}$; $p_{\text{FI}} = 0.22$). *ZNF259* included 18 rare variants with MAF ranging from 0.01% to 4.9%, including three missense SNPs.

Conclusion: Common variants at *ZNF259* have previously been associated with lipid levels and CHD but not FI. Using the MARV method and tool, we demonstrate for the first time a role of *ZNF259* RVs in T2D/CHD-related trait variability, suggesting shared pathophysiology.

SNPs in *FGF5* and *ZNF652* show parent-of-origin specific effects on blood pressure in families from the Botnia studyA. Lessmark¹, R.B. Prasad¹, P. Almgren¹, G. Kovacs², M. Vitai², T. Tuomi^{3,4}, L. Koranyi², O. Melander¹, L. Groop^{1,5};¹Department of Clinical Science, Lund University, Malmö, Sweden, ²Heart Center Foundation, DRC, Balatonfüred, Hungary, ³Folkhälsan Research Centre, ⁴Department of Medicine, Helsinki University Central Hospital, ⁵Finnish Institute of Molecular Medicine, Helsinki University, Helsinki, Finland.

Background and aims: Hypertension affects ~1 billion people and causes ~9.4 million deaths worldwide each year. There is a strong heritable component; however the genetic variants identified so far explain only ~1% of the heritability. There are differences in disease expression between the genders that cannot be fully explained by hormonal differences alone, and some genetic basis for the sex-specific effects has been suggested in previous studies. Further, Lascaux-Lefebvre et al (Diabetes Metab. 2001) and others have suggested the impact of parental histories and specifically, a stronger maternal influence on blood pressure. Parent-of-origin effects (POE) could explain some of these biases, but they would not be detected in a case-control setting. Our study aims to explore these effects in two of the largest family based cohorts.

Materials and methods: Families from the Botnia cohort (n=4189, 1083 families) were genotyped on the Sequenom mass array for 13 SNPs that has previously shown an association with blood pressure in GWAS studies and Systolic Blood Pressure (SBP), Diastolic Blood Pressure (DBP) and Mean Arterial Pressure (MAP) were measured. Correlations between the parent and offspring phenotypes were analysed, and tests for association and parent-of-origin effects were performed using a family based linear regression model (qTDT). SNPs showing parent-of-origin effects will be replicated in families from the Hungarian Transdanubian Biobank (n=9279, 1022 families).

Results: The correlation between SBP, DBP and MAP were stronger between mothers and offspring (r_{MAT}) than between fathers and offspring (r_{PAT}) (SBP: $r_{\text{MAT}} = 0.222$ $r_{\text{PAT}} = 0.140$ $p_{\text{DIFF}} = 0.002$, DBP: $r_{\text{MAT}} = 0.215$ $r_{\text{PAT}} = 0.120$ $p_{\text{DIFF}} = 0.001$, MAP: $r_{\text{MAT}} = 0.245$ $r_{\text{PAT}} = 0.137$ $p_{\text{DIFF}} < 0.001$). The SNP rs16998073 in fibroblast growth factor 5 (*FGF5*), showed the strongest POE. The A-allele, previously associated with lower DBP, showed a trend for lower DBP when inherited from the father (Pat_effect = -0.021, $p_{\text{PAT}} = 0.07$), but higher DBP when inherited from the mother (Mat_effect = +0.020, $p_{\text{MAT}} = 0.08$), with the total test for POE reaching significance ($p_{\text{POE}} = 0.005$). The POE test also reached significance for MAP (Pat_effect = -0.019, Mat_effect = +0.020, $p_{\text{POE}} = 0.006$) and SBP (Pat_effect = -0.019, Mat_effect = +0.015, $p_{\text{POE}} = 0.04$). The SNP rs16948048 near zinc finger protein 652 (*ZNF652*) reached significance for POE ($p_{\text{POE}} = 0.03$) on DBP, with the A allele, previously associated with lower DBP, associated with lower DBP when inherited maternally (Mat_effect = -0.029, $p_{\text{MAT}} = 0.03$) but neutral when inherited paternally (Pat_effect = +0.003, $p_{\text{PAT}} = 0.79$) in the current study.

Conclusion: We show here for the first time parent-of-origin specific effects of SNPs previously associated with blood pressure. This could explain some of the gender specific effects in traits and the correlation between individual parents and offspring observed and highlights the need to consider parent-of-origin effects while investigating genetic associations for blood pressure traits. Studies to replicate this parent-of-origin effect in families from Hungary are underway.

Heritability of human serum lysophospholipids and ether phospholipidsT. Frahnow¹, M.A. Osterhoff^{1,2}, A.-C. Seltmann¹, S. Hornemann¹, M. Kruse¹, S. Sales³, J.L. Sampaio⁴, K. Simons^{4,3}, A.F.H. Pfeiffer^{1,2};¹Clinical Nutrition, German Institute for Human Nutrition Potsdam-Rehbrücke, Nuthetal, ²Charité - University of Medicine Berlin, ³Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, ⁴Lipotype GmbH, Dresden, Germany.

Background and aims: Although lipidomics, the study of lipids, have a great potential as clinical tool for monitoring metabolic changes in health and disease, hardly anything is known about the heritability of lipids. We therefore use the cohort of our intervention study in twins to investigate similarities and differences in the lipid profile of mono- and dizygotic twins.

Materials and methods: In the NUGAT (NUtriGenomic Analysis in Twins) study, 46 healthy twin pairs (34 monozygotic, 12 dizygotic) were standardized for their nutritional behavior due to a period of six weeks on a high-carbohydrate, low-fat diet. This standardization was followed by an interventional low-carbohydrate, high-fat diet for another six weeks. Extensive characterization of the metabolic responses was performed after the low fat (LF) and after 1 (HF1) and 6 (HF6) weeks of high fat diet (HFD) to evaluate rapid and long-term effects. A lipid profile of 307 lipids out of 18 classes were part of the examination including 2 classes of lysophospholipids (n=27) and 2 classes of ether phospholipids (n=39). For the study of heritability, the ACE model was applied. This model is based on a correlation analysis of the mono- and dizygotic twins, in which the proportion of variance is determined that can be traced back to

additive genetics (A), common environment (C) and individual environment (E) of the twins. The ACE model was also checked against the AE model.

Results: Both classes of lysophospholipids showed stable and high proportions of heritability ($A \geq 0.5$) for the screening (Scr) and during the study. Although both classes didn't differ very much and showed the same reaction pattern, the lysophosphatidylcholines (LPC) had slightly higher inheritance (Scr: 0.72, LF: 0.60, HF1: 0.80, HF6: 0.66) than the lysophosphatidylethanolamines (LPE; Scr: 0.70, LF: 0.55, HF1: 0.75, HF6: 0.51). The single members of LPC ($n=18$) and LPE also showed these high A-values with the solitary exception of the LPCs with 19 C-atoms and different number of double bonds ($0 \leq A \leq 0.46$). In contrast the concentrations of the ether phospholipid classes seemed much more environmentally determined ($0 \leq A \leq 0.46$). Moreover the reaction pattern differed between the ethers of phosphatidylcholine (PC-O; Sc: 0.00, LF: 0.00, HF1: 0.46, HF6: 0.00) and the ethers of phosphatidylethanolamine (PE-O; Sc: 0.24, LF: 0.40, HF1: 0.41, HF6: 0.00). Their single members also varied in their heritability. For the PC-Os ($n=26$) the length of their fatty acids seemed to have the strongest impact. The longer the fatty acids, the less heritable they were.

Conclusion: Although we understand more and more, how lipids act and interact under different environmental conditions, it is necessary to clarify how and how much we can affect these progresses in individuals (e.g by nutrition). There is evidence that especially lipids with odd fatty acids were able to reduce the diabetes risk. Our data showed strong differences in the heritability of lipid classes and also that classes like lysophospholipids, which can be associated with inflammation, seemed to be genetically determined. These findings may be part of an explanation for phenomena like metabolically healthy obesity and the ability to compensate the unfavorable effects of HFDs.

Use of Danish National Registers to identify parental history of type 2 diabetes for gene-environment interaction and association studies

D.R. Witte^{1,2}, M.E. Jørgensen³, I. Brandslund^{4,5}, B. Carstensen³, N. Grarup⁵, T. Hansen⁵, T. Jørgensen⁶, A. Linneberg^{6,7}, O. Pedersen⁵, J. Wohlfahrt⁸, A. Kurbasic^{3,9};

¹Department of Public Health, Aarhus University, ²Danish Diabetes Academy, Odense, ³Clinical Epidemiology, Steno Diabetes Center, Gentofte, ⁴Department of Clinical Biochemistry, Vejle Hospital, Vejle, ⁵The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, ⁶Research Centre for Prevention and Health, The Capital Region of Denmark, Glostrup, ⁷Department of Clinical Experimental Research, Rigshospitalet Glostrup, ⁸Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark, ⁹Lund University Diabetes Centre, Lund University, Malmö, Sweden.

Background and aims: Family history is one of the major independent risk factors for type 2 diabetes, reflecting both a shared underlying genetic susceptibility and environment. The study of interactions between genetic variants and family history of diabetes is a powerful way of examining gene-environment interactions as it investigates whether the over-all level of known and unknown genetic and environmental factors which cluster in families, modifies the genetic associations. We aimed (1) to assess whether it is feasible to obtain systematic data concerning parental history of diabetes (PHD) through linkage between several Danish National Registers (DNR) and (2) to enrich a composite genetic study of diabetes (The LuCAMP study) with register-derived PHD data in order to examine the modifying effect of PHD on known genetic markers of diabetes risk.

Materials and methods: We obtained records of diabetes diagnosis for the parents of the 5447 LuCAMP participants (968 with T2DM) by

record linkage in the DNR. Logistic regression was used to assess the interaction between PHD and 30 known genetic variants associated with diabetes risk, adjusting for age and sex.

Results: Among participants with diabetes, 42% ($n=409$) had PHD, while only 28% of participants without diabetes had PHD ($n=1236$); OR for diabetes by PHD: 1.92 (95%CI: 1.66;2.22). Four SNPs (rs5945326, rs7957197, rs340874 and rs7578597) showed nominally statistically significant ($p < 0.05$) interaction with PHD (either parent). For three of these (rs5945326, rs7957197, and rs7578597) the diabetes risk associated with the risk allele was lower among people with PHD (OR_{int} : 0.77, 0.69 and 0.63 respectively), while for rs340874 the risk was higher (OR_{int} : 1.24). Odds ratios were broadly consistent when examining maternal PHD, paternal PHD and PHD from both parents separately for these four SNPs, although not all sub-analyses were statistically significant. Five further SNPs (rs8042680, rs13266634, rs896854, rs7961581 and rs10010131) showed nominally statistically significant interactions with maternal PHD, paternal PHD or PHD from both parents without showing a significant interaction for PHD from either parent. None of the interaction p-values remained statistically significant after Bonferroni correction for multiple comparisons.

Conclusion: We showed that it is possible to use the Danish National Registers to enrich extant genetic studies in Denmark with parental history of diabetes data. Our approach can be used to discover signals of modification of some genetic determinants of diabetes by parental history of diabetes.

Familial clustering of Japanese patients with adult-onset type 1 diabetes mellitus from the database of “Tokai Clinical Study Group of Diabetes”

K. Hosokawa¹, S. Tsunekawa¹, Y. Seino², Y. Hamada², Y. Oiso¹;
¹Department of Endocrinology and Diabetes, ²Department of Metabolic Medicine, Nagoya University Graduate School of Medicine, Japan.

Background and aims: The prevalence of Type 1 diabetes mellitus (T1DM) in Japanese is known to be much lower than in Caucasians. Meanwhile, previous studies reported that the λ sibling(λ_s), which represents the ratio of the risk of T1DM in siblings of patient with T1DM to that of general population, was much higher in Japanese than in Caucasians (15 in Caucasians and 65-271 in Japanese, respectively). However, those studies were based on the data of subjects whose onset of T1DM was under the age of 20 years old, and showed the risk only in siblings. The aim of this study is to investigate familial clustering of T1DM in Japanese subjects with adult-onset T1DM.

Materials and methods: This cross sectional study was performed with 737 subjects with T1DM from the database of “The Tokai Clinical Study Group of Diabetes” enrolled from 28 hospitals. Assuming the subjects as probands, the familial clustering was investigated using questionnaires regarding the family history, including parents, siblings, and children, of T1DM. In addition, we classified the probands into the different groups according to the subtypes of T1DM development; slowly progressive, acute, and fulminant-onset, or their onset-age; 0-12, 13-19, 20-39, and $40 \leq$ years old.

Results: The mean age of probands was 53.6 years old, and the onset of T1DM in 85.3% of them was above the age of 20 years old. 6.2% of the probands had at least one T1DM family member. The prevalence of T1DM was 2.3% in siblings, 1.2% in parents and 0.8% in children. The risk of T1DM in the siblings, parents, and children of proband was respectively 164, 89, and 59 times higher than the general population in which the prevalence is 0.014% in Japanese. Among 3 subtypes of T1DM, the acute-onset group showed the highest familial risk (acute-onset; 2.4%, slow progressive-onset; 1.0%, fulminant-onset; 1.1%). Meanwhile, the one-way Cochran-Armitage trend test demonstrated that,

among 4 groups of their onset-age, the earlier-onset group showed the significantly higher risk of T1DM in their siblings and fathers, but not mothers. Furthermore, among 17 families in which both parents and their children had T1DM, the onset-age of T1DM of children in 16 families was earlier than that in their parents'.

Conclusion: In this study, the risk of T1DM in the family of Japanese patients with adult-onset T1DM was much higher than that of Caucasians, even though the prevalence of T1DM is much lower in Japan. Furthermore, families of acute-onset and early-onset probands showed the highest risk of developing T1DM, suggesting that the high familial clustering could be attributed to genetic factors. This study also demonstrated that the parental risk in early-onset proband was associated to father, but not mother, and this finding might support EURODIAB study that showed the high risk in children of fathers with T1DM. The children of probands in 16 out of 17 families were observed to develop T1DM earlier than their parents, supporting that the incidence of T1DM especially in young children is worldwide increasing. However, further study is needed to elucidate the genetic susceptibility contributing the most to the high familial clustering in Japanese.

Family history of diabetes and cardiovascular disease is associated with cardiometabolic markers in offspring at age 12: the PIAMA study

A.M.W. Spijkerman¹, N.E. Berentzen^{1,2}, L. van Rossem², U. Gehring³, J.C. de Jongste⁴, A.H. Wijga¹;

¹Centre for Nutrition, Prevention and Health Services, National Institute for Public Health and the Environment, Bilthoven, ²Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, ³Institute for Risk Assessment Sciences (IRAS), Division of Environmental Epidemiology, Utrecht University, ⁴Department of Pediatrics, Erasmus University Medical Center, Sophia Children's Hospital, Rotterdam, Netherlands.

Background and aims: The associations of family history of type 2 diabetes and cardiovascular disease (CVD) with cardiometabolic markers in offspring have been well documented. Type 2 diabetes and CVD share risk factors and often co-occur. We investigated cardiometabolic risk factors in children with a (combined) family history of diabetes and CVD (myocardial infarction (MI) and stroke).

Materials and methods: We used data of 1379 children of the Dutch Prevention and Incidence of Asthma and Mite Allergy (PIAMA) birth cohort, for whom family history of diabetes, MI and stroke were parent-reported, and cardiometabolic markers (waist circumference (WC), cholesterol, blood pressure (BP), glycated haemoglobin (HbA1c)) were measured at age 12. The following categories were created for each child: 'no family history'; 'moderate family history' (1-2 grandparent(s) with late disease onset); or 'strong family history' (parent(s) with disease; grandparent(s) with early disease onset; or 3-4 grandparents with late disease onset). Differences in cardiometabolic markers between children with no family history and children with a moderate or strong family history were assessed by multiple linear regression analyses.

Results: Children with a strong family history of diabetes, (N=146, 11%) had 2.02 cm higher WC (95%CI 0.91-3.13), 0.19 mmol/l higher total cholesterol (TC) (95%CI 0.06-0.32), 0.18 higher total-to-high-density-lipoprotein cholesterol ratio (TC/HDLc ratio) (95%CI 0.004-0.36) and 0.68 mmol/mol higher HbA1c (95%CI 0.17-1.20) than children with no family history of diabetes. Children with a strong combined family history of diabetes and CVD (N=414, 30%) had 0.13 mmol/l (95%CI 0.03-0.23) higher TC and 0.17(95%CI 0.03-0.31) higher TC/HDLc ratio than children with no family history. Moderate family history of diabetes or moderate combined family history were not associated with any of the cardiometabolic markers.

Conclusion: At age 12, children with a strong family history of diabetes and a strong combined family history of diabetes and CVD had

significantly higher levels of cardiometabolic markers compared to children without family history. Family history of these diseases, in particular family history of diabetes, is a useful tool to identify children at high risk for the development of future cardiometabolic diseases in order to offer preventive interventions.

The identification of wrist circumference cut off for insulin resistance prediction in a population of children/adolescents

G. Campagna¹, M. Spoletini¹, M. Calanchini², S. Zampetti¹, L. Marandola¹, G. Leto¹, F. Lucantoni¹, L. Pacifico³, E. Di Benedetto², A. Fabbri², R. Buzzetti¹;

¹Experimental Medicine, Sapienza, University of Rome, ²Medicina dei Sistemi, Tor Vergata University, ³Pediatrics, Sapienza, University of Rome, Rome, Italy.

Background and aims: Insulin resistance plays a central role in the pathogenesis of the metabolic syndrome and its prevalence in the paediatric population is increasing, particularly among obese children/adolescents. In a previous study we observed a close relationship among wrist circumference, its bone component, and insulin resistance in overweight/obese children/adolescents. The aim of this study was to identify the wrist circumference cut off for the prediction of insulin resistance in a population of children/adolescents.

Materials and methods: We recruited n=1134 (M=583, F=551; mean age: 10.3±2.9) overweight/obese children/adolescents in the Department of Pediatrics of our University and n=114 (M=58, F=56; mean age: 11.8±2.9) normal weight controls in a hospital. We evaluated the following anthropometric and biochemical parameters: body weight (kg), height (cm), wrist circumference (cm), BMI-z score, fasting glucose (ml/dl), fasting insulin levels (μU/ml). The wrist circumference was measured using a tension-gated tape measure positioned over the Lister tubercle of the distal radius and over the distal ulna. The subjects were divided into two groups according to Tanner stage (TS): prepubertal (TS 1), pubertal (TS from 2 to 5). Insulin resistance was estimated according to the homeostasis model assessment of insulin resistance (HOMA-IR). HOMA-IR cut off values for insulin resistance in the pre-pubertal period were: 2.22 in females and 2.67 in males; in the pubertal period were: 3.82 in females and 5.22 in males. The data were analyzed through logistic regression and ROC curves, with SAS software 9.3.

Results: We observed that the cut-off of wrist circumference to predict insulin resistance in the pre-pubertal subjects were: ≥15.8 cm in males (sensitivity 0.70, specificity 0.73), ≥15.4 cm in females (sensitivity: 0.36, specificity: 0.82); in the pubertal subjects were ≥17.7 cm in males (sensitivity: 0.52, specificity: 0.84) and ≥15.2 cm in females (sensitivity: 0.85, specificity: 0.40). The linear regression demonstrated a positive correlation between wrist circumference and HOMA-IR (R²=0.09, p<0.0001).

Conclusion: The wrist circumference, an easy method to detect anthropometric parameter, could be utilized to identify children/adolescents with increased risk for insulin resistance, thus avoiding testing the entire population of overweight/obese children.

289

Ratio of waist-to-calf circumference is associated with NAFLD and hepatic fibrosis in type 2 diabetes independently of obesity and insulin resistance

Y. Lee¹, E. Han¹, G. Kim¹, S. Kim¹, B.-W. Lee¹, E. Kang¹, C. Ahn¹, H. Lee¹, K. Huh², B.-S. Cha¹;

¹Department of Internal Medicine, Yonsei University College of Medicine, ²Huh's Diabetes Center and the 21st Century Diabetes and Vascular Research Institute, Seoul, Republic of Korea.

Background and aims: Although the term sarcopenic obesity refers to the loss of skeletal muscle mass with increased body fat that occurs with ageing, assessment of sarcopenic obesity is not feasible due to the requirement of specific imaging modalities such as dual-energy X-ray

absorptiometry. For a clinical practice, we previously validated waist-to-calf circumference ratio (WCR) as a simple index to assess the proportion between abdominal obesity and leg muscle lean mass, which were significantly associated with carotid atherosclerosis in patients with type 2 diabetes (Diabetes Care. 2011;34:2067-71). Sarcopenic obesity is closely linked to various cardiometabolic disorders, while its influence on non-alcoholic fatty liver disease (NAFLD) or steatohepatitis has not been fully determined in type 2 diabetes. Therefore, we aimed to investigate whether WCR is associated with NAFLD and hepatic fibrosis in patients with type 2 diabetes.

Materials and methods: This was an observational study performed in 5,806 consecutively enrolled patients with type 2 diabetes. Hepatic steatosis was diagnosed using ultrasonography. Insulin resistance was assessed using the insulin tolerance test (ITT). NAFLD fibrosis scores (NFS) and FIB-4 scores were calculated to define advanced fibrosis in subjects with NAFLD.

Results: The prevalence of NAFLD and obesity (BMI≥25 g/m², Asian definition) were 44.6% and 38.9%, respectively, in the whole study population of type 2 diabetes. The proportion of NAFLD was higher in subjects with increasing WCR tertiles regardless of gender (the lowest WCR tertile vs. the highest WCR tertile, 32.6% vs. 52% in men, 24.1% vs. 58.0% in women, both Ps<0.0001). This relationship between WCR tertiles and NAFLD appeared significant even after stratification with obesity or insulin resistance status assessed by ITT (Ki values). Multiple logistic regression analysis also demonstrated this independent association between WCR tertiles and NAFLD after adjusting for confounding factors related to obesity or insulin resistance (ORs=1.32 to 1.36 in men, Ps<0.01 and ORs=1.14 to 1.24 in women, Ps<0.05). Serum levels of liver enzymes (AST and ALT) and an inflammatory marker, CRP were all elevated with increasing WCR tertiles in both men and women (All Ps<0.001). Furthermore, among the NAFLD population, subjects with the highest WCR tertile were likely to have advanced fibrosis compared with other individuals regardless of obesity (hepatic fibrosis assessed by NFS and FIB-4: ORs=2.27 and 2.15, respectively; both Ps<0.001).

Conclusion: WCR is associated with increased risks of NAFLD and advanced hepatic fibrosis in type 2 diabetes independently of obesity or insulin resistance. This suggests that WCR which indirectly reflects sarcopenic obesity may be a useful and practical anthropometric index to predict fatty liver and its fibrosis in type 2 diabetes.

Associations between type 2 diabetes-related genetic scores and OGTT derived traits, in obese children and normal weight controls

A. Morandi¹, A. Bonnefond^{2,3}, L. Yengo^{2,3}, S. Lobbens^{2,3}, C. Lévy-Marchal⁴, J. Weill⁵, A. Grandone⁶, L. Perrone⁶, E. Miraglia del Giudice⁶, C. Maffei¹, P. Froguel^{2,3};

¹Unit of Pediatric Diabetes and Metabolic Disorders, University of Verona, Italy, ²CNRS-UMR8199, Lille Pasteur Institute, ³Lille University, ⁴Inserm CIE 05 – Department of Clinical Epidemiology, Paris, ⁵Pediatric Endocrine Unit, Lille University Hospital, France, ⁶Department of Woman, Child and of General and Specialized Surgery, Second University of Naples, Italy.

Background and aims: A total of 62 single nucleotide polymorphisms (SNPs) have been associated with type 2 diabetes (T2D) and pooled together into an additive T2D genetic risk score (GRS-T2D) in European adults. Of these SNPs, 21 have been recognized to affect β-cell function and 10 to affect insulin resistance (IR), and have been pooled into a β-cell function GRS (GRS-β) and an IR GRS (GRS-IR) respectively. Here, we aim to investigate the associations between these GRSs and OGTT derived traits in obese and normal-weight adolescents and young adults.

Materials and methods: In a sample of 1,076 obese children/adolescents (11.4±2.8 years old) and 1,265 normal weight adolescents and young adults (21.1±4.4 years old) of European ancestry, we performed a

standard OGTT to assess fasting glucose homeostasis traits, i.e. fasting plasma glucose [FPG] (mmol/l), fasting insulin [FI] (mU/l), HOMA-B ($20 \times \text{FI} / [\text{FPG} - 3.5]$) and HOMA-IR ($\text{FPG} \times \text{FI} / 22.5$), post-load glucose homeostasis traits, i.e. insulinogenic index [II] ($\Delta \text{Insulin}_{30} / \Delta \text{Glucose}_{30}$), insulin sensitivity index [ISI] ($k / \sqrt{[\text{Glucose}_0 \times \text{Insulin}_0 \times \text{Average-Glucose} \times \text{Average-Insulin}]}$), disposition index [DI] ($[\text{ISI} \times 100 \times \text{Insulin}_{30} / [\text{glucose}_{30} \times (\text{glucose}_{30} - 3.89)]]$) and 2-hours plasma glucose [2-hG] (mmol/l), and the presence of pre-diabetic conditions, i.e. impaired glucose tolerance [IGT], and impaired fasting glucose [IFG]. The genotyping of SNPs was performed with Metachip arrays (Illumina). We assessed the associations of T2D-related traits with GRS-T2D, GRS- β and GRS-IR using linear or logistic regression models adjusted for gender, age and BMI. Here, we only report associations that were significant after Bonferroni multiple test correction (i.e. with a $p < 0.0015$).

Results: The GRS-IR was not associated with any variable either in obese children or in normal weight controls, while the GRS-T2D was associated with only II (-0.02 per allele) and DI (-0.02 per allele) in normal weight young adults but with no variable in obese children. GRS- β was associated with HOMA-B (-0.02 per allele), II (-0.04 per allele) and DI (-0.03 per allele) in normal weight children, with FPG (+0.02 per allele) and DI (-0.03 per allele) in obese children, and with FPG (+0.01 per allele), HOMA-B (-0.02 per allele), II (-0.03 per allele) and DI (-0.03 per allele) in meta-analyzed data. None of the scores was associated with any binary trait.

Conclusion: Among T2D related genetic scores, only GRS- β shows significant associations with glucose homeostasis traits in both obese children/adolescents and in normal weight controls. These associations highlight that GRS- β influences both fasting and post-load glucose homeostasis. The fact that GRS-T2D is associated with II and DI only in normal weight participants, may be explained by a higher influence of non genetic factors in obese compared to non obese subjects.

Age associated DNA methylation changes in adipose tissue is linked to type 2 diabetes

T.S. Rönn¹, P. Volkov¹, L. Gillberg², A. Perflyev¹, P.-A. Jansson³, A. Vaag², L. Groop⁴, E. Nilsson¹, C. Ling¹;

¹Epigenetics & Diabetes, Clinical Sciences, Malmö, Sweden, ²University of Copenhagen, Denmark, ³Sahlgrenska University Hospital, Gothenburg, Sweden, ⁴Diabetes and Endocrinology, Clinical Sciences, Malmö, Sweden.

Background and aims: Ageing is a risk factor for several common diseases, including type 2 diabetes, and has been suggested to contribute to increased epigenetic variability. Epigenetic factors, e.g. DNA methylation, provide a link between genetic and non-genetic factors, and could be involved in phenotype transmission and disease development. The current aim was to investigate the effect of age on DNA methylation in human adipose tissue.

Materials and methods: The Infinium HumanMethylation450 BeadChip was used to analyse the genome-wide DNA methylation pattern in adipose tissue from 96 healthy men with an age span between 23 and 80 years. The association between age and DNA methylation of individual CpG sites was tested using a random effect mixed model, including cohort as the random effect variable and age, BMI, and HbA1c as fixed factors.

Results: DNA methylation data was obtained for 456,800 CpG sites in the 96 men. Age was positively correlated with the average level of DNA methylation in adipose tissue ($p = 1.1 \times 10^{-5}$). After correction for multiple testing, we found 31,567 individual CpG sites significantly associated with age. Among these sites, 90.6% showed a positive whereas only 9.4% showed a negative relation between age and the level of DNA methylation, in agreement with the result of average DNA methylation. Of the CpG sites significantly associated with age, 24,514 are annotated

to 11,036 unique genes, whereas 7,053 of the CpG sites are intergenic. We proceeded to test if the age-associated methylation differences also can be identified in diseased subjects, by comparing our results with a recently published case-control study identifying 15,627 CpG sites with differential DNA methylation in adipose tissue from subjects with type 2 diabetes compared with non-diabetic age-matched controls. We found an overlap of 1,278 differentially methylated CpG sites, 90% of which changed in the same direction due to age and type 2 diabetes. These CpG sites include many novel loci, but also established diabetes susceptibility genes such as JAZF1. To obtain further biological insight into the significant associations between DNA methylation and age, we used WebGestalt to perform a KEGG pathway analysis on the 11,036 genes with one or more CpG sites significantly associated with age. Significant enrichment was found for 31 pathways, including e.g. the MAPK and Wnt signaling pathways, pathways in cancer and type 2 diabetes mellitus. **Conclusion:** We have shown extensive epigenetic alterations in adipose tissue due to ageing, some which previously also have been shown to be present in type 2 diabetic patients. Our study supports a role for epigenetic mechanisms in the development of age related diseases such as type 2 diabetes.

Lower risk for obesity among adolescents living at higher altitudes: a cross-sectional analysis in the Peruvian population

O.O. Woolcott¹, C. Gutierrez², O.A. Castillo³, R.M. Elashoff⁴, D. Stefanovski¹, R.N. Bergman¹;

¹Diabetes and Obesity Research Institute, Cedars-Sinai Medical Center, Los Angeles, USA, ²Instituto de Medicina Tropical Daniel A. Carrión, ³Instituto Nacional de Biología Andina, Universidad Nacional Mayor de San Marcos, Lima, Peru, ⁴Department of Biomathematics, University of California, Los Angeles, USA.

Background and aims: A significant inverse association between obesity and altitude has been reported in the adult population of the United States, adjusting for multiple covariates. However, whether this relationship extends to the pediatric populations remains unknown. The aim of the present study was to determine the association between altitude and obesity among adolescents, adjusting for several factors.

Materials and methods: We explored the association between altitude and obesity in the adolescent population of Peru, a country with topographic, socio-economic, cultural, and ethnic features differing from those of the United States and Europe. We utilized data publicly available online from the Food and Nutrition National Center of Peru, CENAN, for 2009-2010, the last period for which data relevant for a model analysis are available. The CENAN used a nationally representative sample selected by the National Home Survey. An important feature of this survey is the on-site measurements of body weight and height using standardized methods. Final analysis included 7,618 adolescent subjects (14-19 years old). Obesity was defined as the BMI-for-age in months at or above 95th percentile for sex. Percentiles were estimated using the Centers for Disease Control and Prevention 2000 growth charts. Multilevel mixed-effects Poisson regression was used to estimate the relative risk for obesity, adjusting for several factors including age, sex, physical activity, out-migration rate, urbanization, and latitude, accounting for nested data (region level) and the random effects between subjects.

Results: The crude prevalence of obesity among adolescents was 3.7% between 0–1,499 m and 0.9% at high altitude ($\geq 1,500$ m). Boys had substantially less crude prevalence of obesity at high altitude as compared with girls living at high altitude (0.86% and 0.93%, respectively). Overall, the relative risk for obesity, adjusted for age, sex, physical activity, out-migration rate, urbanization, and latitude was as follows:

1.00 between 0–499 meters (reference category), 1.63 (95% confidence interval 1.05 to 2.53) between 500–1,499 m, 0.59 (0.33 to 1.07) between 1,500–2,999 m, and 0.28 (0.14 to 0.56) at $\geq 3,000$ m.

Conclusion: Among Peruvian adolescents, the risk for obesity was lower at altitudes above 3,000 m. These findings suggest that geographical elevation is an important factor linked to obesity not only among adults but also in the pediatric population. Exploring the underlying mechanisms of this association could provide new insights in the pathogenesis of obesity. Supported by: NIH, Alexander von Humboldt Foundation, UCLA-CTSI

Metabolic syndrome in elderly women: Is waist circumference the correct 'entrance criteria'?

K. Dragsbæk, J.S. Neergaard, M. Karsdal, C. Christiansen; Nordic Bioscience, Herlev, Denmark.

Background and aims: More than 20% of the world's adult population is considered having metabolic syndrome (MetS). MetS is used to identify patients at greater risk of developing cardiovascular diseases (CVD) and type II diabetes (T2DM). The consensus definition set out by the International Diabetes Federation (IDF) defines large waist circumference as the 'entrance criteria' for identifying MetS and thereby high risk patients. This study aimed to investigate the risk of developing CVD based on number of MetS risk factors rather than waist circumference. Subjects were further stratified based on body weight and body composition in order to determine rate ratios (RR) and incidence within the specified groups.

Materials and methods: Demographics, DEXA scans and serum samples were collected from 1999-2001 on 5855 women aged 73.1 ± 6.3 . CVD diagnoses were collected from Danish National Disease Registries primo 2015. Subjects with a preexisting CVD event at baseline were excluded from analysis. Presence of MetS and number of abnormalities were assessed by the IDF criteria for triglycerides, HDL-cholesterol, blood pressure, and fasting glucose. Initially, RR for a CVD event was determined in subjects with ≥ 2 MetS risk factors (corrected for age and BMI) by Poisson regression analysis. Thereafter, RR for development of CVD was determined based on BMI (corrected for age and number of MetS risk factors). Lastly, stratification was made based on BMI (underweight (UW): < 18.5 , normal weight (NW): 18.5-24.9, overweight (OW): 25.0-29.9, fat: ≥ 30) and body composition defined as central/peripheral (C/P) fat mass ratio stratified into quartiles (Q1-Q4) in order to determine RR and incidence in the specific groups.

Results: An increase in CVD risk of 27% was found throughout the cohort solely by number of MetS risk factors (≥ 2 vs. < 2), RR=1.27 (1.14-1.42). Moreover, the risk for developing CVD was increased with increasing BMI (UW: RR=0.88 (95% CI: 0.52-1.47), NW: RR=1 (ref), OW: 1.18 (1.04-1.32), FAT: RR=1.29 (1.11-1.50)). This indicates that both number of MetS risk factors and BMI is associated with CVD events. However, within all groups, regardless of stratification (BMI or body composition), a significant increase in risk of CVD event was found for subjects having ≥ 2 MetS risk factors (Table 1). This indicates that number of risk factors, rather than BMI or body composition, are the underlying denominator for CVD outcome. The CVD incidence increased between groups highlighting that increasing BMI and central fat mass increase the risk of a CVD event.

Conclusion: Number of risk factors and BMI are both of importance in defining subjects at risk of developing CVD. However, the risk of developing a CVD event was increased with ≥ 2 MetS risk factors regardless of BMI or body composition in elderly women. It is proposed that number of risk factors should be used for optimal identification of patients at increased risk of CVD. Large waist circumference or BMI > 30 should be employed as an individual risk factor rather than the 'entrance criteria' for MetS in elderly women.

				CVD RISK ≥ 2 vs. < 2 MS risk factors		CVD INCIDENCE	
		Person years at risk	Number of cases	RR	95% CI	Incidence pr 1000 person years	95% CI

Different relationship between body fat distribution and diabetes mellitus: analysis of the 2008-2010 Korean national health and nutrition examination surveys

J. Huh, J. Lim, M. Lee, J. Shin, C. Chung;

Internal medicine, Yonsei University, Wonju College of Medicine, Wonju-Si, Republic of Korea.

Background and aims: The aim of this study was to investigate the association between the regional body fat distribution, especially leg fat mass and the presence of diabetes mellitus (DM) in older populations.

Materials and methods: A total of 3,027 men and 3,548 postmenopausal women aged 50 years or older were analyzed from Korea National Health and Nutrition Examination Surveys (2008-2010). Body compositions including muscle mass and regional fat mass were measured using dual-energy X-ray absorptiometry.

Results: Obesity indices such as body weight, body mass index (BMI), waist circumference, total body fat (%) and truncal/arm fat mass were higher in diabetes patients compared with those non-diabetes patients. However, leg fat mass was lower in postmenopausal women with diabetes but not in men (Table 1). In multiple logistic regression analysis, a 1-kilogram increase in trunk fat mass was associated with 15% increase in the presence of DM in men and 19% increase in women after adjustment for confounding factors. Conversely, each kilogram increase in leg fat mass was significantly associated with 51% reduction of DM in men and 44% reduction in women. In partial correlation analysis adjusted for age, leg fat mass was positively correlated with appendicular skeletal muscle mass and HOMA- β . There was significant negative association between leg fat mass and glycated hemoglobin in both genders and fasting glucose in women (Table 2). When the participants were classified four groups according to sex-specific leg fat mass quartiles, the odds ratios (OR) for the presence of DM significantly decreased gradually as leg fat mass increased in both sexes (men: Quartile 1 vs. Quartile 2 vs. Quartile 3 vs. Quartile 4 : OR [95% CI]=1 vs. 0.43 [0.31-0.60] vs. 0.32 [0.23-0.46] vs. 0.13 [0.09-0.21]; women: Quartile 1 vs. Quartile 2 vs. Quartile 3 vs. Quartile 4 : OR [95% CI]=1 vs. 0.41 [0.30-0.57] vs. 0.32 [0.22-0.46] vs. 0.13 [0.08-0.21], respectively) after adjustment for potential confounding factors (Table 3). To define the relative importance of leg fat mass and leg muscle mass on DM, we categorized subjects into four groups: HF-LM, HF-HM, LF-LM, and LF-HM based on the median values of leg fat mass and leg muscle mass. As a result, higher leg fat mass significantly lowered the risk of DM regardless of leg muscle mass status in both genders ($p < 0.001$).

Conclusion: In conclusion, our study demonstrated that, in contrast to trunk and arm adiposity, there is a favorable association of leg adiposity

with DM in Korean adults aged 50 years or older. We also found the contributory effects of lower extremity fat on DM are more dominant than those of lower extremity muscle. Our findings support the notion that subcutaneous fat and glucose metabolism are intimately interlinked.

Table 1. Characteristics of the study population according to the presence of DM

Predictors of severe obesity and associated morbidity in the Malmö Preventive Project: a population-based cohort study

P.M. Nilsson¹, B. Zöller², J. Sundquist¹, K. Sundquist¹;

¹Department of Clinical Sciences, ²Department of Clinical Sciences, Lund University, Malmö, Sweden.

Background and aims: Severe obesity represents an increasing medical problem of relevance for type 2 diabetes. This study aimed to evaluate risk markers for developing severe obesity as well as the prospective morbidity risk associated with severe obesity in a population-based screening and intervention programme.

Materials and methods: In total, 18,200 individuals from a population-based cohort underwent a baseline examination in 1972-1991 and were re-examined in 2002-2006 in Malmö, Sweden. In total, 809 (4.4%) patients with severe obesity (BMI ≥35 kg/m²) were found at re-examination, and predictive risk factors from baseline were identified. Total and cause-specific morbidity were followed in national registers in all severely obese patients, as well as in age- and sex-matched normal weight controls (n=1618).

Results: Men and women developing severe obesity differed significantly from matched controls in baseline variables associated with the metabolic syndrome (BMI, triceps skinfold, blood pressure, fasting-glucose, triglycerides), as well as in fasting-insulin, liver enzymes, cholesterol, and uric acid. Both male and female obese subjects were on average shorter than controls (p<0.001). Female but not male severe obesity was associated with family history of hypertension. Abstaining from alcohol was more common in female severely obese subjects (p<0.001), but not among male subjects (p=0.324), compared with normal-weight controls. Incident cancer (p=0.002), coronary events (p=0.022), stroke (p=0.002), heart failure (p<0.001), atrial fibrillation (0<0.001), and diabetes (p<0.001) during follow-up was higher among severely obese persons compared to normal-weight controls.

Conclusion: Variables associated with the metabolic syndrome are significant predictors for development of severe obesity after a long-term follow-up. Severe obesity is associated with cardiovascular morbidity, cancer and incident diabetes. This calls for improved weight control in persons with certain predictors of this condition, as well as better risk factor control in patients with severe obesity.

Maternal exposure of autoantibodies protects the child from islet autoimmunity in early childhood if the mother does not have type 1 diabetes (TEDDY)

C. Torn¹, Å. Lernmark¹, K. Vehik², E. Bonifacio³, M. Rewers⁴, O. Simell⁵, J. Toppari⁵, A. Ziegler⁶, B. Akolkar⁷, W. Hagopian⁸, D. Schatz⁹, J.-X. She¹⁰, J. Krischer², the TEDDY Study Group;

¹Department of Clinical Sciences, Lund University, Malmö, Sweden, ²Pediatric Epidemiology Center, University of South Florida, Tampa, USA, ³Faculty of Medicine, Technische Universität, Center for Regenerative Therapies, Dresden, Germany, ⁴Department of Pediatrics, University of Colorado at Denver and Health Sciences Center, USA, ⁵Department of Pediatrics, University of Turku, Finland, ⁶Department of Pediatrics, Diabetes Research Institute, Munich, Germany, ⁷National Institutes of Diabetes and Digestive and Kidney Disorders, Bethesda, , ⁸Pacific Northwest Institute, Seattle, ⁹Department of Pediatrics, University of Florida, Gainesville, ¹⁰Medical College of Georgia, Atlanta, USA.

Background and aims: Maternal islet autoantibodies transferred via placenta indicate presence of type 1 diabetes (T1D) or an increased risk of T1D in the mother. However, little is known concerning the child's risk of islet autoimmunity (IA) or T1D. The aim was to explore whether exposure of maternal autoantibodies in absence of maternal T1D affects the child's risk to develop IA in early childhood.

Materials and methods: Children with an increased genetic risk for T1D were followed from birth in The Environmental Determinants of Diabetes in the Young (TEDDY-study). Maternal venous blood sample was collected at the child's age of 9 months if: the mother had T1D (n=297), of a child of a mother without T1D that was positive for any islet autoantibodies at age 3-6 months or if the mother had any other type of diabetes (type 2, gestational or maturity onset of diabetes in the young (MODY) (n=538).

Results: During the follow-up for a median of 65 months (IQR 49-86) IA developed in 14.1% (42/297) of children born to a mother with T1D and in 12.8% (69/538) of children born to a mother without T1D. Children exposed to maternal islet autoantibodies from non-T1D mothers were less likely to develop IA (HR=0.26; 95%CI 0.08-0.84; p=0.0236) as compared with un-exposed children. In contrast, children exposed to maternal autoantibodies and born to mothers with T1D had similar risk of IA as compared with un-exposed children. (HR=1.08; 95%CI 0.58-2.0; p=0.8137).

Conclusion: Exposure of maternal autoantibodies indicated decreased risk for IA in early childhood in children without a mother with T1D, but not for children to mothers with T1D as compared with un-exposed children.

Identification of potential circulating beta cell biomarkers

S.F. Hansson¹, P. Vachet¹, M. Hammar¹, O. Korsgren^{2,3}, P. Davidsson¹;

¹Translational Science, AstraZeneca, R&D Mölndal, Mölndal, ²Immunology, Genetics and Pathology, Uppsala University, ³The Nordic Network for Clinical Islet Transplantation, Uppsala, Sweden.

Background and aims: Therapies to promote the preservation and restoration of functional pancreatic β-cell mass are essential for the treatment of type 2 diabetes (T2D). A major challenge for the development of such therapies is the lack of adequate biomarkers to assess changes in β-cell health with therapeutic intervention and disease stage. Monitoring β-cell mass and function during the disease progression could lead to a better

understanding of pathogenesis and an improved treatment. In this study, proteomic analysis of human islets of Langerhans was carried out in order to search for such biomarkers.

Materials and methods: Human islets and exocrine pancreatic tissue were provided by the Nordic Network for Clinical Islet Transplantation. One and two dimensional (2D) SDS-PAGE was used for separation of islet and exocrine tissue extracts and the entire 1D gel lanes or the 2D gel spots with two fold increased expression in islets, were subjected to in-gel digestion. The resulting peptides were analyzed by liquid chromatography FTICR mass spectrometry. Proteins were identified by searching against the Swiss-Prot database using Mascot, requiring at least two unique peptides, at 95% level of confidence for a valid protein identification. Following in silico filtering for islet enriched expression using the Human Protein Atlas, candidates were further investigated using Western blotting (WB) and immunohistochemistry (IHC). Quantification of Secretagogin (SCGN) levels in human plasma from age, body mass index, and gender matched T2D patients and healthy control subjects, provided by Uppsala University Hospital, was enabled by ELISA (BioVendor).

Results: In the islet protein extracts, 1700 proteins were identified and following in silico filtering for islet enriched expression, one of the candidate proteins, SCGN, were highly expressed in human islets both on mRNA and protein level. Furthermore, WB also showed that the protein was secreted into the culturing media with an indication that high glucose (16.5 mM) exposure for 1 h resulted in higher intracellular levels and reduced SCGN levels in the cell media. Double staining of human pancreatic tissue with SCGN and insulin showed co-localisation of the two proteins, indicating that SCGN was predominantly expressed in β -cells. Finally, ELISA allowed for the quantification of SCGN in plasma of T2D patients (n=15) as well as in healthy subjects (n=16). Significantly increased SCGN levels (p=0.03) could be observed in the diabetic patients.

Conclusion: To identify a circulating biomarker of β -cell mass offers a challenge since the dispersed islets constitutes only 1–2% of the total pancreatic mass, and the insulin producing β -cells even a smaller fraction within the islets. This demands that a suitable biomarker must be highly expressed and secreted mainly from the β -cells in order to reflect their health, functional status or mass. SCGN met these criteria and could also be quantified in human plasma, suggesting a potential of SCGN as a β -cell biomarker. However further studies will be required to determine whether the increase of plasma SCGN reflects the mass of β -cells present in the islets of T2D patients.

298

Altered lipid metabolism preceding onset of islet autoimmunity and type 1 diabetes

T. Marinkovic¹, T. Hyötyläinen¹, I. Mattila¹, P. Pöhö², M. Knip³, M. Oresic¹;

¹Systems Medicine, Steno Diabetes Center, Gentofte, Denmark, ²University of Helsinki, ³Children's Hospital, University of Helsinki and Helsinki University Central Hospital, Finland.

Background and aims: Dysregulation of lipid and amino acid metabolism has been shown to take place already prior to the first seroconversion to islet autoimmunity in progression to Type 1 diabetes (T1D). Previously we also observed by lipidomic analysis of cord blood that lipid dysregulation is found in newborn infants who developed T1D early in life while it is not associated with development of beta-cell autoimmunity in general. In order to gain a global view of metabolome in progression to islet autoimmunity and T1D, here we studied serum metabolome in children from the DIABIMMUNE cohort, who seroconverted to one or more autoantibodies and matched controls.

Materials and methods: Children were divided into four groups according to the number of autoantibodies they developed during the follow-up: 12 children progressed to two or more islet autoantibodies (≥ 2 Aab) group, 8 children developed one Aab persistently (1pAb), 21 children

developed one Aab transiently (1tAb). 81 children were controls matched for gender, HLA genotype, country (Finland, Estonia) and date of birth. Among the 12 children from ≥ 2 Aab group, four progressed to T1D. The study included a longitudinal series of samples (cord blood, 3, 6, 12, 18, 24, 36 months of age) from three case groups and controls. Metabolomic analysis of serum samples was performed by applying two global analytical platforms to study molecular lipids and polar metabolites, respectively. The two metabolomics datasets (876 molecular lipids and 355 polar metabolites) were clustered using the model-based clustering, which resulted in 18 and 13 clusters of molecular lipids and polar metabolites, respectively. Linear mixed effect models were applied at cluster level to further analyze the metabolomics data. The fixed effects accounted for in the models were group effects at different time points, effect of age as well as the effect of age of seroconversion to islet autoantibodies.

Results: The significant differences were mainly observed for the ≥ 2 Aab and 1pAb groups, while 1tAb group tended to have very similar metabolite profiles as the controls. Specifically, in ≥ 2 Aab group, triglycerides were downregulated at early age and lysophosphatidylcholines were upregulated, as compared to controls. In contrast, in the 1pAb group triglycerides were upregulated while lysophosphatidylcholines were downregulated. No significant changes were observed for major membrane lipids such as phosphatidylcholines (PC). Regarding metabolites, in ≥ 2 Aab and 1 Aab groups the cluster containing TCA cycle metabolites and metabolites of branched chain amino acid (BCAA) metabolism (excluding BCAAs themselves) was downregulated in cord blood. In ≥ 2 Aab group this cluster remained downregulated while in the 1Aab group became upregulated at about 2 years of age.

Conclusion: The children who seroconvert to two or more autoantibodies (as well as to T1D) have markedly different metabolic profile from those children who progress to a single islet autoantibody. Identification of the underlying pathways may lead to improved disease detection and to novel clues for disease prevention.

Antigen-based immunotherapies do not prevent progression of autoimmune diabetes: a systematic review and meta-analysis

E. Bekiari¹, C. Rizava¹, A. Liakos¹, M. Sarigianni¹, G. Nikolaidis¹, M. Rika², P. Boura², D.R. Matthews³, A. Galli-Tsinopoulou⁴, A. Tsapas^{1,3};

¹Clinical Research and Evidence-Based Medicine Unit, Second Medical Department, ²Second Medical Department, Aristotle University of Thessaloniki, Greece, ³Harris Manchester College, University of Oxford, UK, ⁴Fourth Pediatric Department, Aristotle University of Thessaloniki, Thessaloniki, Greece.

Background and aims: Antigen-based immunotherapies aim to attenuate the destructive autoimmune process against pancreatic β -cells in patients with recent-onset autoimmune diabetes. We performed a systematic review and meta-analysis to assess their efficacy and safety in tertiary prevention of autoimmune diabetes.

Materials and methods: We searched in major bibliographic databases (MEDLINE, COCHRANE, EMBASE), trial registries, conference proceedings and reference lists of included studies and relevant reviews, for randomized controlled trials of antigen-based immunotherapies (GAD-alum, Diapep277, oral insulin, nasal insulin, NBI-6024, insulin B-chain fragment) in patients with recent-onset autoimmune diabetes (less than 60 months after diagnosis or C-peptide levels after mixed meal stimulation more than 0.2 nmol/L). Our primary outcome was residual β -cell function by means of fasting and stimulated (both glucagon and mixed meal) C-peptide. We also synthesised data for change in HbA_{1c} and daily insulin dose, incidence of any and severe hypoglycaemic events, and incidence of severe adverse events. Finally, we assessed risk of bias and graded the quality of the body of evidence.

Results: We identified 22 eligible studies, 15 of which were included in the meta-analysis. Risk of bias was deemed high in 14 of them, while in the remaining two it was unclear or low. Overall, there were no differences in fasting [weighted mean difference (WMD) 0.01 nmol/L; 95% CI -0.09 to 0.11; $I^2=73%$] or mixed meal stimulated (WMD 0.02 nmol/L/min; 95% CI -0.08 to 0.12; $I^2=50%$) C-peptide compared with placebo. Glucagon stimulated C-peptide was maintained higher (WMD 0.13 nmol/L/min; 95% CI 0.05 to 0.21; $I^2=0%$) in patients treated with Diapep277. Moreover, there was no change in daily insulin dose (WMD 0.02 IU/kg; 95% CI -0.04 to 0.09; $I^2=51%$) or HbA_{1c} (WMD -0.06%; 95% CI -0.35 to 0.23; $I^2=42%$) versus placebo. Finally, antigen-based immunotherapies were not effective in reducing the incidence of severe hypoglycaemic events. Nonetheless, there was no increase in the incidence of severe adverse events (risk ratio 0.87; 95% CI 0.53 to 1.44; $I^2=0%$). The overall quality of the body of evidence was very low.

Conclusion: Antigen-based immunotherapies are not effective in preventing the progression of autoimmune diabetes in newly-diagnosed patients.

Figure. Forest plot depicting weighted mean difference for change in HbA_{1c}. SE: standard error. IV: inverse variance. ABIs: antigen-based immunotherapies.

Residual beta cell function in diabetes children followed and diagnosed in the TEDDY study compared to controls

H. Elding Larsson¹, A. Steck², J. Krischer³, R. Veijola⁴, J. Toppari⁵, M. Rewers⁶, W. Hagopian⁶, M. Haller⁷, S. Ahmed⁸, M.D. Butterworth³, K. Vehik³, Å. Lernmark¹, TEDDY Study Group;

¹Department of Clinical Sciences, Malmö, Lund University, Malmö, Sweden, ²University of Colorado, Barbara Davis Center for Childhood Diabetes, Denver, ³University of South Florida, Pediatrics Epidemiology Center, Tampa, USA, ⁴University of Oulu, Department of Pediatrics, Oulu, ⁵Turku University, Department of Pediatrics, Turku, Finland, ⁶Pacific Northwest Diabetes Research Institute, Seattle, USA, ⁷Department of Pediatrics, University of Florida, Gainesville, ⁸Immunology of T1D, JDRF International, USA.

Background and aims: Participation in prospective follow-up studies is associated with a reduction in symptoms and ketoacidosis at diabetes onset, but it is not known whether this close monitoring also leads to better outcomes beyond diagnosis. We hypothesize that children diagnosed with type 1 diabetes through The Environmental Determinants of Diabetes in the Young (TEDDY) study are diagnosed earlier in the time course of diabetes and that they will have a higher level of C-peptide at diagnosis compared with control children diagnosed through the community.

Materials and methods: TEDDY children were enrolled at 3–4.5 months of age and followed every 3 months for autoantibodies against insulin, GAD65 and IA-2 and for the development of clinical diabetes. Control subjects are matched to diabetic TEDDY subjects by age of diagnosis within one year and have at least one islet autoantibody at diagnosis. After diagnosis of type 1 diabetes, all participants undergo visits at diabetes onset and then at 3, 6, 12, 18 and 24 months and annually thereafter. The primary outcome measure is the AUC of C-peptide in response to a

Mixed Meal Tolerance Test (MMTT) over time. The goal is to follow all subjects until the loss of detectable endogenous C-peptide.

Results: A preliminary analysis of 46 TEDDY and 43 control children revealed that TEDDY children diagnosed with diabetes often had no symptoms (58%) at onset and none had ketoacidosis (DKA) compared to 100% with diabetes symptoms and 18% DKA in the controls. Mean HbA_{1c} was lower in TEDDY (6.4%) than control (7.6%) children (p < 0.0001). The TEDDY children had significantly higher residual C-peptide AUC than the controls analyzed by a generalized linear model with repeated measures (p = 0.0062). The decrease in residual C-peptide during follow up did not differ between TEDDY and control children (p = 0.1976).

Conclusion: The earlier diagnosis of type 1 diabetes in TEDDY children studied so far appears to be associated with higher MMTT levels of residual C-peptide. Although the loss of C-peptide may be parallel, it remains to be determined whether early symptom-free diagnosis of diabetes has a long term benefit.

Serum microRNAs as novel biomarkers for diagnosis of type 1 diabetes mellitus

L. Liu, D. Yang, J. Yan, H. Xu, W. Xu, B. Yao, J. Weng;

Department of Endocrinology, The Third Affiliated Hospital, Sun Yat-sen University, Guangzhou, China.

Background and aims: New Strategies and biomarkers for early detection of type 1 diabetes mellitus (T1DM) are sorely needed. We aimed to explore the diagnostic value of serum microRNAs (miRNAs) in newly diagnosed patients with T1DM.

Materials and methods: Serum miRNA expression was investigated in patients with T1DM (duration of diabetes ≤ 1 year) and age-, gender-matched healthy individuals recruited between August 2011 and June 2014. Firstly, microarray was used to screen 2006 miRNAs in 6 T1DM patients and 6 healthy controls. Quantitative reverse-transcriptase polymerase chain reaction assay (qRT-PCR) was then applied to evaluate the expression of differentially altered miRNAs. A logistic regression model was developed using a training cohort (characteristics as shown in table). Area under the receiver operating characteristic curve (AUC) was used to assess diagnostic accuracy. Finally, the model was validated by leave-one-out cross-validation and another independent validation cohort (characteristics as shown in table).

Results: Microarray analysis discovered that thirty-one serum miRNAs were significantly different between T1DM patients and healthy controls (fold expression change ≥ 2, P < 0.05). Six miRNAs (miR-642a-3p, miR-320c, miR-1225-5p, let-7b-5p, miR-26b-5p, miR-144-3p) were verified by qRT-PCR in the training cohort (P < 0.05 for each). A logistic regression model combining miR-320c, miR-1225-5p, age and body mass index (BMI) was developed, which provided a high diagnostic accuracy of T1DM (AUC = 0.817 for training data set, 95% confidence interval 0.732–0.904, P = 0.000). The cross-validation error rate based on logistic regression models was 18.3%. The satisfactory diagnostic performance of the model persisted in the validation cohort (AUC = 0.804, 95% confidence interval 0.688–0.921, P = 0.000).

Conclusion: Our results identified a panel based on the expression of serum miRNAs with considerable diagnostic value for T1DM. Further research is necessary to explore whether these have clinical implications for early detection of disease.

Table. Characteristics of participants in the training and validation cohorts

Characteristics	T1DM cases	Healthy controls	P value
Training cohort	n = 40	n = 56	---
Age (years)	22.31 ± 1.90	20.00 ± 1.34	0.308
Female (n, %)	26 (65%)	35 (62.5%)	0.802
BMI [‡] (kg/m ²)	18.75 ± 0.46	19.73 ± 0.38	0.104
Disease duration (months)	8.54 ± 0.74	---	---
HbA _{1c} [§] (%)	7.4 (6.4, 9.8)	5.1 (4.9, 5.3)	0.000
FCP [¶] (ng/ml)	0.25 (0.09, 0.34)	---	---
PCP2h (ng/ml)	0.57 (0.27, 0.80)	---	---
Validation cohort	n = 33	n = 29	---
Age (years)	21.18 ± 1.76	20.90 ± 2.14	0.919
Female (n, %)	18 (54.5%)	14 (48.3%)	0.622
BMI (kg/m ²)	18.42 ± 0.63	21.28 ± 0.50	0.001
Disease duration (months)	6.93 ± 1.28	---	---
HbA _{1c} (%)	8.9 (7.5, 12.6)	5.1 (4.9, 5.2)	0.000
FCP (ng/ml)	0.28 (0.10, 0.55)	---	---
PCP2h(ng/ml)	0.54 (0.29, 0.75)	---	---

Predicting islet cell death using miRNAs: small molecules giving big insights

R.J. Farr¹, M.V. Joglekar¹, A. Akil², A. Januszewski¹, C. Taylor³, V. Cotta³, M. Craig³, A. Jenkins¹, A.A. Hardikar¹;

¹NHMRC Clinical Trials Centre, University of Sydney, ²UNSW, Sydney, ³O'Brien Institute, ACU, Melbourne, Australia.

Background and aims: Death of insulin-producing beta cells is a common feature of type 1 diabetes (T1D), including after islet transplantation as well as Latent Autoimmune Diabetes of Adults (LADA) and type 2 diabetes (T2D). The death of these islet beta cells is a slow process that commences several months-years prior to clinical onset of T1D. We currently lack tools to quantitatively detect islet cell loss prior to the clinical onset of diabetes, or to predict the progression of established T1D. MicroRNAs (miRNAs), a subset of small non-coding (nc)RNAs, are promising biomarkers as i) some of these are significantly altered in circulation between individuals with or without diabetes, ii) show high stability in blood, iii) offer ease of detection and iv) are resistant to freeze-thaw degradation. We identified a set of ncRNAs that are either enriched in islet beta cells or differentially expressed in individuals with diabetes. This set of ncRNAs, which we refer to as the RAPID signature (RNA-based Analysis for Predicting Islet Death) can potentially predict islet beta cell death during diabetes progression.

Materials and methods: Next Generation Sequencing (NGS) and quantitative (q)PCR profiling studies were conducted on developing human pancreases and adult islets. MicroRNAs in plasma from individuals with newly diagnosed or established T1D, compared to age and gender

matched controls, were profiled on the OpenArray™ (OA) platform followed by validation on ViiA7 platform.

Results: To determine the most reproducible high-throughput qPCR platform on which to assess the RAPID signature, we undertook a robust comparison of multiple nano- and micro-fluidics platforms (OA, Dynamic Array® (DA), TaqMan Low Density Arrays/TLDA and the standard 96-well (low throughput) platform on the ViiA7 system). Data from OA was more reproducible (median assay CV 2.1%) than DA and best correlated with the 96-well platform (R²=0.88). We therefore used OA platform for future assays. NGS and qPCR studies identified 20 miRNAs that are enriched during pancreas development and remain highly expressed in adult islets. Twenty four other miRNAs were identified to be differentially expressed (fold change >2, P-value <0.05) in individuals with T1D, compared to age and gender matched controls (see Fig. 1). Validation of the above selected miRNAs in multiple T1D individuals (vs controls) will lead to refining the RAPID signature into a minimal set of miRNAs that can reliably measure the death of islet beta cells and diabetes progression.

Conclusion: Our studies will inform medical researchers and clinicians as to how to predict the development of T1D, and monitor response to interventions such as islet transplantation, vaccines and drugs that aim to retard beta cell loss or promote beta cell regeneration, and also guide the development of new treatments to lessen the burden of diabetes.

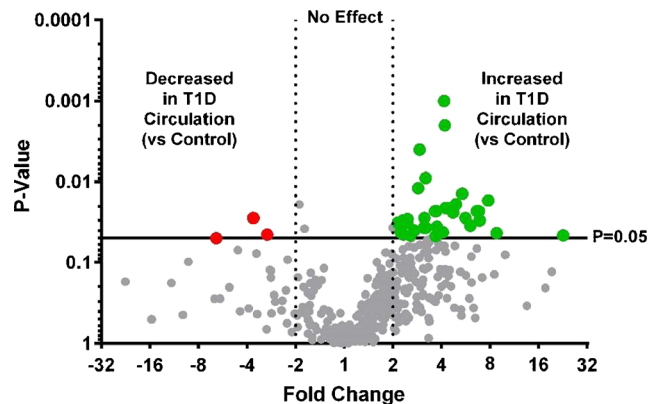

Figure 1. Volcano plot of differentially expressed circulating microRNAs in T1D individuals compared to age and gender matched controls.

A toddler with type 2 diabetes

M. Yafi, K. Collins;

Pediatric Endocrinology, The University of Texas, Houston, USA.

Background and aims: Type 2 Diabetes Mellitus continue to be a major health problem related to pediatric obesity. Early identification of pediatric patients at risk, prompt diagnosis and early therapy are major factors to partial reversal of the disease.

Materials and methods: We present a case report of early onset of Type 2 Diabetes in a 3 year-old child with description of the clinical course.

Results: A 3 ½-year-old Hispanic female presented to the pediatric endocrinology clinic for evaluation of obesity. She had symptoms of polyuria and polydipsia. Her past medical history was unremarkable. She was born full term. Birth weight was 3.2 kg. Her family history is significant for obesity in parents with no history of diabetes. Diet review revealed poor family nutritional habits with uncontrolled counting of calories and fat. On physical examination, weight was 35 kg (>95 percentile) and height was 95% percentile. Her BMI was also 95% for age. The patient had no cushinoid features, no thymomegaly and her Tanner Stage was I.

Laboratory tests revealed: Fasting plasma glucose 230 mg/dl (12.6 mmol/l) hemoglobin A1C 7.2% insulin 48.8 ulu/ml (339 pmol/L) (normal range 0–29.1 ulu/ml, 0–202 pmol/L) C-peptide 6.9 ng/ml 2.2 nmol/L (normal range 0–3.3, 0–1.09 nmol/L). Lipid and liver panels were normal. Immune markers for Type 1 Diabetes were negative. Based on symptoms, physical findings of obesity and laboratory results the diagnosis of Type 2 Diabetes was made. The patient was started on liquid Metformin 500 mg daily. Diabetes and nutritional education were performed. We asked the family to implement lifestyle modification by controlling their food portions, total caloric intake and increased physical activities. The patient made significant improvement in weight reduction that lead to normalization of blood glucose levels. The Metformin therapy was decreased by 50% each month, and then stopped. Six months after diagnosis, the patient was at 75% of weight, had normal blood glucose levels, hemoglobin A1C of 5.3% and was off therapy.

Conclusion: Reversal of type 2 diabetes in children is possible by:

1. Early screening of obese children
2. Early diagnosis
3. Appropriate therapy
4. Lifestyle modification

Physical activity in a large cohort of insulin-treated type 2 diabetes patients: PROGENS ARENA study

T. Klupa^{1,2}, M. Mozdzan³, J. Kokoszka-Paszko⁴, M. Kubik⁵, M. Masierek⁶, M. Czerwinska⁷, M.T. Malecki^{1,2};

¹Department of Metabolic Diseases, Jagiellonian University Medical College, ²University Hospital, Krakow, ³Outpatient Diabetes Clinic, University Hospital in Lodz, ⁴Diabetes Department, Klimontowicz Hospital, Gorlice, ⁵Outpatient Diet Clinic Fit & You, MedEvac Medical Center, Lodz, ⁶Bioton S.A., Warsaw, ⁷Outpatient Diabetes Clinic, Krakow, Poland.

Background and aims: Data from multiple studies present a consistent picture indicating that regular physical activity substantially reduces the risk of type 2 diabetes mellitus (T2DM). Additionally, in subjects with a diagnosis of T2DM, exercise helps to increase insulin sensitivity, control weight, and improve cardiovascular risk profiles. Unfortunately, the level of physical activity seems to be low among T2DM individuals. Moreover, it was suggested that starting insulin therapy may be associated with an even further decrease in physical activity. We aimed to estimate the level of physical activity in a large cohort of insulin-treated T2DM patients. All of them were participants of the PROGENS ARENA study which was designed to assess the role of behavior-oriented educational intervention in T2DM.

Materials and methods: There were 2500 insulin treated T2DM patients (55.41% women) included into the study. The mean age of the study participants was 64.92±9.31 years, mean BMI 31.44 kg/m²±4.49, mean diabetes duration 12.43±6.86 years, mean baseline HbA1c 8.46%±1.21. All the patients used both prandial and basal insulins. The proportion of subjects using prandial short acting human insulin was 50.27%, others used rapid acting insulin analogues (in the model of multiple daily injections or as a component of a pre-mixed regimen). At the study onset all the patients filled out a questionnaire concerning health-oriented behaviors including physical activity.

Results: Only 57.4% of examined T2DM patients (51.79% women and 64.36% men) declared any form of deliberate physical activity. Most of the group (82.33%) reported a minimal level of exercise, such as walk or seasonal garden activities. Only 17.4% of patients declared moderate physical activity (swimming, jogging, biking); it is of note that this level of activity was declared more often by men than women (24.88% vs 11.37%). Intense exercise (including participation in sport competitions) was reported only by 0.27% of the study participants. The majority of T2DM patients declared undertaking any form of deliberate physical activity only 1–2 times per week, exercise was performed on daily basis only by 22.26% of T2DM patients.

Conclusion: Insulin-treated T2DM patients are characterized by a very low level of physical activity. The subject of exercise should be considered a very important target in diabetes education.

Physical activity in patients with type 2 diabetes and hypertension: insights into motivations and barriers from the MOBILE study

M. Duclos^{1,2}, S. Dejager³, N. Postel-Vinay⁴, S. Di Nicola⁵, S. Quere³, B. Fiquet³;

¹Department of Sport Medicine and Functional Explorations, G. Montpied University Hospital, Clermont-Ferrand, ²Nutrition department University of Auvergne, INRA, UMR 1019, UNH, CRNH Auvergne, Clermont-Ferrand, ³Medical and Scientific Affairs, Novartis pharma, Rueil Malmaison, ⁴Department of Hypertension, Georges Pompidou European Hospital, Paris, ⁵Biostatistics, Inferential, Paris, France.

Background and aims: While Physical Activity (PA) is key in the management of type 2 diabetes (T2DM) and hypertension, it is difficult to implement in practice and many patients do not achieve recommended levels of PA.

Materials and methods: Cross sectional, observational study conducted in 2014 in France. Participating physicians (cardiologists and diabetologists) were asked to recruit two physically-active and four inactive patients, screened with the Ricci-Gagnon self-questionnaire (active if score ≥ 16). Patients subsequently completed the validated IPAQ-SF self-questionnaire, as well as all the physicians to assess their own level of PA. The objective was to evaluate the achievement of an individualized HbA1c target and blood pressure goal ($<140/90$ mmHg) in the active vs. inactive cohort, to explore the correlates for meeting both targets by multivariate analysis, and to examine the barriers and motivations to engage in PA as expressed by active and inactive patients.

Results: 1766 patients were analyzed. Active ($n=628$) vs. inactive ($n=1138$) patients were more often male, younger, less obese, had shorter durations of diabetes, fewer complications and other health issues, such as osteo-articular disorders ($p < 0.001$ for all). Their diabetes and hypertension control was better and obtained despite a lower treatment burden. The biggest difference in PA between the active vs. inactive patients was the percentage of patients who declared engaging in regular leisure-type PA (97.9% vs. 9.6%), also reflected in the percentage with vigorous activities in IPAQ-SF (59.5% vs. 9.6%). Target glycemic and blood pressure control was achieved by 33% of active and 19% of inactive patients ($p < 0.001$). In multivariate analysis, active patients, those with fewer barriers to PA, with lower treatment burden, and with an active physician, were significantly more likely to reach the combined glycemic and blood pressure goal. Having an active physician was the strongest correlate: participants were 4 times more likely to be at targets vs. those with an inactive physician. The physician's role also emerged in the motivations (reassurance on health issues, training on hypoglycemia risk, and direct prescription and monitoring of the PA by the physician). A negative self-image was the highest ranked barrier for the inactive patients, followed by lack of support and encouragement, and by medical concerns and fear of injury.

Conclusion: Physicians should consider PA prescription as seriously as any drug prescription, with the same need to monitor compliance and the response-effect, and take into account motivations and barriers to PA to tailor advice to patients' specific needs and reduce their perceived constraints.

Physical activity and the incidence of diabetes: evidence from the China Kadoorie Biobank study

D.A. Bennett¹, L. Li², H. Du¹, Y. Gou³, Z. Bian³, J. Chen⁴, Z. Chen¹;
¹Nuffield Department of Population Health, University of Oxford, UK, ²Department of Epidemiology and Biostatistics, Peking University, ³Chinese Academy of Medical Sciences, ⁴China National Center for Food Safety Risk Assessment, Beijing, China.

Background and aims: The estimated prevalence of diabetes in China is high and increasing. Higher physical activity is associated with decreased risk of diabetes in Western populations, but evidence from Chinese populations is limited. Moreover, most previous studies have assessed mainly recreation-related physical activity rather than total activity from different domains.

Materials and methods: We analysed prospective data of over 0.5 million people aged 30-79 years who were recruited into the China Kadoorie Biobank Study from 10 areas in China. Information about the frequency, duration and type of activity was collected via a questionnaire and an estimate of intensity in metabolic equivalent of task (MET) was assigned to each activity based on the literature. Physical activity was calculated as MET hours per day (MET-h/d) spent on work, commuting, housework, and non-sedentary recreational activities. Data on diabetes incidence was collected via linkage with mortality and morbidity registries and the national health insurance system. After excluding individuals with a prior history of cardiovascular disease or diabetes (including screen detected) at baseline, Cox regression models were used to yield hazard ratios (HRs) relating physical activity to diabetes risk adjusting for age, sex, study area, body mass index and other potential confounding factors. The HRs were corrected for 'regression dilution bias' using a self-correlation (~ 0.52) for MET-h/d ascertained from a re-survey of about 20,000 individuals conducted on average 3 years later to ascertain the association with "usual" physical activity.

Results: The study population included 463,347 participants (59% female; mean age 51 years; mean physical activity 21.8 MET-h/d). During 7-years of follow-up there were 8866 incident diabetes events recorded. There was a strong inverse association of "usual" physical activity with risk of incident diabetes with a log-linear dose-response relationship. Comparing the highest (≥ 40 MET-h/d) with the lowest (< 8 MET-h/d) physical activity group, there was a 27% lower (95% CI: 18%, 36%) risk of diabetes. Each usual 4 MET-h/d increase, (approximately an hour of brisk walking per day), was associated with 2.7% (95%CI: 1.4%, 4.1%) risk reduction. The associations did not change materially after exclusions of individuals with other prior chronic diseases, exclusion of the first two years of follow-up, and varied little across different subgroups of participants.

Conclusion: In Chinese adults, higher usual physical activity was associated with a lower risk of diabetes. These findings suggest that targeted strategies to increase levels of physical activity in China could have a major health impact.

Evolution of physical activity patterns and subsequent type 2 diabetes risk: results from the E3N-EPIC cohort study

G. Fagherazzi¹, G. Gusto¹, A. Affret¹, S. Neqqache¹, B. Balkau², F. Clavel-Chapelon¹, F. Bonnet^{1,3};

¹Lifestyle, genes and health, Inserm, ²Inserm, VILLEJUIF, ³CHU, Rennes, France.

Background and aims: Physical activity (PA) is the main modifiable risk factor to prevent or postpone type 2 diabetes mellitus (T2DM). However, the association between the evolution of PA and subsequent risk of T2DM is not well known. The aim of this study was to evaluate the

association between 5-year changes in patterns of PA and T2DM incidence in the large E3N-EPIC cohort study.

Materials and methods: The study population was constituted of 60,992 women followed from 1997 to 2008. During the follow-up, 1,982 cases of T2DM were observed. Mutually exclusive patterns of PA were constructed using latent class analysis (LCA) and latent transition analysis (LTA). The associations between the 5-year evolutions (from 1993 to 1997) of PA patterns and incident T2DM were assessed by multivariate Cox models. Results were expressed as risk ratios (RR) and 95% confidence intervals.

Results: Four PA patterns were identified: «high PA level», «moderate PA level», «gardening/do it yourself» and «low PA level». Between 1993 and 1997, a total of 10,952 women (18%) increased somehow their levels of PA. After adjustment for established risk factors of T2DM and stratification on body mass index (BMI), maintaining a high level of PA was associated with a decrease of T2DM incidence when compared to women who stayed at a low level of PA (RR=0.77 (0.60-0.99) and 0.71 (0.58-0.87) for women with a BMI lower than or higher than 25 kg/m² respectively). Increasing the level of PA between 1993 and 1997 was associated with a borderline decreased risk in both strata of BMI (RR=0.89 (0.73-1.10) and 0.89 (0.77-1.03) for women with a BMI lower than or higher than 25 kg/m² respectively).

Conclusion: Using an innovative method in T2DM epidemiology, associations between evolutions of PA patterns and T2DM were quantified for the first time in such a large population. We have found that maintaining a high level of PA over time was associated with a decreased risk of T2DM, independently of BMI.

Lower mortality with physical activity in type 1 diabetes of extreme duration: Joslin 50-Year Medalist study

S.A. D'Eon, D.M. Pober, L.J. Tinsley, S.M. Hastings, G.L. King, H.A. Keenan;

Vascular Cell, Joslin Diabetes Center, Boston, USA.

Background and aims: Physical activity (PA) is often discussed as a crucial aspect of type 1 diabetes management, however, very little is understood about the effect of PA on mortality in those with the disease. This analysis examines the association in a unique group of individuals who have had type 1 diabetes for 50 or more years (the Joslin 50-Year Medalists).

Materials and methods: All Medalists (n=955, 54.1% female) provided documentation of 50 years of insulin dependence, resided in the US, and were examined at the Joslin Diabetes Center. The median HbA1c was 7.1%, age 65.0y, duration of diabetes 53.0y, age at onset 11.0y, with a median BMI of 25.6 kg/m² and daily insulin dose of 0.4 U/kg. PA was assessed by self-report and validated by the Paffenbarger Questionnaire.

Results: Medalists who reported being physically active (77.5%) had a significantly lower HbA1c (7.1 v 7.2%, p<0.01), BMI (25.3 v 27.4 kg/m², p<0.0001), and triglycerides (64.0 v 73.5 mg/dL, p<0.001). Additionally, those reporting PA had higher eGFR (72.7 v 66.4 mL/min/1.73 m², p<0.01) and HDL-C (64.0 v 57.0 mg/dL, p<0.0001) levels. The rates of cardiovascular disease (CVD) (37.1 v 48.9%) and nephropathy (10.3 v 21.0%) were significantly different in the active group compared to the inactive group (p<0.01 and p<0.0001, respectively). Proliferative diabetic retinopathy and neuropathy were not significantly different (p>0.05). Ten percent (n=99, 42.4% female) of Medalists have passed away, 61 (61%) of whom reported being physically active. Among these individuals median age (74.0 v 64.0y, p<0.0001), age at diagnosis (12.0 v 11.0y, p<0.01), duration (57.0 v 52.0y, p<0.0001), HbA1c (7.2 v 7.1%, p=0.05), and eGFR (53.5 v 73.7 mL/min/1.73 m², p<0.0001), were significantly different than the rest of the cohort. Prevalence of neuropathy, nephropathy, and CVD were higher in the deceased group (p<0.05). The most frequent cause of death was CVD (n=42), followed

by cancer (n=9), end-stage renal disease (n=5), and accidents (n=5). We investigated the influence of PA on mortality by Cox proportional hazards regression. The group crude hazard ratio (HR)=0.47, (95%CI 0.31, 0.72) for PA compared to non-PA indicates a substantial protective effect. After adjusting for potential covariates including, age, sex, HbA1c, history of CVD, nephropathy, and use of antihypertensives, PA remained independently associated with protection from all-cause mortality (HR=0.50, 95%CI 0.31, 0.78). To counter the possibility of reverse causality we duplicated analyses without subjects who passed away within 1 or 3 years of enrollment into the study and found similar results.

Conclusion: This longitudinal analysis confirms that PA is associated with increased survival probability independent of other factors in an aging population of older type 1 diabetic individuals, providing evidence of PA as an important means of reducing the burden of mortality in this population.

Skin autofluorescence is related to tobacco smoke and nicotine exposure

R.P. van Waateringe¹, M.J. Mook-Kanamori^{2,3}, S.N. Slagter¹, M.M. van der Klauw¹, J.V. van Vliet-Ostapchouk¹, R. Graaff¹, H.L. Lutgers¹, K. Suhre^{4,5}, M.M. El-Din Selim⁶, A.H. Takiddin⁶, H. Al-Homsi⁶, K.A.S. Al-Mahmoud⁶, B.H.R. Wolfenbuttel¹, D.O. Mook-Kanamori^{3,7};

¹Department of Endocrinology, University Medical Centre Groningen, Netherlands, ²Department of Physiology and Biophysics, Weill Cornell Medical College, Doha, Qatar, ³Department of Biostatistics, Epidemiology and Scientific Computing, Epidemiology Section, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia, ⁴Bioinformatics Core, Weill Cornell Medical College, Doha, Qatar, ⁵Helmholtz Zentrum München, Research Center for Environmental Health, Neuherberg, Germany, ⁶Department of Dermatology, Hamad Medical Corporation, Doha, Qatar, ⁷Department of Epidemiology, Leiden University Medical Centre, Netherlands.

Background and aims: Tobacco smoke has been found to be an exogenous source of reactive glycation products. Skin autofluorescence (SAF), reflecting advanced glycation endproducts (AGE) accumulation in the skin, has been shown to predict diabetes-related cardiovascular complications and is higher among smokers compared to non-smokers. In the present study, we examined the association of different smoking behaviors and nicotine exposure with SAF using both epidemiological and metabolomics data.

Materials and methods: We used a large population-based dataset from the LifeLines Cohort Study and metabolomics data from the Qatar Metabolomics Study of Diabetes (QMDiab). Smoking behavior and exposure to tobacco smoke from others (secondhand smoking (SHS)) were assessed in a questionnaire in 9,009 individuals including 314 individuals (3.5%) with type 2 diabetes (T2DM) participating in the LifeLines Cohort Study. In QMDiab nicotine exposure was measured in saliva, plasma and urine in 374 individuals of whom 190 individuals (51%) with type 2 diabetes. SAF was measured non-invasively in all individuals using the AGE Reader.

Results: Urinary cotinine N-oxide, a marker of nicotine exposure, was found to be positively associated with SAF in QMDiab (p=0.03). HbA1c (p=0.010) and type 2 diabetes (p<0.0001) were most strongly associated with higher SAF levels among former and current smokers participating in the LifeLines Cohort Study. We observed a gradual increase in SAF with the number of hours being exposed to SHS. SAF levels of former smokers decreased to levels of never smokers after 15 years of smoking cessation (Figure 1).

Conclusion: We have demonstrated that tobacco smoke exposure, assessed by questionnaire as well as by cotinine N-oxide in urine, is significantly associated with SAF. Both active smoking and exposure to

secondhand smoking are associated with higher SAF levels. Smoking cessation has beneficial effects on SAF levels.

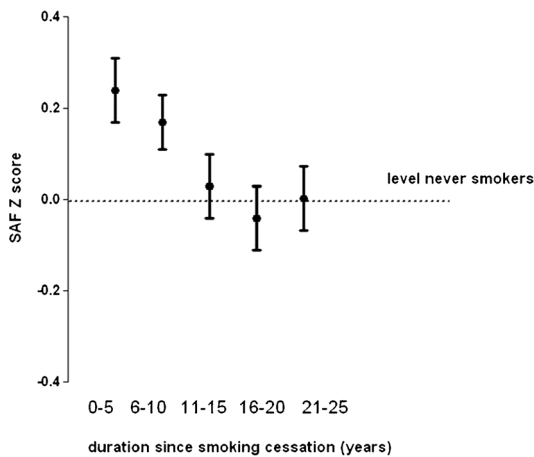

Figure 1. Effect of smoking cessation on skin autofluorescence in former smokers (LineLines data)

Association between diabetes and exposure to pesticides: a systematic review and meta-analysis

G. Ntritsos¹, F.K. Kavvoura^{2,3}, M. Chondrogiorgi¹, E.E. Ntzani^{1,4}, I. Tzoulaki^{5,1}, E. Evangelou^{1,5},

¹Department of Hygiene and Epidemiology, University of Ioannina, School of Medicine, Greece, ²Oxford Centre for Diabetes, Endocrinology & Metabolism (OCDEM), ³Oxford National Institute for Health Research (NIHR) Biomedical Centre, UK, ⁴Centre for Evidence-Based Medicine, Brown University, Providence, USA, ⁵Department of Biostatistics and Epidemiology, Imperial College London, UK.

Background and aims: Diabetes mellitus is a worldwide epidemic, currently affecting more than 350 million people and expected to reach 550 million by 2050. It represents a major global public health challenge. Diabetes aetiology is considered to be an interplay between genetic and environmental factors. Emerging evidence suggests that environmental contaminants, including pesticides play an important role in the pathogenesis of diabetes. We performed a systematic review of observational studies that assessed the association between exposure to pesticides and diabetes.

Materials and methods: A comprehensive literature search of peer-reviewed original research pertaining to pesticide exposure and any health outcome, published until December 2014, with no language restriction, was conducted. The association between exposure to any pesticide and all types of diabetes was examined. Separate analyses for studies that recruited only Type 2 diabetes (T2D) participants were performed. Odds ratios (OR) using fixed and random-effects models were calculated. Random effects are reported in view of the presence of heterogeneity. Risk estimates were transformed in order to be comparable across studies. Heterogeneity was assessed using the I^2 (0–100%).

Results: We identified 21 studies assessing the association between pesticides and diabetes, in a total of 66,714 individuals (5,066 cases/ 61,648 controls). Most studies did not report the specific diabetes type. The summary OR for the association of the exposure to any type of pesticide and diabetes was 1.61 (95% CI: 1.33–1.95, $p=9 \times 10^{-7}$), with large heterogeneity ($I^2=68.2\%$). Studies evaluating T2D only ($n=12$ studies), showed a similar summary effect 1.64 (95% CI 1.39–1.92, $p=2 \times 10^{-9}$)

however heterogeneity disappeared ($I^2=0\%$). Analysis by type of pesticide showed an increased risk with less heterogeneity ($I^2=0-87\%$). The summary effects ranged from 1.19 (95% CI: 1.05–1.35, $p=0.007$, $I^2=0\%$) for the exposure to chlordane, up to 2.34 (95% CI: 1.53–3.59, $p=9 \times 10^{-5}$, $I^2=43.7\%$) for exposure to trans-nonachlor. The study type and the measurement of the exposure did not affect the effect estimate. Egger's test was significant suggesting the presence of small-study effects. High heterogeneity was attributed mainly to the synthesis of observational studies.

Conclusion: This systematic review supports the hypothesis that exposure to various types of pesticides increases the risk of diabetes. Subgroup analyses did not reveal any differences in the risk estimates based on the type of studies or the measurement of the exposure. Analysing each pesticide separately reduces heterogeneity and the different effect sizes suggest that some pesticides are more likely to contribute to the development of diabetes than others.

Diabetes mellitus as a risk factor for community-acquired pneumonia in hospital admissions

M. Martins^{1,2}, J.M. Boavida², J.F. Raposo^{1,2}, F. Froes³, B. Nunes⁴, R.T. Ribeiro^{1,2}, M. Macedo^{1,2}, C. Penha-Gonçalves⁵;

¹NOVA Medical School / Faculdade de Ciências Médicas (MEDIR Group), Universidade NOVA de Lisboa, CEDOC, Chronic Diseases Research Center, ²APDP - Diabetes Portugal (Education and Research Centre/APDP-ERC), ³Service of Pneumology, Hospital Pulido Valente, Centro Hospitalar Lisboa Norte, ⁴Department of Epidemiology, Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisbon, ⁵Instituto Gulbenkian de Ciência, Oeiras, Portugal.

Background and aims: Respiratory infections are frequently associated with diabetes mellitus (DM). Health Authorities and Medical Societies recommend several general measures (e.g., smoking cessation and control of chronic illnesses), as well as flu and pneumococcal vaccination of people with DM. Portugal has one of the highest prevalence rates of DM within the European context. We have therefore, carried out a retrospective, nation-wide register analysis of hospitalized patients that aimed to estimate the prevalence of DM among community-acquired pneumonia (CAP) patients and evaluate the impact of DM in hospital length of stay and in-hospital mortality.

Materials and methods: Anonymized data from 157,291 CAP adult patients referring to the period 2009-2012 were extracted from the National Hospital Discharge Database of DRGs (Diagnostic-Related Groups). Patients included in the study had CAP as main diagnosis on admission within the age range 20-79 that matched the PREVADIAB - National Prevalence Study. Data for analysis were clean from double entries, day cases and hospitalizations >90 days. We also excluded individuals with HIV and with iatrogenic immunosuppression. Nation-wide DM statistics from 2009 to 2012 were collected from the PREVADIAB study.

Results: Within the 74,175 CAP episodes that matched the inclusion criteria we found a high burden of DM that tended to increase over time, from 23.7% in 2009 to 28.1% in 2012. Importantly, the DM prevalence in CAP patients was significantly higher when compared to the national DM prevalence ($P < 0.0002$), particularly in women. We found that episodes of CAP in DM patients had in average 0.8 days longer hospital stay as compared to patients without DM ($P < 0.0001$) totalling an estimated 15,370 days of stay attributable to DM in 19,212 CAP admissions. In-hospital mortality was also significantly higher in CAP patients that have DM (15.2%) vs without DM (13.5%) ($P = 0.002$).

Conclusion: Taken together, our data show a significant increase in the prevalence of DM in subjects hospitalized with CAP reinforcing the relevance of DM as a risk factor for CAP. This longitudinal study provides indications that DM patients acquiring CAP are older, have longer hospitalization time and have higher mortality rates than CAP patients without DM. Importantly, our study also highlights that the relative impact of diabetes was greatest in younger adults (20-39 years) and in women. Thus, this nation-wide study identified people with DM as a priority group for adoption of general measures to prevent CAP, and more specifically for flu and prophylactic pneumococcal vaccination. These results have informative value for strategies of patient awareness and future healthcare guidance, particularly for people with diabetes under 40 years and for DM women.

Influenza in patients with diabetes and obesity: vaccine effectiveness against hospitalised influenza and complications after hospitalised influenza-like illness

F. Galtier^{1,2}, P. Loulergue^{3,2}, P. Vanhems^{4,2}, X. Duval^{5,2}, S. Jouneau^{6,2}, D. Postil^{7,2}, F. Letois¹, N. Lenzi², C. Merle^{8,2}, F. Carrat^{9,2}, O. Launay^{3,2}; ¹CIC 1411, CHRU & Inserm, Montpellier, ²Inserm, FCRIN I-REIVAC, ³CIC 1417, APHP & Inserm, Paris, ⁴GH Edouard Herriot, Lyon, ⁵CIC 1425, APHP & Inserm, Paris, ⁶CIC 1414, CHRU & Inserm, Rennes, ⁷CIC 1435, CHRU & Inserm, Limoges, ⁸MIT, CHRU, Montpellier, ⁹Inserm, UMR-S 707, Paris, France.

Background and aims: Diabetic subjects are at risk for influenza complications, and vaccination has long been recommended in this population in France. Recent data show that the same applies to obese subjects, and recent French recommendations are to vaccinate subjects with a BMI ≥ 40 . Since 2012-13, we have conducted multicentre test negative case

control studies to estimate influenza vaccine effectiveness (IVE) against hospitalized laboratory confirmed influenza in Europe. A sub-analysis performed on the data from 6 hospitals in France considered the results among subjects with diabetes (DM) and obesity (Ob).

Materials and methods: During the 2012-13 and 2013-14 seasons, we swabbed all patients hospitalized for influenza related illness, aged ≥ 18 , and reporting an influenza-like illness (ILI) within 7 days before admission (cases: PCR positive for influenza; controls: negative for any influenza virus). Influenza vaccination was recorded. By logistic regression we calculated IVE by influenza subtype (adjusted for age, sex and number of children) and risk factors for complications (adjusted for age, sex, influenza infection, vaccination, DM and Ob).

Results: Among the 848 patients included, influenza was confirmed in 253. IVE was 69% (95% IC: 38-84, $P < 0.001$) and 40% (95% IC: 01-64, $P < 0.05$) in the 2012-13 and 2013-14 seasons, resp. DM or Ob was present in 286 subjects (DM: 197; Ob: 152; both: 63), influenza was confirmed in 85/286, and vaccine coverage was 54%, 45% and 44% in DM, Ob and other subjects, resp. ($P = 0.05$). Subjects with DM were older (DM: 71 ± 17 ; Ob: 61 ± 18 ; both: 69 ± 12 ; other: 65 ± 20 , $P = 0.001$). Overall adjusted IVE in subjects with DM or Ob was 55% (95%CI: 19-75, $P < 0.01$). Table 1 shows IVE according to virus subtype, metabolic disease and season. Complications during hospitalizations for ILI were respiratory failure ($N = 160$), heart failure ($N = 100$), renal failure ($N = 79$) and death ($N = 27$). In multivariate analysis, renal failure was associated with DM (OR 2.57, 95%CI: 1.55-2.48, $P < 0.001$) and Ob (OR 1.73, 95%CI: 0.99-3.03, $P = 0.05$). Heart failure was associated with age (65-74: OR 2.57, 95%CI: 1.28-5.16, $P = 0.008$); ≥ 75 : OR 4.15, 95%CI: 2.26-7.64, $P = 0.0001$), Ob (OR 1.76, 95%CI: 1.04-3.00, $P = 0.03$) and DM (OR 1.55, 95%CI: 0.99-2.51, $P = 0.07$). Respiratory failure, death and length of inpatient stay were not associated with DM or Ob.

Conclusion: In patients with DM or Ob, IVE is similar to that reported in general population. However vaccine coverage is insufficient, especially in Ob. DM and Ob increase the risk of cardiac and renal complications in subjects hospitalized with ILI.

Direct medical costs of severe hypoglycaemic events amongst type 2 diabetes patients in the UK: a retrospective database study

K. Tunceli¹, T. Holbrook², J. Williams¹, R. Shankar¹, J. Chen¹, L. Radican¹, J. Piercy²;

¹Merck & Co. Inc, Kenilworth, USA, ²Adelphi Real World, Manchester, UK.

Background and aims: Hypoglycaemia is a common complication in type 2 diabetes mellitus (T2DM) patients. Treatments raising insulin levels independently of blood glucose, such as oral insulin secretagogues (sulfonylureas and glinides) and exogenous insulin, can increase the risk of hypoglycaemia. This study aims to provide an up to date estimate of the direct medical costs of severe hypoglycaemic events amongst T2DM patients to the UK healthcare system.

Materials and methods: A retrospective cohort design was undertaken with linked UK Clinical Practice Research Datalink (CPRD) and Hospital Episodes Statistics (HES) databases, selecting patients initiated on any mono, dual, or triple combination therapies for treatment of T2DM between 2008 and 2012, and observing severe hypoglycaemic events and costs estimated up to end of regimen +90 days, or end of recorded data (minimum of 1 day, maximum 6 years). All patient characteristics were described at treatment initiation for mono, dual, or triple combination therapies. Severe events were defined as events requiring hospital treatment with hypoglycaemia-specific diagnosis or procedure code. Costs were estimated using Healthcare Resource Groups (HRGs version 4) and tariffs derived from the National Tariff 2013-14, and primary care follow-up appointment costs using Personal Social Services Research Unit (PSSRU) 2014, and drug prescription costs using Prescription Cost Analysis for England 2008-13. Results from the linked sample were extrapolated using the full HES census dataset to provide national cost estimates.

Results: There were 857 severe events observed, with a mean observation period of 510; 522; 503 days (mono, dual, triple therapy respectively, regardless of regimen), among 60,335; 31,610; 10,298 patients identified in the linked sample. 56; 58; 61% of admitted patients were male, with a mean age of 63.8; 62.4; 61.2 years in three groups. Mean diabetes duration at admission was 3.0; 5.6; 7.3 years in the three groups, with a mean HbA1c of 7.7%; 8.3%; 8.8%. The event rate was 5.3; 7.0; 6.6 per 1000 patient-years in the three groups with a mean per-event secondary care cost of £3,558; £3,477; £2,989, and primary care follow-up cost of £56 per event in each group. Extrapolating to national data (17,622 episodes observed in full 2013-14 HES data), estimated national cost to the NHS per year was £61,193,413.

Conclusion: Severe hypoglycaemic events impose a substantial burden upon the NHS. Further research is required to quantify the extent to which events could be prevented, and the associated potential cost savings to NHS budgets.

Towards a better understanding of acute post-prandial hyperglycaemic episodes: a patient perspective

S. Heller¹, C.E. Kosmas², N. Kragh³, A. Nikolajsen³, A.J. Lloyd²;

¹School of Medicine and Biomedical Sciences, University of Sheffield, ²Patient Reported Outcomes, ICON plc, Oxford, UK, ³Novo Nordisk, Bagsvaerd, Denmark.

Background and aims: Prolonged or severe episodes of hyperglycaemia have been associated with the development of micro- and macrovascular long term complications such as neuropathy and atherosclerosis. Previous studies have demonstrated comparable effects of acute hyperglycaemia on cognitive function and mood to hypoglycaemia. This study aimed to explore the impacts of acute post-prandial hyperglycaemia (PPHG) on health-related quality of life in people with insulin-dependent diabetes mellitus.

Materials and methods: Twenty-four adults (≥ 18 yrs) with Type 1 ($n = 14$) and Type 2 ($n = 10$) insulin-dependent diabetes took part in a qualitative study. Data were collected via one-to-one telephone interviews in the US ($n = 10$) and two focus groups in the UK ($n = 14$). The study was reviewed and approved by an independent ethics board and participants provided written informed consent. Interviews and focus groups were audio-recorded and transcribed verbatim. Anonymised transcripts were analysed using a thematic analysis approach, supported by qualitative software (MAXQDA).

Results: A number of common themes were identified associated with participants' awareness and experience of acute PPHG (such as variability, frequency and duration). Some participants felt that the food eaten and activities undertaken had an effect on the speed with which glucose rose and the time taken for glucose levels to return within normal range.

Increased thirst and frequency/urgency of urination, tiredness, feeling lethargic and suddenly hot and sweaty were consistent symptoms when discussing PPHG. Other symptoms included dizzy spells and “fogginess”, impaired concentration and difficulty thinking quickly. Some participants worried about these symptoms and found them “unnerving”. Participants’ perceived physical and cognitive impacts of acute PPHG could affect their work and perceived ability to drive. Experiences of acute PPHG episodes also prompted changes in behaviour including avoiding social events, leaving early or avoiding them altogether, arranging with employers to take breaks in the working day and constant worry that resulted in restrictive diets. Anxieties about PPHG episodes were most frequently related to concerns that repeated episodes could have on long term health. Some participants expressed particular fears that severe and long lasting episodes (compared to short lived “routine” periods of PPHG) would lead to diabetic complications.

Conclusion: This study advances our understanding of the every-day impact of acute PPHG on individuals with diabetes, which to the authors’ knowledge has not been previously explored using qualitative methods. Analysis of the interview transcripts provided rich insight into participants’ experiences of PPHG. The data will be used to guide development of a self-reported outcome measure of the impact of PPHG, to allow a more systematic and quantitative study involving a larger sample.

315

Hospital incidental diagnosis of diabetes: a population study

P. Francesconi¹, F. Profili¹, L. Policardo¹, R. Anichini², G. Seghieri¹; ¹Epidemiology, Agenzia Regionale Sanità, Florence, ²Diabetes Unit, Ospedale S.Jacopo, Pistoia, Italy.

Background and aims: Uncertainty remains on how the diagnosis is being made of new, not previously identified, incident diabetes. Newly diagnosed diabetes, has been, indeed, mainly identified after admission to intensive care units or after hospitalizations due to acute cardiovascular events and seems to bring about, in such conditions, an excess risk of fatal events. Purpose of this study was to present a new method apt to identify incidentally diagnosed diabetes (IDD) among a large population of hospital discharged patients, determining, moreover, their risk of mortality, as compared with that of subjects with known diabetes (KD).

Materials and methods: Among 214,991 individuals discharged in year 2011 from both medical and surgical wards of all hospitals of Tuscany, Italy we identified IDD when all these conditions were satisfied: a.: absence in the regional diabetes registry, b.: no previous hospital discharge with main or secondary diagnosis of diabetes (ICD-9-CM 250.xx), c.: no past prescriptions of glucose lowering drugs (GLD) (ATC class A10A or A10B), d.: no evidence of legal certifications including those enabling patients to free prescriptions of consumables, clinical chemistry tests, specialists’ consultations related to the diabetic condition. Diagnosis of incidental diabetes also required e.: record for at least two GLD prescriptions, with the first prescription occurring within 30 days after the index discharge and the second over the next six months. In addition, two-year (2012–2013) adjusted mortality risk, expressed as hazard ratio (HR), was tested through a Cox regression analysis, comparing IDD subjects and KD patients having had at least one hospital admission in 2011 and alive at 1st January 2012 (n=865 and 31,715 respectively).

Results: IDD was found in 974 patients in one year, corresponding to 375.6 per 100,000 hospitalized people. The great majority of IDD patients were discharged by medical wards (88%). The adjusted relative risk [RR(95%CI)] of IDD, as evaluated in hospitalized population, exponentially increased with age and was three-fold higher in migrants of non-Italian ancestry; RR: 3.18 (1.87–5.42). Furthermore IDD risk was associated with male gender; RR: 1.24 (1.09–1.41) and with greater burden of existing co-morbidities, as evaluated by Charlson Co-morbidity index in previous hospitalizations; [(RR:63.51 (49.78–81.03) in those with Charlson Co-morbidity index \geq 2], while was reduced among patients of general practitioners adhering to shared guidelines resulting in a proactive

model of care delivery RR: 0.75(0.63–0.91). In the cohort of IDD patients alive at 1st January 2012, (n=865) the hazard ratio(HR) of two-year-mortality, adjusted for main confounders, was not different from that of matched KD subjects (HR=1.08; 95%CI: 0.92–1.26; p=NS).

Conclusion: IDD is relatively common among hospitalized individuals and, in our population, occurs more commonly in older male subjects, migrants of non-Italian ancestry, and in patients of physicians non-adhering to a shared care model of diabetes care. Finally, people with IDD have similar mortality risk compared with matched KD individuals.

316

Normoalbuminuric male but not female patients with type 2 diabetes have a normal life expectancy after 14 years of follow-up (ZODIAC-50)

N. Kleefstra^{1,2}, S.H. Hendriks¹, K.J.J. van Hateren¹, K.H. Groenier³, G.W.D. Landman¹, A.H.E. Maas⁴, H.J.G. Bilo^{1,2};

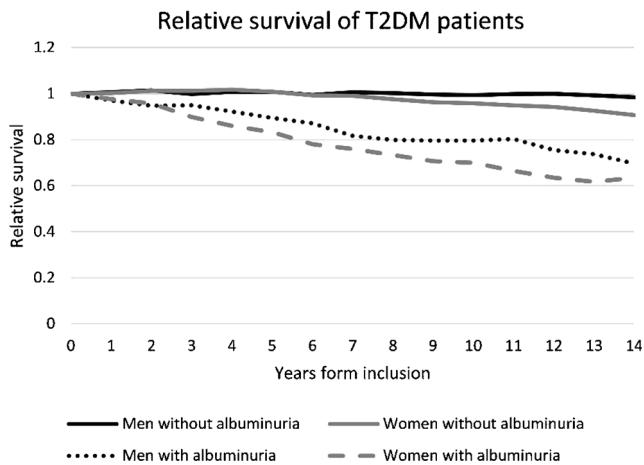

¹Diabetes Centre, Isala Clinics, Zwolle, Netherlands, ²Department of Internal Medicine, ³Department of General Practice, University of Groningen and University Medical Center Groningen, ⁴Department of Cardiology, Radboud University Medical Center, Nijmegen, Netherlands.

Background and aims: When compared to the general population, the relative risk for cardiovascular mortality in patients with type 2 diabetes (T2DM) has been described to be substantially higher in women compared to men. To what extent gender influences mortality risk in the Netherlands is unclear as it is known from previous studies that overall mortality in patients with diabetes in the Netherlands is low compared to many other countries. The aim of the present study was to investigate gender differences in life expectancy in primary care treated patients with type 2 diabetes in the Netherlands.

Materials and methods: Patients with T2DM participating in a prospective observational cohort study (ZODIAC) in the Netherlands were included. Inclusion in this cohort took place in 1998, 1999 and 2001. Vital status was assessed in 2013 and life expectancy was calculated using relative survival analysis. Using the Hakulinen method, the relative survival was expressed as the ratio of observed survival of patients observed divided by the survival of the general population in the Netherlands with the same age (data available from Statistics Netherlands). Analyses were performed for men and women separately and for subgroups of patients with and without albuminuria.

Results: A total of 1791 patients was included of which 56% was female. Mean age was 67 (SD 12) years and the median diabetes duration was 4 (ICR: 2–9) years. Microalbuminuria was present in 29% and macroalbuminuria in 9% of patients at baseline. After 14 years 49% (874) patients died, of which 43% from cardiovascular causes. The relative survival was 0.87 (95%CI: 0.80 - 0.93) for men and 0.81 (95%CI: 0.75 - 0.87) for women with T2DM. In the subgroup of patients without microalbuminuria the relative survival was 0.99 (95%CI: 0.90 - 1.05) for men and 0.91 (95%CI: 0.84 - 0.98) for women. In the subgroup of patients with albuminuria the relative survival was 0.70 (95%CI: 0.58 - 0.81) for men and 0.63 (95%CI: 0.54 - 0.74) for women (figure 1).

Conclusion: In primary care treated T2DM patients, the life expectancy of men and women was 13% and 19% lower after 14 years of follow-up compared to men and women in the general population, respectively. In the subgroup of patients without albuminuria, male patients had the same life expectancy compared to the general population, while the life expectancy in women still was lower. These results confirm that overall, patients with T2DM, have a lower life expectancy compared to the general population, but that the absence of albuminuria increases this expectancy considerably, even to normal in men.

Fruit and vegetable consumption and risk of prediabetes and type 2 diabetes in a Swedish prospective study

A.A. Barouti, A. Hilding, C.-G. Östenson, A. Björklund;

Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Fruit and vegetable intake has been proposed for the prevention of type 2 diabetes (T2D) but the evidence from observational studies is inconclusive or even scarce when it comes to other glucose tolerance abnormalities, like prediabetes. Therefore, we investigated the association between fruit, vegetable or combined fruit and vegetable intake and the risk of deterioration in glucose tolerance (to prediabetes or T2D), in a prospective population-based cohort study.

Materials and methods: Subjects were 2296 men and 3180 women aged 35–56 years old at baseline, without previously diagnosed diabetes, who participated in the Stockholm Diabetes Prevention Program and were followed for 8–10 years. For all participants, anthropometric and clinical measurements, an OGTT for the assessment of prediabetes (impaired fasting glucose and/or impaired glucose tolerance) or type 2 diabetes, an extensive questionnaire on lifestyle factors and a food frequency questionnaire were carried out at both baseline and follow-up. Men and women differed in fruit and vegetable consumption, so we used sex-specific tertiles of intake for our analyses.

Results: Median intake of fruit and vegetables at baseline was higher among women compared to men: 185 vs 103 g/day for fruit ($p < 0.001$) and 163 vs 117 g/day for vegetables ($p < 0.001$). Higher intake of fruit (>148 compared to <64 g/day) was associated with a 27% lower risk of deteriorating glucose tolerance in men, after adjusting for age, family history of diabetes, BMI, physical activity, smoking, education and blood pressure (OR: 0.73, 95% CI: 0.55–0.98); more specifically the risk of developing prediabetes from normal glucose tolerance (NGT) decreased by 26% (OR: 0.74, 95% CI: 0.52–1.05). Vegetable consumption in men was inversely but not significantly associated with the risk of prediabetes or T2D. In women, vegetable consumption appeared protective, and especially the middle tertile of total vegetable intake was significantly associated with a lower risk of developing T2D from NGT (OR: 0.42, 95% CI: 0.20–0.90). Intake of a specific vegetable subgroup (green leafy vegetables) reduced also the risk of developing T2D in women. The multivariate adjusted OR for the highest (>42 g/day) compared to the lowest (<12 g/day) intake of green leafy vegetables was 0.33 (95% CI: 0.16–0.68). The consumption of fruit and vegetables combined showed no significant associations.

Conclusion: Higher consumption of fruit was associated with a reduced risk of deteriorating glucose tolerance in men, especially for the progression from NGT to prediabetes, whereas in women vegetable consumption and specifically higher intakes of green leafy vegetables, reduced the risk of developing T2D from NGT. Overall, the findings from this Swedish study population add to the evidence of a beneficial effect of fruit and vegetables on T2D risk, and provide new insight for the prevention of prediabetes.

Exposure to persistent organic pollutants in early pregnancy and risk of gestational diabetes mellitus

L. Chatzi¹, M. Vafeiadi¹, T. Roumeliotaki¹, G. Chalkiadaki¹, P. Rantakokko², H. Kiviranta², E. Fthenou¹, S.A. Kyrtopoulos³, M. Kogevas⁴;

¹Department of Social Medicine, Faculty of Medicine, University of Crete, Heraklion, Greece, ²Department of Environmental Health, National Institute for Health and Welfare, Kuopio, Finland, ³National Hellenic Research Foundation, Institute of Biology, Medicinal Chemistry and Biotechnology, ⁴National School of Public Health, Athens, Greece.

Background and aims: Persistent Organic Pollutants (POPs) are a group of diverse substances, including polychlorinated biphenyls (PCBs) and organochlorine pesticides that are resistant to biodegradation and ubiquitously present in our environment. Exposure to endocrine disrupting chemicals such as POPs has been linked to type 2 diabetes and metabolic disturbances in epidemiological and animal studies, but little is known about POPs exposure during pregnancy and the development of gestational diabetes mellitus (GDM). The purpose of this study was to determine the extent to which, exposure to current low levels of different POPs in the first trimester of pregnancy is associated with GDM risk in 639 women from the RHEA pregnancy cohort in Crete, Greece.

Materials and methods: Concentrations of several PCBs, dichlorodiphenyldichloroethene (DDE), and hexachlorobenzene (HCB) were determined in first trimester maternal serum by triple quadrupole mass spectrometry. POPs were treated as continuous variables on a log10 scale. We defined total PCBs as the sum of all congeners, non dioxin-like PCBs as the sum of PCB 153, 138, 170 and 180, and dioxin-like PCBs as the sum of PCB 118 and 156. Pregnant women were screened for gestational diabetes mellitus (GDM) between 24 and 28 weeks of gestation, and GDM was defined by the criteria proposed by Carpenter and Coustan. Adjusted odds ratios (ORs) and 95% confidence intervals (CIs) were estimated using multivariable logistic regression models.

Results: Geometric mean HCB, DDE and PCBs serum concentrations in pregnant women were 88, 2043 and 295 pg/ml respectively. 68 (7%) women had GDM. On multivariable regression analyses, a 10-fold increase in total PCBs was associated with increased risk of GDM (OR=4.44; 95% CI: 1.17, 16.79) after adjusting for pre-pregnancy BMI and several other confounders. The association was more pronounced for non dioxin-like PCBs (OR=4.42; 95% CI: 1.19, 16.43). Prenatal DDE and HCB exposure were not significantly associated GDM risk.

Conclusion: These findings suggest that women with high PCBs levels in early pregnancy had higher risk for GDM. Further studies are needed to replicate these results and to evaluate potential biological mechanisms underlying the observed associations.

Comparison of glycaemic outcome and relation to changes in liver fat content in low-carb vs low-fat dietary regimes for prediabetic subjects

U. Kaiser¹, S. Kabisch^{1,2}, M. Kemper¹, C. Honig¹, C. Gerbracht¹, A.F.H. Pfeiffer^{1,2};

¹Clinical Nutrition, German Institute of Human Nutrition, Potsdam, ²German Center for Diabetes Research, Munich, Germany.

Background and aims: Very low carb diets (LCD) were reported to rapidly reduce liver fat and to improve glucose metabolism more effectively than low fat diets (LFD) in metabolic syndrome subjects. However, this observation is confounded by small sample sizes and could not be replicated by others. The aim of this study was to investigate the effect of a sequential short-term very low carb hypocaloric vs. low fat hypocaloric diet followed by an isocaloric moderately low carb or low fat dietary intervention on glycemic parameters, intrahepatic lipids (IHL) and risk factors for cardiovascular disease in prediabetic subjects.

Materials and methods: In a subcohort of the Prediabetes Lifestyle Intervention Study (PLIS; n=99) we conducted a two-step dietary intervention with two different regimes. The initial 3 wk-phase was hypocaloric (ca. 1500 kcal/day), the second phase (11 months) represented the maintenance period. We compared a 3 week very low-carbohydrate diet followed by moderate carb diet (short term: < 40 g carbohydrates/day, long term: < 40% of daily energy intake) and a low-fat diet (fat intake<30% of daily energy intake). Metabolic assessment took place after 3 weeks, 6 and 12 months and was based on 2-hour oral glucose tolerance tests and magnetic resonance spectroscopy (for IHL).

Results: While both interventions showed similar significant short-term reduction and long-term maintenance of reduced glucose levels and liver fat content (LCD vs LFD; relative change in IHL after 6 months: -42,2±29,2% vs -24,6±65,8%, p=0,382), short-term reductions in mean (± SD) fasting glucose levels were significantly greater in the LCD-group (-11,1±12,1 mg/dl vs -3,7±10,9 mg/dl, p=0,002). After 3 weeks, reduction of blood pressure was greater in LCD (systolic: -12±13 mmHg vs -4±15 mmHg, p=0,002; diastolic: -7±8 mmHg vs -4±9 mmHg, p=0,019), whereas in triglycerides the LCD-improvement reached only a trend effect (p=0,073). In the LFD-group, reductions in C-reactive protein (CRP: 0,1±3,6 mg/dl vs -0,7±2,2 mg/dl, p=0,017) and high density lipoprotein (HDL: -0,8±10,6 mg/dl vs -6,2±6,2 mg/dl, p=0,001) could be observed, but did not sustain in the maintenance period. The same long-term attenuation applied to blood pressure and triglycerides. No short-term diet-specific effect on low density lipoprotein (LDL) was observed (p=0,263) after 3 weeks, whereas a significant reducing LCD-effect was assessed after 6 months (-19,1±20,8 mg/dl vs -9,9±18,3 mg/dl, p=0,003). Correlation analysis showed, that despite similar magnitude of metabolic changes, liver fat reduction under low-fat diet is tightly linked to weight loss (p=0,003), but not in the low-carb group (p=0,170).

Conclusion: Low-carb and low-fat diets are similarly effective to reduce glycemic parameters and liver fat content, whereas the improvement in other cardiovascular risk parameters was more pronounced under the low-carbohydrate diet. The underlying mechanisms appear to differ regarding dietary composition suggesting an individualization of dietary strategies.

Association of dairy foods with impaired glucose metabolism and diabetes mellitus in The Maastricht Study

S.J.P. Eussen¹, M.J.C. van Dongen¹, N.W. Wijckmans¹, N.W. Wijckmans¹, L. den Biggelaar¹, S.J.W. Oude Elferink², C.M. Singh-Povel², M.T. Schram³, S.J.S. Sep³, C.J. van der Kallen³, A. Koster⁴, N. Schaper³, R.M.A. Henry³, C.D.A. Stehouwer³, P.C. Dagnelie¹;

¹Department of Epidemiology, Maastricht University, ²FrieslandCampina, Wageningen, ³Department of Internal Medicine, Maastricht University Medical Center, ⁴Department of Social Medicine, Maastricht University, Netherlands.

Background and aims: Observational studies suggest an inverse association between total dairy intake and diabetes risk. However, there is a lack of information on the relation of specific dairy products with impaired glucose metabolism (IGM) and type 2 diabetes (T2DM).

Materials and methods: Individuals aged 40-75 y were recruited for The Maastricht Study. All participants filled out a 254-food item food frequency questionnaire (FFQ), covering 41 specific dairy items that captured differences between full fat, semi-skimmed, and skimmed products, as well as fermented and non-fermented products. Glucose metabolism status was assessed by an oral glucose tolerance test and participants were informed on their glucose metabolism status after returning the FFQ. 2,508 Individuals were available to estimate odds ratios (ORs (95%CI)) for IGM (n=501) and newly diagnosed (ND) T2DM (n=129), with

adjustment for BMI, physical activity, smoking, education, energy intake, and intake of vegetables, fruits, meat, and fish.

Results: For IGM, fully adjusted analyses revealed inverse associations, with ORs (95% CI) comparing the highest with the lowest tertile of intake of 0.73 (0.55 - 0.96) for skimmed products and 0.74 (0.54 - 0.99) for fermented products. These dairy products were not associated with ND T2DM. In contrast, full fat products were positively associated with ND T2DM (OR (95%CI): 2.01 (1.16-3.47)), whereas total dairy intake was inversely associated with ND T2DM (OR (95%CI): 0.46 (0.24-0.86)).

Conclusion: Individuals with a high consumption of skimmed and fermented products had a lower odds of having IGM, and individuals with a high consumption of total dairy products had a lower odds of having ND T2DM. High intake of full fat products was not related to IGM, but increased the odds of ND T2DM.

Adherence to Mediterranean diet reduces ten-year diabetes risk. The role of TNF- α and homocystein as potential mediators

E. Kolovertou¹, D. Panagiotakos¹, C. Chrysohoou², E. Georgousopoulou¹, V. Metaxa², I. Skoumas², D. Tousoulis², C. Stefanadis², C. Pitsavos²;

¹Department of Nutrition and Dietetics, School of Health Science and Education, Harokopio University, ²First Cardiology Clinic, School of Medicine, University of Athens, Athens, Greece.

Background and aims: Beyond its cardioprotective effects, Mediterranean diet has been reported to offer an anti-diabetic protection. The aim of this study was to investigate the effect of long term adherence to Mediterranean diet on ten-year diabetes incidence, and examine inflammatory and oxidative stress biomarkers as candidate mediators of this relationship.

Materials and methods: At baseline (2001-2), a random sample of 1514 men and 1528 women (>18 years) without any clinical evidence of cardiovascular disease, were enrolled in the study. Several socio-demographic, clinical, biochemical and other variables were studied in relation to diabetes development (i.e., fasting blood glucose >125 mg/dL or the use of antidiabetic medication, WHO, ICD-10 criteria). Adherence to Mediterranean diet was evaluated using MedDietScore (range 0-55) and score tertiles (low, moderate and high adherence to the diet) were calculated. In 2011-2012 the ten-year follow up was performed.

Results: 191 new diabetes cases were recorded. The ten-year incidence of diabetes was calculated 13.4% and 12.4% among men and women respectively. Moderate and high adherence to Mediterranean diet were found to reduce the risk of diabetes by 49% (95%CI: 0.30, 0.88) and 62% (95% CI: 0.16, 0.88) respectively, compared with low adherence, taking into consideration age, sex, years of education, family history of diabetes, hypercholesterolemia, hypertension, smoking habits, physical activity and central obesity (waist circumference \geq 94/80 for men and women respectively). Trend analysis revealed a logarithmic relationship ($p=0.042$). Men with waist circumference >94 cm and women >80 cm were found to benefit the most. Whole grains, fruits and legumes were found to exert the greatest predictive ability. When various biomarkers were entered in the fully adjusted model, the antidiabetic effect of Mediterranean diet was found to be mediated by TNF- α and homocysteine levels.

Conclusion: The present work demonstrates the beneficial role of Mediterranean dietary pattern against type 2 diabetes development, which extends Mediterranean diet's therapeutic potential to other cardio-metabolic disorders. The possible participation of TNF- α and homocystein in this pathway is proposed. The components of Mediterranean which are responsible for this protection require more investigation.

A high diet quality based on dietary recommendations does not reduce the incidence of type 2 diabetes in the Malmö Diet and Cancer cohort

E. Sonestedt, E. Mandalazi, I. Drake, E. Wirfält, M. Orho-Melander; Department of Clinical Sciences Malmö, Lund University, Malmö, Sweden.

Background and aims: A high diet quality index based on the Nordic nutrition recommendations and Swedish dietary guidelines has previously been associated with reduced risk of cardiovascular disease and mortality in the Malmö Diet and Cancer cohort. The aim was to investigate if this diet quality index was associated with risk of type 2 diabetes.

Materials and methods: Out of 26,172 participants (44 to 74 years) from the Malmö Diet and Cancer cohort study, 2,829 type 2 diabetes incident cases were identified from registers during 18 years of follow-up. A modified diet history method was used to estimate dietary intakes. A diet quality index was constructed based on adherence to the recommended intakes of saturated fat, polyunsaturated fat, fish and shellfish, dietary fiber, fruit and vegetables, and sucrose.

Results: After adjustments for potential confounders, we observe no significant association between diet quality index and type 2 diabetes risk. Hazard ratio for highest vs. lowest index category were among men 1.05 (95% CI: 0.88, 1.25; P-trend=0.94) and among women 1.03 (95% CI: 0.87, 1.22; P-trend=0.34). Exclusion of individuals reporting a substantial diet change in the past and energy mis-reporters did only marginally affect the results.

Conclusion: This study found no significant association between a high diet quality index based on the current dietary recommendations and reduced incidence of type 2 diabetes. Further investigation is needed to better understand how overall diet quality and individual dietary components are associated with the development of type 2 diabetes.

Paternal chronic high-fat diet consumption reprogrammes the gametic epigenome and induces transgenerational inheritance of metabolic disorder

T. de Castro Barbosa^{1,2}, S. Verstehe², P. Alm¹, L.R. Ingerslev², J. Massart³, M. Rasmussen², I. Donkin², K. Qian², R. Sjögren³, J.M. Mudry³, L. Vetterli³, S. Gup⁴, A. Krook⁴, J.R. Zierath^{2,3}, R. Barrès²;

¹Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden, ²The Novo Nordisk Foundation Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark, ³Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden, ⁴Department of Veterinary Disease Biology, University of Copenhagen, Denmark.

Background and aims: Genetic and non-genetic (environmental) factors are strongly implicated in obesity. Increasing evidence indicate that paternal obesity is associated with epigenetic inheritance of metabolic disorders in the next generations. However, a direct evidence of the molecular carriers remains elusive. We hypothesized that paternal chronic high-fat diet (HFD) consumption transgenerationally alters the gametic epigenome, affecting the metabolism of the offspring.

Materials and methods: F0-male rats fed either HFD or chow diet for 12 weeks were mated with chow-fed dams to generate F1 and F2 offspring. Motile spermatozoa were isolated from F0 and F1 breeders to determine DNA methylation and small non-coding RNA (sncRNA) expression pattern by deep sequencing.

Results: Newborn offspring of HFD-fed founders had reduced body weight and decreased beta-cell mass when compared to offspring from chow-fed breeders. F1 and F2 adult females from F0 founders fed a HFD

were glucose intolerant and resistant to HFD-induced weight gain. No major phenotype was observed in male offspring, suggesting sex-specific responses. HFD-fed F0 and their F1 male offspring presented similar changes in the epigenome of spermatozoa, showing altered DNA methylation and sncRNA expression profile when compared to respective controls. Altered expression of the miRNA let-7c in sperm of F0 and F1 breeders was also observed in the white adipose tissue of female offspring, leading to a transcriptomic shift in let-7c putative target genes. **Conclusion:** Our results indicate that chronic HFD consumption transgenerationally reprograms the gametic epigenome, which may be the molecular mechanism involved in the transmission of environmentally-induced metabolic dysfunction to the next generations. *Supported by: Novo Nordisk Foundation, Swedish Research Council, European Res Council*

The effect of haptoglobin polymorphism and PPAR- γ agonists on carotid artery intima-media thickness in type 2 diabetic patients: seven years follow-up

M. Káplár¹, B. Coghi¹, J. Kulcsár¹, R. Esze¹, Z. Karányi¹, L. Oláh², K. Szabó², R.K. Czuriga-Kovács², T. Magyar², H.P. Bhattoa³, J. Hársfalvi⁴, G. Paragh¹;

¹Institute of Internal Medicine, ²Department of Neurology, ³Department of Laboratory Medicine, University of Debrecen, ⁴Department of Biophysics and Radiation Biology, Semmelweis University, Budapest, Hungary.

Background and aims: Patients with Type 2 diabetes mellitus are predisposed to accelerated atherosclerosis. Subclinical atherosclerosis can be measured by carotid artery intima-media thickness (cIMT), which predict cardiovascular and all-cause mortality independently. Lately the role of non traditional risk factors such as haptoglobin polymorphism, elevated homocysteine levels, inflammatory factors, etc. have emerged in the pathogenesis of diabetic vascular complications. Haptoglobin (Hp) plays an important role in iron metabolism and additionally modulates atherosclerosis given its antioxidant effect. Hp (1-1) provides a stronger antioxidant effect as compared to Hp (1-2) and Hp (2-2) polymorphisms. A strong association between haptoglobin polymorphism and coronary sclerosis, as well as carotid artery intima-media thickness (cIMT) has been reported previously. Peroxisome proliferator-activated receptor- γ (PPAR- γ) agonists (rosiglitazone and pioglitazone) are oral antidiabetic agents with insulin sensitizer properties. These bind to nuclear PPAR- γ receptor and have pleiotropic effects, some of which are independent of their glucose lowering action. There are no data available in the literature regarding the long term effect of these agents on cIMT and their association with haptoglobin polymorphism. Our aim was to investigate the effect of haptoglobin polymorphism on cIMT in Type 2 diabetic patients during a 7 years follow-up with respect to the applied treatment (antidiabetic agents, aspirin) as well as metabolic and conventional cardiovascular risk factors.

Materials and methods: We recruited 114 patients in 2005 and 2006, and Hp polymorphism, CRP level, HbA1c and lipid parameters were determined. Seven years later control examinations were performed and we tried to find any association between Hp polymorphism and changes in cIMT. During the follow-up period 29 patients were treated with rosiglitazone for 46 \pm 23 months on average. Following rosiglitazone restriction, treatment of 11 patients was continued with pioglitazone for 12 \pm 5 months.

Results: Our results showed a decrease in cIMT of patients treated with PPAR- γ agonists compared to those having been on other medications. In the latter group, an increase in cIMT was noticed and the difference between the two groups was significant ($p=0.003$). Regarding PPAR- γ treatment and Hp polymorphism significant improvement of cIMT in Hp(1-1 1-2) patients ($p=0.016$), and moderate, non-significant increase of cIMT in Hp(2-2) group was found, respectively. There was no significant difference in lipid parameters and HbA1c between the groups, nor aspirin treatment and smoking influenced significantly the changes in cIMT.

Conclusion: In patients with Hp(1-1 1-2) polymorphism PPAR- γ agonists significantly decreased the subclinical atherosclerosis in Type2 diabetics during the seven years follow-up.

Effect of exercise on Pharmacokinetics (PK) of Basal Insulin pglispro (BIL) and insulin Glargine (GL) in type 1 diabetes mellitus patients

H. Linnebjerg¹, E. Lam², S. Choi², M.P. Knadler¹, N. Porksen¹, V.P. Sinha³, P. Garhyan¹, O. Klein⁴, L. Nosek⁴, T. Heise⁴;

¹Eli Lilly and Company, Indianapolis, USA, ²Lilly-NUS Centre for Clinical Pharmacology Pte Ltd, Singapore, ³Food and Drug Administration, Silver Spring, USA, ⁴Profil, Neuss, Germany.

Background and aims: BIL is a novel basal insulin that has a prolonged duration of action related to a delay in insulin absorption and a reduction in clearance. As exercise may potentially affect insulin absorption, this study investigated the effect of exercise on PK of BIL and GL.

Materials and methods: Forty patients with T1DM received 0.5-U/kg subcutaneous doses of either BIL or GL once daily in the thigh for 20 days. In each treatment arm, patients were randomised to 1 of 2 sequences, providing an intra-subject comparison: a 45-minute exercise challenge at 50%-70% VO₂ max (17 hours postdose; ~6 hours after a meal) on Day 17 and no exercise on Day 20, or vice versa. On both days, PK samples were collected for 24 hours after insulin dosing. Frequent blood sampling for PK and blood glucose (BG) was conducted from 17 to 20 hours postdose (0-3 hours after start of the exercise).

Results: Mean BIL concentrations increased with exercise, reaching a peak at 1 hour and returning to pre-exercise levels within 3 hours after starting exercise. BIL AUC during a dosing interval at steady state (AUC_{0-24,ss}) was increased by 13% with exercise compared to no exercise. BIL AUC for 3 hours after the start of exercise (AUC₀₋₃) and maximum observed concentration at steady state (C_{max,ss}) were increased by 63% and 64%, respectively, with exercise compared to no exercise. These differences were statistically significant. In contrast, for GL, these PK parameters were not affected by exercise. Mean baseline (pre-exercise) BG levels were 138 mg/dL (7.7 mmol/L) with exercise vs 122 mg/dL (6.8 mmol/L) without exercise in the BIL treatment arm, and 145 mg/dL (8.0 mmol/L) with exercise vs 148 mg/dL (8.2 mmol/L) without exercise in the GL arm. Over the 3-hour period after exercise start, mean (±SD) BG levels were similar with or without exercise following BIL or GL dosing (BIL: 86.0±26.5 mg/dL [4.8±1.5 mmol/L] with exercise vs 90.7±30.2 mg/dL [5.0±1.7 mmol/L] without exercise; GL: 113±31.8 mg/dL [6.3±1.8 mmol/L] with exercise vs 125±48.9 mg/dL [6.9±2.7 mmol/L] without exercise).

Conclusion: While exercise transiently increased systemic exposure following BIL but not GL dosing, the mean glucose concentration appeared comparable. With the reduced receptor binding affinity and attenuated peripheral glucose uptake of the hepato-preferential drug BIL, further research is warranted to delineate the hypoglycaemia risk with exercise.

Improvement in hepatic metabolism is associated with reduced conversion to diabetes in IGT subjects treated with pioglitazone (ACT NOW study)

A. Gastaldelli^{1,2}, D. Tripathy², M. Gaggini¹, N. Musi², R.A. DeFronzo²;

¹Metabolism Unit, CNR Institute of Clinical Physiology, Pisa, Italy, ²University of Texas Health Science Center, San Antonio, USA.

Background and aims: Increased liver enzymes are markers of fatty liver disease (FLD) and of progression to type 2 diabetes (T2DM). Pioglitazone has been shown not only to delay onset of T2DM, but also to ameliorate fatty liver and improve hepatic function. We recently have shown that subjects with FLD have increased plasma amino acid concentrations and that the ratio of glutamate/(serine+glycine) (GSG index) was associated with degree of hepatic fibrosis measured by liver biopsy. The aim of this study was to evaluate the changes observed in parameters of

hepatic function after 2.4 year of pioglitazone treatment in subjects with impaired glucose tolerance (IGT) and the relationship with onset of T2DM.

Materials and methods: 441 IGT subjects who participated in the ACT NOW Study and had complete end-of-study metabolic measurements were randomized to receive pioglitazone (45 mg/day) or placebo and were observed for a median of 2.4 years. Indices of insulin sensitivity (Matsuda index [MI]), lipid profile (triglycerides, HDL, LDL), liver enzymes, plasma amino acid concentrations, adipose tissue IR (FFA x Ins), hepatic IR index (Glu 0-30 min x Ins 0-30 min), and index of hepatic damages, ie GSG index and AST/ALT score were measured.

Results: Pioglitazone reduced IGT conversion to diabetes by 72% (P<0.0001) and decreased AST (from 26 to 22 U/l), ALT (from 30 to 24 U/l) and TG (from 123 to 106 mg/dl) concentrations compared to placebo (p<0.001). Pioglitazone, compared to placebo, markedly decreased hepatic IR (-2637 vs -259 mMxpM), AST/ALT (+0.08 vs -0.08) and the GSG index (-0.6 vs +0.9), all p<0.0001 documenting improved hepatic metabolism. Changes in GSG index correlated with changes in hepatic IR (r=0.26), adipose tissue IR (r=0.29) and matsuda index (r=-0.28, all p<0.0001). In the pioglitazone group, after 2.4 year, fewer subjects converted to T2DM (n=15 vs 45). New T2DM subjects showed increased or no change (rather than decrease) in GSG index, hepatic IR, AST, ALT and TG concentrations.

Conclusion: Reduced conversion of IGT to T2DM after pioglitazone treatment is strongly related to the improvement in hepatic function.

Effectiveness of shared decision making using a support decision tool to achieve treatment targets in type 2 diabetes mellitus patients. A randomised trial (OPTIMAL)

H. Den Ouden, R.C. Vos, G.E.H. Rutten;

University Medical Centre Utrecht, Julius Centre for Health Sciences and Primary Care, Netherlands.

Background and aims: No more than 15% of type 2 diabetes mellitus (T2DM) patients achieve all treatment goals regarding glycaemic control, lipids and blood pressure. Shared decision making (SDM) may increase that percentage; however, not all support decision tools are appropriate. Because the ADDITION-Europe study demonstrated two (almost) equally effective treatments but with slightly different intensities, it may be a good starting point to discuss with the patients their diabetes treatment, taking into account both the intensity of treatment, clinical factors and patients' preferences. We aimed to evaluate whether such an approach increased the proportion of patients that achieve all three treatment goals.

Materials and methods: Cluster-randomised trial in 35 general practices that participated from 2002-2009 in the ADDITION study. Both ADDITION and non-ADDITION T2DM patients, 60-80 years, known with T2DM for 8-12 years, were included. GPs from the intervention group were trained in SDM with the decision support tool. During the first visit the intensity of treatment, personalised targets and treatment priorities were established. Participants underwent 3-monthly check-ups as usual and a yearly rearrangement of priorities and discussion of treatment targets with the repeated use of the decision tool. The control group continued treatment as before. Follow-up: 24 months. Primary outcome: the proportion of patients who achieve all three treatment goals (intensive treatment: HbA1c 45-53 mmol/mol (6.5-7%), BP <135/85 mmHg, total cholesterol <3.5 mmol/mol; less intensive treatment: HbA1c <53 mmol/mol, BP <140 mmHg, total cholesterol <4.5 mmol/mol). Intention-to-treat analyses (ITT). To analyse the proportion of achieved treatment goals for blood pressure, lipids and HbA1 relative risks will be calculated, with the control group as reference. P <0.05 is considered statistically significant.

Results: In total 157 participants. In the intervention group 25 patients decided to continue less intensive treatment and 10 patients continued

intensive treatment. 34 patients (61.1%) switched from less intensive to intensive treatment and 3 the other way round. After one year, mean values of HbA1c, BP and total cholesterol had not changed in both groups. Compared to the control group, the proportion of patients achieving treatment targets in the intervention group did not improve (table 1). Two-years results will be available in Mai 2015 and presented during EASD Annual meeting 2015.

Conclusion: After shared decision making more than 60% of type 2 diabetes patients decided to choose stricter treatment targets. This led to a non-significant decrease in achieved treatment targets after 1 year, without a change in mean values for HbA1c, blood pressure and cholesterol levels.

Table 1: Patients who achieved separate and all treatment targets. Baseline and 1 year follow-up (n, %), with relative risk and p-value between groups.

	Intervention group, Patients on target		Control group, Patients on target		Relative risk	p-value
	Baseline n=72	Follow up n=71	Baseline n=85	Follow up n=85		
HbA1c (mmol/mol)	49 (68.1)	54 (76.1)	44 (55.0)	49 (62.0)	1.23 (0.99-1.52)	0.079
Blood pressure (mmHg)	36 (50.0)	32 (45.1)	39 (50.0)	43 (54.4)	0.83 (0.60-1.15)	0.327
Total cholesterol (mmol/l)	33 (45.8)	23 (32.4)	40 (54.1)	35 (49.3)	0.66 (0.44-1.00)	0.060
All three treatment targets	12 (16.7)	10 (14.1)	13 (15.3)	14 (16.5)	0.86 (0.40-1.81)	0.824

The effect of a vegetarian vs conventional hypocaloric diet on serum concentrations of persistent organic pollutants in patients with type 2 diabetes

J. Veleba¹, H. Kahleova¹, S. Tonstad², J. Rosmus³, A. Mari⁴, P. Fišar³, M. Hill⁵, T. Pelikanova¹;

¹Department of Diabetology, Institute of Clinical and Experimental Medicine, Prague, Czech Republic, ²Department of Endocrinology, Morbid Obesity and Preventive Medicine, Oslo University Hospital, Norway, ³State Veterinary Institute, Prague, Czech Republic, ⁴C.N.R. (National Research Council), Padua, Italy, ⁵Institute of Endocrinology, Prague, Czech Republic.

Background and aims: Emerging evidence suggests that environmental factors described as persistent organic pollutants (POPs) are involved in the development of type 2 diabetes (T2D). POPs may be present especially in fatty fish, fish and seafood, meat and dairy products. The aim of this study was to explore the effect of a vegetarian vs. conventional diet on serum levels of POPs in T2D patients after 12 weeks of a dietary intervention.

Materials and methods: 74 subjects with T2D were randomly assigned to either follow a vegetarian diet without fish or meat (n=37) or a control group who followed an isocaloric conventional diabetic diet (n=37). Both diets were calorie restricted (-500 kcal/day). To measure insulin sensitivity, the hyperinsulinemic (1 mU.kg⁻¹.min⁻¹) isoglycemic clamp was conducted. β -cell function was assessed using a mathematical model after a test meal. Magnetic resonance imaging of the abdomen was performed to measure the amount of visceral fat. We measured serum levels of 44 POPs. Dioxins and dioxin-like POPs were analyzed by isotope dilution high resolution gas chromatography and mass spectrometry after clean up on silica and carbon columns. Non-dioxin-like POPs were analyzed by gas chromatography with electron capture detector. All measurements were performed at 0 and 12 weeks. For statistical analysis we used repeated measures ANOVA and a multivariate regression model. Correlations were calculated using Pearson's correlations.

Results: We did not observe any difference between the groups in serum levels of most POPs in response to both hypocaloric diets. In the groups

combined, changes in serum concentrations of the POPs were correlated to changes in HbA1c ($r=+0.34$; $p<0.01$), fasting plasma glucose ($r=+0.41$; $p<0.01$) and β -cell function measured as insulin secretion at a reference glucose level ($r=-0.37$; $p<0.01$), independent of changes in body weight and volume of visceral fat.

Conclusion: Our findings support the relationship between POPs and diabetes, especially β -cell function.

Differential effects of a two-year insoluble cereal fiber intervention in prediabetic subjects (the OPTImal Fiber Trial - OPTIFIT)

C. Honig¹, S. Kabisch¹, C. Gerbracht¹, M. Kemper¹, S. Homemann¹, A. Fischer², A.F.H. Pfeiffer^{1,3};

¹Department of Clinical Nutrition, German Institute of Human Nutrition, Potsdam-Rehbrücke, ²J. Rettenmaier & Söhne GmbH + Co KG, Rosenberg, ³Department of Endocrinology, Diabetes and Nutrition, Campus Benjamin Franklin, Charité Universitätsmedizin, Berlin, Germany.

Background and aims: The development of type 2 diabetes is believed to be associated with some dietary factors including potential beneficial effects of dietary fibre. Epidemiological studies have highlighted their putative preventive role and especially insoluble fibre seems to improve insulin sensitivity and therefore reduce the risk of type 2 diabetes. On this behalf a prospective 2-year-study was performed to investigate whether a fibre supplementation can delay or inhibit the increase in blood glucose in subjects with prediabetes. Aim of the program was an increased intake of dietary fibre through change of diet (lifestyle intervention course) additionally to fibre supplementation.

Materials and methods: We performed a 24-months randomized, placebo-controlled, double-blind study involving 180 adults with impaired glucose tolerance. They were randomized into two groups receiving different types of fibre supplement. All subjects started with a one-year lifestyle program including group-based consultations and 4-day food records at regular intervals. During the second year of study they only received their study supplement and were asked to continue their regular intake twice daily. Blinded fibre supplement was either enriched with insoluble oat fibre adding 15 g of fibre per day to the normal nutrition or served as a placebo. Every 6 months anthropometric data and serum markers were assessed. In total 136 participants completed the first study year and 108 subjects completed the whole trial.

Results: The 2-h-OGTT glucose levels improved significantly in both intervention groups after the first study year (placebo-group: Δ -10,5 mg/dL, $p=0.020$ vs. fiber-group: Δ -17,3 mg/dL, $p<0.001$) as well as markers of insulin sensitivity (HOMAIR, OGIS180, ISIFFA), weight ($p<0.001$), waist ($p<0.001$) and hip circumference ($p<0.001$). In the fiber-group visceral and subcutaneous adipose tissue were significantly reduced (p 19 g fiber/day, Δ -17,0 mg/dL, non-adjusted $p=0.002$) compared to the lowest fiber consumption (<15 g fiber/day, Δ -10,6 mg/dL, non-adjusted $p=0.102$). Several features of metabolic syndrome were significantly improved in both groups at the end of the study. Due to the supplementation the subjects in the fibre group effectively enhanced their fibre intake by approx. 13,4 g per day (placebo-group: 1,5 g per day), revealing good and continuous compliance of the study participants

Conclusion: The OPTIFIT-study showed that also in Germany a lifestyle intervention can significantly improve risk factors for type 2 diabetes. An increased intake of dietary fibre can significantly improve parameters of glucose levels and insulin sensitivity. Fat metabolism, anthropometric data and the extent of fatty liver disease were positively affected by the intervention.

Identifying people at high risk for type 2 diabetes: preliminary results from the Kerala Diabetes Prevention Programme

B. Oldenburg¹, T. Sathish¹, K.R. Thankappan², S. Balachandran², F. D'esposito¹, E. Mathews², P. Lorgelly³, P. Absetz⁴, P.Z. Zimmet⁵, J. Shaw⁵, R.J. Tapp¹;

¹The University of Melbourne, Australia, ²Sree Chitra Tirunal Institute for Medical Sciences and Technology, Trivandrum, India, ³Monash University, Melbourne, Australia, ⁴University of Tampere, Finland, ⁵Baker IDI Heart and Diabetes Institute, Melbourne, Australia.

Background and aims: The majority of people with type 2 diabetes mellitus (T2DM) live in low- and middle- income countries. Limited longitudinal studies among Asian Indians have assessed the performance of diabetes risk scores in identifying those at high risk for T2DM. We evaluated the performance of a diabetes risk score to recruit participants into a diabetes prevention program and determined the one-year change in glucose metabolism.

Materials and methods: The Kerala Diabetes Prevention Program is a cluster randomised controlled trial of a peer-led, group-based lifestyle intervention on reducing the incidence of T2DM in rural Kerala, India. The present analyses were limited to those in the control arm, with preliminary data available. At baseline, the Indian Diabetes Risk Score (IDRS), with a cut-point ≥ 60 was used to identify those at high risk for T2DM among 1306 participants. Participants with an IDRS cut-point ≥ 60 and without known T2DM attended a mobile clinic and underwent an oral glucose tolerance test (OGTT). Pre-diabetes and diabetes were defined using the World Health Organisation criteria.

Results: The mean (standard deviation) age of participants in the control arm was 47.1 (7.4) years and 47% were females. The IDRS risk factors were age ≥ 35 years (97.9%), family history of diabetes (51.9%), physical inactivity (79.4%) and central obesity (72.4%). At baseline, 47.1% (n=615) of participants screened were identified as being at high risk for T2DM, using the IDRS and of those 54.5% (n=335) had normal glucose tolerance (NGT), 29.1% (n=179) had pre-diabetes and 16.4% (n=101) had diabetes, based on OGTT. Of those with NGT at baseline, 26% progressed to pre-diabetes and 3.2% progressed to T2DM, by one year. Among those with pre-diabetes at baseline, 27.6% reverted to NGT and 19% progressed to T2DM by one year.

Conclusion: This is one of the first diabetes prevention programs in a developing country to use a diabetes risk score to identify people at high risk for T2DM. This study identified a large proportion of people with NGT who progressed to pre-diabetes or diabetes within one year, these participants would normally be excluded from diabetes prevention programs. These findings provide evidence to support the usefulness of a diabetes risk score to identify people at high risk for T2DM, among Asian Indians.

Implementation and preliminary outcomes of the Madrid city council diabetes prevention program (ALAS, High Risk Strategy) applied to workers

M. Martínez¹, C. Martín², O. Borrego³, F.J. Sobrino⁴, C. Segador², M. Dama², I. Bordel⁴, N. Calle², L. Lobato⁴, J. Moreno³, P. García⁵;

¹Prevention and Promotion Health Service of Madrid City Council, ²Diabetes Unit, ³Healthy Habits, ⁴Health Workers Unit, ⁵Madrid Salud, Prevention and Promotion Health Service of Madrid City Council, Spain.

Background and aims: In people with prediabetes, lifestyle interventions directed at weight loss and increasing physical activity are effective in preventing the progression to type 2 diabetes. The Madrid City Council Diabetes Prevention Program (ALAS, High Risk Strategy), has been implemented among its employees. Aims: 1 -To achieve 5%-7% weight reduction ; 2- To improve glycemic control.

Materials and methods: During a medical examination, Madrid City Council workers are encouraged to complete the Findrisc test. Those with positive results, that means, puntuacion ≥ 15 are asked to undergo Oral glucose tolerance test (OGTT). When they fulfill criteria for prediabetes, they are invited to participate in the ALAS program. It is delivered over 6 months and consists of 10 group sessions in a Workshop format. There are 6 weekly core sessions the main content of which are: healthy diet, physical activity and emotional management, and 4 more sessions directed at maintenance.

Results: 852 workers fulfilled Findrisc test. 76 people got positive results, from these, 53 (69,73%) underwent (OGTT). Up to February 2015, 43 participants have completed the Madrid City Council Diabetes Prevention Program (ALAS, High Risk Strategy), 30 had Prediabetes (70%) and 13 Normoglycemic at high risk (30%). Participants ages ranged from 37 to 68 (mean 53.6 SD=7,6), 20 males (46,5%) and 23 females (53,5%). At program completion, participants lost a mean of 4,73 Kg or 5,03% of body weight and 23% have normalized the glycemic control; 35% achieved 5% or more weight loss; 56% people attended 6 or more sessions. Weight loss was negatively associated with age, and positively with male gender and attendance. Factors contributing to program success are their implementation in the setting of work health screening, given the employees busy schedules and family responsibilities.

Conclusion: In people with prediabetes, lifestyle interventions are effective to achieve weight loss and to improve glycemic control. It should be encouraged to pass the Findrisc Test during health examinations in the workplace. Such a program could be introduced as part of the health screening examination that companies provide. It could be relevant to the health of employees to implement Diabetes Prevention Program in the workplace.

PS 010 Prevalence of type 1 diabetes and gestational diabetes around the world

332

The prevalence of gestational diabetes largely increases if the WHO-1999 cut-off values of the 75-gram oral glucose tolerance test are replaced with the WHO-2013 criteria

J.J. van Zanden¹, B.J. Schering², S.H. Koning², K. Hoogenberg³, B.H.R. Wolffenbuttel², H.L. Lutgers²;

¹Laboratory of Clinical Chemistry, Certe, Medical Laboratory North, ²Endocrinology and Metabolism, University of Groningen, University Medical Center Groningen, ³Internal Medicine, Martini Hospital Groningen, Netherlands.

Background and aims: The prevalence of gestational diabetes (GDM) is rising and contributes to a growing burden to global obstetric health care. In 2013, the WHO adopted the stricter cut-off glucose values for diagnosis of GDM of the IADPSG-2010 criteria. In the Netherlands, we have used the WHO 1999 criteria for GDM so far. In this study, we evaluated the prevalence of GDM applying the currently used WHO-1999 criteria compared to the new WHO-2013 criteria.

Materials and methods: Retrospective evaluation of blinded laboratory results of all 75-gram OGTTs performed between January 2011 and August 2014 by Certe, a regional primary- and secondary healthcare laboratory which covers a large rural area and urban area in northern Netherlands of approximately 550,000 inhabitants. Women could be referred by their midwife or gynaecologist to perform an outpatient OGTT if they had risk factors for GDM or symptoms suggestive of GDM (e.g. polyhydramnion). From this database, GDM prevalence was determined using the current national guideline based on the diagnostic WHO-1999 criteria: positive if fasting plasma glucose is ≥ 7.0 mmol/l and/or 2-h glucose value ≥ 7.8 mmol/l after a 75-gram OGTT. GDM prevalence was also determined using the WHO-2013 cut-off values: fasting plasma glucose ≥ 5.1 mmol/l and/or 2-h glucose value ≥ 8.5 mmol/l after a 75-gram OGTT.

Results: A total of 6130 OGTTs were carried out in the study period, 193 (3%) were incomplete (0.6% failed because of intolerance caused by nausea/vomiting, for the remaining 2.4% there was no registration of the cause of failure). Mean (\pm SD) age of the women was 30.3 ± 5 years. The prevalence of GDM in this cohort was 19% using the WHO-1999 cut-off values and 30% using the WHO-2013 cut-off values (+58%). GDM was diagnosed solely on fasting glucose in 64% by WHO-2013 criteria contrasting to 1% by WHO-1999 cut-off values where the 2-h glucose value was the major determinant of GDM-diagnosis. Prevalence of GDM increased with maternal age category (WHO1999/WHO2013): 18-25 years 14%/23%; 25-30 years 14%/24%; 30-35 years 21%/33%; 35-40 years 24%/35%; >40 years 30%/48%.

Conclusion: Adjusting our national guideline to the new WHO-2013 criteria will have a major impact on the prevalence of GDM, a 1.5 fold increase mainly because a larger proportion of GDM based on abnormal fasting glucose levels. This will lead to a higher referral rate to secondary obstetric care, necessitating a shared-care model for obstetric and diabetes care between primary and secondary obstetric care facilities. Furthermore it remains to be seen whether the WHO-1999 GDM-negative but WHO-2013 GDM-positive screeners have better maternal and neonatal outcomes.

333

Prevalence and risk factors for thyroid pathology in patients with diabetes mellitus

M.V. Arnaudova, I.K. Daskalova, T.T. Totomirova; Military Medical Academy, Sofia, Bulgaria.

Background and aims: The aim of this study was to assess the prevalence and risk factors for thyroid pathology among patients with type 1 and type 2 diabetes mellitus

Materials and methods: The study was conducted in our clinic during the period of January 2012 - December 2013. It was a retrospective study. The total study population included 829 patients with type 1 (14.8%) and type 2 diabetes (85.2%). The study group consisted of 532 women (64.2%) and 297 men (35.8%).

Results: Thyroid pathology was found in 78 (63.4%) of patients with type 1 diabetes and 507 (71.8%) of patients with type 2 DM. In type 1 diabetes group with established thyroid pathology the most common disorder was autoimmune thyroid disease - 45 (36.5%), while nodules were diagnosed in 31 patients (25.2%). In type 2 DM group the most common disorder were nodules - 332 (47.0%), while patients with autoimmune thyroid disease were 152 (21.5%). In type 2 DM group the risk of developing thyroid pathology increased by 1,074 times in comparison to type 1 diabetes. The risk of developing nodules increased by 1,142 times accordingly, and the risk of auto-immune thyroid disease decreased. The comparative analysis of patients with single and multiple nodules showed a statistically significant difference in terms of age - patients with multiple nodules were older - 61.35 ± 10.78 years and those with single nodules 57.7 ± 12.45 years. In type 1 diabetes mellitus a statistically significant correlation between age and presence of nodular formations was found. This correlation was not established in terms of auto-immune thyroid disease. In patients with type 2 diabetes mellitus statistically significant correlation was established between age and thyroid pathology in general as well as between age and the presence of nodular formations. In terms of AITD such correlation was not found.

Conclusion: Data comparison in type 1 and type 2 diabetes mellitus showed that aging increases the risk of nodular changes in both type 1 and type 2 diabetes, i.e., age can be perceived as an absolute risk factor for developing thyroid pathology, namely nodular pathology. According to our data in type 1 and type 2 diabetes, female sex is a risk factor for the development of nodular pathology and AITD.

334

Plasma lipids at type 1 diabetes onset predicts residual beta cell function after 6 and 12 months

A. Overgaard¹, S. Porksen¹, M.-L.M. Andersen¹, S. Fredheim¹, H.B. Mortensen¹, P. Meikle², F. Pociot¹;

¹Herlev Hospital, Copenhagen, Denmark, ²Baker IDI Heart and Diabetes Institute, Melbourne, Australia.

Background and aims: The exact mechanisms triggering and regulating progression towards beta-cell failure in type 1 diabetes (T1D) are poorly understood. It is generally acknowledged, however, that both genetic and environmental components are involved. A detailed understanding of the pathogenesis of T1D is a criterion for the development of preventive strategies. In particular, the identification of early metabolic modifications is promising in the study of etiological pathways. Recent research indicates that modulations of multiple plasma phospholipids precedes the presence of autoantigens in the development of T1D. These observations suggests the potential of metabolomic biomarker panels in monitoring health and potential decline in beta-cell function before T1D symptoms appear. Thus, we hypothesize that new biomarkers in the form of metabolite panels, and in particular lipids, in plasma from children with recent onset T1D will reflect the remaining beta cell function. This could lead to the development of new biomarker panels for decline in beta-cell function before T1D manifests itself clinically.

Materials and methods: For this study we used a total of 129 patients <15 years of age followed in the Danish Remission Phase Study. The patients were followed for 12 months (n=40 additionally returned at 60 months) from the diagnosis of T1D. Demographic and anthropometric data, insulin therapy as well as blood samples for centralized measurement of Hemoglobin A1c and meal-stimulated C-peptide were collected prospectively 1, 3, 6, 12 and 60 months after diagnosis. Multiple reaction monitoring lipidomics were used to characterize the lipid profiles of the participants of the cohort at each time point.

Results: Seven diacylglycerols (DG) and total amount of DG all of them carrying either 16:1 or 18:1 fatty acids, or both, were significantly associated, after Benjamini-Hochberg correction, to a decrease in stimulated C-peptide after six months, and three of these: DG 16:1/16:1, DG 18:1/18:1 and DG 16:1/18:1 and total DG were also associated to a decrease in stimulated C-peptide after 12 months. Six triacylglycerols (TG) and total TG were also associated to a decrease in stimulated C-peptide after six months, and three of these and total TG were also associated to a decrease in stimulated C-peptide after 12 months. All of the TGs contained at least one 16:1 or 18:1 fatty acid. Six cholesterol ester (CE) and total CE were associated to a decrease in stimulated C-peptide at six months, of these three and total CE were associated to stimulated C-peptide decrease at 12 months. CE 24:0 were only associated to a decrease in stimulated C-peptide after 12 months. Oxidated PC (OxPC) and PC 36:4a were significantly associated to an increase in stimulated C-peptide after 6 and 12 months. Another phospholipid, sphingomyelin 34:2 were also associated to a decrease in stimulated C-peptide after 12 months.

Conclusion: These observations provide evidence that lipid disturbances predicts decline in beta cell function, and could by closer examinations lead to better classification of patients and the progression of the disease as well as to the identification of new pharmaceutical drug targets.

A comparison of diabetes type 1 in South Asian and Caucasian patients in the UK: the Type 1 in Minority Ethnic populations (TIME) study

K.N. Sarwar¹, S.M.R. Gillani², B.M. Singh², P. Saravanan³, P. Narendran¹;

¹Endocrinology, Queen Elizabeth Hospital Birmingham, ²Endocrinology, Royal Wolverhampton NHS Trust, ³Endocrinology, University of Warwick, UK.

Background and aims: Diabetes type 2 (T2D) is up to six times more common in people of South Asian origin than in white Caucasians in the UK. Furthermore, onset is earlier with higher morbidity and mortality. Diabetes type 1 (T1D) has not previously been characterised in this group, despite South Asians comprising over 7% of the UK population. Recent reports suggest the prevalence of T1D is similar across South Asian and white Caucasian ethnicities. The aim of the TIME study was to characterise and compare T1D between South Asian and background white Caucasian populations.

Materials and methods: We performed a case controlled analysis of 417 patients across two centres in the West Midlands, UK (a region in the UK with one of the highest South Asian populations) matching for age and gender (one South Asian patient matched to two white Caucasian). Data for 177 patients was analysed from the Queen Elizabeth Hospital (QEH) and 240 patients from New Cross Hospital (NCH).

Results: The results are shown in Table 1. Values are median (interquartile range) with * indicating a p value <0.05.

Conclusion: In conclusion, we found that South Asians with T1D presented at a later age, and had more significant macrovascular risk factors than white Caucasians. Interestingly, there was no difference in glycaemic control or prevalence of microvascular complications. As for T2D, these findings have important implications for service delivery and personalised healthcare.

Table 1: A comparison of diabetes type 1 in South Asian and Caucasian patients in the UK

Characteristic (number of pts)	NCH South Asian (80)	NCH Caucasian (160)	QE South Asian (59)	QE Caucasian (118)
Male	43 (54%)	86 (54%)	34 (58%)	68 (58%)
Female	37 (46%)	74 (46%)	25 (42%)	50 (42%)
Age (yrs)	33.5 (23.75-45)	34 (23.75-45)	36 (28-44.5)	36 (28-44.75)
Age at diagnosis (yrs)	16 (9.75-24)*	12 (8-18)*	17.5 (10.75-26)	15 (10-22)
Duration of disease (yrs)	17 (9-28.25)*	21.5 (13.75-32)*	17 (8-23)	19 (7-28.5)
HbA1c (mmol/mol)	75 (61.5-88.5)	76 (63-91)	66.1 (55.25-81.75)	70.5 (61-83.6)
Systolic BP (mmHg)	121 (113-132)	125 (115-132)	130 (120.5-141.5)	131.5 (120.3-144)
Diastolic BP (mmHg)	-	-	86 (80.5-90)*	82 (77.25-88.75)*
Weight (kg)	72.4 (58.9-82.35)	73.6 (64-90)	74 (58.65-85.75)	76.5 (66.2-88)

National childhood diabetes register: disease onset, diabetes control and therapeutic data in the Czech Republic

K. Picková¹, J. Venháčová², J. Škvor³, P. Konečná⁴, J. Chudáčková⁴, D. Neumann⁵, J. Vosáhlo⁶, J. Strnadel⁷, S. Koloušková¹, O. Cinek¹, Z. Šumník¹, ČENDA Project Group;

¹Department of Pediatrics, 2nd Faculty of Medicine, Charles University in Prague and Motol University Hospital, ²Department of Pediatrics, Faculty of Medicine, Palacky University, Olomouc, ³Department of Pediatrics, Masaryk Hospital, Ústí nad Labem, ⁴Department of Pediatrics, University Hospital, Brno, ⁵Department of Pediatrics, University Hospital, Hradec Kralove, ⁶Department of Pediatrics, 3rd Faculty of Medicine, Charles University in Prague, ⁷Clinic of Pediatrics, University Hospital, Ostrava, Czech Republic.

Background and aims: The Czech National Childhood Diabetes Database (ČENDA) is a centralized web-based national database that stores treatment and outcome data in children and adolescents with diabetes, allowing for anonymous comparison among diabetes clinics. The goals of the ČENDA database are to provide longitudinal data of childhood diabetes control and to identify strengths and weaknesses in the system of care. Here we present the first two years of the database.

Materials and methods: Since 2013, the database collects data on every patient treated by 48 participating pediatric diabetes outpatient clinics. Importantly, a prerequisite for participation is to report every patient cared for. Data include characteristics of the disease onset and annual summaries of clinical care, including every tested HbA1c value. Protocols have been implemented ensuring complete anonymization and patient data protection.

Results: The database contains data of 2192 children and young people with diabetes; this is estimated to be 70% of all Czech pediatric patients according to the highly accurate national incidence register. In 2013, complete annual data were available for 1972 patients (1025 boys and 947 girls) up to the age of 18. Of these, 95% had type 1 diabetes, 3% had genetically proven monogenic diabetes, 1% had type 2 diabetes and 1% were stated as other type of diabetes. Median HbA1c was 66.3 (average 69.3; IQR 57-78) mmol/mol. The proportion of children reaching target therapeutic goal of 59 mmol/mol declines from 34% in 0-4 years old children to 25% in 15-18

the years old. Out of children treated by insulin, 75% were on multiple daily injections (MDI), 24% were on continuous subcutaneous insulin infusion (CSII) and 1% were on conventional therapy. The proportion of children treated by CSII rises significantly with age, being 6.8% in 0–4 years old children and 33% in the 15–18 years old. HbA1c values do not differ between children on MDI and CSII therapy. The total daily insulin dose varied by age and diabetes duration; the lowest dose was observed in children younger than 4 years (0.65 U/kg/day), the highest dose was in adolescents 15–18 years old (0.84 U/kg/day). Celiac disease was reported in 11.5%, and 18.3% of children were treated for autoimmune thyroid disease. Significant differences have been noted between clinics in almost all of the observed parameters.

Conclusion: With a coverage over 70%, the ČENDA database offers a representative view of childhood diabetes in the Czech Republic. The comparison of pediatric diabetes clinics shows large differences in treatment processes, complications and outcomes, notably in the proportion of patients reaching therapeutics targets. Detailed data analyses will help identify key areas for further improvement of the system of pediatric diabetes care. *Supported by: Czech Diabetes Society, MZČR National action plans and concepts*

337

Rising incidence of childhood type 1 diabetes in Wielkopolska province, Poland

E. Niechcial¹, B. Skowrońska¹, I. Krzyško¹, A. Gertig-Kolasa¹, W. Stankiewicz¹, M. Michalak², P. Fichna¹;

¹Department of Paediatric Diabetes and Obesity, ²Department of Informatics and Statistics, Poznan University of Medical Sciences, Poznan, Poland.

Background and aims: Over the past decades, a rapidly increasing incidence of childhood type 1 diabetes has been reported in many parts of the world. In Poland, the first epidemiological register was conducted in Wielkopolska between 1970–1985, where the estimated average incidence rate was 4.4/105 for the age group 0–16 years. In 80s and early 90s of the 20th century according to data from epidemiological programs EURODIAB and DiaMond, Poland was included to a very low incidence of type 1 diabetes countries with an incidence rate estimated around 6.6 / 105. This study aims to assess the current incidence of type 1 diabetes among children in Wielkopolska.

Materials and methods: The analysis involved cases of new onset type 1 diabetes that were recorded in Wielkopolska Register of Childhood Diabetes from 2008 to 2013. The degree of completeness of the registry overall has been estimated at 95.0%. The denominator for the analysis were children ≤14 years with residency in the study area, which was defined geographically to correspond with administrative and census boundaries of Wielkopolska. Diabetes was diagnosed based on WHO criteria and first day of insulin administration was assumed the time of diagnosis. Total, sex-, and age-specific incidence rates per 100,000 person-years were calculated for each calendar year. A direct standardization method was used to estimate age and sex standardized rates, assuming a reference population comprising equal numbers in each of the sex- and age-specific groups (0–4, 5–9, and 10–14 years). The 95% CI was calculated using the Gaussian approximation to the Poisson log-likelihood. The demographic data was obtained from the Statistical Office in Poznan.

Results: 571 new cases of type 1 diabetes: 259 girls and 312 boys were identified during the period January 2008 - December 2013. The mean age at diagnosis was 9.0±4.3 years. The trend for increased incidence of type 1 diabetes has been observed in children aged 0–14 (2008: 15.6/105, 95% CI: 8.6–22.4; 2013: 24.3/105, 95% CI: 20.2–28.4). The highest annual incidence was reported among those aged 5–9 years (2008 - 22.8/105-95% CI: 15.6–30.0; 2013 - 27.2/105-95% CI: 19.7–34.6). The fastest incidence increase was found in the youngest age group (2008 - 7.1/105, 95% CI: 3.2–11.0; 2013 - 17.4/105, 95% CI: 11.5–23.2). Diabetes has

occurred more often in autumn and winter months comparing to spring/summer months, except for 2012 when the seasonality was not observed. **Conclusion:** Incidence rate of type 1 diabetes is rising in Wielkopolska. Such rapid increase in very short period rather is associated with environmental factors than changing in genetic background. Seasonality of the disease is not a regular occurrence, which suggests increasing role of non-seasonal factors in the growing incidence. The fastest increase of type 1 diabetes incidence was noticed among the youngest children. The peak incidence is steadily moving towards younger age groups of children which indicates that paediatric diabetes health care will be extended and there is a higher risk of developing chronic complications in younger patients. The accelerating trend needs to be well monitored due to the search for its causes, prevention and the possibility of customizing medical care.

338

Effect of ethnicity on clinical presentation with type 1 diabetes and on humoral autoimmunity, within ADDRESS-2 (After Diagnosis Diabetes Research Support System)

V. Bravis¹, A. Kaur¹, H. Walkey¹, I. Godsland¹, C. Dayan², M. Peakman³, P. Bingley⁴, D. Dunger², N. Oliver¹, D.G. Johnston¹;

¹Dpt of Endocrinology, Diabetes & Metabolism, Imperial College, London, ²Institute of Molecular & Experimental Medicine, Cardiff University School of Medicine, ³Dpt of Clinical Immunology, King's College, London, ⁴Dpt of Diabetes & Metabolism, University of Bristol, ⁵Dpt of Paediatrics, University of Cambridge, UK.

Background and aims: In type 1 diabetes (T1D), most comparisons across the literature are within and between countries, but not by ethnicity per se. That is, in part, due to the fact that many of the countries are relatively homogenous with regards to ethnicity. Here, we examined the effect of ethnicity on the clinical presentation and humoral autoimmunity, within people with incident T1D recruited to ADDRESS-2.

Materials and methods: ADDRESS-2 comprises of a multi-ethnic cohort of people with incident T1D, aged 5–60 years old, characterized on the basis of clinical and demographic features and, in many, islet-specific antibodies (Ab) (GAD65, IA-2, ZnT8). From 01/09/2011 to 28/02/2014, patients with T1D were recruited to ADDRESS-2, within 6 months of diagnosis, from 134 recruiting sites in the UK.

Results: 1,580 patients were recruited (1,453 White-Europeans (WE); 909 male; 867 children). Of the non-WE patients, 52 were Asian (A), 20 Black (B), 55 Mixed/Other (MO). Osmotic symptoms (95%), weight loss (84%), fatigue (84%) were the main presenting symptoms and occurred in comparable frequency in all ethnic groups ($p > 0.05$). Symptom duration was greater in WE people ($p = 0.002$). 42% presented with diabetic ketoacidosis. Ketoacidosis rates were similar in WE (43%) and non-WE (38%) ($p > 0.05$). Ethnicity did not independently predict symptom duration or mode of clinical presentation. Family history of diabetes (FHDM) was reported at comparable frequencies between ethnic groups ($p > 0.05$). A ethnicity was a strong, independent predictor of FHDM (OR=1.9; $p = 0.03$). Ethnicity did not predict HbA1c or insulin dose requirements at the time of presentation. Of all patients, 926 (59%) provided a blood sample for Ab testing. 84% (774/926) had at least one Ab present. Ab positive status was associated with WE (85%) more than non-WE (67%) ethnicity ($p = 0.001$). WE ethnicity was a strong, independent predictor of Ab presence in children (5–16 years; OR=4.1; $p = 0.01$) and adults (17–60 years: OR=2.3; $p = 0.02$). A (OR<5; $p = 0.01$) and B (OR<5; $p = 0.04$) ethnicities strongly and independently predicted Ab absence. MO ethnicities less strongly predicted that (OR<0.5; $p = 0.08$). None of the potential confounding variables that may explain the effect of ethnicity increased the OR above 0.5 for non-WE ethnicities, on multiple regression analyses. WE patients were significantly more likely to have multiple

(versus single) Ab present compared to non-WE patients (RR=1.9; $p=0.01$).

Conclusion: ADDRESS-2 is a registry-based recruitment study of representative patients with a clinical diagnosis of T1D, over a wide age range and multiple ethnicities. It offers important information on the clinical and anthropometric characteristics of patients presenting with T1D. Although T1D is a condition that mostly affects people of WE ethnicity, there were no major differences in presentation across different ethnicities. Presence of islet cell Ab was much higher in WE patients compared with non-WE. Ethnicity was a strong, independent predictor of Ab status and frequency in children and adults presenting with T1D.

Characteristics of newly diagnosed adults with type 1 diabetes in the UK and their evolution over the first 5 years

S. Ramtoola¹, U.J. Ploug², N. Kragh², M.E. Nyeland²;

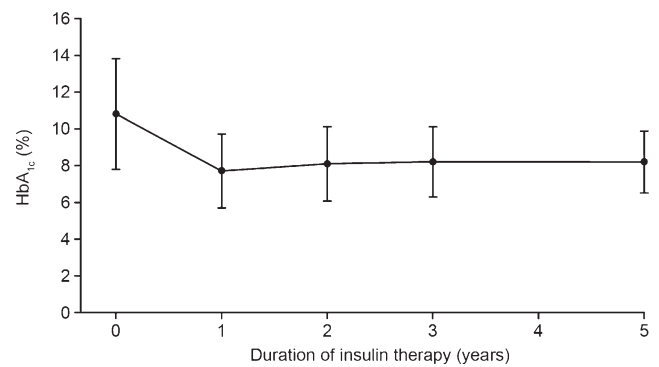

¹Royal Blackburn Hospital, Blackburn, UK, ²Novo Nordisk, Søborg, Denmark.

Background and aims: The aim of this study was to ascertain the weight, BMI characteristics and comorbidities of adults with newly diagnosed type 1 diabetes (T1D) in the UK and assess the impact of initiating insulin therapy on their glycaemic control and weight profile over the first 5 years after diagnosis.

Materials and methods: This study was a non-interventional, retrospective, cohort study utilising data from the UK Clinical Practice Research Datalink (CPRD) database between 2001 and 2013. Patients were selected based on a recorded diagnosis (C10* read codes) of T1D or fulfilling the NHS criteria for T1D, in whom onset of continuous insulin treatment was within 12 months of diagnosis. Patients included were aged 18–85 years, with a body mass index (BMI) of 11–50 kg/m² and a full medical history of at least 12 months prior to diagnosis ($n=2430$). Using this dataset, HbA_{1c} and BMI levels were compared at baseline and 12, 24, 36 and 60 months after insulin therapy was initiated.

Results: At baseline, patients (63.3% male, 36.7% female) had a mean \pm SD age of 40.8 \pm 16.1 years, HbA_{1c} of 10.8% \pm 3.0, and a BMI of 25.3 \pm 5.5. Mean BMI and BMI distribution of study patients were comparable to that of the UK general population. Following initiation of insulin therapy, mean HbA_{1c} statistically significantly (only taking inter-subject variation into consideration) declined from 10.8% \pm 3.0 to 7.7% \pm 2.0 at 12 months ($P<0.01$), but subsequently statistically significantly increased to 8.1% \pm 2.0 at 24 months, remaining stable thereafter at 8.2% \pm 1.9 and 8.2% \pm 1.7 at 3 and 5 years, respectively (Figure 1). Mean BMI consistently increased from 25.3 \pm 5.5 at baseline, to 27.2 \pm 5.8, 27.4 \pm 5.7, 27.5 \pm 5.6, and 27.9 \pm 5.5 kg/m² at 1, 2, 3 and 5 years, however, only the increase in the first 12 months was statistically significant (only taking inter-subject variation into consideration).

Conclusion: Whilst insulin therapy exerted an initial reduction in HbA_{1c} at 12 months, mean HbA_{1c} at 12 months was still above the NICE targets, and further deteriorated soon after, stabilizing between 2 and 5 years after initiation of treatment. After beginning insulin therapy, T1D patients were susceptible to long-term cumulative weight gain and increase in BMI, with deeper entrenchment into pathophysiological BMI weight categories. This study supports the concept of “glycaemic streaming” and suggests that further intensification of efforts is required right from diagnosis and initiation of insulin therapy to support patients with T1D to achieve and maintain glycaemic control targets. Currently weight control is a side issue in UK T1D patient education and treatment strategies which focus primarily if not almost exclusively on the titration of insulin to achieve HbA_{1c} targets. This study illustrates the need for greater emphasis on weight management in national T1D education programmes.

Obesity associated variants within FTO are functionally connected to multiple genes in the locus

I. Aneas, D. Sobreira, M. Rodriguez-Oquendo, M. Nobrega; University of Chicago, USA.

Background and aims: Several studies directly implicated FTO as the obesity gene. Genome-wide association studies have linked non-coding variants within FTO introns with increased risk for obesity and type 2-diabetes. Recently, our group has discovered that the obesity-associated elements within *fto* interact with *Irx3*, a distant gene on the genome that appeared to be the functional obesity gene. Our data showed that FTO obesity-associated region contain enhancers that drive *Irx3*- like expression, whereas *Fto* expression is primarily regulated by regions proximal to its promoter. eQTL mapping showed altered *Irx3* expression (not *Fto*) in the human brain and null mice demonstrated that *Irx3* is also a regulator of body mass and composition. However, involvement of *Fto* gene and/or other genes in the phenotype couldn't be rejected.

Materials and methods: To identify all possible genomic interactions between the 47 kb obesity-associated interval and promoters of genes located within a megabase window downstream FTO locus, we performed circular chromosome conformation capture followed by high throughput sequencing (4C-seq) in adult mouse brain (8 weeks). In order to determine a potential role for *Irx5* expression (and exclude *IRX6*) in the regulation of body mass index and metabolism, we used the CRISPR-Cas9 system to create *Irx5* and *Irx6* Knock-out mice.

Results: Using 4C-seq, we observed strong long -range interaction between the obesity-associated FTO intron not only with *Irx3*, but also *Irx5*. No interaction was observed with *IRX6* promoter. Mice homozygous for an *Irx5* and *Irx6* null allele are viable and fertile, with no evidence of embryonic lethality. *Irx5*KO mice showed a significant reduction in body weight. Importantly, the percentage of fat mass was significantly reduced without marked change of the lean mass ratio, due to an increase in browning of white adipose tissue. Similar phenotype was observed for *Irx3*KO mice. After the mice were subjected to 45% high fat diet (HFD) for 10 weeks, *Irx5*KO showed improved glucose intolerance and insulin resistance compared to control littermates. *Irx6*KO mice did not show any weight loss phenotype and HFD lead to glucose intolerance similar to observed in WT controls. Compound animals *Irx3/Irx6* and *Irx3/Irx5* are being generated and heterozygote animals are being evaluated for metabolic phenotypes.

Conclusion: These results strongly suggest that *Irx5*, together with *Fto* and *Irx3*, is also responsible for controlling body mass, body composition and energy metabolism. Our data shows that obesity-associated SNPs within FTO are functionally connected with multiple genes and that misregulation of *Irx3* and *Irx5* expression, but not with *Irx6*, that is indeed located in another transcription activation domain (TAD), might lead to obesity in mice.

Identification of novel susceptibility genes for diabetes- and obesity-related traits in two backcross populations of obese and lean mice

T. Schallschmidt¹, S. Lebek¹, A. Chadt¹, Y. Schulte¹, M. Damen¹, T. Stermann¹, C. de Wendt¹, B. Knebel¹, A. Schürmann², H. Al-Hasani¹;

¹Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Leipzig Center for Diabetes Research, Heinrich-Heine-University; German Center for Diabetes research (DZD), Duesseldorf, Germany, ²Department of Experimental Diabetology, German Institute of Human Nutrition (DIfE), Nuthetal, Germany.

Background and aims: Type 2 diabetes (T2D) in humans is influenced by a combination of numerous adipogenic and diabetogenic alleles. In outcross experiments of obese and lean mouse strains, several QTL (Quantitative Trait Loci) for obesity and hyperglycemia were separated. Mouse models could therefore help to identify several key obesity and diabetes modifier genes. In order to find further disease genes we performed two new crossbreeding approaches and subsequent QTL analysis. The obese New Zealand Obese (NZO) mouse which represents a poly-genetic model for the human metabolic syndrome and T2D, was crossed with the two lean mouse strains C3HeB/FeJ and 129/OlaHsd.

Materials and methods: We measured phenotypic traits associated with obesity and T2D in two backcross populations of 600 individuals each (300 males, 300 females). Animals were fed a high-fat-diet (45% fat/cal.) throughout the experiment. Body weight, body composition, plasma glucose and insulin concentrations during fasted and fed states were measured at different time points. At 21 weeks of life mice were sacrificed and tissues were harvested for the analysis of metabolic regulators. We genotyped both N2 populations with the help of a genome-wide high-density SNP panel. Linkage analysis was performed by in silico calculation of phenotype-genotype associations. Moreover, differential gene expression between the parental strains in liver, skeletal muscle, WAT, BAT and pancreatic islets was analysed by Affymetrix microarrays.

Results: Genetic linkage analysis revealed several highly significant QTL for metabolic traits in both backcross populations. In the NZOx C3HeB/FeJ backcross, major QTL for blood glucose were identified on chromosomes 4 (32 cM, logarithm of odds (LOD) 8.4), 7 (12 cM, LOD 14.0) and 15 (13 cM, LOD 7.5). Interestingly, a QTL for blood glucose at 32 cM on Chr. 4 was detected in both backcrosses (NZOx 129/OlaHsd and NZOx C3HeB/FeJ), indicating the contribution of an NZO allele. However, the largest effects were contributed by Chromosome 7, where maximum LOD scores overlapped for blood glucose, body weight, lean mass, final plasma insulin and BMI. Moreover, this locus appeared to be responsible for almost 80% of the total prevalence of hyperglycaemia in the male NZOx C3HeB/FeJ backcross population. Using microarray data we were able to detect several candidate genes within the loci with tissue-specific differential expression between the strains.

Conclusion: We identified novel QTL associated with obesity and T2D through a mouse genetics approach. Moreover, we were able to determine promising candidate genes for the diabetogenic effect of the most striking QTL on chromosome 7. Sequencing and functional assays of these candidates will help to identify the causal genes. Furthermore, interval-specific congenic introgression of 129, C3H and NZO into diabetes-resistant C57BL/6J will be performed to narrow down the candidate region and therefore serve as a second approach to identify novel diabetes genes.

Obesity modulates Ankrd26 gene expression by inducing epigenetic changes of its promoter

G.A. Raciti¹, R. Spinelli¹, A. Desiderio¹, M. Campitelli¹, L. Parrillo¹, M. Longo¹, F. Zatterale¹, V. Vastolo¹, P. Ungaro¹, C. Miele¹, I. Pastan², F. Beguinot¹;

¹CNR Research Unit at the Department of Translational Medical Sciences (DiSMET), “Federico II” University of Naples, Italy, ²National Cancer Institute (NCI), National Institute of Health (NIH), Bethesda, USA.

Background and aims: Ankyrin repeat domain 26 (Ankrd26) gene is a novel actor in the pathogenesis of obesity and T2D. This gene indeed plays an important role in the control of food intake, fat mass and glucose tolerance in vivo in mice. Based on our MeDIP-seq data, Ankrd26 gene seems to be a target sensitive to environmental exposure and to epigenetic modifications. Here, we aimed to investigate whether obesity in vivo impacts on Ankrd26 gene transcription by causing epigenetic modifications

Materials and methods: Obesity was induced by feeding 8 weeks (w) old male C57BL/6 mice with a high fat diet (HFD; ~60% energy from fat) up to 22 w. Gene expression was evaluated by Real-time qPCR in tissues from obese mice and lean mice (STD). DNA methylation of Ankrd26 promoter was investigated by MeDIP-qPCR and bisulfite sequencing analysis in both lean and obese mice

Results: HFD-fed mice are heavier than STD-fed mice already upon 8 w of obesogenic treatment reaching a 50% increase of body weight compared with lean mice at the end of the treatment. Obese mice exhibit also increased fasting blood glucose, impaired glucose tolerance and reduced insulin sensitivity at 8 and 22 w compared with controls (Table 1). Upon 8 w of treatment Ankrd26 mRNA expression is slightly decreased in the epididymal white adipose tissue (WAT) from obese mice compared with lean mice (STD 0.544±0.036 AU vs. HFD 0.521±0.021 AU). By contrast, 22 w of treatment leads to a significant decrease of Ankrd26 mRNA in WAT from obese mice (STD 0.509±0.011 AU vs. HFD 0.483±0.008 AU, $p<0.001$). Similar to WAT, Ankrd26 mRNA levels are decreased in the tibial skeletal muscle (STD 0.578±0.019 AU vs. HFD 0.558±0.011 AU, $p<0.01$), but not in the liver (STD 0.492±0.023 AU vs. HFD 0.500±0.028) from obese mice upon 22 w of HFD compared to controls. Consistent with the lower Ankrd26 expression in obese mice, MeDIP-qPCR analysis shows a 2-fold increase in DNA methylation enrichment of a region covering the Ankrd26 promoter (-462 bp to -193 bp) in pooled WAT genomic DNA from 22 w HFD-fed obese mice compared with lean mice (STD IP=0.407±0.171% vs. HFD IP 0.814±0.047%, $p<0.05$). Bisulfite sequencing also reveals in obese mice a consistent and specific hyper-methylation of 2 cytosine residues at -436 bp (% of methylation: STD 62% vs. HFD 90%, $p<0.001$), and -431 bp (% of methylation: STD 38% vs. HFD 83, $p<0.001$) from Ankrd26 Transcription Starting Site. By contrast, no differences in the methylation state of these two specific CpG sites were observed between lean and obese mice upon 8 w of treatment (% of methylation -436 bp: STD 71% vs. HFD 83%; % of methylation -431 bp: STD 65% vs. HFD 58%)

Conclusion: Obesity regulates in a time dependent manner the expression of the Ankrd26 gene by inducing methylation of specific CpG sites on Ankrd26 promoter

Variable	8 weeks		22 weeks	
	STD (n=11)	HFD (n=12)	STD (n=9)	HFD (n=12)
Body weight (g)	24.7 ± 0.6	34.4 ± 0.9 ^a	26.4 ± 0.9	38.8 ± 1.0 ^b

New animal models reveal that two genes are candidates for the onset of type 2 diabetes associated with obesity in rats

D. Sasaki, J. Koto, R. Watadani, Y. Seto, A. Tanida, K. Honda, K. Matumoto;

Kyoto Sangyo University, Japan.

Background and aims: Obesity is a major factor for the onset of type 2 diabetes. However, little is known how obesity induces the onset of type 2 diabetes. So far, many genes responsible for obesity and type diabetes were identified by genome-wide association studies, but only few genes are common between obesity and type 2 diabetes. Since it is difficult to directly search for diabetogenic genes associated with obesity, the use of double congenic rats introgressing both fa/fa obese and diabetogenic gene is an essential component of genetic investigation. In this study, we investigate to identify diabetogenic genes associated with obesity using new obese animal models.

Materials and methods: We generated several congenic strains: (1) single lean congenic introgressed Nidd2 QTL derived from OLETF rat into F344 (F.O-Nidd2/of), (2) single obese congenic introgressed Lepr^{-/-} locus into F344 (F.ZF-Lepr) and (3) double congenic rats having obese and Nidd2 QTL region (F.ZF-Lepr&Nidd2/of). Each strain was phenotyped for plasma glucose, insulin levels and insulin resistance by insulin tolerance test (ITT). In 25 weeks of age, they were sacrificed and then liver, skeletal muscle and abdominal fat tissues were dessected and stored at -80°C until use. RNA and protein levels were determined using reverse transcription-quantitative PCR and western blotting analyses, respectively.

Results: The double congenic strain, F.ZF-Lepr&Nidd2/of (Lepr^{-/-} and Nidd2/of) showed significantly higher glucose levels (60, 90, 120 min after glucose loading : $p<0.001$ vs F.ZF-Lepr), and significantly lower hypoglycemic response to insulin than those of the obese control strain, F.ZF-Lepr (Lepr^{-/-}) (30, 60, 90, 120 min after insulin injection : $p<0.05$ vs F.ZF-Lepr). These phenotypes were observed specifically in the obese strains, but not in the lean strains. These results indicate that the Nidd2/of locus harbours a diabetogenic gene associated with obesity. We measured the expression of 60 genes in the Nidd2/of QTL region between the strains and found that the levels of the mRNA expression of five genes were significantly different between the strains under condition of obesity. Three genes among the five genes were differentially expressed both in obese and lean rats, while the other two genes, Coq2 and Plac8 were differentially expressed specifically only in the obese rats, suggesting that these genes are candidates for the onset of type 2 diabetes associated with obesity in rats (Coq2 : $P=0.00387$ and Plac8 : $p=0.00122$)

Conclusion: Our data show that Coq2 and Plac8 were candidate genes for the onset of type 2 diabetes associated with obesity in rats.

344

Nicotinamide nucleotide transhydrogenase and the glucose regulation of mitochondrial glutathione oxidation, NADPH concentration and insulin secretion in mouse islets

L.R.B. Santos, C. Muller, A.H. Souza, H.K. Takahashi, J.-C. Jonas; UCL, Brussels, Belgium.

Background and aims: Changes in glutathione redox state (E_{GSH}) were recently measured with the redox-sensitive GFP2 probe fused to glutaredoxin 1 (GRX1-roGFP2) and its mitochondrial form (mt-GRX1-roGFP2) in rat islet cell clusters and human islets. We found an inverse correlation between 1) the acute glucose-mediated reduction in E_{GSH} and 2) the acute rise in NAD(P)H autofluorescence and glucose stimulation of insulin secretion (GSIS). Nicotinamide nucleotide transhydrogenase (NNT) is one of several NADPH-producing enzymes in mitochondria that could contribute to these acute glucose effects. Its spontaneous inactivating mutation in C57BL6/J mice was shown to reduce the GSIS

due to reductions in ATP production, β -cell depolarization and Ca^{2+} influx. Here, we tested the impact of a lack of NNT on the acute glucose regulation of mitochondrial E_{GSH} and its role in GSIS and key stimulus-secretion coupling events by comparing islets from C57BL6/J mice with islets from closely-related C57BL6/N mice that express wild-type NNT (J vs. N islets).

Materials and methods: Islets were isolated from 8-16 week-old female C57BL6/J and /N mice. After isolation, the islets were (co)infected with adenoviruses coding (mt-)GRX1-roGFP2, NNT+mCherry (to express wild-type NNT in J islets) or mCherry alone as control, and cultured for 2-4 days. The mitochondrial and cytosolic E_{GSH} , the reduced and oxidized forms of NADP and NAD, ATP and the sum ATP+ADP, the intracellular Ca^{2+} concentration, and insulin secretion were measured after 30-60 min incubation or during perfusion at increasing glucose concentrations from 0.5 (G0.5) to 30 mmol/L (G30) in the presence of 4.8 or 30 mmol/L extracellular K^+ (K4.8 or K30).

Results: In N islets, glucose acutely and significantly reduced mitochondrial E_{GSH} as in rats and humans while increasing NADH/(NADH+NAD⁺) (G30 0.22 ± 0.03 vs. G0.5 0.05 ± 0.01 , $p < 0.01$), NADPH/(NADPH+NADP⁺) (G30 0.72 ± 0.08 vs. G0.5 0.48 ± 0.06 , $p < 0.05$) and ATP/(ATP+ADP) ratios (G30 0.83 ± 0.003 vs. G0.5 0.69 ± 0.003 , $p < 0.001$), Ca^{2+} and insulin secretion in K4.8 or K30 ($p < 0.05$). In J islets, the glucose-induced rises in NADH/(NADH+NAD⁺) (0.21 ± 0.04 vs. 0.04 ± 0.01 , $p < 0.01$), ATP/(ATP+ADP) (0.85 ± 0.01 vs. 0.71 ± 0.02 , $p < 0.001$) and $[\text{Ca}^{2+}]_i$ were similar to those in N-islets. There were also no significant differences between mice for their lack of cytosolic E_{GSH} response to glucose. In contrast to N islets, mitochondrial E_{GSH} was low at all glucose concentrations and NADPH/(NADPH+NADP⁺) was not increased in G30 compared to G0.5 (0.83 ± 0.03 vs. 0.78 ± 0.03) and not decreased by 10 μM of mitochondrial uncoupler FCCP in G30 (0.83 ± 0.02). The GSIS in K4.8 and K30 was 66% lower ($p < 0.05$) in J vs. N islets, but the relative amplifying action of glucose in K30 was preserved (fold-increase vs. G0.5). Importantly, adenovirus-mediated expression of NNT in J islets restored the glucose regulation of mitochondrial E_{GSH} and the glucose (G30 0.84 ± 0.01 vs. G0.5 0.52 ± 0.04 , $p < 0.001$) and FCCP (0.64 ± 0.05 , $p < 0.05$ vs. G30) regulation of the NADPH/(NADPH+NADP⁺) ratio as observed in N islets, and significantly increased GSIS in both K4.8 and K30 conditions.

Conclusion: NNT is responsible for the glucose-induced rise in NADPH/(NADPH+NADP⁺) ratio and reduction in mitochondrial E_{GSH} in pancreatic islets, and increases the GSIS by acting at a site distal to Ca^{2+} influx. The results also suggest that NNT works in the reverse mode of operation in islets exposed to a low glucose concentration or to FCCP.

Mitochondrial mutations affect cellular calcium homeostasis in the aging organism and could support development of type 2 diabetes mellitus

J. Niemann, C. John, M. Tiedge, S. Baltrusch;

Institute of Medical Biochemistry and Molecular Biology, University Rostock, Germany.

Background and aims: It was postulated that mutations in the mitochondrial genome (mtDNA) which accumulate in age can contribute to the pathogenesis of type 2 diabetes mellitus (T2DM). In mice there is a maximum value in ROS generation in liver at the age of 9 months. At an advanced age there is a decreased value in ROS generation and a reduced membrane potential in C57BL/6N mice (control). However, in conplastic C57BL/6N-Tac-mtNOD/LtJ-mice (mtNOD) carrying a point mutation in complex IV of the respiratory chain ROS generation remains constantly high and membrane potential increased in age. The aim of this study was to examine if an altered calcium homeostasis contributes to this adaption in the mtNOD mouse strain.

Materials and methods: Hepatocytes of 3, 6, 9 and 12 months old control- and mtNOD mice were isolated and transfected with the cyto(plasmatic)-CAR-GECO and the mito(chondrial)-GEM-GECO vector. Fluorescence intensity of the resulting proteins depends on calcium binding. Cells were analysed after starvation and subsequent glucose supply (25 mmol/l) by means of fluorescence microscopy. In addition, RNA was isolated from hepatocytes and gene expression of uncoupling protein 2 (UCP2) and the mitochondrial calcium uniporter (MCU) were investigated by quantitative Real-Time PCR.

Results: Cytosolic Calcium influx after glucose supply was comparable at the age of 3 months in both strains. At the age of 6 months this influx was reduced in controls and mtNOD mice. The cytosolic calcium influx was highest in 12 months old controls with a significant increase compared to 6 months old mice. In contrast, in mtNOD mice cytosolic calcium influx in 9 and 12 months old animals was comparable to 3 months old animals. Interestingly, the age dependent pattern of glucose-induced cytosolic calcium influx was in line with the gene expression of UCP2 suggesting a relationship of both parameters. At the age of 3 months mitochondrial calcium influx was significantly higher in mtNOD mice compared to controls. A slight increase of the mitochondrial calcium influx was observed in controls during aging, whereas there is a strong and significant decrease in mtNOD mice. Notably, the age dependent decline of the glucose-induced mitochondrial calcium influx after fasting occurred inversely to the increase in the mitochondrial membrane potential in hepatocytes. Gene expression of the MCU was comparable in 3 month old animals. It remained unchanged during aging in controls, whereas a significant increase was observed in 9 and 12 versus 3 months old mtNOD mice.

Conclusion: The mitochondrial calcium influx declined at the age of 9 months in both strains compared to the cytosolic calcium influx in hepatocytes. However, control and mtNOD mice adapted in a different manner. Control mice increased the cytosolic calcium influx, whereas mtNOD up-regulated MCU gene expression. Our data suggest reduced sensitivity to external triggers including insulin in mtNOD mice in age. Thus, the C57BL/6N-Tac-mtNOD/AtJ mouse strain represents an interesting model to study trigger effects of age dependent mitochondrial regulation in the pathogenesis of T2DM.

346

Deletion of the type 2 diabetes-associated gene product STARD10 in mice impairs insulin secretion and action

G.A. Rutter, G.R. Carrat, M.-S. Nguyen-tu, P. Chabosseau;

Dept. Cell Biology, Div. Diabetes, Endocrinology & Metabolism, Imperial College, London, UK.

Background and aims: Genome-wide association studies have identified more than 90 loci associated with type 2 diabetes risk. Recently-identified common genetic variants in the ARAP1/STARD10 locus affect fasting proinsulin levels (rs11603334) and glucose-induced insulin secretion (rs1552224) in man. The implicated single nucleotide polymorphisms (SNPs) are located in the 5'UTR of the ARAP1 gene and ~40 kb downstream of the STARD10 gene. The product of the latter gene, StAR-related lipid transfer (START) domain containing 10, is involved in the intracellular transport of phospholipids. Here, we show that global deletion of the StarD10 gene in mice leads to marked defects in both insulin secretion and insulin sensitivity.

Materials and methods: Null alleles of StarD10 (Tm1a), bearing a LacZ-neo-STOP cassette downstream of exon 2, were provided through the International Mouse Phenotyping Consortium (IMPC) and maintained on a C57BL6 background. Loss of StarD10 mRNA from liver and islets was confirmed by qRT-PCR. Transgenic mice were generated by pronuclear injection of DNA encoding FLAG-tagged StarD10 under tetracycline-regulated promoter control. Crossing with RIP7-rtTA mice, expressing the reverse tetracycline transactivator under the control of the rat insulin promoter, allowed β -cell-specific, tetracycline-inducible expression in adult mice, and was confirmed by qRT-PCR analysis and

Western (immuno-) blotting. Measurement of glycemic parameters in vivo, islet isolation, intracellular Ca²⁺ imaging and insulin secretion, were performed using standard protocols.

Results: Compared to wild type (WT) littermates, mice deleted globally for StarD10 (KO), and assessed at 14–16 weeks of age, displayed increased fed glycemia (WT, 8.1±0.1 mmol/L vs KO, 9.7±0.3, *p*<0.001), intraperitoneal glucose (1 g/kg; AUC: WT, 1169±34 WT vs KO, 1274±30 mmol/l*min., *p*=0.034) and insulin (0.75 U/kg; AUC: WT, 875±62 vs KO, 670±34 pM*min., *p*<0.01) tolerance. Glucose- (3 g/kg) stimulated insulin secretion was also sharply reduced in vivo in knockout mice (AUC: WT, 50.37±22.53 vs KO, 40.57±6.65 pM*min., *p*=0.026). Correspondingly, glucose- (17 vs 3 mM) induced insulin secretion (WT, 0.86±0.05%; KO, 0.21±0.03% *p*<0.001) and cytoplasmic Ca²⁺ increases, assessed using the entrappable fluorescent probe fluo-2, and confocal imaging of whole islets (fold-change: WT, 23.5%±1.7 fold change vs KO, 15.4%±1.9, *p*<0.001) were reduced in islets from KO mice versus those from WT littermates. Transgenic StarD10 male mice displayed a tendency towards reduced glucose tolerance (AUC: WT, 1251±36; Tg: 1397±69 mmol/l*min., *p*=0.076) at 16 weeks, but were otherwise normoglycemic. Correspondingly, adenovirus-mediated overexpression of StarD10 in mouse islets exerted no effect on insulin secretion stimulated by glucose (17 vs 3 mmol/L) or KCl (30 mM/L). However, overexpression of StarD10 potentiated apoptosis induced by staurosporine (1 μM) in mouse islets, as assessed by Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) staining (control: 1.85±0.23%; StarD10: 4.60±0.62%; *p*<0.0001).

Conclusion: These data indicate that lowered expression of StarD10 gene in risk allele carriers may contribute to exaggerated disease risk, and may act both via changes in insulin secretion and action.

A novel gene, R3h domain containing-like, might play a role in muscle regeneration

K. Sakamoto, M. Takemoto, T. Ishikawa, R. Ishibashi, P. He, A. Hattori, M. Yamaga, M. Shoji, S. Ide, K. Ide, H. Kawamura, K. Kobayashi, H. Tokuyama, Y. Maezawa, K. Yokote;

Department of Clinical Cell Biology and Medicine, Chiba University Graduate School of Medicine, Japan.

Background and aims: Skeletal muscles are fundamentally important not only for physiological activities but also for maintaining normal glucose homeostasis. Sarcopenia, a loss of muscle mass that is often seen in the elderly patients with type 2 diabetes, might be caused by the disability of muscles to regenerate, thus inducing frailty and insulin resistance. Although the number of geriatric patients with type 2 diabetes has increased worldwide, the mechanisms underlying sarcopenia and muscle regeneration have not yet been understood. We previously reported that the R3h domain containing-like (R3hdml) gene, a podocyte-specific transcript, inhibited TGF-β-induced p38 MAPK signaling. Furthermore, it has been reported that TGF-β-induced p38 MAPK signaling is important for muscle regeneration. In addition, a meta-analysis of genome-wide association studies has identified a gene locus including the R3hdml gene as a risk allele for type 2 diabetes in East Asians. Therefore, we have begun investigating the function of R3hdml in skeletal muscle, particularly focusing on muscle regeneration.

Materials and methods: R3hdml expressions in skeletal muscle regeneration model mice [10 mM cardiotoxin (CTX) was injected in the tibialis anterior muscle or quadriceps] were evaluated by real-time polymerase chain reaction (qPCR) and western blotting (WB). C2C12 cells, a mouse myoblast cell line, were differentiated into myotubes in the presence of 2% horse serum for 5 days; thereafter, the expressions of R3hdml as well as transcription factors that related to muscle differentiation were examined by qPCR and WB. R3hdml was then silenced with small interfering RNA (siRNA)

and the effects of R3hdml on the formation of myotubes were examined. The expressions of R3hdml in skeletal muscle were also studied in wild-type control mice, db/db mice fed or not fed a high-fat diet for 7 weeks.

Results: R3hdml was not detected in skeletal muscle under physiological conditions. However the expressions of R3hdml were increased upon injury of skeletal muscle with CTX indicating that R3hdml expressions were induced by skeletal muscle regeneration. Neither R3hdml mRNA nor protein were detected in undifferentiated C2C12 cells, however their expressions increased along with differentiation of C2C12 cell. The expression of Pax 7, a marker for early muscle differentiation, was decreased and myotubule formation was attenuated by 26.1% when the R3hdml gene was silenced by siRNA in C2C12 cell. Finally, the expressions of R3hdml were also increased in skeletal muscle under diabetic conditions where chronic inflammation and muscle regeneration took place to a lesser extent compared to CTX model.

Conclusion: Since the disability of muscles to regenerate were often observed in geriatric patients with type 2 diabetes, R3hdml, a novel skeletal muscle expressed gene, may play a role not only in glucose metabolism but also in sarcopenia development through the modulation of skeletal muscle regeneration.

PS 012 Prevalence of type 2 diabetes and related factors around the world

348

Evaluation of clinical risk factors for diabetes screening in a large cohort of subjects in a primary care setting

L. Czupryniak¹, M.T. Małecki², K. Strojek³, E. Szymańska-Garbacz¹, P. Bijoś⁴, J. Loba¹;

¹Medical University of Lodz, ²Collegium Medicum, Cracow, ³Silesian Medical University, Lodz, ⁴TEVA Pharmaceuticals, Kutno, Poland.

Background and aims: Timely diagnosis of diabetes remains a global challenge as many subjects with diabetes are unaware of their condition. A simple diagnostic strategy which could help decrease the rate of undiagnosed diabetes is needed. The aim of this study was to evaluate the performance of classical clinical risk factors in screening for diabetes in a large group of individuals in a primary care settings.

Materials and methods: In 2014 we conducted a primary care physician-based nationwide screening programme aiming at identifying individuals with undiagnosed diabetes or prediabetes. A total of 561 primary care physicians (PCPs) took part in the programme, and 21 726 subjects were enrolled. The inclusion criteria were following: no earlier diagnosis of diabetes or prediabetes (i.e. IFG and/or IGT) and the presence of at least one classical risk factor: age>45 yrs, family history of diabetes, sedentary lifestyle, smoking, presence of fatty liver disease, hypertension, hyperlipidemia, coronary artery disease, peripheral artery disease, obstructive sleep apnoea syndrome, polycystic ovary syndrome, history of stroke, gestational diabetes or having a child with birth weight>4 kg as well as BMI>25 kg/m² or waist circumference>80 cm in women or 94 cm in men. All subjects underwent fasting plasma glucose (FPG) measurement, and those individuals in whom its value exceeded 125 mg/dl were referred to have second FPG measured at least one week later, while those in whom the initial FPG measurement was between 100 and 125 mg/dl had an oral 75 g glucose tolerance test (OGTT) performed.

Results: The prevalence of all risk factors assessed in the examined cohort is presented in Table 1. In the whole group diabetes was diagnosed in 4221 (19.4%), and prediabetes in 5829 (26.8%) of the subjects, thus 10 050 (46.3%) of the individuals in the study were found to have any degree of glucose metabolism abnormalities. The majority of diabetes cases (2825/4221, i.e. 66.9% of the diagnosed group) were diagnosed based on two FPG measurements >125 mg/dl. In 6265 (28.8%) of the subjects the concomitant presence of three main unmodifiable risk factors, which are also simply identified in PCP setting, i.e.: age>45 years, family history of diabetes and BMI>25 kg/m² were found. In this subgroup 1989 (31.7%) individuals were found to have diabetes and 2101 (33.5%) to have prediabetes, thus, the rate of glucose metabolism abnormalities reached 65.2% in these subjects. The odds ratio for diabetes in this subgroup was 2.757 (95% CI 2.57-2.957), and for diabetes or prediabetes it was 2.998 (2.818-3.189), as compared to those with only one or two co-existing features.

Conclusion: Our data support the use of classical clinical risk factors in screening for diabetes in a primary care setting. Particular effort should be put into testing individuals older than 45 years who have a family history of diabetes and are overweight.

	N	%
Age> 45 yrs	17 740	81.7
Sedentary lifestyle	13 814	63.6
Hypertension	13 427	61.8
BMI>25 kg/m ²	13 379	61.6
Hyperlipidemia	12 842	59.1
Waist circumference >80 (F) or >94 cm (M)	12 728	58.6
Family history of diabetes	10 890	50.1
Smoking	8 635	39.7
Alcohol abuse	3 122	14.4
Coronary artery disease	4 803	22.1
Fatty liver disease	4 345	20.0
Peripheral artery disease	2 794	12.9
Obstructive sleep apnoea	2 041	9.4
History of stroke	1 344	6.2
Giving birth to child >4 kg	2 118	19.6 (of women)
History of gestational diabetes	1 820	16.8 (of women)
Polycystic ovary syndrome	1 267	11.6 (of women)

One in four subjects above the age of 20 years could have diabetes in Bangalore

S.M. Rajbhandari^{1,2}, Diabetacare Screening Team;

¹Diabetes Dept, Chorley & South Ribble Hospital, Chorley, UK,

²Diabetacare, Bangalore, India.

Background and aims: The number of people with diabetes in India is increasing due to population growth and aging, urbanization, increasing prevalence of obesity and physical inactivity. Despite this, there are no good studies on the prevalence of diabetes and risk factors associated with it. This cross-sectional population survey was undertaken to determine the prevalence of diabetes and impaired glucose in an urban population of Bangalore, India and its association with dietary habits.

Materials and methods: Subjects were invited to attend screening for blood glucose, blood pressure, dietary history and anthropometric measurement at various venues across the city of Bangalore. Local publicity in and around the venue were done few days prior to the event. It was a free event and people could come anytime without appointment.

Results: 3882 subjects were screened over a period of 15 months at 32 venues. Out of this 29 subjects below the age of 20 years and 133 subjects without blood glucose data were excluded from analysis. Diabetes (DM) was defined as history of self-reported condition or random blood glucose of 11.1 mmol/L (200 mg%) or more. Impaired glucose (IG) was defined as those subjects with diabetes or random blood glucose of 7.8 mmol/L (140 mg%) or more. Out of 3720 patients the prevalence of DM was 24.5% (n=913) and that of IG was 30.5% (n=1134). Out of these 846 (21.8%) subjects were already known to have diabetes. Of the remaining 2874 people, 67 (2.3%) had possible diabetes and 288 (10.0%) had IG, which were discovered on the day. Prevalence of both diagnosed and undiagnosed diabetes was high in older subjects (Table 1). There were no relation (p>0.05) in blood pressure (BP), weight and Body Mass Index (BMI) in this population between subjects with or without diabetes. Regarding dietary habit, there was no difference in BP, weight, BMI and blood glucose between vegetarian and non-vegetarian subjects. Interestingly there were significantly more males in non-vegetarian group (53.1% vs 60.4; p=0.01).

Conclusion: Our data suggest that DM & IG is present in about a quarter of the urban Indian population. 10% of population above the age of 20 years have glucose abnormalities of which they are not aware. Therefore regular screening from the general population in urban area is necessary to avert or delay the progression to DM and reduce diabetes-related morbidity and mortality.

Age Group (Years)	20 - 29	30 - 39	40 - 49	50 - 59	60 - 69	> 70
Total number	730	872	766	694	500	158
Diagnosed Diabetes	19 (2.6%)	83 (9.5%)	185 (24.2%)	262 (37.8%)	219 (43.8%)	78 (49.4%)
Not known to have Diabetes	711	789	581	432	281	80
Undiagnosed Impaired Glucose	20 (2.8%)	59 (7.5%)	77 (13.3%)	76 (17.6%)	43 (15.3%)	13 (16.3%)
Undiagnosed Diabetes	2 (0.3%)	9 (1.1%)	22 (3.8%)	18 (4.2%)	11 (3.9%)	5 (6.3%)

The prevalence of hypothyroidism is gender-neutrally increased by autoimmune diabetes but unaffected by type 2 diabetes: the population-based HUNT study in Norway

H.F. Fleiner¹, B.O. Åsvold², V. Grill¹;

¹Department of Cancer Research and Molecular Medicine, ²Department of Public Health and General Practice, Norwegian University of Science and Technology, Trondheim, Norway.

Background and aims: Associations between autoimmune diabetes and hypothyroidism are known, but insufficiently characterized. Some previous studies suggest that type 2 diabetes is associated with hypothyroidism. The aims were to analyse the impact of autoimmune diabetes on the prevalence of hypothyroidism specifically with regard to gender, and to test for associations between type 2 diabetes and hypothyroidism.

Materials and methods: Cross-sectional population-based studies of adults in two surveys of the HUNT Study. Data were available for 34,287 participants of HUNT2 (1995-97) and 48,598 participants of HUNT3 (2006-08). Prevalence of hypothyroidism was assessed by self-report, TSH measurements and, for HUNT3, linkage with the Norwegian Prescription Database.

Results: In HUNT2, the prevalence of hypothyroidism was in nondiabetics 2.7 fold higher among women (8.3%) than in men (3.1%). Autoimmune diabetes increased the prevalence in women to 15.8% and in men to 10.9%. Thus, compared with having no diabetes, autoimmune diabetes was associated with a 64% higher age-adjusted prevalence of hypothyroidism among women (prevalence ratio [PR] 1.64, 95% confidence interval [CI] 1.15-2.34) but an almost three times higher age-adjusted prevalence of hypothyroidism among men (PR 2.93, 95% CI 1.90-4.52). Type 2 diabetes was not associated with the prevalence of hypothyroidism. In HUNT3 the associations were broadly similar to those in HUNT2.

Conclusion: 1) The enhancing effect of autoimmune diabetes on the prevalence of hypothyroidism was gender neutral, thus decreasing the difference in prevalence between women and men, 2) type 2 diabetes did not incur increased risk of hypothyroidism, thus contradicting the notion that increased surveillance for hypothyroidism is necessary in patients with type 2 diabetes.

Prevalence of diabetes mellitus and its associated risk indicators in a peripheral region of Bangladeshi population

F. Jasmine¹, K. Fatema^{2,3}, L. Ali⁴;

¹Department of Health Promotion and Health Education, ²Department of Epidemiology, Bangladesh University of Health Sciences, Dhaka, Bangladesh, ³The School of Public Health and Community Medicine, Faculty of Medicine, The University of New South Wales, Sydney, Australia, ⁴Department of Molecular and Cell Biology, Bangladesh University of Health Sciences, Dhaka, Bangladesh.

Background and aims: A large racial heterogeneity in diabetes suggests that there is a need of conducting epidemiological studies in different

communities. There is scarcity of such studies in Bangladesh, particularly in remote rural areas. The objectives of this study were to estimate the prevalence of diabetes and to identify its associated risk indicators in a rural population of Bangladesh.

Materials and methods: In 2008, a large cohort was initiated that followed up in 2011 where we screened a proportion (subset of 63708 participants, aged 31-74) of this cohort for cardiovascular disease related risk factors using WHO CVD Risk Management Package 2002' under a cross-sectional design. The study participants (n=1732, male=834 and female=898) were randomly selected from the subset and screened in a camp setting. Diabetes was diagnosed based on WHO study group Criteria after a 2-hr OGTT, body mass index (BMI), waist-hip ratio (WHR), blood pressure and lipid profile were also estimated.

Results: The prevalence of diabetes was found to be 14.2% (95%CI 12.6-15.9) and that of impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) was 7.9 (95%CI 6.7-9.3) and 4.3 (95%CI 3.4-5.3) respectively. The prevalence of diabetes and impaired glucose regulation differed between males and females (p<0.005), but, both increased with age in males as well as in females. After adjusting for potential confounders WHR, hypertension, smoking, triglyceride and cholesterol were found as significant independent risk indicators for the occurrence of diabetes in this population.

Conclusion: Fairly a high prevalence of diabetes was observed in this remote rural Bangladeshi population. Preventive programs, particularly targeted to WHR management, lipid profile control through lifestyle modification should be strengthened in rural areas. Most of the existing research conducted in Bangladeshi rural settings has been in rural areas adjacent to urban spaces, whereas a remote rural area is one geographically and behaviorally distinct from urban influences.

352

Nation-wide estimated prevalence of diabetes in Greece: identification of patients with prescribed pharmacological treatment among 94.5% of the total Greek population

S. Liatis¹, G. Dafoulas¹, N. Tentolouris¹, A. Kokkinos¹, M. Arvanitis¹, E. Diakoumopoulou¹, C. Kani², A. Politi², P. Litsa², P.P. Sfikakis¹, K. Makrilakis¹;

¹First Department of Propaedeutic Medicine, Diabetes Center, Athens University Medical School Laiko Hospital, ²Medicines Department, National Organization for the Health Care Services Provision, Athens, Greece.

Background and aims: The prevalence of diabetes in Greece is virtually unknown, despite several regional, small-scale epidemiological studies. Since Greece is among the first countries that developed a nationwide electronic drug prescription system, we aimed to identify all patients with prescribed pharmacological treatment for diabetes.

Materials and methods: The Business Intelligence database system of the Greek National Organization for Healthcare Services Provision (EOPYY), which includes big data from e-prescriptions and handwritten prescriptions, was used to provide analytics on these patients (date of birth and gender, based on the unique citizens' social security numbers and the relevant ICD-10 codes). Permission for use of anonymized data was obtained by the administration of EOPYY together with the positive recommendation of the General Secretariat for Public Health of the Greek Ministry of Health, in accordance to the national legislation on Personal Data Protection.

We defined people with diabetes as those who received at least two prescriptions with an ICD-10 code relevant to diabetes (E10, E11 or O24), dispensed by Greek pharmacies between January 1st 2014 and December 31st 2014.

Results: This analysis included 10,222,778 individuals (5,012,226 (49.03%) males and 5,210,552 (50.97%) females, representing 94.5% of the total Greek population, according to the 2011 national census)

and revealed that the prevalence of drug-prescribed diabetes is 7.21% (736,900 individuals). There is no difference between males and females (360,335 vs. 376,565; 7.19% vs. 7.23%, respectively). There is a strong positive association with age, increasing from 0.12% at the age group of 5–14 years, to 3.45% at the age group of 45–54 years and up to 32.11% in those older than 75 years (p for trend < 0.001).

Conclusion: In this first nation-wide analysis of data for the prevalence of drug-prescribed diabetes in Greece, it was found that its prevalence is 7.21%, one of the highest in Europe. It is presumed that these data provide reliable estimates of descriptive epidemiology of diabetes, since the analysis of such big databases largely overrides incorrect diagnosis-associated limitations that an electronic prescription system may have.

353

Trends in diabetes mellitus in Greece from 2003 to 2014 with a future projection. The SALAMINA study

O. Apostolou¹, A. Koutsovasilis¹, P. Stamataki², M. Pappa¹, D. Kraniou¹, S. Pappas¹, A. Sotiropoulos¹;

¹3rd Internal Medicine Department & Diabetes Center, General Hospital of Nikaia-Piraeus, ²Salamina Navy Hospital, Athens, Greece.

Background and aims: Diabetes mellitus (DM) is becoming a world-wide epidemic. The International Diabetes Federation (IDF) recently readjusted its estimations on DM, predicting a higher prevalence, and, according to its data, the prevalence in Greece should be 10.2% for 2013. The aim of the present study is to examine DM prevalence in the adult population of Salamina island, where relevant studies have been carried out in 2003 and 2006 with the same methodology, as well as to estimate DM prevalence in Greece for 2032 according to most recent data.

Materials and methods: Data was derived from three consecutive population-based surveys conducted in Salamina, during three election days (13 October 2002, 15 October 2006 and 25 May 2014). In all three surveys the same selection procedure was used and data was collected using the same questionnaire, completed by almost the same team of interviewers. There were 2805 randomly selected adults (≥ 20 years) in 2002, 3478 in 2006 and 2527 in 2014 of similar age and sex distribution to the target population. Demographic and anthropometric data relevant to DM (duration, medication, family history) as well as presence of cardiovascular risk factors or other comorbidities were recorded. Statistical analysis was carried out with SPSS v21.0 (Chicago, Illinois, USA).

Results: There was no statistically significant difference in age in all three surveys ($p=0.251$). The overall crude prevalence of diabetes increased significantly, from 245 (8.7%) in 2002 to 358 (10.3%) in 2006 and to 318 (12.6%) in 2014 ($p=0.028$). The rates per age group for the 2002, 2006 and 2014 surveys were: 0.4%, 0.6% and 0.3% ($p=0.128$) in individuals aged 20–29, 3.6%, 3.7% and 1.9% ($p=0.048$) in individuals aged 30–39%, 7.3%, 7.2% and 9.4% ($p=0.033$) in individuals aged 40–49, 21.6%, 21.2% and 26.4% ($p=0.026$) in individuals aged 50–59, 31.8%, 31.2% and 30.2% ($p=0.214$), in individuals aged 60–69, and 35%, 36% and 31.8% ($p=0.030$) in individuals aged over 70. The mean age for diabetes diagnosis was 57.6 ± 11.9 while the mean diabetes duration was 12.3 years for 2014 comparable with the other two surveys ($p=0.086$). Only 3.2% of participants reported they were under dietary treatment in 2014 ($p=0.016$), while more diabetes patients were under insulin treatment (26.4%) compared to those in 2002 and 2006 ($p=0.012$). 79.7% of the individuals who answered the questionnaire had had laboratory tests for glucose levels and lipids during the last 12 months in 2014 which is a significantly higher rate compared to higher the rest of the surveys ($p=0.022$). Using a Markov model to estimate the future diabetes prevalence, a dramatic increase in diabetes prevalence was predicted for 2032 (19.8%)

Conclusion: DM prevalence is higher than the one predicted according to older studies, basically confirming IDF's predictions. An increase of prevalence is observed in younger ages and, according to the prediction for

2032, approximately one out of five people in Greece will have diabetes which indicates a dramatic increase in diabetes prevalence among Greek adults.

354

Screening for prediabetes in adults aged 45–55 years in primary care setting should be universal rather than risk-factors based

J. Loba, E. Szymanska-Garbacz, M. Pawlowski, M. Saryusz-Wolska, L. Czupryniak;

Medical University of Lodz, Poland.

Background and aims: Current guidelines recommend yearly screening towards glucose metabolism disturbances in individuals aged >45 years, in whom risk factors for diabetes development are present. However, as prediabetes is a clinically silent condition, its early diagnosis remains a challenge. Middle aged professionally active adults are particularly non-compliant with screening procedures. We conducted a study aiming at assessing the use of risk factors-based screening for impaired fasting glucose (IFG) in primary care setting.

Materials and methods: 5276 diabetes-free individuals (2963 women; 56% women) aged 45–55 years, who had at least one risk factor for diabetes development took part in a nationwide diabetes screening programme conducted at primary care level. The participants underwent full medical examination and had their fasting plasma glucose (FPG) assessed during a visit at their primary care physician office.

Results: Normal FPG (>100 mg/dl) was found in 1421 (27%), while IFG (100–125 mg/dl) in 1860 (35%) persons. FPG >125 mg/dl was found in 1995 (38%) individuals, and they were excluded from further analysis. The prevalence of well established risk factors for glucose metabolism disturbances in IFG and NFG individuals is presented in the Table. Sedentary lifestyle, family history of diabetes and newly diagnosed hypertension were similarly prevalent in both studied groups, however even when differences in prevalence of other risk factors reached statistical significance, the actual difference was relatively small, with the exception of the history of IFG as it was found almost twice as often in persons with IFG as compared to those with normal fasting plasma glucose.

Conclusion: In conclusion, the prevalence of IFG in adults aged 44–55 years with risk factors is high. Prediabetes screening programmes conducted in high risk population in this age group should be universal rather than risk factors based. In particular, they must not be based on family history of diabetes or sedentary lifestyle as these factors are equally often present in persons with IFG as well as normal fasting glucose.

	IFG (n=1860)		NFG (n=1421)		Absolute prevalence difference (APD) %	Relative prevalence difference (APD/IFG in %)	p
	n	%	n	%

Racial differences in glycaemic marker levels among individuals without diabetes: the coronary artery risk development in young adults studyA.P. Carson¹, P. Muntner¹, E. Selvin², M.R. Carnethon³, M.D. Gross⁴, W.T. Garvey¹, C.E. Lewis¹;¹University of Alabama at Birmingham, ²Johns Hopkins University, Baltimore, ³Northwestern University, Chicago, ⁴University of Minnesota, Minneapolis, USA.

Background and aims: Prior studies have reported that glycaemic marker levels vary by race and ethnicity among individuals without diabetes. However, it is unclear whether these racial differences occur among both individuals at high-risk for diabetes (i.e., prediabetes) and those with normal glycaemic levels and, if so, whether these differences are clinically meaningful. The aim of this study was to assess glycaemic marker levels (i.e., fasting glucose, 2-hour post-challenge glucose from OGTT, HbA1c, glycated albumin, fructosamine, and 1,5-anhydroglucitol) by race among individuals with and without prediabetes in a cohort study of adults in the United States.

Materials and methods: The Coronary Artery Risk Development in Young Adults (CARDIA) Study is a prospective cohort study of 5,115 African American and white adults, age 18–30 years at baseline (1985–86), from four field centers. This analysis included 2,465 participants who attended the year 20 examination (2005–06), had glycaemic marker data available, and did not have diabetes (defined as fasting glucose ≥ 126 mg/dL, 2-hour post-challenge glucose ≥ 200 mg/dL, HbA1c $\geq 6.5\%$, or use of diabetes medications). Prediabetes was defined as a fasting glucose of 100–125 mg/dL, 2-hour post-challenge glucose of 140–199 mg/dL, or HbA1c of 5.7–6.4%. Multiple regression models were used to assess the association of race with each glycaemic marker, stratified by prediabetes status.

Results: The mean age of participants was 45 years. Overall, 42% of participants were African American, 55% were female, and 39% had prediabetes. Among those with prediabetes, African Americans had lower fasting glucose (−1.59 mg/dL), but higher HbA1c (0.26%), glycated albumin (0.82%), and fructosamine (8.96 $\mu\text{mol/L}$) compared with whites after multivariable adjustment. No racial differences were observed for 2-hour post-challenge glucose or 1,5-anhydroglucitol among those with prediabetes (Table). Similarly, among normoglycaemic individuals, African Americans had lower fasting glucose (−2.24 mg/dL) and 1,5-anhydroglucitol (−0.66 $\mu\text{g/mL}$), but higher HbA1c (0.04%), glycated albumin (0.61%), and fructosamine (5.97 $\mu\text{mol/L}$) compared with whites. No racial difference was observed for 2-hour post-challenge glucose among normoglycaemic individuals (Table).

Conclusion: Racial differences in glycaemic marker levels were observed across the glycaemic spectrum, among both individuals with prediabetes or normal glycaemia. These differences were small and not clinically divergent, although African Americans tended to have slightly more adverse glycaemic levels than whites for most glycaemic markers. Further investigation of the potential prognostic implications, if any, are warranted.

Table. Glycaemic marker levels for African Americans and whites, stratified by prediabetes status in the CARDIA Study

Glycaemic Marker	Prediabetes			Normal Glycaemia		
	Least Square Means	β (95% CI)		Least Square Means	β (95% CI)	
	African American (N=482)	White (N=483)	African American versus White	African American (N=562)	White (N=938)	African American versus White
Fasting glucose (mg/dL)	100.57	102.16	−1.59* (−2.86, −0.32)	89.01	91.25	−2.24* (−2.99, −1.50)
2-hr post-challenge glucose (mg/dL)	116.02	118.87	−2.85 (−7.70, 2.00)	93.57	91.97	1.60 (−0.97, 4.16)
HbA1c (%)	5.76	5.50	0.26* (0.21, 0.31)	5.25	5.22	0.04* (0.00, 0.07)
Glycated albumin (%)	12.96	12.14	0.82* (0.66, 0.99)	12.73	12.12	0.61* (0.50, 0.73)
Fructosamine ($\mu\text{mol/L}$)	228.29	219.33	8.96* (6.46, 11.46)	228.41	222.44	5.97* (4.13, 7.80)
1,5-anhydroglucitol ($\mu\text{g/mL}$)	19.91	19.87	0.04 (−0.78, 0.87)	18.80	19.46	−0.66* (−1.30, −0.03)

356

Changes in the use of antidiabetic, antihypertensive, and hypolipidaemic drugs within 30 months after Roux-en-Y gastric bypass surgeryS.B. Gribsholt¹, E. Svensson², R.W. Thomsen², H.T. Sørensen², D.K. Farkas², B. Richelsen¹;¹Department of Endocrinology and Internal Medicine, ²Department of Clinical Epidemiology, Aarhus University Hospital, Denmark.

Background and aims: In the majority of patients undergoing Roux-en-Y gastric bypass (RYGB) surgery, obesity-related complications such as diabetes and hypertension may improve or remit, with concomitant reduction or discontinuation of medications. Relapse of these complications may occur in some patients after a few years, but studies with long-term follow-up are sparse. We investigated long-term changes in use of antidiabetic, antihypertensive, and hypolipidemic drugs among patients, who underwent RYGB surgery. Furthermore, we compared changes in use of these drugs among RYGB patients with that in a matched comparison cohort of persons without RYGB.

Materials and methods: The study included all 9,908 individuals undergoing RYGB in Denmark during 2006–2010 and a 10:1 matched general population comparison cohort of 99,080 persons, using age, gender, and RYGB/index date as matching variables. We ascertained complete data on medication use from population-based medical databases. All subjects were followed from 6 months prior to the RYGB/index date until 30 months following this date. We computed the proportion of subjects in each cohort with current drug use and prevalence ratios (PRs) comparing use 6 months before and 30 months after the RYGB/index date, using Poisson regression analysis.

Results: The mean age in both cohorts was 40.6 years; 21.7% were male. Figure 1 shows changes in drug use prior to and following the RYGB/index date. Among the RYGB patients 16.5% used antidiabetic drugs 6 months before surgery, while 4.7% were on antidiabetic drugs 30 months after surgery [PR=0.27 (95% confidence interval (CI): 0.27, 0.27)]. In the comparison cohort 2.0% used antidiabetic drugs 6 months before the index date and 2.4% used them 30 months after the index date [PR=1.25 (95% CI: 1.24, 1.25)]. Like antidiabetic drugs, use of hypolipidemic drugs decreased in the RYGB cohort: 14.4% used them 6 months prior to surgery vs. 7.3% 30 months after surgery [PR=0.49 (95% CI: 0.48, 0.49)]. In the comparison cohort 3.8% used hypolipidemic drugs 6 months before the index date, while 5.4% used them 30 months later [PR=1.41 (95% CI: 1.41, 1.42)]. For antihypertensives, 43.2% of RYGB patients were users prior to their surgery compared with 26.1% 30 months after surgery [PR=0.67 (95% CI: 0.67–0.67)]. In the comparison cohort 10.1% used antihypertensives 6 months before and 11.9% 30 months after the index date [PR=1.22 (95% CI: 1.22–1.22)].

Conclusion: In this nationwide population-based study, we observed large reductions in use of antidiabetic, hypolipidemic, and antihypertensive drugs occurring rapidly after RYGB surgery. This reduction was maintained over 30 months of follow up, with little indication of relapse as indicated by drug use. Nonetheless, use of these drugs remained higher among RYGB patients than in the matched comparison cohort.

Figure 1. Use of antidiabetic, antihypertensive, and hypolipidemic drugs among 9,908 patients who underwent Roux-en Y Gastric Bypass surgery and 99,080 persons in a matched comparison cohort, from 6 months before and until 30 months after the surgery/index date.

Impact of pre-existing cardiovascular disease on treatment initiation with SU in Denmark: a registry based population study

J. Rungby¹, N. Lassota², A.D. Jørgensen², R. Ibsen³, J. Kjellberg⁴; ¹Gentofte University Hospital and Dept. Biomedicine, Aarhus University, Gentofte and Aarhus, ²MSD Danmark, Ballerup, ³12Minds, Aarhus, ⁴KORA - Danish Institute for Local and Regional Government Research, Copenhagen, Denmark.

Background and aims: Uncertainties about the cardiovascular (CV) safety of sulphonylureas (SU) are reflected in package labels and treatment guidelines. Utilizing Danish national registries, we examined whether this has affected the prescription patterns for SU in Denmark.

Materials and methods: We analysed the development of new SU users (initiation of SU monotherapy or SU supplementation to any other anti-diabetic drugs) from 2006 to 2012. History of CV disease (ICD-10: I00-I99) 0-13 years prior to initiating SU treatment was assessed in this population and among new users of any other oral anti-diabetic drug (OAD). Since there has been speculation that gliclazide might be associated with a more benign CV profile than other SU's an additional analysis was conducted where gliclazide was excluded from the SU group. Furthermore the analysis was done separately for two sub-groups of CV disease, namely of coronary heart disease (ICD-10: I20-I25, I46) and myocardial infarct (ICD-10: I21-I22).

Results: We observed a reduction in the number of new SU users during the period from 10,530 to 3,876, representing a decrease of 63.2% (figure 1). The relative proportion of new SU users with pre-existing CV disease increased numerically from 2006 to 2012 (46.9% vs. 48.7%; $p=0.06$). During the entire period the proportion of new SU users with pre-existing CV disease remained higher than the corresponding proportion for other OAD's (figure 1, $P<0.001$ all years). It did not alter the result to exclude the new users of gliclazide (8-12% of the new users of SU). The proportion of new SU users with pre-existing coronary heart disease was also found to be higher than the corresponding proportion for other OAD's ($P<0.05$ all years). For patients with pre-existing myocardial infarction the proportion was higher all years although not significant in years 2009 and 2012.

Conclusion: In Denmark the initiation of SU treatment declined from 2006 to 2012. The proportion of new SU users with pre-existing CV disease remained high, approaching 50% over the entire period and was larger than the corresponding proportion for new users of other OADs. Irrespective of definitions of SU group and type of CV disease, we found that initiation of SU therapy was more common among patients with CV disease compared to patients without history of CV disease. This

indicates that pre-existing CV disease did not negatively impact clinicians' usage of SU.

Medication persistence and adherence in type 2 diabetes patients using fixed- versus loose-dose combination products

E. Sorstadius¹, T. Lokhandwala², W. Lee³, N. Smith⁴, C. Sternhufvud¹, J. Mukherjee⁵;

¹Global payer evidence and pricing, AstraZeneca, Molndal, Sweden, ²Xcenda, Palm Harbor, ³Xcenda, San Francisco, ⁴Bristol-Myers Squibb, Lawrenceville, ⁵Bristol-Myers Squibb, Wallingford, USA.

Background and aims: To compare medication persistence and adherence between type 2 diabetes mellitus (T2DM) patients using fixed-dose combination (FDC) and loose-dose combination (LDC) products.

Materials and methods: A retrospective cohort study design using United States' administrative claims data from Jan 1, 2009 through Dec 31, 2013 was employed. Patients with a prescription for at least 1 FDC or 2 LDC medications filled (on the same date) between Jan 1, 2010 and Dec 31, 2012 were identified as the target population, with the index date defined as the fill date. The identified population was restricted to patients with a T2DM diagnosis (non-diagnostic medical claim with ICD-9 CM codes of 250.x0, 250.x2) and at least 1 additional oral anti-diabetic prescription (of the same regimen [FDC/LDC] as the index prescription) within 12 months following the index date. A 12-month pre-index period was used to obtain baseline characteristics. Persistence (no ≥ 30 day gap) and adherence (medication possession ratio [MPR]) were assessed while the patients were on the index regimen up to a maximum of 1-year (follow-up period) starting on (and including) the index date. Patients on triple therapy over follow-up were excluded. The odds of persistence and adherence [MPR ≥ 0.8] to therapy were assessed using logistic regression after adjusting for baseline covariates and the hazard of non-persistence was similarly assessed using a Cox proportional hazards model.

Results: Of the 23,361 patients identified, 12,590 (53.9%) were on FDC therapy and 10,771 (46.1%) were on LDC therapy. The majority of patients were male (62.4%) with a mean (SD) age of 54.9 (11.2) years. The mean (SD) number of unique prescription classes was 2.6 (2.9). A statistically significantly greater proportion of FDC patients were persistent (32.1% vs 26.6%, $p<0.0001$) and adherent to therapy (57.0% vs 50.7%, $p<0.0001$) when compared to LDC patients. Average duration of persistence was significantly longer among the FDC patients when compared to the LDC patients (207.1 [± 136.3] vs 186.3 [± 130.0] days, $p<0.0001$). After adjusting for baseline characteristics, the odds of non-persistence in therapy were 21% lower among T2DM patients on FDC therapy when compared to those on LDC therapy (OR=0.79, 95% CI

[0.74, 0.85], $p < 0.0001$). The odds of being adherent to therapy (MPR/DTMPR ≥ 0.8) were 28% higher among T2DM patients on FDC therapy when compared to those on LDC therapy (OR=1.28, 95% CI [1.20, 1.36], $p < 0.0001$). Furthermore, T2DM patients on FDC therapy had a 12% lower risk of being non-persistent at any point in time compared to those on LDC therapy (HR=0.88, 95% CI [0.84, 0.91], $p < 0.0001$).

Conclusion: Management of T2DM using FDC therapies provides a compliance benefit to patients when compared to LDC therapies, most likely due to reduced medication burden. This compliance benefit may translate to better glycemic control and possible reduction in healthcare utilization and costs due to improved disease management.

Use of sodium-glucose co-transporter 2 inhibitors among US patients with type 2 diabetes

S. Rajpathak¹, S. Yu¹, S.S. Engel¹, Z. Li², C.-P.S. Fan², J. Tang², B. Hanna², J. Williams¹, A. McNeill¹;
¹Merck & Co., Inc., Kenilworth, ²Asclepius Analytics LLC, Brooklyn, USA.

Background and aims: Sodium-glucose co-transporter 2 inhibitors (SGLT-2i) are a new class of oral antihyperglycemic agents (AHA) used to manage hyperglycemia in patients with type 2 diabetes mellitus (T2DM). A retrospective study was conducted using MarketScan database to assess treatment patterns and characteristics of patients using SGLT-2i compared to other oral AHAs.

Materials and methods: Patients initiating oral AHA between 3/29/2013 and 6/30/2013 (index period) qualified for the study. The index date was set as the first oral AHA prescribed in the index period. Included were patients ≥ 18 years who had continuous enrollment of ≥ 1 year before and ≥ 90 days after the index date. Those with T1DM, gestational or secondary diabetes, pregnancy, or metformin use for polycystic ovarian syndrome were excluded. Patients were assigned to SGLT-2i and non-SGLT-2i cohorts based on their index drug. Between-group differences were assessed using Wilcoxon rank-sum tests for continuous variables and χ^2 tests for categorical variables.

Results: Of the 69,511 patients in the study, 2.8% ($n=1,917$) initiated a SGLT-2i (canagliflozin was the only available SGLT-2i during the study period), and the rest were initiated on other oral AHAs. 30.2% patients were initiated on a 300 mg dose of canagliflozin and of the 68.4% who initiated 100 mg dose, 9.5% escalated to higher dose within 90 days. Compared to patients on other oral AHAs, canagliflozin patients were younger (55.1 vs. 56.1 years, $p < 0.01$) and had a higher proportion of males (56.1% vs. 51.0%, $p < 0.01$). In addition, canagliflozin patients used more concomitant medications during baseline (anti-hypertensive: 77.7% vs. 64.1%; lipid-lowering: 72.8% vs. 49.4%; NSAID: 26.8% vs. 22.8%; beta-blockers: 27.2% vs. 25.0%, all $p < 0.01$) and already had more advanced antihyperglycemic treatment regimens compared to those on other oral AHAs. Furthermore, canagliflozin patients were also more likely to have micro-vascular complications (23.6% vs. 12.7%, $p < 0.01$), including nephropathy (4.4% vs. 2.5%, $p < 0.01$), as well as hypertension (62.0% vs. 56.5%, $p < 0.01$) and hyperlipidemia (62.9% vs. 50.9%, $p < 0.01$).

Conclusion: US patients initiating SGLT-2i were already on multiple AHAs and higher prevalence of comorbidities at baseline compared to patients initiating other AHAs.

360

Patient characteristics, treatment and prevalence/incidence of the type 2 diabetes population in Sweden: a nationwide study from 2006 to 2013

D. Nathanson¹, A. Norhammar¹, T. Nyström¹, M. Thuresson², J.W. Eriksson³, J. Bodegard⁴;
¹Karolinska Institutet, Stockholm, ²Statisticon, Uppsala, ³Uppsala University, ⁴AstraZeneca, Södertälje, Sweden.

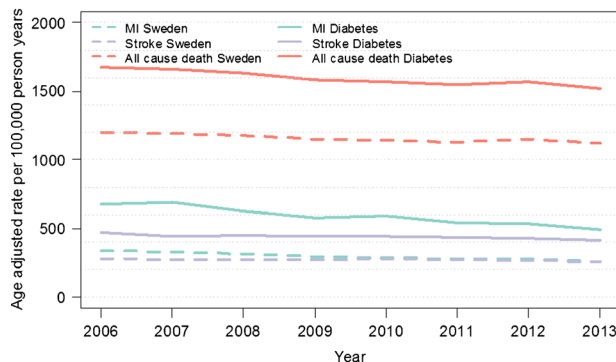

Background and aims: In a modern nation-wide setting characterise patterns of glucose lowering treatment and prevalence and incidence of type 2 diabetes (T2DM) in Sweden.

Materials and methods: Patients who dispensed any glucose-lowering drug (GLD) between 2006 and 2013 were identified in the Swedish Prescribed Drug Register and linked with the Swedish National Patient Register and the Cause of Death Register. Patients with type 1 diabetes and gestational diabetes were excluded. Information on comorbidities and medical events were collected from main and secondary diagnoses at discharge.

Results: In 2013 the prevalence of GLD-treated T2DM was 4.4% ($n=355,114$) and incidence 368 per 100,000 patients (28,023). Prevalence of T2DM patients with GLD treatment increased during 2006–2013 by 51% while the incidence remained stable. The mean age was 67 years and 56% were male. Previous cardiovascular disease was present in 34%, micro-vascular disease in 26%, cancer in 19% and 4% had chronic kidney disease. Treatment with statin, antihypertensives and low dose aspirin was present in 56%, 70% and 35% respectively. The most frequently used GLDs were metformin (69%), insulin (28%) and SU (17%). Incretin based GLDs were used in low proportions (DPP4; 6% and GLP-1; 3%). During 2006–2013 the use of SU decreased by 55% while insulin use increased by 29%. After direct age adjustment, the standardized risk ratio for myocardial infarction, stroke and all-cause mortality was 1.9, 1.6 and 1.4-fold respectively in T2DM patients (Figure).

Conclusion: The number of T2DM patients on glucose lowering drugs in Sweden has increased by 51% the last seven years despite stable T2DM incidence. The incidence of drug treated T2DM was more than twice as high as previously reported which illustrates the general problem to report on true incidence of T2DM accurately with high risk for underestimation. Despite improved medical care the last decade individuals with T2DM still have increased risk of cardiovascular disease and death compared to the general population. The use of SU is declining and seems to be replaced by insulin and less by incretin based glucose lowering drugs.

Figure 2: Age-adjusted rates of myocardial infarction (MI), stroke and all-cause mortality in patients with T2DM and the general Swedish population 2006–2013.

First-line and intensified treatment with glucose lowering drugs in the Swedish type 2 diabetes population

T. Nyström¹, J. Bodegard², D. Nathanson¹, M. Thuresson³, J.W. Eriksson⁴, A. Norhammar¹;

¹Karolinska Institutet, Stockholm, ²AstraZeneca, Södertälje, ³Statisticon, ⁴Uppsala University, Sweden.

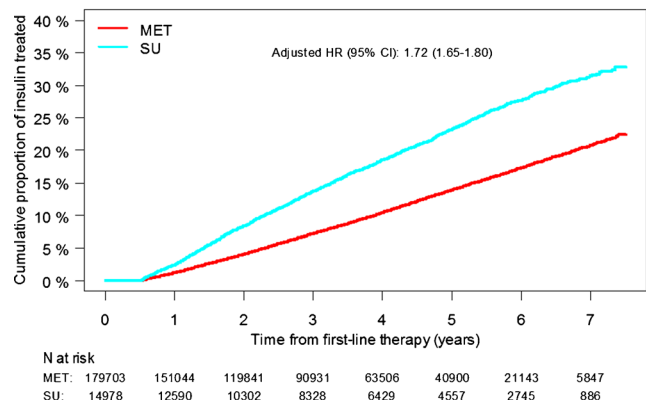

Background and aims: To investigate initiation of first-line glucose lowering drug (GLD) treatment, and subsequent GLD treatment, and prior cardiovascular disease (CVD) for all type 2 diabetes (T2DM) patients in Sweden.

Materials and methods: T2DM patients who were GLD naïve and initiated on their first-line GLD treatment during 2006–2013 were identified in the Swedish Prescribed Drug Register. Patients with type 1 diabetes or gestational diabetes were excluded. Patients were linked with the Swedish National Patient- and Cause of Death registry. Index date was defined as date of patients first GLD dispense. Definition of a non-insulin antidiabetic drug (NIAD) start was any dispense recorded whereas insulin start was defined when treatment duration exceeded 6 months. From 1987 to index date, baseline information on CVDs (coronary heart disease, heart failure, stroke and peripheral artery disease) was collected from the Swedish National Patient Register. Cox survival models adjusted for age, gender, first-line GLD treatment time and any history of CVDs were used to estimate likelihood of early treatment intensification during up to 7 years of follow-up.

Results: In 232,749 T2DM patients, first-line GLD treatment were initiated with either mono NIAD, insulin (alone or in combination with NIAD), or dual NIAD (86%, 13% and 2% respectively). Insulin treated patients, in comparison to mono- and dual NIAD groups were slightly older (64, 63 and 59 years) and had more CVD (36%, 29% and 21%). Despite higher CVD burden, insulin treated patients had significantly less CVD preventive treatment with statin, antihypertensive and low dose aspirin, compared to NIAD groups. Among 199,562 patients initiated on mono NIAD, metformin was most common (90%) followed by sulfonylurea (SU 8%), and other NIADs (2%). Patients initiated with SU were older (72 vs. 62 years), had more CVDs (43% vs. 27%) and were more often treated with low dose aspirin and less with statins, compared to the metformin group. Initiation with SU was associated with earlier intensification to a second and a third-line NIAD, or insulin, compared with metformin; hazard ratio (95% CI): 1.74 (1.69–1.79), 1.76 (1.65–1.88) and 1.72 (1.65–1.80).

Conclusion: In Sweden newly diagnosed T2DM patients are treated much in concordance to diabetes guidelines, beginning with metformin. Noteworthy, patients initiated with SU were associated with earlier insulin treatment intensification. One third of GLD naïve patients had a history of CVD, clearly demonstrating the burden in T2DM patients.

Figure: Likelihood of early insulin start in patients who were either initiated on first-line treatment with sulfonylurea (SU) or metformin (MET).

Patient-related predictors for attaining early glycaemic control in type 2 diabetes: a population-based study

E. Svensson¹, L.M. Baggesen¹, R.W. Thomsen¹, T. Lyngaa¹, L. Pedersen¹, H. Nørrelund², E.S. Buhl³, C.L. Haase³, S.P. Johnsen¹;

¹Department of Clinical Epidemiology, Aarhus University hospital, ²Aarhus University hospital, ³Novo Nordisk Scandinavia AB, Copenhagen, Denmark.

Background and aims: Early glycaemic control in type 2 diabetes (T2DM) may reduce the risk of microvascular and possibly macrovascular complications. However, data on patient-related predictors for achieving HbA1c targets is sparse. We examined predictors of early glycaemic control with particular emphasis on the effects of age and comorbidity.

Materials and methods: We included all individuals registered with a first-time glucose-lowering drug prescription in Northern Denmark between 2000 and 2012. We obtained data on glycated hemoglobin (HbA1c) levels at baseline and within 3 to 6 months after treatment start, comorbidities, and medications from population-based medical databases. Success in reaching HbA1c target (less than 7%) one year after treatment start was examined by Poisson regression analysis, comparing T2DM patients who were frail (i.e., over 65 years with comorbidities) with healthy T2DM patients (less than or equal to 65 years and no comorbidity). Individual patient-related predictors included age, gender, marital status, and presence of non-psychiatric comorbidities (Charlson Comorbidity Index (CCI) level). We adjusted all analyses for age, gender, pre-treatment HbA1c, diabetes duration, and micro- and macrovascular complications at baseline. In a sub-sample, we had information on BMI. We repeated all analyses in this sample.

Results: We identified 38,418 eligible T2DM patients (median age 63 years). Of these, 27,545 (72%) achieved HbA1c target of less than 7% at three to six months after drug initiation. After adjustment for potential confounders mentioned above, there was no difference in achievement of an early glycaemic target of 70 years vs. 60–70 years) or marital status (adjusted RR=0.98 [95% CI 0.96–1.00] comparing widowers with married individuals). Female gender (adjusted RR=0.97 [95% CI 0.96–0.98] for females vs. males) and presence of comorbidity at baseline (adjusted RR=0.94 [95% CI: 0.90–0.97] for patients with CCI≥3 compared to CCI=0) were weakly associated with non-achievement of HbA1c target. The strongest predictor of early glycaemic control was the pre-treatment HbA1c level (adjusted RR=0.63 [95% CI: 0.61–0.64] for baseline HbA1c of 7.5–8.9%, and 0.58 [95% CI: 0.57–0.59] for baseline HbA1c of over or equal to 9%, respectively, compared with HbA1c less

than 7.5%). In a sub-cohort with available BMI measurements (n=4,166), results were consistent after additional adjustment for BMI, and BMI per se was not associated with the chance of successful early glycaemic control.

Conclusion: In this large population-based study of incident treated T2DM patients in Denmark, older frail patients had a similar chance of achieving early glycaemic control as 65 years and younger patients without comorbidity. The strongest predictor of reaching HbA1c target less than 7% was the pre-treatment HbA1c level.

Using diabetes risk scores to select high-risk individuals for diabetes prevention in the United States: a cost-effectiveness analysis

K. Mühlenthal¹, X. Zhou², B. Bardenheier³, P. Zhang³, E. Gregg³, M.B. Schulze¹;

¹Molecular Epidemiology, German Institute of Human Nutrition Potsdam Rehbruecke, Nuthetal, Germany, ²Merck, North Wales, ³Division of Diabetes Translation, Centers for Disease Control and Prevention, Atlanta, USA.

Background and aims: Several scoring systems have been developed for predicting future risk of type 2 diabetes within the past years. While the performance of these risk scores has been evaluated in detail, few studies have evaluated the application of those scoring systems to identify the targeting population for diabetes prevention. This study aimed to apply the framework of cost-effectiveness analysis to determine the optimal threshold of two previously developed risk scoring algorithms, the German Diabetes Risk Score (GDRS) and the Atherosclerosis Risk in Communities (ARIC) 2009 score while using them for identifying high risk individuals with which to intervene.

Materials and methods: To determine the performance of the two risk scores in a US population, receiver operating characteristic (ROC) analysis was performed combining data from the Atherosclerosis Risk in Communities (ARIC) study and the Cardiovascular Health Study (CHS) (N combined=17,291; aged 44 to 91 years). Survival analysis was applied to determine diabetes incidence rates according to a broad range of risk thresholds (5% to 20% by 1% increments; 25%, 30% and 35%) for the two risk scores. The threshold-specific incidences were incorporated into a Markov-based simulation model. Two scenarios were simulated wherein the 1-stage scenario included stratification by the risk score only and the 2-stage scenario additionally included a glucose test (threshold 100 mg/dl) in the identified high-risk group. Identified high-risk individuals were assumed to receive a low-cost community-based intervention with a risk reduction of 12.5% per year. Simulation samples were obtained from the 2001-2004 National Health and Nutrition Examination Survey (NHANES). Incremental cost per quality adjusted life year gained was calculated by progressively increasing the score threshold.

Results: The area under the ROC curve (ROC-AUC) for the GDRS and the ARIC 2009 score were 0.691 (0.677-0.704) and 0.720 (0.707-0.732), respectively. The incremental cost-effectiveness ratios (ICER) in a 1-stage scenario ranged from \$36,447 (GDRS) and \$33,404 (ARIC 2009 score) for 35% risk to \$51,318 (GDRS) and \$60,170 (ARIC 2009 score) for the lowest risk cut-off of 5% risk. The selected risk cut-off for an ICER <\$50,000 would be 7% for the GDRS and 9% for the ARIC 2009 score. In the 2-stage scenario with an additional glucose test in the selected high-risk group, ICERS for all cut-offs were below \$50,000.

Conclusion: The results of this study suggest that a non-invasive diabetes risk score can be a valuable tool to identify high-risk individuals for a lifestyle intervention. The optimal thresholds of the GDRS and the ARIC 2009 score were 7% and 9%, respectively when using a 1-stage screening with the risk scores only and 5% for both scores when using an additional glucose test with 100 mg/dl threshold in the identified high-risk group in a 2-stage screening.

A comparison of different glucometabolic markers for prediction of future type 2 diabetes in young and middle-aged subjects: a 20-year follow-up study

M.L. Nielsen¹, M. Pareek¹, M. Leósdóttir², K. Højlund¹, P.M. Nilsson², M.H. Olsen¹;

¹Department of Endocrinology, Odense University Hospital, Denmark,

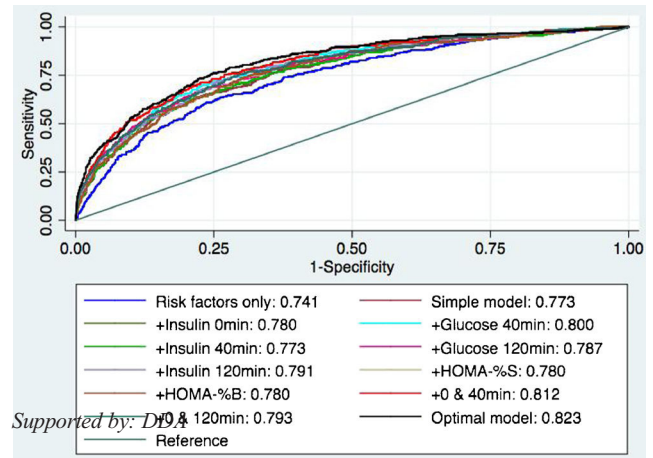

²Department of Cardiology, Skåne University Hospital, Malmö, Sweden.

Background and aims: Risk prediction models for type 2 diabetes mellitus (T2DM) often incorporate a few common risk factors (RF) including fasting blood glucose (FBG). Further addition of other glucometabolic risk markers (GRM) incl. multiple measurements during OGTT may improve prediction, but superiority of one over other at long-term follow-up remains unproven. The purpose of this study was to assess the added predictive value of various GRM (fasting plasma insulin, homeostatic model assessment derived insulin sensitivity (HOMA-%S) and beta-cell function (HOMA-%B), and 40 and 120 min BG and plasma insulin during OGTT) to a model with RF (age, BMI, systolic blood pressure, total cholesterol, triglycerides, family history) and FBG.

Materials and methods: We assessed improvement in the prediction of incident T2DM (through re-examination and registries) during 20-year follow-up in a random population sample of 3576 men free from DM and cardiovascular disease at baseline, using the above-mentioned GRM. Their additive value to a model with RF and FBG was evaluated using Cox proportional hazards regression, receiver-operating characteristic (ROC) analysis, and integrated discrimination improvement (IDI).

Results: Median age at inclusion was 48 (IQR 47–48) years. During follow-up (median 20 (IQR 20–20) years), 300 new cases of DM developed. The ROC-curves are depicted in figure 1. Addition of FBG to a model with RF alone resulted in significant improvement (likelihood-ratio $X^2=106.62$ ($p<0.0001$); AUC 0.773 vs. 0.741, $X^2=10.26$ ($p=0.001$); IDI 0.04 ($p<0.0001$)). All models with an additional GRM performed significantly better than the model with RF+FBG (AUC 0.780–0.800 vs. 0.773, $p<0.05$ for all comparisons). The largest improvement was seen for 40 min BG (likelihood-ratio $X^2=72.47$ ($p<0.0001$); AUC 0.800, $X^2=11.84$ ($p<0.0001$); IDI 0.03 ($p<0.0001$)), which performed non-significantly better than 120 min BG ($p=0.2$) and 120 min insulin ($p=0.3$) and significantly ($p<0.05$) better than all other GRM. The optimal prediction model (AUC 0.823) included RF, FBG, fasting insulin, BG and insulin at both 40 and 120 min and performed significantly better than the models with RF+FBG+40 min BG and insulin (AUC 0.812, $X^2=4.77$ ($p=0.03$); likelihood-ratio $X^2=48.62$ ($p<0.0001$)) and RF+FBG+120 min BG and insulin (AUC 0.793, $X^2=16.14$ ($p=0.0001$); likelihood-ratio $X^2=81.04$ ($p<0.0001$)), respectively. The model with 40 min BG and insulin further performed significantly better than the model with 120 min measurements only (AUC $X^2=4.14$, ($p=0.04$)).

Conclusion: GRM provided a significantly better prediction of future DM risk during long-term follow-up than knowledge of RF and FBG alone. Although multiple measurements during OGTT possessed incremental predictive value, the addition of 120 BG and insulin was associated with limited benefit beyond measurements at 0 and 40 min only.

The association between GAD65 antibody levels and incident diabetes in a population-based cohort: the Hoorn study

A.D.M. Koopman^{1,2}, E. Voerman^{1,2}, F. Rutters^{1,2}, S.P. Rauh^{1,2}, C.D.A. Stehouwer³, P.J. Elders^{2,4}, G. Nijpels^{2,4}, J.M. Dekker^{1,2};

¹Department of Epidemiology and Biostatistics, ²EMGO+ Institute for health and care research, VU University medical centre, Amsterdam,

³Department of Internal Medicine and Cardiovascular Research, Maastricht University medical centre, Maastricht, ⁴Department of General Practice, VU University medical centre, Amsterdam, Netherlands.

Background and aims: GAD antibodies are autoantibodies against the enzyme glutamic acid decarboxylase (GAD). Up until now it is not clear whether GAD antibody positivity is predictive for the development of diabetes. Prospective studies on whether the presence of GAD antibodies predicts diabetes are rare and provide contradicting results. Therefore, the aim of this study was to assess the association between levels of GAD65 antibodies and incident diabetes after 6.5 years in the general Dutch population.

Materials and methods: We assessed the association in 1302 men and women of the Hoorn study, a population-based cohort. Participants with prevalent diabetes at baseline were excluded. Diabetes status at baseline and follow-up was defined according to WHO criteria 2011, including fasting plasma glucose levels, 2 h post load plasma glucose and HbA1c values. GAD65 antibody levels were measured in serum by means of a standardized radioligand assay and subsequently were expressed as indexes. GAD65 antibody positivity was defined as indexes equal or above the 99th percentile point. Logistic regression analysis was performed to compare GAD antibody positive participants to GAD antibody negative participants.

Results: Of the 1302 participants (age $60.3\pm 7y$, 45.8% male), 11.1% had developed diabetes after 6.5 years. For GAD65 antibody positive participants the Odds Ratio (OR) for developing diabetes was 7.09 (95% confidence interval (CI): 2.35–21.40), compared to GAD65 antibody negative participants. After adjustment for age, sex, follow-up duration and glucose metabolism status at baseline, the OR for developing diabetes was 4.86 (95% CI: 1.45–16.29). In sensitivity analyses, the adjusted standardized regression coefficients for HbA1c levels, fasting glucose levels and 2 h post load plasma glucose levels were 0.141 ($p<0.001$), 0.149 ($p<0.001$) and 0.058 ($p=0.015$) in GAD65 antibody positive participants, compared to GAD65 antibody negative participants.

Conclusion: Within our population-based cohort, GAD65 antibody positivity was strongly and independently of glucose metabolism status at baseline associated with an increased risk of developing diabetes during 6.5-year follow-up.

Continuous glucose monitoring at the early phases of type 2 diabetesL.H. Hakaste¹, F. Sambo², A. Facchinetti², C. Cobelli², L.C. Groop³, T. Tuomi¹;¹Folkhalsan Research Centre, Helsinki, Finland, ²University of Padova, Italy, ³Lund University Diabetes Centre, Malmo, Sweden.

Background and aims: Little is known about glucose variability in the early phases of type 2 diabetes (T2D). In an effort to improve the risk prediction of T2D, we studied whether a particular pattern of glucose excursion in subjects with impaired glucose tolerance (IGT) would be associated with a decrease in insulin secretion, increase in glucose excursions and/or diabetes after 1.5 (or 5) years follow-up. We also compared a single capillary glucose measurement at 2 hours (2 h) after a standardized test-meal eaten at home with a 2 h oral glucose tolerance test (OGTT) in diagnosis of T2D.

Materials and methods: 36 subjects with IGT and 25 with T2D from the Botnia Study participated in a 2 h OGTT and a one-week continuous glucose monitoring (CGM), during which they ate two test meals at home after 10–12 hours fasting and measured capillary glucose at 0, 60 and 120 minutes after the meal. They filled in a questionnaire and kept a food and exercise diary during the CGM. A follow-up visit will be completed 1–1.5 years after the first visit in March–June 2015, with a similar study protocol except for one of the test meals eaten at the study center with blood sampling. Subjects with known diabetic complications, HbA1c >8% (63.9 mmol/mol), fasting plasma glucose (PG) >10 mmol/l, or treated with insulin, GLP1-analogues, or sulphonylureas were excluded. Metformin was stopped two days before the CGM. None of the participants was on glitazone, gliptine or acarbose medication.

Results: At the first visit, the IGT and T2D groups had similar age, BMI, waist and hip circumference and blood pressure, but fasting PG, 2 h glucose at OGTT and B-HbA1c were significantly higher in those with T2D (6.86 mmol/l and 5.84 mmol/l; 11.44 mmol/l 9.29 mmol/l; 37.7 mmol/mol and 44.7 mmol/mol, respectively) (table). The glucose excursions were significantly larger in the T2D subjects compared with IGT subjects estimated as area under curve above 6 mmol/l (52.58 vs. 84.35, $p=0.0041$), or as mean or largest amplitude of excursion ($p=0.047$) (table). As the 2 h glucose was significantly lower after test meal than after OGTT, both insulin and incretin responses will be analyzed during the follow-up visit. Longitudinal changes in glucose excursions, insulin secretion and glucose tolerance will be analyzed in August 2015.

Conclusion: Glucose variability during the CGM was significantly higher in subjects with T2D compared to those with IGT. It will be interesting to see whether a subgroup of IGT subjects with a higher risk for deterioration of glucose tolerance can be identified based on glucose excursions.

Covariate	IGT [n = 36]	T2D [n = 25]	P-value
Gender (M/F)	21 / 15	10 / 15

Incremental value of a past fasting glucose for the prediction of type 2 diabetes mellitus. The Whitehall II study

A.G. Tabák^{1,2}, M. Kivimäki², T.N. Akbaraly^{2,3}, E.J. Brunner², D.R. Witte⁴, A. Hulman⁵, D. Vistisen⁶, K. Færch⁶, G.D. Batty², M.J. Shipley²;

¹1st Department of Medicine, Semmelweis University, Faculty of Medicine, Budapest, Hungary, ²Epidemiology and Public Health, University College London, UK, ³Inserm U 1061, Montpellier, France, ⁴Aarhus University, Denmark, ⁵University of Szeged, Hungary, ⁶Steno Diabetes Centre, Gentofte, Denmark.

Background and aims: Lifestyle interventions can reduce the risk of type 2 diabetes by more than 50% in high risk populations. In order to effectively identify such high-risk individuals, current diabetes prediction models require improvement. Accordingly, we examined the impact of adding a previous fasting glucose measurement to the Framingham Offspring Diabetes Risk Score (FOS-DRS).

Materials and methods: In an cohort of British government workers taking part in 5-yearly clinical examinations, 338 incident cases of type 2 diabetes were observed (75 g OGTTs or self-report of diabetes or use of antidiabetic medication) in two 5-year baseline-follow-up data cycles (n=3550 and n=4140). FOS-DRS was re-estimated with Weibull regression using baseline data on age, sex, parental history of diabetes, body mass index, systolic blood pressure, hypertensive medication, HDL-cholesterol, triglyceride, and fasting glucose. Then, we added fasting glucose values measured 5 years earlier to the existing model. The value of adding past fasting glucose was examined by C-statistics, net reclassification improvement (NRI), and integrated discrimination improvement (IDI); calibration by the Hosmer-Lemeshow test.

Results: As anticipated, previous fasting glucose concentration was an independent predictor of type 2 diabetes (OR 1.98, 95% CI: 1.56–2.52). Its addition to the FOS-DRS significantly improved discrimination (FOS-DRS vs. additional glucose, C-statistic: 0.774 vs. 0.783, $p=0.031$; 3-category NRI: 4.7%, 95%CI 0.6–8.8%, IDI: 0.007, $P<0.0001$); however, calibration was imperfect for both models (both $p<0.05$). Most of the improvement of NRI was related to an increase in the predicted risk of incident diabetes cases.

Conclusion: In the present study, the addition of a routinely available past clinical measure (fasting glucose) to an optimized clinical diabetes risk score improved its prediction.

Predicting risk of progression to diabetes from prediabetes defined by HbA_{1c} or fasting plasma glucose in Koreans

C.-H. Kim¹, E.-H. Kim², S.-J. Bae², H.-K. Kim²;

¹Internal Medicine, Soonchunhyang University, Bucheon, ²Asan Medical Center, Seoul, Republic of Korea.

Background and aims: Although both HbA_{1c} and fasting plasma glucose (FPG) criteria have been recommended as screening tests for prediabetes, the performance of these tests in predicting future risk of diabetes remains to be established. We assessed 5-year progression rate to diabetes in individuals identified as having prediabetes by HbA_{1c} and FPG criteria in a large cohort of Koreans.

Materials and methods: We analyzed data of 17,971 Korean adults (age 20–79 years, 39% women) who underwent routine medical check-ups in 2007–2008 (baseline) and followed up in 2012–13 with a median 5.1-year (range 3.1–6.7 years) interval. Patients who had diabetes at baseline were excluded. Prediabetes at baseline was defined as FPG 5.6–6.9 mmol/l or HbA_{1c} 39–46 mmol/mol [5.7–6.4%]. Diagnosis of diabetes at follow-up was based on FPG ≥ 7.0 mmol/l, HbA_{1c} ≥ 48 mmol/mol [6.5%], or use of antihyperglycemic medications. Odds ratios (ORs) for developing diabetes were estimated using multiple logistic regression analysis.

Results: Among the 17,971 participants who did not have diabetes at baseline, the prevalence of prediabetes was 30.6% (n=5495) by FPG and 20.4% (n=3664) by HbA_{1c} criteria. A total of 723 subjects (4.0%) developed diabetes during the 5-year follow-up. Only 0.4% of subjects who had normoglycemia (FPG <5.6 mmol/l and HbA_{1c} <39 mmol/mol) at baseline developed diabetes. Individuals with prediabetes identified by HbA_{1c} test had a higher 5-year rate of progression to diabetes compared to those by FPG test (14.7% vs. 10.4%, $P < 0.001$). This trend was consistent regardless of age, sex, BMI, and family history of diabetes. Among individuals diagnosed as prediabetes discordantly by the two tests, subjects diagnosed by HbA_{1c} only had a higher risk of progression to diabetes compared to those by FPG alone (6.0% vs. 3.9%, $P < 0.001$) (Table). Individuals diagnosed as prediabetes by both criteria had much higher rate of progression to diabetes (22.3%). Receiver operating characteristic curve analysis showed that area under the curve was greater for HbA_{1c} (0.855, 95% CI 0.840–0.870) compared to that for FPG (0.830, 0.813–0.846) ($P = 0.006$). The OR of developing diabetes adjusted for conventional risk factors was also higher for prediabetes by HbA_{1c} (9.91, 95% CI 8.24–11.9) compared with that by FPG (7.29, 5.97–8.89) ($P = 0.026$). When we subdivided the prediabetes group, individuals with higher FPG (6.1–6.9 mmol/l) and HbA_{1c} (42–46 mmol/mol) had substantially higher risk of progression to diabetes compared to those with FPG 5.6–6.0 mmol/l and HbA_{1c} 39–41 mmol/mol, respectively (Table).

Conclusion: Although the HbA_{1c} test identified fewer individuals with prediabetes than did FPG test, the predictive power for progression to diabetes assessed by HbA_{1c} was stronger than that assessed by FPG. However, these two tests could independently and additively predict risk of progression to diabetes, and combined use of both tests could more efficiently identify individuals at risk for diabetes.

Table. Incidence and OR of diabetes after 5 years according to baseline diagnosis of prediabetes

	n	Incident diabetes (%)	Age- and sex-adjusted OR (95% CI)	Multivariate adjusted OR (95% CI)
Prediabetes by				
None (normal)	10761	48 (0.4%)	1 (reference)	1 (reference)
FPG only	3544	137 (3.9%)	8.52 (6.10–11.9)	7.66 (5.39–10.9)
HbA _{1c} only	1713	130 (6.0%)	14.4 (10.1–20.4)	11.9 (8.24–17.3)
Both (FPG & HbA _{1c})	1951	435 (22.3%)	61.3 (45.0–83.4)	46.7(33.6–64.9)
Fasting plasma glucose				
<5.6 mmol/l	12474	151 (1.3%)	1 (reference)	1 (reference)
5.6–6.0 mmol/l	4062	215 (5.3%)	4.27 (3.45–5.29)	3.66 (2.91–4.60)
6.1–6.9 mmol/l	1433	357 (24.9%)	24.9 (20.2–30.5)	21.1 (16.8–26.3)
HbA_{1c}				
<39 mmol/mol	14305	185 (1.3%)	1 (reference)	1 (reference)
39–41 mmol/mol	2561	216 (8.4%)	6.85 (5.59–8.40)	5.54 (4.47–6.88)
42–46 mmol/mol	1103	322 (29.2%)	30.7 (25.2–37.5)	23.2 (18.7–28.7)

Prediabetes by FPG: FPG 5.6–6.9 mmol/l

Prediabetes by HbA_{1c}: HbA_{1c} 39–46 mmol/mol (5.7–6.4%)

Multivariate adjusted OR: adjusted for age, sex, BMI, smoking, alcohol intake, physical activity, family history of diabetes, hypertension, serum triglycerides and HDL-cholesterol levels.

369

FINDRISC score and glycaemic measures, better than HbA_{1c}, as predictor and monitor of diabetes incidence within 5 years

R.T. Ribeiro^{1,2}, J.F. Raposo^{1,3}, J.M. Boavida⁴, M. Macedo^{1,3}, I. Correia^{1,2}, R. Andrade^{1,3}, A. Silva¹, R. Duarte^{1,2}, J.L. Medina², L. Gardete-Correia^{1,2};

¹APDP - Diabetes Portugal (Education and Research Centre - APDP/ERC), ²SPD - Portuguese Society of Diabetology, ³CEDOC-NOVA Medical School, ⁴National Programme for Diabetes, Lisbon, Portugal.

Background and aims: Diabetes is a rising epidemic, with increasing social and economic impact. PREVADIAB, the first Portuguese nationwide study on the prevalence of diabetes, showed that 11.7% of the general population has diabetes; while nearly 25% already showed prediabetes (IFG, IGT, or both). Five years after, we aimed to evaluate the role of diabetes incidence predictors in a non-diabetic cohort of the initial study.

Materials and methods: From the 5167 individuals recorded on the database of the first PREVADIAB, people evaluated as non-diabetics (either designated with “normal” or “prediabetes” based on both fasting glycemia and/or 2 h post-load challenge) were called for reassessment. Thus, people aged between 23 and 83 years, taken from 73 of the original 122 locations, were recruited 5 years after the initial call, being representative of the non-diabetic distribution observed on the first study. An OGTT was again performed and HbA_{1c} quantified to evaluate glycemic control. WHO criteria were used for the diagnosis of diabetes. For diabetes risk assessment, we applied the Finnish Diabetes Risk Score (FINDRISC) to information from the original study, specific to this subgroup.

Results: The present cohort consisted of 1024 participants. In relation to the deterioration of glycemic control with time, 3.8% of individuals were diagnosed with diabetes in the intervening 5 years, while an additional 5.0% were shown here to have undiagnosed diabetes. In terms of matching the initial diabetes risk score categories to the incidence of diabetes, while no individual initially characterized with the lower FINDRISC score (below 7) progressed to diabetes, 25.9% of individuals initially characterized with the higher risk score (above 20) developed a diagnosis of diabetes within these 5 years. Initial HbA_{1c} was also shown to be related to diabetes incidence, but with a similar sensitivity only at $\geq 6.3\%$. In terms of diabetes detection, applying HbA_{1c} diagnostic criteria

($\geq 6.5\%$) did not add significantly to criteria based on OGTT measures, while on the other hand merely 25.5% of participants found with undiagnosed diabetes were detected by the HbA1c criteria cut-off.

Conclusion: Primary prevention strategies targeted to high risk populations are usually more cost-effective than the ones targeted to general populations. Initial HbA1c showed to be strongly related to 5 years diabetes incidence only already at a high range, while it was shown to perform poorly in detecting undiagnosed diabetes. Thus, this 5-year prospective analysis argues in favor of the FINDRISC, a non-invasive inexpensive tool, as adequate to evaluate risk of diabetes development in the general population. More, it also argues for the necessity of glycemic measures, and not solely HbA1c, to monitor diabetes incidence in high-risk individuals.

Risk of hospitalisation for heart failure between dipeptidyl peptidase 4 inhibitors vs sulfonylureas and saxagliptin vs sitagliptin in a U.S. claims database

J.J. Sheehan¹, K. Tsai², S. Johnston³, A. Ghannam¹, K. Cappell³, R. Fowler³, I. Kalsekar¹, A. Fu⁴;

¹Medical Affairs, AstraZeneca, Fort Washington, ²Epidemiology, AstraZeneca, Gaithersburg, ³Truven Health Analytics, Bethesda, ⁴Population Sciences, Georgetown University, Washington D.C., USA.

Background and aims: In the SAVOR trial, the risk of hospitalization for heart failure (hHF), a component of the secondary endpoint, was increased with saxagliptin compared to placebo. This observational cohort study used a large U.S. insurance claims database to compare the risk of hHF between patients with type 2 diabetes mellitus (T2DM) treated with dipeptidyl peptidase-4 inhibitors (DPP-4is) vs. sulfonylureas (SUs) and between those treated with saxagliptin vs. sitagliptin.

Materials and methods: Methods followed the U.S. Food and Drug Administration's Mini-Sentinel protocol for active surveillance of anti-diabetic agents. Patients initiated treatment between Aug-1-2010 and Aug-30-2013 and had no use of the comparator treatments in the 12 months before treatment initiation (baseline). Each comparison consisted of patients matched 1:1 on a propensity score (nearest neighbor; caliper=0.01) based on demographics, general clinical characteristics, and hHF risk factors measured at baseline. The primary study outcome was time to hHF, defined as the number of days from treatment initiation until hHF or censoring at cessation of the initiated treatment, use of the alternative comparator treatment, loss to follow-up, or 8/30/2013, whichever was earlier. Time to hHF was compared between the matched groups using Cox proportional hazards models. Analyses were stratified by presence of baseline cardiovascular disease (CVD).

Results: The table shows the main study results. The propensity score matches achieved balance on all patient characteristics included within the propensity score models; across the 4 models, the standardized differences for matched covariates ranged from 0%–2.3%; values <10% are considered to be indicative of adequate balance. Within the comparison of DPP-4i vs. SU among patients with no baseline CVD, those who were treated with a DPP-4i had significantly ($P=0.013$) lower hazards of hHF compared to those who were treated with an SU. In all other comparisons there were no statistically significant differences in the risk of hHF between DPP-4i and SU or between saxagliptin and sitagliptin. Sensitivity analyses on subgroups (patients with no baseline use of loop diuretics, patients with no baseline or follow-up use of thiazolidinediones, and patients with characteristics similar to those included in the SAVOR trial) and using alternative assumptions of time at risk produced consistent results (not shown).

Conclusion: In this analysis of U.S. patients with T2DM in a real-world setting, there was no evidence of increased risk of hHF for DPP-4is relative to SUs or for saxagliptin relative to sitagliptin.

Table. Main Study Results for Propensity Score Matched Cohorts								
	DPP-4i vs. SU				Saxa vs. Sita

Pharmacological treatment changes in 4,143 patients with dysregulated type 2 diabetes referred to a tertiary diabetes center

N. Safai, M. Ridderstråle;

Patient Care, Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Changes to the pharmacological treatment are common when addressing dysregulated type 2 diabetes (DT2D). We have previously described improvements in such patients referred from primary care. Our aim here was to describe the most common pharmacological treatment changes implemented in these subjects.

Materials and methods: Pharmacological treatment data before and after a six to nine month treatment program for all patients referred to a tertiary diabetes center between Jan 1st 2001 and Jan 1st 2013 were extracted from the electronic medical records ($n=4,143$). Patient population and metabolic control data have been described previously; *e.g.* proportion with HbA1c <53 mmol/mol improved from 25% to 47%; blood pressure <140/<85 mmHg from 41% to 52%, and LDL cholesterol <2.6 mmol/l from 56% to 74%. Only between treatment class comparisons were performed, and non-parametric analysis was used throughout.

Results: 61% of patients were on metformin (Met) on referral: 18% prescribed Met alone, 28% a combination of Met and sulphonyl urea (SU), and 14% of Met and insulin (Ins). Any other Met combination, including triple therapy, was virtually non-existent (about 1%). SU alone was seen in 10% of the patients, and 7% of patients were on Ins monotherapy. The combination of SU and Ins was less common at 2%. Total daily insulin dose at referral was 55 ± 47 IE/day ($n=924$). At discharge the dose in all subjects on insulin was 54 ± 44 IE/day ($n=1,462$), was increased to 61 ± 50 IE/day in those already on Ins at baseline ($n=914$; $p<0.0001$), and 43 ± 31 IE/day ($n=548$) in those put on Ins. Only 1% was on GLP-1-analogue alone and 0.2% on DPP4-i alone at baseline. 9 out of 10 patients who were on Met at referral remained so, and in total 67% were on Met at discharge (Figure 1): Met alone 19%; Met/SU 20%; Met/Ins 18%; and 11% on other combinations: Met/GLP-1 4.2%; Met/GLP-1/Ins 2.1%; Met/DPP4-i 1.3%; Met/SU/Ins 1.1%; Met/SU/GLP-1 1.0%; Met/SU/DPP4-i 0.9%; Met/DPP4-i/Ins 0.4%. SUs were withdrawn more commonly than Met (39%), whereas Ins was rarely discontinued (6%). The HbA1c lowering effect differed significantly between patients receiving different treatment alternatives and was particularly beneficial when including a GLP-1 analogue in triple therapy (-18 vs. -12 mmol/mol, $p=0.0001$). In addition to medication controlling glycaemia we observed increases in the use of antihypertensive drugs (from 63% to 75%), and lipid-lowering drugs (from 55% to 76%), and antithrombotic therapy (from 53% to 75%; $p<0.001$ for all changes).

Conclusion: When patients are referred from primary care to a tertiary center for DT2D, Ins and Met are the most likely drugs to be continued or newly prescribed, whereas SUs are more likely to be discontinued. The role for newer agents and triple combinations merit further investigation. Even if there are many different drugs available for glycaemic control this remains a major task in comparison to the management of lipids and blood pressure where goal attainment is achieved in greater proportions of patients, even with DT2D.

Figure 1 Treatment at referral (baseline) and at end of programme (9 months after) $p<0.001$. Metformin (Met), sulphonylurea (SU), insulin (Ins), GLP-1 analogue (GLP-1), DPP4-inhibitor (DPP4-i), antihypertensive (AH), antithrombotic therapy (AT). $N=4,143$

Longitudinal changes in type 2 diabetic patient medication treatment patterns from 2006 to 2012

W. Weng, Y. Liang, E. Kimball, T. Hobbs, S. Kong, B. Sakurada, J. Bouchard;

Clinical, Medical & Regulatory Affairs, Novo Nordisk Inc., Plainsboro, USA.

Background and aims: It is important to understand changes in diabetes treatment patterns over time in order to optimize treatment paradigms. This was a longitudinal study of real-world claims data from a single cohort ($N=35017$) of patients newly diagnosed in 2006 with Type 2 Diabetes (T2D) which followed changes in their treatment patterns and costs from 2006 to 2012.

Materials and methods: The Truven Health MarketScan® Database was used, from which claims data for only US-based newly diagnosed T2D patients were examined. Inclusion criteria were: at least 2 diagnoses according to ICD-9 codes for T2D, or 1 T2D diagnosis and at least 1 OAD claim, and allowing 1 diagnosis for T1D, ≥ 18 years of age, continuous enrolment starting from 2006 (index year) to 2012 in a plan with prescription benefits, and with at least 1 anti-diabetic drug prescription during the study. Data were analyzed for drug treatment patterns, and for costs of inpatient and outpatient services, emergency department use, and medications and supplies.

Results: Approximately 28% of newly diagnosed patients had no prescriptions for anti-diabetic drugs in 2007, and this decreased to 22% in 2012. The percentage of patients who received only OADs, but no injectables, during the enrollment period remained between 65% and 69%. Among these patients, the percent receiving 1 OAD fell from approximately 70% to 60%, those receiving 2 OADs rose from 25% to 31%, and patients prescribed 3 OADs increased from 4.5% to 8%. Less than 1% received 4 or more OADs. Monotherapy with Metformin (Met) progressively fell from 35% to 31% of patients. Monotherapy with SUs fell from 7% to 6%, and for TZDs fell from 5% to 1.8% of patients. Dual OAD combinations were used by 17.8% of patients in 2007, progressively rising to 20% in 2012. Insulin monotherapy was initiated by only 0.2% of patients in 2007, rising to 1.7% in 2012. Patients using combined insulin and OAD therapy grew from <1% in 2007 to 6.5% in 2012. Combined GLP-1 agonist/OAD therapy grew from 2.3% to 3.3% of patients in 2012. From 2007 to 2012, total Met use (single and multiple therapy) grew from 56% to 62% of patients. Similarly, total SU use grew from 20% to 27%, TZD use fell from 18% to 10%, and DPP-4 inhibitor use grew from 2% to 15% of patients in the cohort. The total percent of patients using insulin or GLP-1, with and without OADs, rose to 7% and 4% of patients, respectively, in 2012. Total annual costs/T2D patient rose from \$9817 to \$12551 (based on 2012 levels), with the largest contribution coming from outpatient costs (\$4140 to \$5485), followed by costs for all drugs (\$2897 to \$3275), for inpatient services (\$1421 to \$1695) and emergency department use (\$960 to \$2096).

Conclusion: From 2006 to 2012, OAD monotherapy in this cohort of newly diagnosed patients declined and dual OAD therapy rose. Costs for all forms of resource utilization increased, resulting in net overall cost increases of \$2734 per T2D patient/year.

DISCOVERing treatment of type 2 diabetes in real world settings using electronic medical record databases

N. Hammar¹, B. Charbonnel², P. Fenici³, L. Garcia-Alvarez⁴, M.B. Gomes⁵, K. Hashigami⁶, J. Hiller⁴, L. Ji⁷, K. Khunti⁸, A. Nicolucci⁹, S. Pocock¹⁰, M.V. Shestakova¹¹, I. Shimomura¹², F.A. Surmont¹³, J. Medina¹⁴;

¹AstraZeneca (AZ), Södertälje, Sweden, ²Univ of Nantes, France, ³AZ, Melbourn, UK, ⁴IMS Health, London, UK, ⁵Rio de Janeiro State Univ, Brazil, ⁶AZ, Tokyo, Japan, ⁷Diabetes Center, Peking Univ People's Hospital, Beijing, China, ⁸Univ of Leicester, UK, ⁹Ctr for Outcomes Res and Clinical Epidemiology, Pescara, Italy, ¹⁰London School of Hygiene & Tropical Med, UK, ¹¹Endocrinology Res Ctr, Moscow, Russian Federation, ¹²Osaka Univ, Japan, ¹³AZ, Shanghai, China, ¹⁴AZ, Madrid, Spain.

Background and aims: Despite evidence of improved long term complications with risk factor control in patients (pts) with type 2 diabetes mellitus (T2DM), there is a lack of comparative global data on T2DM treatments (tx) and control from different regions. The availability of existing electronic medical records (EMR) in some countries offers the opportunity to gain insights into the disease, pt characteristics and management patterns, as well as clinical evolution. This study aims to provide descriptive EMR data from the real-world clinical setting on second and further line anti-diabetic tx use among T2DM patients in Canada (CAN), France (FR), Germany (DE), specifically those treated by general practitioners (DE GPs), and the United Kingdom (UK). The main outcomes of interest were changes in T2DM tx, glycaemic control in response to second-line tx and proportion of pts reaching A1c < 7% during the follow-up period.

Materials and methods: Retrospective multi-country non-interventional, cohort study utilising longitudinal EMR data from pre-existing databases. Pts with T2DM aged ≥ 18 years, initiating a second line anti-diabetic tx at baseline, and with a minimum follow-up of 6 months, were included.

Results: A total of 22,272 T2DM pts initiating second-line tx were identified from May 2011 to April 2014. Of these pts, 805 were from CAN, 432 from FR, 8,140 from DE and 12,895 from the UK. Mean A1c at initiation of second-line tx was > 7.5% in all countries (CAN: 8.8%; FR: 7.83%; DE GPs: 8.01%; UK: 9.0%). The most common first-line monotherapies were metformin (CAN: 81.7%; FR: 91.7%; DE GPs: 79.40%; UK: 88.6%), and sulphonylureas (SU) (CAN: 13.4%; FR: 4.9%; DE GPs: 12.14%; UK: 10.7%). The most frequently initiated second-line therapies were combination tx: metformin and DPP4 combination (CAN: 38.6%; FR: 38.4%; DE GPs: 45.2%; UK: 21.4%) and metformin and SU combination (CAN: 25.7%; FR: 15.7%; DE GPs: 21.28%; UK: 53.2%). Reductions in A1c were observed from baseline throughout the follow up period in all countries (mean A1c at 6 months in CAN: 7.4%; FR: 6.94%; DE GPs: 7.03%; UK: 7.6%).

Conclusion: Despite availability of guidelines, all countries studied had high A1c at baseline with many pts failing to achieve A1c < 7% with second-line therapy. There are large intercountry variations in glycaemic control and second-line tx initiated. After failure of metformin monotherapy, the most common drugs added by physicians were DPP4 inhibitors and SU. Although reductions in A1c were achieved, mean values remained mostly above the recommended target of 7%. Data derived from real-world analyses such as this, where EMR sources are exploited to fill in gaps in evidence, may be useful to inform on the clinical utility of different tx applied in routine practice. The long term glycaemic control in

the real world on micro and macrovascular outcomes is being investigated in the DISCOVER program.

Characteristics and prescription behaviour of insulin glargine users among patients with type 2 diabetes mellitus

X. Huang¹, C.-P.S. Fan², Z. Li², B. Hanna², J. Tang², J. Williams¹;

¹Merck & Co., Inc, Kenilworth, ²Asclepius Analytics LLC, Brooklyn, USA.

Background and aims: Type 2 Diabetes Mellitus (T2DM) is a progressive disease and treatment intensification is often required. When oral antidiabetic drugs (OAD) fail to maintain glycaemic control, initiating insulin therapy is recommended by the ADA and EASD. Published analyses of randomized controlled trials suggest advantages of initiating insulin therapy with long-acting basal insulin (e.g. insulin glargine or insulin detemir) compared to conventional intermediate-acting human basal insulin (e.g. NPH). However, target treatment populations and real-world patterns of insulin glargine use have not been well documented. This study examined the characteristics and prescription behavior of patients (pts) initiating insulin glargine in Germany.

Materials and methods: A retrospective cohort study utilized a sample from the Germany IMS Disease Analyzer data. Included were pts with T2DM who initiated any basal insulin (i.e. intermediate-acting or long-acting insulin) in 2009-2013, ≥ 18 years (yrs), with continuous medical records. Eligible pts were classified into glargine or non-glargine cohort, depending on their index insulin. Between-cohort differences in 1-yr baseline patient characteristics, 1-yr post-index cumulative insulin dose and 1-yr post-index concomitant OAD use were assessed using Wilcoxon rank-sum tests for continuous and χ^2 tests for categorical variables. Multivariable linear regression was used to compare the cumulative insulin dose in the glargine vs. non-glargine cohort, adjusting for baseline HbA1c and other characteristics.

Results: 14,886 basal insulin initiators were included, 47.0% and 53.0% were in the glargine cohort and non-glargine cohort, respectively. Among the glargine cohort, 85.3% initiated glargine only and 14.7% initiated glargine with short-acting insulin. Among the non-glargine cohort, 31.2% initiated NPH only, 16.3% initiated insulin detemir only, and 52.5% initiated either NPH or insulin detemir with short-acting insulin. Compared to the non-glargine cohort, the glargine cohort had higher HbA1c (8.7% vs. 8.6%), and a greater proportion had diabetes-related macro-vascular complications (17.0% vs. 7.7%), hypertension (32.6% vs. 15.1%) and hyperlipidemia (15.4% vs. 7.6%) at baseline. Post insulin initiation, compared to the non-glargine cohort, a higher proportion of the glargine cohort used concomitant OADs (DPP-4: 21.3% vs. 11.7%), but they had a lower cumulative insulin dose (9,753 vs. 10,288 IU) (all $p < 0.01$). Regression analysis demonstrated that among pts with baseline HbA1c < 8% and between 8-9%, the glargine cohort used 124 IU and 963 IU less insulin over 1 year compared to the non-glargine cohort, respectively.

Conclusion: Almost 1/2 of basal insulin initiators initiated insulin glargine. Pts initiating insulin glargine had more comorbidities and T2DM related macro-vascular complications at baseline. In the 1-yr post-initiation, the insulin glargine cohort had higher use of concomitant OAD, but a lower cumulative insulin dose.

Second-line treatment with sulfonylurea compared to DPP4 inhibitors demonstrated associations with earlier treatment intensification with insulin

J. Bodegard¹, D. Nathanson², T. Nyström³, M. Thuresson⁴, A. Norhammar⁵, J.W. Eriksson⁶;

¹AstraZeneca, Södertälje, ²Department of Clinical Science and Education, Karolinska Institutet, ³Karolinska Institutet, Stockholm, ⁴Statisticon AB, Uppsala, ⁵Department of medicine, Karolinska Institutet, Stockholm, ⁶Department of Medical Sciences, Uppsala University, Sweden.

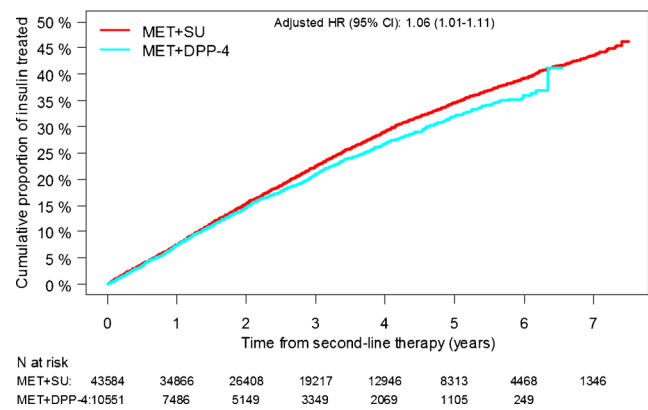

Background and aims: To investigate the initiation of second-line blood glucose lowering drug (GLD) treatment, patient characteristics and subsequent drug intensification for type 2 diabetes (T2DM) patients.

Materials and methods: T2DM patients who were on monotherapy with non-insulin antidiabetic drug (NIAD) and initiated on their second-line GLD treatment during 2006–2013 were identified in the Swedish Prescribed Drug Register and linked with the Swedish National Patient and Cause of Death registries. Index date was defined as the date of patients second GLD dispense after monotherapy on NIAD. Definition of a non-insulin antidiabetic drug (NIAD) start was any dispense recorded whereas insulin start was defined when treatment duration exceeded 6 months. From 1987 to index date, baseline information on comorbidity was collected from the Swedish National Patient Register. Cox survival models adjusted for age, gender, first line duration and prior cardiovascular disease were used to estimate risk of early treatment intensification during up to 7 years of follow-up.

Results: Of the 102,085 T2DM patients initiated on second-line treatment, 73% were on metformin, 22% on SU, 3% on metiglinid and 2% on other treatments in first line. Second-line was initiated by add-on of either one or more NIAD (67%) or switch to insulin (33%). Insulin patients, compared to the NIAD combinations, were older (70 vs. 64), had more history of cardiovascular- (50% vs. 31%) and microvascular disease (29% vs. 17%). In the 68,351 patients (on NIAD only); the most frequent dual-combination was metformin+sulfonylurea (SU) (64%) followed by metformin+DPP4i (15%). Metformin+SU vs metformin+DPP4 were older (65 vs 61 years), less frequently men (59 vs 62%), whereas the history of cardiovascular-, (32 vs 28%) and microvascular disease (18 vs 15%) were similar. Blood pressure-, lipid lowering and low dose aspirin treatment were also similar in the two groups. Compared with metformin+DPP4, metformin+SU was associated with earlier treatment with insulin, hazard ratio (95% CI): 1.06 (1.01–1.11).

Conclusion: In type 2 diabetes patients in Sweden, approximately 70% of second-line treatment was initiated with dual NIADs and more than 30% with insulin. Metformin+SU was the most frequent second-line combination, and demonstrated associations with earlier treatment with insulin compared with the metformin+DPP4 combination.

Figure: Likelihood of early insulin start in patients who were either initiated on second-line treatment with metformin (MET)+sulfonylurea (SU) or MET+DPP4i.

The beta cell and insulin resistance in polycystic ovary syndrome: new insights into the origins and prevention of type 2 diabetes

J. Tomlinson¹, A. Mari², A. Tura², K. Bond³, E. Stenhouse⁴, R.P. Vincent⁵, J. Pinkney⁶;

¹Pool Health Centre, Redruth, Cornwall, UK, ²Institute of Biomedical Engineering of the Italian National Research Council, University of Padua, Italy, ³Research and Development, Royal Cornwall Hospital, Truro, ⁴School of Nursing and Midwifery, University of Plymouth, ⁵Clinical Biochemistry, King's College Hospital, London, ⁶Peninsula Schools of Medicine and Dentistry, University of Plymouth, UK.

Background and aims: Polycystic Ovary Syndrome is a risk factor for type 2 diabetes (T2D) and cardiovascular disease (CVD) but the mechanisms are poorly understood. The aim of this study was to investigate how the interplay of insulin secretion and action results in glucose dysregulation in PCOS.

Materials and methods: 48 non-diabetic lean and obese women with PCOS (Rotterdam criteria) and 53 BMI-matched controls were studied. Insulin secretion was calculated by a model of insulin secretion and beta cell function from glucose and C-peptide levels, and Insulin Sensitivity Index (ISI) by the method of Matsuda, from a 6-point, 2 hour, 75 g oral glucose challenge. Adiposity was measured by bioimpedance and anthropometry.

Results: 1) Women with PCOS and controls were well matched for BMI (mean [SD]28.83 [6.98] vs 29.42 [7.17] kg/m²; p=0.68) and there was no difference in Beta Cell Glucose Sensitivity (BCGS), which is the mean slope of the dose-response function, representing the static relationship between glucose and insulin secretion (median [IQR] 83.3 [62.2-131.9] vs 102.4 [64.1-145.8] pmol/min/mL/mmol; p=0.57). 2) ISI was strongly related to BMI category (<25, 25-29.9, 30-34.9, >35) (ANOVA; p<0.001), and waist circumference (WC) and visceral fat (VF) (r=0.50-0.58; p<0.001). Although ISI did not differ in PCOS vs controls, Insulin at 2 hrs was higher in PCOS (371.63 [261.14-578.07] vs 263.91 [150.01-488.93] pmol/l; p=0.03) and strongly associated with VF (r=0.52; p<0.001) and 2 hr glucose (r=0.66; p<0.001). In both groups, WC and VF correlated strongly with HDL cholesterol (r=-0.42 to -0.64; all p<0.004), systolic blood pressure (r=0.24-0.71; p=0.09-<0.001) and C-reactive protein (r=0.49-0.56; all p<0.002). 3) Women with PCOS and 2 hr glucose >7.5 vs <7.5 mmol/l, had lower BCGS (43.5 [23.6] vs 109.0 [68.5] pmol/min/mL/mmol; p=0.04), higher WC (116.8 (15.8) vs 93.5(15.9) cm; p<0.01) and VF (14.6 (4.2) vs 10.3 (4.6); p=0.05), and despite non-significantly lower ISI (0.42 [0.25-0.96] vs 0.94 [0.53-1.36]; p=0.29) levels of insulin at 2 hrs were much higher (964.0 (579.2-1214.7) vs 328.2 (242.2-475.7) pmol/l; p=0.01). In PCOS, WC was strongly associated with increasing 2 hr glucose, but this was only present in women in the lowest quartile of BCGS (r=0.80; p=0.003).

Conclusion: PCOS predisposes to T2D and CVD as a result of insulin resistance (IR) which is exacerbated by central obesity. Although neither PCOS nor central obesity impair BCGS per se, women who also have poor BCGS possess the critical defect that renders them unable to compensate for increasing IR, and therefore predisposes to T2D. These results show that the pathogenesis of T2D in women with PCOS conforms to the models postulated by DeFronzo and Reaven, in which glucose levels are determined by an interplay of insulin secretion and resistance, with adiposity being a dominant influence on IR. The findings suggest that waist circumference and 2 hr glucose could be used to stratify risk, and highlight the importance of healthy weight to reduce the risks of T2D and CVD in women with PCOS.

The shape of plasma insulin and insulin-to-glucose ratio curves during an oral glucose tolerance test and prediction of future risk of type 2 diabetes

H. Yang, S.-H. Lee, B. Kang, Y.-R. Yang, J. Cho, B. Cha, K.-H. Yoon; Endocrinology and Metabolism, The Catholic University of Korea, School of Medicine, Seoul, Republic of Korea.

Background and aims: The pattern of glucose curve during oral glucose tolerance test (OGTT) is known to be associated with degree of insulin sensitivity and secretory function as well as with the risk of type 2 diabetes development in adults and adolescents. However little is known about the patterns of insulin or insulin-to-glucose (I/G) ratio curves. In this prospective follow-up study, we aimed to evaluate the risk for future diabetes development according to the shape of plasma insulin and I/G ratio during 75 g OGTT.

Materials and methods: Among subjects enrolled in a community-based cohort named Chungju Metabolic disease Cohort, those who performed OGTT during 2007-2010 and repeated the test during 2011-2014 were included. Subjects with diabetes at baseline were excluded. Blood samples were obtained at 0-, 30-, and 120-min to measure glucose and insulin levels and I/G ratio was calculated for each time points. Compared to the insulin or I/G ratio value at 30-min, those showing lower value at 120-min was classified as having downward-slope, while those with higher value was classified as having upward-slope of insulin or I/G ratio curve, respectively.

Results: Among 1126 subjects, 117 (10.39%) developed type 2 diabetes after 4 years. Compared to the baseline value, the AUC(0-30 min) of insulin and I/G ratio curves, insulinogenic index and Stumvoll index increased in diabetes-nonconverters after follow-up, which was not shown in diabetes-converters. HOMA-beta and Matsuda index did not show significant change, while BMI and HOMA-IR increased in both groups. Among subjects with downward (n=482) and upward (n=644) slope of insulin curve, 3.9% and 15.2% developed diabetes, respectively. Among subjects with downward (n=328) and upward (n=798) slope of I/G ratio curve, 3.0% and 13.4% developed diabetes, respectively. Those showing upward slope of insulin curve demonstrated crude odds ratio (OR) of 4.924 (95% CI, 2.541-9.542) and adjusted OR of 3.804 (2.276-6.538) for development of diabetes. Similarly, subjects showing upward slope of I/G ratio curve demonstrated crude OR of 4.924 (2.541-9.542) and adjusted OR of 3.804 (2.276-6.358) for future diabetes.

Conclusion: The shape of insulin or I/G ratio curve during OGTT may help to identify subjects who are at risk of diabetes development. Further studies in different ethnicities are required to confirm our study results.

378

Non-alcoholic fatty liver disease predicts type 2 diabetes mellitus, but not pre-diabetes, in Xi'an, China: a 5-year cohort study

B. Gao¹, J. Ming², S. Xu², Y. Fang², Q. Ji²;

¹Department of Endocrinology, Xijing Hospital, Fourth Military Medical University, The Key Laboratory of Biomedical Information Engineering of Ministry of Education, Xi'an Jiaotong University School of Life Science and Technology, ²Department of Endocrinology, Xijing Hospital, Fourth Military Medical University, Xi'an, China.

Background and aims: Emerging studies have focused the association between non-alcoholic fatty liver disease (NAFLD) and the risk of type 2 diabetes mellitus (T2DM) but the results were inconsistent. In addition, few studies have put focus on the association between NAFLD and the

risk of pre-diabetes. We aimed to investigate whether NAFLD diagnosed by ultrasonography could predict the risk of T2DM and pre-diabetes in Chinese population.

Materials and methods: The population-base cohort study, which was held in Xi'an, Northwestern China, was based on China National Diabetes and Metabolic Disorders Survey (2007–2008). During a follow-up of 5 years, 508 healthy subjects were included as study sample. NAFLD was determined by abdominal ultrasonography. T2DM and pre-diabetes were diagnosed based on oral glucose tolerance test. Cox proportional hazard regression was utilized to examine the association between NAFLD and the development of diabetes and pre-diabetes.

Results: Of 508 subjects, 97 (19.1%) were diagnosed as NAFLD and 411 (80.9%) were as non-NAFLD; 20 (3.9%) developed diabetes and 85 (16.7%) developed pre-diabetes during follow-up. The incidence of diabetes and pre-diabetes in the NAFLD group was 20.6 and 51.6 per 1000 person-years, respectively, whereas that in non-NAFLD group was 4.9 and 29.2 per 1000 person-years, respectively. Cox proportional hazard regression showed that the multivariable-adjusted relative risk (RR) of T2DM and pre-diabetes in the NAFLD group was 4.462 [95% confidence interval (CI): 1.855–10.734, $P < 0.001$] and 1.642 (95% CI: 0.965–2.793, $P = 0.067$), respectively, compared with non-NAFLD group.

Conclusion: NAFLD was a significant predictor for T2DM, but not for pre-diabetes, in Xi'an, China. More future cohort studies are needed to confirm the present findings.

Table Multivariate analysis of non-alcoholic fatty liver disease in predicting type 2 diabetes mellitus and pre-diabetes

Variable	Crude		Adjusted*	
	RR (95% CI)	P value	RR (95% CI)	P value
Diabetes				
Non-NAFLD	1.000		1.000	
NAFLD	4.247 (1.768–10.204)	<0.001	4.462 (1.855–10.734)	<0.001
Pre-diabetes				
Non-NAFLD	1.000		1.000	
NAFLD	1.788 (1.110–2.881)	0.017	1.642 (0.965–2.793)	0.067

NAFLD: non-alcoholic fatty liver disease; RR: relative risk; CI: confidence interval.

*: Relative risks and 95% CI were calculated using a backward stepwise method. The covariables were age, gender, educational level, cigarette smoking, alcohol drinking, physical activities, family history of diabetes, BMI, blood pressure, fasting glucose level, 2-hour glucose level, serum triglyceride, HDL cholesterol level.

379

Serum uric acid predicts incident type 2 diabetes mellitus only in women after adjusting body compositions

Y. Hong, Y.-B. Lee, S.-E. Lee, J. Jun, W. Hong, T. Yu, M.-K. Lee, J. Kim; Samsung Seoul Hospital, Republic of Korea.

Background and aims: Serum uric acid (SUA) level has been reported to be associated with incident type 2 diabetes mellitus (T2DM) and body composition. However, several previous studies reported combined results for men and women after adjusting for sex and there were no studies that body compositions were taken into account. Thus, we designed this longitudinal sex-specific follow-up study to elucidate the association of SUA levels with incident T2DM including body compositions as an adjusting factor with large scale.

Materials and methods: A retrospective longitudinal study was performed to evaluate the association between SUA levels and the development of T2DM. A total of 21,714 participants (12,307 men and 9,407 women) taking a medical health check-up program without diagnosed T2DM at baseline were enrolled. Separate analyses were performed for men and women including body compositions as a confounding factor.

Cox proportional hazards models were used to quantify the independent association between SUA levels and incident T2DM.

Results: During 109,438 person-years of follow-up, there were 1,768 (1,269 in men, 499 in women, respectively) incident cases of T2DM between 2006 and 2012. After full adjustment for multiple associated confounders including body compositions, SUA levels were significantly associated with incident T2DM in women (per 1 mg/dl, hazard ratio (HR)=1.125, 95% confidence interval (CI): 1.005–1.260, $p = 0.041$). In men, however, this association lost statistical significance after adjusting for multiple associated confounders (per 1 mg/dl, HR=1.009, 95% CI: 0.952–1.069, $p = 0.762$).

Conclusion: This study demonstrated that SUA levels are associated with incident T2DM only in women and do not predict incident T2DM in men after adjusting body compositions. Abbreviations: T2DM, type 2 diabetes mellitus; SUA, serum uric acid; BMI, body mass index; BP, blood pressure; LDL, low density lipoprotein; HDL, high density lipoprotein; FFM, fat-free mass; FM, fat mass.

Background and aims: Patients with type 2 diabetes mellitus (T2DM) exhibit a typical pattern of dyslipidemia with low HDL cholesterol, high triglycerides and a low LDL cholesterol per apolipoprotein B (LDL-C/apoB) ratio reflecting small LDL particles. We hypothesized that high triglycerides, low HDL cholesterol and a low LDL-C/apoB ratio predict incident T2DM among non-diabetic patients with established coronary artery disease (CAD).

Materials and methods: We enrolled 655 non-diabetic patients with angiographically proven stable CAD. Prospectively, the incidence of T2DM was recorded over a mean follow-up period of 6.1 ± 3.7 years. Diabetes was diagnosed according to ADA criteria.

Results: From our non-diabetic coronary patients, 358 (54.7%) at baseline had normal fasting glucose (NFG) < 100 mg/dl, and 297 (45.3%) had impaired fasting glucose (IFG) ≥ 100 mg/dl. During follow-up, T2DM was newly diagnosed in 17.4% of our patients. Baseline IFG compared to NFG was associated with a strongly increased risk of T2DM (26.6% vs. 9.8%; adjusted OR 3.34 [2.17–5.16]; $p < 0.001$). Low HDL cholesterol, high triglycerides, and a low LDL-C/apoB ratio after multivariate adjustment including fasting glucose significantly predicted incident diabetes in the total study cohort (OR 0.65 [0.49–0.86]; $p = 0.003$, 1.40 [1.13–1.74]; $p = 0.002$ and 0.54 [0.41–0.71]; $p < 0.001$, respectively) and also when we separately analyzed patients with IFG (OR 0.67 [0.46–0.97]; $p = 0.032$, 1.42 [1.03–1.96]; $p = 0.032$ and 0.56 [0.39–0.79]; $p = 0.001$, respectively) and NFG (OR 0.62 [0.40–0.96]; $p = 0.034$, 1.38 [1.03–1.86]; $p = 0.033$ and 0.49 [0.32–0.76]; $p = 0.001$, respectively).

Conclusion: We conclude that among patients with angiographically proven stable CAD the incidence of diabetes is high, particularly among those with IFG. Importantly, high triglycerides, low HDL cholesterol and a low LDL-C/apoB ratio significantly predict incident diabetes independently from baseline glycemia.

A mathematical disease progression model for the effect of diet and exercise in subjects with impaired glucose tolerance in the Finnish Diabetes Prevention Study (FDPS)

S.M.S. Ghadzi^{1,2}, M.O. Karlsson¹, V.D. de Mello³, M. Uusitupa³, M.C. Kjellsson¹, Finnish Diabetes Prevention Study Group;

¹Department of Pharmaceutical Biosciences, Uppsala University, Sweden, ²School of Pharmaceutical Sciences, Universiti Sains Malaysia, Penang, Malaysia, ³Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio Campus, Finland.

Background and aims: Mathematical modelling is frequently used to characterize and quantify underlying mechanisms of complicated physiological responses. For this purpose, Silber et al developed an integrated glucose-insulin (IGI) model describing dynamic glucose and insulin after glucose provocations in healthy and type 2 diabetic subjects. Although being able to describe the two populations, the progression from healthy to diabetic is missing in the IGI model. The aim of this project was to develop the IGI model to include disease progression for a population with impaired glucose tolerance (IGT), quantifying the effect of diet and exercise intervention.

Materials and methods: Data derived from the randomized Finnish Diabetes Prevention Study (FDPS) and consisted of yearly OGTTs (from baseline, year 0 to the fourth year), one IVGTT at the start of the study (baseline) and one IVGTT at the end of the study (fourth year). One hundred and one out of 552 subjects with impaired glucose tolerance who were randomly assigned to a lifestyle intervention group (diet and exercise) or a control group were studied. Subjects who developed diabetes were excluded from the study at the time of diagnosis. All longitudinal measurements of glucose and insulin after IVGTT and OGTT were used to fit the IGI model with mixed-effect methodology (NONMEM version 7.3). Disease progression was investigated on the pathophysiologically most reasonable parameters of the model. The effect of diet and exercise was investigated on the parameters identified to be involved in disease progression.

Results: Disease progression was found to affect the first phase insulin secretion, the maximal effect of incretin on insulin release and the insulin sensitivity, represented as insulin-dependent glucose elimination (p value <0.001); only the maximal effect of incretin on insulin release was unaffected by changes in lifestyle. For the control group, decreases of 7.5%/year and 4.7%/year were observed on first phase insulin secretion and insulin-dependent glucose elimination. With diet and exercise intervention, the decrease in the first phase insulin secretion was only 1.3%/year and the insulin-dependent glucose elimination increased by 3.1%/year. These values represent patients in the pre-diabetic state as occurrence of diabetes was an exclusion criterion for the study.

Conclusion: The disease progression was successfully included in the IGI model to describe changes in glucose provocation data from subjects with IGT, independent of lifestyle intervention program.

Circulating concentrations of endothelin-1 predict impaired glucose tolerance and type 2 diabetes in women but not in men: a prospective study in the Vara-Skövde cohort

J. Olausson¹, B. Daka², M.I. Hellgren², C.A. Larsson^{2,3}, U. Lindblad², P.-A. Jansson¹;

¹Molecular and Clinical Medicine, Medicine, Sahlgrenska Academy, ²Department of Public Health and Community Medicine/Primary Health Care, Sahlgrenska Academy, Medicine, Sahlgrenska Academy, Gothenburg, ³Department of Clinical Sciences, Social Medicine and Global Health, Lund University, Malmö, Sweden.

Background and aims: Endothelial dysfunction is mechanistically coupled to insulin resistance and is characterised by an imbalance

between nitric oxide and endothelin-1 (ET-1). Although ET-1 expression is increased in insulin resistance and type 2 diabetes (T2D) it is unclear whether ET-1 may be a forerunner of these conditions. Our current aim was to investigate whether circulating ET-1 levels may predict the incidence of impaired glucose tolerance (IGT) and T2D in a population based prospective study.

Materials and methods: During 2002-2005, 2816 adult participants (age 30-74 years) were randomly selected from two municipalities in south-western Sweden. At baseline circulating ET-1 levels and metabolic risk factors were measured while glucose metabolism was assessed by performing an oral glucose tolerance test (OGTT, 75 g). Moreover, blood sampling, including OGTT, being performed in 1338 participants at baseline was repeated at the follow-up between 2012-2014. After excluding participants with IGT, T2D or missing information on ET-1 at baseline, 1152 participants were left for further analysis. General linear models (GLM) were employed to estimate differences in ET-1 levels in participants with or without impaired glucose metabolism. In addition, logistic regressions were used to estimate the odds ratio (OR) for incident IGT or T2D by 1 pg/ml difference in ET-1 level at baseline. All analyses were performed using SPSS 21.

Results: Age- and municipality-adjusted GLM showed that circulating baseline ET-1 levels were significantly higher in women who developed incident IGT and T2D compared with women with normal glucose metabolism at the follow-up (2.8 ± 1.2 , $n=67$ vs 2.4 ± 1.3 pg/ml, $n=518$, $p=0.013$). In contrast, we observed no difference in ET-1 levels in men comparing participants with or without IGT/T2D at the follow-up (2.2 ± 1.3 , $n=83$ vs 2.3 ± 1.2 pg/ml, $n=483$ $p=0.589$). There was a significant age-independent interaction term between sex and ET-1 ($p=0.027$). Further, sex-stratified logistic regression was significant in women (OR: 1.3, 95% CI: 1.1-1.6, $p=0.013$), but not in men (OR: 0.9, 95% CI: 0.8-1.4, $p=0.513$). Finally, the predictive value of ET-1 for IGT/T2D at the follow-up in women remained significant after further adjustment for age, municipality, waist-hip ratio, CRP, smoking, leisure time physical activity, and systolic blood pressure (OR: 1.3, 95% CI: 1.1-1.7, $p=0.010$).

Conclusion: This longitudinal population-based study shows that higher circulating ET-1 levels predict development of incident IGT and T2D in women but not in men. ET-1 might be an early marker for increased T2D risk in women, and, thus, a target for future treatment and prevention strategies.

Increment of serum bilirubin affects incident type 2 diabetes

S.-E. Lee, T.Y. Yu, Y. Hong, W.J. Hong, J.E. Jun, Y.-B. Lee, M.-K. Lee, J.H. Kim;

Internal Medicine, Samsung Medical Center, Seoul, Republic of Korea.

Background and aims: Bilirubin is not only the byproduct of heme catabolism but also an important antioxidant in vivo. Serum bilirubin level has been reported to be associated with incident type 2 diabetes mellitus (T2DM). However, there have been no longitudinal studies to determine the association between changes of serum bilirubin levels and incident T2DM. The aim of current study was to investigate the relationship between baseline serum bilirubin (BB) levels and percentage changes in serum bilirubin (PCB) levels and incident T2DM in a large-scale longitudinal study.

Materials and methods: A total of 24185 participants taking annual medical health check-up program between 2006 and 2012 were enrolled. Multivariable-adjusted Cox regression models were fitted to assess the relative risk of incident T2DM by baseline and percentage change during follow-up in bilirubin levels. PCB levels were defined as follows; changes in serum bilirubin levels were calculated from baseline to the end of follow-up or until a year before the last date of diabetes diagnosis, divided by BB, and multiplied by 100.

Results: After exclusion of subjects with T2DM at the baseline and at the first visit of follow-up, liver disease, and missing data, 20233 participants were investigated and median follow-up duration was 60.23 months. 1275 new cases of T2DM occurred during follow-up. There was no significant difference in BB levels between the group with incident T2DM and the group without incident T2DM ($P>0.05$), while PCB levels of those groups were significantly different ($P<0.001$). When dividing BB and PCB levels into quartiles, the proportions of participants observed to develop T2DM were not different among BB quartiles ($P>0.05$), however, the proportions of incident T2DM significantly increased across quartiles of PCB (from the lowest to the highest quartile, 3.9% in the first, 4.2% in the second, 7.0% in the third, and 9.7% in the fourth; $P<0.001$). After adjusting multiple potential confounders including fasting blood glucose level and HbA_{1c}, the HR of incident T2DM in the highest quartile of PCB was more than two times that of the lowest quartile group (HR 2.038 [95% CI 1.722 - 2.412]; P for trend <0.001). This association was still significant when PCB was analyzed as a continuous variable, per 1% increase, the HR of incident T2DM was 1.006 (95% CI 1.005 - 1.007; $P<0.001$). In subgroup analysis ($n=13394$) with fasting insulin levels, the result remained significant (HR 1.006 [95% CI 1.005-1.008]; $P<0.001$) after additional adjustment of fasting insulin level and homeostasis model assessment of insulin resistance (HOMA-IR). **Conclusion:** This study demonstrated that an increase in serum bilirubin level, rather than baseline serum bilirubin level itself, can be associated with incident T2DM.

A novel insulin mutation in autosomal dominant diabetes

C.M. Reinauer¹, S. Kummer¹, K. Förtsch¹, C. Bergmann², E. Mayatepek¹, T. Meissner¹;

¹Department of General Pediatrics, Neonatology and Pediatric Cardiology, Heinrich-Heine-University Düsseldorf, ²Center for Human Genetics Bioscientia, Ingelheim, Germany.

Background and aims: Diabetes caused by insulin (*INS*) gene mutations is a rare form of neonatal diabetes, prevalence is estimated at 1 of 200.000 live births in Europe. We report a German female patient with a novel form of permanent neonatal diabetes mellitus.

Materials and methods: The second child of non-consanguineous German parents was born at 40 weeks of gestation; BW 3260 g. At the age of 8 days the girl presented with polyuria, sweating and frequent vomiting. Blood glucose showed significant hyperglycaemia >200 mg/dl without ketosis. Insulin (6.9 mU/l) and C-peptide (1.8 µg/l) were detectable and there were no clinical or laboratory signs of exocrine pancreatic insufficiency. Transabdominal ultrasound showed a normal pancreatic structure. No other symptoms or dysmorphic features were evident. Her father had been treated for diabetes mellitus since the age of 3 months, so far classified as type 1 diabetes, while there was no other case of DM in the family history. Genetic testing identified a novel heterozygous *INS* gene mutation (c.128G>A) in both father and daughter. The missense mutation causes an amino acid exchange of the highly conserved position 43 cysteine (p.Cys43Tyr), resulting in the loss of one disulfide bond. Bioinformatic tools predict an impairment in protein function (MutationTaster, PolyPhen2, SIFT, AlignGVGD).

Results: We considered that the novel mutant insulin might cause β -cell toxicity through endoplasmatic reticulum (ER) stress as described for other *INS* mutations. Low dose insulin therapy was started using continuous subcutaneous insulin infusion (CSII) with insulin U10 dilution at the age of 4 weeks in combination with continuous subcutaneous glucose monitoring (CGMS). Significant hypoglycaemia did not occur, blood glucose could be kept in the range between 100 and 170 mg/dl within the first year of life. Bolus insulin was not introduced until the age of 18 months. At the current age of 24 months, the child is thriving well with HbA_{1c} stable between 60-65 mmol/mol under low dose CSII with 0.3 IU/kg/d without hypoglycaemia. The father shows poor glucose control (HbA_{1c} 111 mmol/mol) due to incompliance, and low but significant C-peptide release even after three decades of diabetes.

Conclusion: This novel *INS* mutation leads to a loss of one disulfide bond. Its phenotype has not yet been described. Low dose CSII was used without overt hypoglycaemia aiming to decrease endogenous insulin production and therefore reduce ER stress to minimize progressive loss of beta cell mass. Follow up will show whether low dose insulin infusion will help to maintain β -cell function due to reduction of ER stress.

miRNA 224 is readily detectable in urine of individuals with diabetes mellitus and a potential indicator of beta cell demise

S. Bacon¹, B. Engelbrecht², J. Schmid³, S. Pfeiffer², C.G. Concannon², A. McCarthy¹, M. Burke¹, J.H.M. Prehn³, M.M. Byrne¹;

¹Endocrinology & Diabetes, Mater Misericordiae University Hospital, ²Department of Physiology & Medical Physics, Royal College of Surgeons in Ireland, ³Centre for Systems Medicine, Royal College of Surgeons in Ireland, Dublin, Ireland.

Background and aims: MicroRNA (miRNA) are a class of non-coding, 19-25 nucleotide RNA critical for network-level regulation of gene expression. HNF1A-maturity-onset diabetes of the young (HNF1A-

MODY) is a monogenic form of diabetes resulting from mutations in the gene encoding the pancreatic transcription factor hepatocyte nuclear factor 1 α (HNF1A). We recently demonstrated that induced suppression of endogenous HNF1A function in INS-1 cells, a cellular model of HNF1A-MODY increased the levels of two miR-224 and miR-103. Using absolute quantitative PCR analysis, we demonstrated that miR-224 and miR-103 levels were significantly elevated in the serum of HNF1A-MODY carriers when compared to controls. miR-224 is a novel miRNA in the field of diabetes. The aim of this current study was to obtain proof-of-concept that miR-224 and miR-103 are also detectable in the urine of HNF1A-MODY carriers, and to determine whether these diabetes-associated miRNA are also elevated in the urine of patients with type 1 and type 2 diabetes mellitus.

Materials and methods: Absolute levels of miR-224 and miR-103 were determined in the urine of n=144 individuals including HNF1A-MODY carriers, participants with type 1, type 2 diabetes mellitus and normal controls. We also correlated urinary levels of miRNA with serum levels and with clinically relevant indices of renal disease.

Results: miR-224 was significantly elevated in the urine of HNF1A-MODY carriers and participants with type 1 diabetes mellitus (see figure 1). miR-103 was highly expressed in urine across all diabetes cohorts when compared to controls. For both miRNA-224 and-103 we found a significant correlation between serum and urine levels ($p<0.01$). miR-224 and miR-103 levels in HNF1A-MODY, type 1 or type 2 diabetes mellitus cohorts did not correlate with the renal indices; albumin creatinine ratio (ACR) or estimated Glomerular Filtration Rate (eGFR).

Conclusion: We here provide the first proof-of-concept study that miRNA can be readily detected in the urine of participants with diabetes. The utilization of urine as a biofluid has multiple advantages in the clinical setting. Urine sampling is non-invasive and not subject to haemolysis. This is important, as blood contamination and haemolysis are the most common artefacts encountered in miRNA detection in fluids. miR-224 is a novel diabetes-associated miRNA which is highly expressed in the urine of HNF1A-MODY carriers and a type 1 diabetes mellitus cohort. We surmise that the differential expression levels of miR-224 in both insulin deficient states may be an attempt to compensate for beta-cell demise. A further novel finding of the current study is the detection of the well-established diabetes-associated miRNA; miR-103 in urine.

Permanent neonatal diabetes: new hopes for a dreadful disease

S. Ioacara^{1,2}, C. Toader¹, A. Oprea¹, A. Reghina^{1,2}, O. Georgescu¹, S. Martin^{1,2}, A. Sirbu^{1,2}, S. Fica^{1,2};

¹Endocrinology and diabetes, "Elias" University Emergency Hospital, ²"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania.

Background and aims: Of the many possible mutations in the KCNJ11 gene, the Q52R is responsible for a severe form of permanent neonatal diabetes (PND) associated with developmental delay and epilepsy (DEND syndrome). None of the previously 3 cases detected worldwide was successfully switched to sulphonylurea (SU). One of them had only a few months survival and the long-term insulin treatment in the other two patients was associated with poor disease control and persistence of developmental deficits.

Materials and methods: A one year and three months old boy was admitted on 28th July 2014 in our emergency university hospital, for a scheduled attempt on switching from insulin to SU for his PND. He was diagnosed with PND at age 2 months, testing negative for major islet autoantibodies. As switching to SU resulted in ketoacidosis, he has since remained on insulin, currently needing 6 U/day. Recent genetic testing performed in Exeter laboratories (Wellcome Trust fund), UK revealed an acquired, rare, but severe point mutation (Q52R) in KCNJ11 gene.

Results: On admission, he had moderate-severe developmental deficit, with moderate hypotonia, but no other significant symptoms. He was just staying horizontally in his bed, without the possibility of rolling over by himself. His weight was 13 Kg, for a 75 cm length, showing no clinical

significant biochemical results except for HbA1c=9.5% (80 mmol/mol), LDH=352 U/L (Normal range: 125–220 U/L), and C-peptide=0.02 ng/ml (intermediate DEND syndrome). He was successfully switched on glibenclamide alone, given every 3–6 h, with a rapid escalation of doses due to lack of initial response. He was discharged from the hospital on 6th August 2014, with a total SU dose around 0.8 mg/Kgc/day. A significant improvement in both metabolic control and developmental deficits was registered after one month. The patient was able to walk and HbA1c was 6.5% at 6 months of SU treatment. Insulin secretion appears to be strongly nutrient dependent, with glucose values dropping after food intake and rising with food deprivation.

Conclusion: This is the first worldwide report of a successful transition from insulin to SU treatment in a patient suffering from PND associated with intermediate DEND syndrome due to Q52R mutation in the KCNJ11 gene. The dramatic improvement in neurologic deficits gives new hopes for what was once considered a dreadful disease.

387

The clinical management of hyperglycaemia in pregnancy complicated by maturity onset diabetes of the young

M.M. Byrne¹, J. Schmid², A. McCarthy¹, J. Edwards³, A. Fleming³, B.T. Kinsley⁴, R.G. Firth⁵, B. Byrne⁶, C. Gavin⁵, S. Bacon¹;

¹Endocrinology & Diabetes, Mater Misericordiae University Hospital, ²Centre for Systems Medicine & Department of Physiology and Medical Physics, Royal College of Surgeons in Ireland, ³Diabetes, Rotunda Maternity Hospital, ⁴Endocrinology & Diabetes, Mater Misericordiae University Hospital and Coombe Women & Infants Hospital, ⁵Endocrinology & Diabetes, National Maternity Hospital, ⁶Endocrinology & Diabetes, Coombe Women & Infants University Hospital, Dublin, Ireland.

Background and aims: Women with Maturity Onset Diabetes of the Young (MODY) are often first identified and diagnosed with diabetes during pregnancy. Genetics and hyperglycemia play an important role in determining fetal size in MODY pregnancies. Observational data on glycemic control and fetal outcomes in pregnancies complicated by glucokinase (GCK) and (hepatocyte nuclear factor-1 alpha) HNF-1 α MODY mutations are lacking. The aim of the current study was to determine the outcomes and clinical management of hyperglycemia using home blood glucose monitoring (HBGM) in MODY pregnancies.

Materials and methods: A retrospective chart review of 37 women with a GCK or a HNF-1 α mutation was conducted. There were 132 pregnancies in these women. Data on variables such as birth weight, mode of delivery and the treatment of hyperglycaemia was recorded. Complications which included congenital anomaly, birth injury, admission to neonatal intensive care unit (NICU) and prolonged neonatal hypoglycemia were recorded. Genotyping of 36 offspring was known. The HBGM recordings of a subset of these women, who were all managed according to our current guidelines for diabetes in pregnancy, with a GCK or HNF-1 α mutation referred to one of the three tertiary centres were analysed. The median of the highest and lowest blood glucose value for each day, at each time point, was averaged over a seven day period. This was performed for each trimester.

Results: The birth weight in non-affected GCK offspring was significantly higher than in the affected GCK offspring (4.8 kg (4.1–5.2) vs. 3.2 kg (3.1–3.7), $p=0.01$). Seven point home blood glucose monitoring (HBGM) over a seven day period in each trimester demonstrated higher fasting and post prandial glycemic excursions in the 1st trimester of GCK pregnancies when compared to HNF-1 α pregnancies (Fasting: 5.8 mmol/l (5–6.4) vs 4.7 mmol/l (4.3–4.9), $p=0.01$ and Post-prandial: 8.6 mmol/l (7.5–10.9) vs 6.2 mmol/l (5.6–7.3), $p=0.04$) despite insulin treatment. There was a higher percentage of miscarriages in the GCK group when compared to the HNF1A-MODY group (33.3% vs 14%, $p=0.07$) which was similar to the background population. Insulin initiated at an early

gestation appeared to lower the incidence of macrosomia in GCK non-affected offspring.

Conclusion: To date, this is the largest study performed specifically looking at glycemic excursions in pregnancies complicated by GCK and HNF-1 α MODY. This study demonstrates that the current management of HNF-1 α pregnancies appears to be appropriate. In GCK pregnancies, however, the glycaemic variability that we have clinically noted warrants attention. There was an increased percentage of both macrosomia and miscarriages in GCK pregnancies highlighting the importance of a diagnosis of GCK-MODY in women prior to conception and the necessity for pre-conception care.

Identification and clinical characteristics of a family with the ARG103PRO mutation in the NEUROD1 gene detected by new generation sequencing

A. Ludwig-Galezowska, M. Szopa, J. Machlowska, J. Skupien, P. Radkowski, M.T. Malecki;

Jagiellonian University Medical College, Krakow, Poland.

Background and aims: Until now there have been only a few families with early onset autosomal diabetes due to mutations in the NEUROD1 gene identified. Moreover, only two of them seemed to meet strict MODY criteria. The introduction of next-generation sequencing (NGS) provides a new opportunity to detect more pathogenic mutations in this gene. The aim of this study was to evaluate a segregation of the Arg103Pro mutation in the NEUROD1 gene detected by NGS in the proband from family and to describe the clinical characteristics of mutation carriers.

Materials and methods: We selected 96 diabetic probands of MODY families, among which 42 patients were earlier tested GCK-MODY and HNF1A-MODY by Sanger sequencing with negative results. Genetic testing was performed by the targeted NGS sequencing using a panel of 29 genes in which mutations have been reported to cause monogenic diabetes. This panel included the NEUROD1 gene.

Results: Among genetic variants detected by NGS, one patient had a missense mutation in the gene NEUROD1. It was the Arg103Pro (CGC / CCC) missense mutation. This mutation affected the DNA binding domain of the NEUROD1 transcription factor. We confirmed this sequence difference by Sanger sequencing. The family with the mutation was included into our MODY registry in 1999 and had previously been tested with negative results for mutations in GCK and HNF1A. 17 family members were invited for further genetic testing. In 11 subjects we confirmed the presence of the mutation. Seven adult mutation carriers (all but one) from three generations have been already diagnosed with diabetes and were treated with different therapeutic models. There were 3 individuals with the Arg103Pro mutation diagnosed before the age of 30 years in the family. The range of age of unaffected mutation carriers was 4–48 years. Interestingly, there was a history of neonatal severe hypoglycemia in a pediatric patient who is also a carrier of the mutation. The clinical course reminded episodes typical for HNF4A-MODY.

Conclusion: The use of the NGS method will likely allow for more frequent identification of rarer forms of MODY. The identified MODY family seems to be just the third NEUROD1 family meeting the criteria of MODY.

Reuptake of secreted carboxyl-ester lipase (CEL) variants, a role in diabetes and exocrine pancreatic disease?

I.M.K. Lavik^{1,2}, M. Dalva^{1,2}, S.J. Steine^{1,3}, P.R. Njølstad^{1,4}, A. Molven^{3,5}, K. Fjeld^{1,2}, B.B. Johansson^{1,2};

¹Department of Clinical Science, KG Jebsen Center for Diabetes Research, ²Center for Medical Genetics and Molecular Medicine, ³Department of Clinical Medicine, Gade Laboratory for Pathology, ⁴Department of Paediatrics, ⁵Department of Pathology, Bergen, Norway.

Background and aims: CEL is a digestive enzyme involved in hydrolysis and absorption of cholesterol and lipid-soluble vitamin esters. We have previously described a syndrome of diabetes and exocrine pancreatic dysfunction caused by mutations in the CEL gene. The mutant protein (CEL-MUT) has a higher tendency to aggregate and undergo endocytosis as compared to the wild-type CEL protein (CEL-WT). Here, we compare the cellular reuptake of CEL-MUT and CEL-WT in HEK293 cells and pancreatic cell lines. We also investigated the intracellular fate of the two protein variants, their effect on viability, as well as their impact on insulin secretion from endocrine cells.

Materials and methods: HEK293 cells stably expressing CEL protein variants were grown for 24 h toward confluence. Conditioned media were added to untransfected cell lines (HEK293, embryonic kidney; INS-1E, insulinoma; 266-6, acinar; PANC-1, ductal) for various durations. Immunostaining and confocal microscopy were performed to investigate endocytosis and degradation of CEL. Cell viability was monitored by quantitation of ATP generated by metabolically active cells and insulin secretion was determined by ELISA.

Results: In HEK293, acinar and INS-1E cells we observed increased uptake of the CEL-MUT protein variant as compared to CEL-WT. After endocytosis the mutant protein was present as intracellular puncta colocalizing with the lysosomal marker LAMP1. The same tendency was noted for CEL-MUT in PANC-1 cells. Exposure to the CEL-MUT protein negatively affected the viability of the investigated cell lines. Preliminary results indicated that long-time exposure of INS-1E cells to the mutated protein leads to a reduced glucose-stimulated insulin secretion compared to when these cells are grown in the presence of the wild-type protein.

Conclusion: Our data indicate that mutated CEL negatively affects insulin secretion. We suggest that extracellular CEL-MUT aggregates are toxic and removed by cell-mediated uptake and degraded by the cells. Taken together, these findings could be relevant for how CEL-MUT cause a disease affecting both the exocrine and endocrine pancreas.

Serum metabolome changes in healthy subjects with different genotypes of NOS1AP in the Chinese population

W. Congrong¹, Y. Zhang², W. Jia¹;

¹Shanghai 6th people's hospital, Shanghai, China, ²Center for Translational Medicine, Shanghai 6th people's hospital, Shanghai, China.

Background and aims: Nitric oxide synthase 1 adaptor protein (NOS1AP), regulates the neuronal nitric oxide synthase (nNOS) activity and has an effect on nitric oxide (NO) release by binding N-methyl-D-aspartate receptors. One functional study showed that rs12742393 could affect NOS1AP gene expression through influencing transcription factor binding. Our previous study showed evidence that rs12742393 in NOS1AP was involved in type 2 diabetes susceptibility in the Chinese population, with C allele as the risk allele (OR 1.17, 95% CI 1.07-1.26; P =0.0005). In this study, we report a comprehensive metabolomic study of different genotypes (AA and CC) of rs12742393 using two complementary analytical platforms, gas chromatography time-of-flight

mass spectrometry (GC-TOFMS) and ultra-performance liquid chromatography quadrupole time-of-flight mass spectrometry (UPLC-QTOFMS).

Materials and methods: Fifty-five healthy participants with normal glucose regulation were selected for metabolomic investigation, including twenty-seven CC homozygote and twenty-eight AA homozygote individuals. All the individuals for the metabolomic analysis were matched strictly with age, sex, BMI, glucose, and lipid related parameters. For all the subjects, venous blood samples were obtained after overnight fasting for at least 10 h and subjected to GC-TOFMS and UPLC-QTOFMS. The GC-TOFMS data was analyzed by ChromaTOF software, the UPLC-QTOF-MS ES+ and ES- raw data were analyzed by the MarkerLynx Applications Manager version 4.1 (Waters, Manchester, U.K.) and then metabolites were identified by comparing the accurate mass, mass fragments, characteristic ions with the available reference standards and published reports, in addition to the web-based resources such as the Human Metabolome Database. The data sets were then analyzed and validated by uni- and multi-variate statistical methods, separately. Principle component analysis (PCA) and orthogonal partial least squares-discriminant analysis (OPLS-DA) were carried out (SIMCA-P 12.0, Umetrics, Umeå, Sweden) and Wilcoxon-Mann-Whitney test was selected to measure the significance of each metabolite.

Results: A total 258 metabolites were identified and seven significantly altered serum metabolites identified in AA carriers relative to CC carriers were selected according to the VIP threshold (VIP>1) in OPLS-DA model coupled with the Mann-Whitney U test (p<0.05). These including Malic acid, Inosine, maltose, adonitol, ribitol, serine and glycine.

Conclusion: We detected seven metabolites showing significant differences between CC and AA carriers of rs12742393 in NOS1AP. These metabolites might associate with the development of type 2 diabetes in subgroup of patients through the crosstalk with NOS1AP protein, which might provide us a new perspective to the mechanism of type 2 diabetes.

Integrated analysis of oxidative phosphorylation changes and characteristic metabolic profiles on diabetes with the mitochondrial DNA 3243 (A>G) mutationY. Zhang¹, C. Wang², W. Jia²;¹Center for Translational Medicine, Shanghai 6th people's hospital, Shanghai, China, ²Department of Endocrinology and Metabolism, Shanghai 6th people's hospital, China.

Background and aims: An A-to-G transition at position 3243 of mitochondrial DNA (A3243G) can result in maternally inherited diabetes and deafness (mitochondrial diabetes). The relationship among mutation heteroplasmy, mitochondrial oxidative phosphorylation (OXPHOS) and metabolic profiles are largely unknown, making great challenges for disease prevention and control.

Materials and methods: Five mitochondrial DNA 3243 (A>G) mutation patients, three of them belong to one family lineage, were included in this project. The participants' body mass index scores, blood pressures, blood glucose and insulin levels at 0, 30, 60, 120 and 180 min were measured in response to a 75 g oral glucose tolerance test. Also they were undergone pure tone test, brain MRI, visual evoked potential, electrocardiogram. A quantitative method based on pyrosequencing was used to analyze the heteroplasmy of these patient. Quantitative reverse transcription-PCR analysis was used to analysis the expression of all the 13 OXPHOS genes. The serum of five mitochondrial DNA 3243 (A>G) mutation patients, five type 2 diabetes patients, five latent autoimmune diabetes in adult and five normal controls were analyzed using gas chromatography time-of-flight mass spectrometry platform.

Results: We found a variety of clinical conditions in association with mitochondrial DNA 3243 A>G mutation, even in asymptomatic subjects. Levels of the mutation heteroplasmy varied among the different sampled blood, buccal cells and urinary sediment of the mutation carriers. In addition, defects in subunits of the OXPHOS complexes and respiratory chain assembly were observed in the mutation carriers. Using GC-MS profiling methods, we found significant changed metabolites that were associated with mitochondrial DNA 3243A>G mutation.

Conclusion: The metabolic profile of mitochondrial DNA 3243 (A>G) mutation was quiet unique. There are some significant changed metabolites were associated with neurotransmitter and energy transfer. The metabolic profile together with the oxidative phosphorylation changes can partly explain the clinical symptoms of mitochondrial DNA 3243 (A>G) mutation.

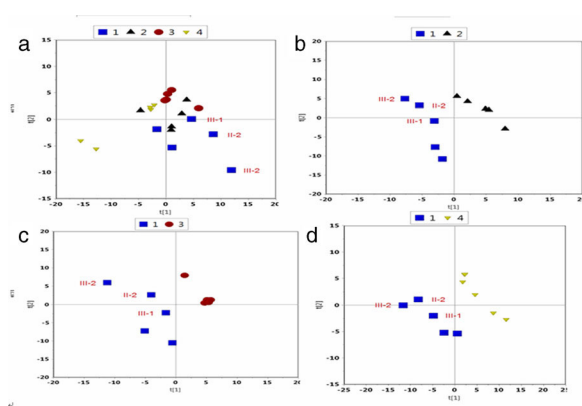

Figure: PLS-DA score plots of ■: mt.3243A>G mutation patients, ▲: Type 2 diabetes patients, ●: LADA patients, ▼: Normal controls. II-2, III-1 and III-2 belong to one family lineage: II-2 is the mother of proband III-2, III-1 is the sister of proband III-2.

Prevalence of retinopathy in adult patients with GCK-MODY and HNF1A-MODYM. Szopa¹, J. Wolkow¹, B. Matejko¹, J. Skupien¹, T. Klupa¹, I. Wybranska¹, M. Borowiec², M.T. Malecki¹;¹Jagiellonian University Medical College, Krakow, ²Medical University of Lodz, Poland.

Background and aims: Maturity onset diabetes of the young (MODY) is a heterogeneous group of monogenic disorders that result in hyperglycemia of various degree and pattern. It constitutes up to 1 million of patients in Europe. Thus, it is very important to understand the consequences of MODY diagnosis, including the risk of vascular complications. Diabetic retinopathy (DR) is a complication considered to be particularly closely related to the duration and degree of hyperglycemia. We aimed to assess the prevalence of DR in adult patients with GCK-MODY and HNF1A-MODY in Poland and to identify biochemical and clinical risk factors associated with its occurrence.

Materials and methods: We examined 74 GCK mutation carriers, 51 with diabetes and 23 with prediabetes, respectively, and 63 patients with HNF1A-MODY. Retinal photographs, twelve for each patient, were done by a fundus camera. Signs of DR were graded according to the DR disease severity scale. Statistical tests were performed to assess differences between the groups and logistic regression was done for the association with DR.

Results: The mean age at examination was 34.5±14.8 and 39.9±15.2 in the GCK-MODY and HNF1A-MODY groups, respectively. Mild nonproliferative DR (NPDR) was found in one patient with the GCK mutation and likely concomitant type 1 diabetes, whereas DR was diagnosed in 15 HNF1A-MODY patients: 9 with proliferative, 3 with moderate NPDR and 2 with mild NPDR. The strongest independent predictors of DR in HNF1A-MODY were markers of glucose control: HbA1c (OR: 2.05, CL%95: 1.2-3.83, p=0.01) and glucose (p=0.006, OR: 1.40, CL%95: 1.12-1.83) analyzed in two separated models. Additionally, arterial hypertension independently predicted DR (OR: 9.06, CL%95: 1.19-98.99, p=0.04) in the model with HbA1c as glycaemic control marker.

Conclusion: In conclusion, DR of any degree was not present in our GCK-MODY group, while in spite of young age almost every fourth subject with HNF1A-MODY showed signs of this complication.

Variants of the SLC30A8 gene associated with anti-ZnT8 antibody and predisposition to type 1 diabetes

C. Semczem, K.F.B. Gomes, A.S. Santos, R.T. Fukui, M.R.S. Correia, R. Batista, M.E.R. Silva;

Laboratório de Carboidratos e Radioimunoensaio-LIM18. Hospital das Clínicas da Faculdade de Medicina, University of São Paulo, Brazil.

Background and aims: The SLC30A8 gene encodes the zinc transporter protein (ZnT8), present in the membrane of insulin granules and expressed mainly in pancreatic beta cells. The ZnT8 protein was identified as an autoantigen in T1D and the rs2466293 and rs16889462 variants were associated with susceptibility to type 1 diabetes (T1D) in Caucasians, but there are few data in Latin-America and in the multi-ethnic Brazilian population. The objective was to evaluate the influence of the variants rs2466293 and rs16889462 in the predisposition to T1D and in the frequency of anti-ZnT8 autoantibody (Ab) which was previously found to be 48.3% in 479 T1D patients living in Sao Paulo city.

Materials and methods: We evaluated 623 patients T1D (age: 25±12.7 years; 367 F / 257 M, 80% white) and 650 controls (age: 29±11.2 years; 243 F / 407 m, 63.4% white). The variants rs2466293 and rs16889462 were genotyped by the Vera Code Golden Gate (Illumina)

methodology. Autoantibodies against zinc transporter (anti-ZnT8) were determined by ELISA (Kronus, USA CV of <7%) and against glutamic acid decarboxylase (anti-GAD65) and tyrosine phosphatase (anti-IA2) by radioimmunoassay (RSR Limited, UK, CV <7%). The genotypic associations were analyzed using the chi-square test or Fisher exact test. $P < 0.05$ was considered significant.

Results: The frequencies of genotypes of rs2466293 and rs16889462 variants were in Hardy-Weinberg Equilibrium, were similar in patients and controls and were independent of gender. However, in non-whites, the rs2466293 AA genotype conferred protection to T1D, prevailing in controls (57.1%) compared to T1D patients (43.7%); $p=0.0233$; OR=0.5821; CI=.3716 to .9117. The rs1688946 AG genotype, although rare, was associated with higher frequency of anti-ZNT8 Ab (75%) when compared to GG (48%); $p=0.0415$; OR=3.245; CI=1.023 to 10.288. None of SLC30A8 variants influenced on age at diagnosis of T1D or on anti-GAD65 and anti-IA2 Abs frequency.

Conclusion: The rs2466293 and the rs16889462 variants in SLC30A8 gene were related to T1D predisposition and to anti-ZnT8 Ab frequency respectively in our population.

GWAS-implicated in type 1 and type 2 diabetes loci: insight into their relative roles in the pathogenesis of Latent Autoimmune Diabetes in Adults (LADA)

D.R.G. Leslie¹, A. Chesi², V.C. Guy², M.I. Hawa¹, J.P. Bradfield³, H. Hakonarson³, C. Thivolet⁴, D. Mauricio⁵, N. Schloot⁶, K.B. Yderstraede⁷, S. Schwartz⁸, B.O. Boehm⁹, S.F.A. Grant²;

¹Department of Immunology and Infectious Disease, Blizard Institute, London, UK, ²Division of Human Genetics, ³Division of Human Genetics, The Childrens Hospital of Philadelphia, USA, ⁴Grenoble University Hospital, France, ⁵Department of Endocrinology and Nutrition, Hospital Univesitari Germans Trias i Pujol, Badalona, Spain, ⁶German Diabetes Center, Dusseldorf, Germany, ⁷Department of Medical Endocrinology, Odense University Hospital, Odense, Denmark, ⁸Main Line Health System, Wynnewood, USA, ⁹University of Ulm, Nanyang technology University, Singapore, Malaysia.

Background and aims: The genetic etiology of adult-onset autoimmune diabetes, including 'latent autoimmune diabetes in adults' (LADA), remains unresolved. LADA exhibits clinical features of both type 1 (T1D) and type 2 (T2D) diabetes. LADA cases present initially as adult-onset diabetes, but not requiring insulin, yet with circulating T1D-associated islet autoantibodies and comprise 5-10% of all adult-onset diabetes in Europe and China.

Materials and methods: Leveraging existing genome-wide SNP genotyping data generated on the Illumina Infinium II OMNI Express platform, we assessed the association of all GWAS-implicated T1D and T2D loci reported to date in 965 LADA subjects and 1134 healthy control subjects recruited from a European multicenter study. Through strict phenotyping criteria, diagnosis was defined by subjects aged 30-70 years, positive for glutamic acid decarboxylase autoantibodies without initial insulin therapy.

Results: The MHC region was strongly associated with LADA (sentinel SNP rs1063355; odds ratio (OR)=1.58; $P=3.24 \times 10^{-10}$). Strong evidence of association was also observed for other T1D-associated loci, including SH2B3 (rs3184504 and rs1265564, OR=1.45; $P=1.18 \times 10^{-6}$), IL7R (rs6897932, OR=1.31; $P=4.34 \times 10^{-5}$ & rs1445898; OR=1.23; $P=2.94 \times 10^{-4}$), PTPN22 (rs2476601 and rs6679677, OR=0.71; $P=2.62 \times 10^{-4}$) and INS (rs689, OR=1.45; $P=3.46 \times 10^{-4}$). Despite these observations, it was interesting to note that there was no association with the strong T1D-associated locus, CLEC16A or, contrary to previous reports, the key T2D TCF7L2 locus. However, when we constrained the dataset on positivity for the IA2 antibody, the TCF7L2 locus did yield nominal evidence of a paucity of the T2D-associated rs7903146 T allele ($n=367$ cases; OR=0.78; $P=0.014$). Conversely, also in the IA2 constraint setting, the HNF1A locus yielded significant (including survival for multiple correction) evidence of an excess of the T2D-associated rs7957197 T allele (OR=1.55; $P=1.04 \times 10^{-4}$). These novel observations require follow-up studies to elucidate the mechanism of action in this setting.

Conclusion: In conclusion, LADA, the major form of adult-onset autoimmune diabetes as defined here, reveals a genetic etiology very similar to childhood-onset T1D, with the striking exception of CLEC16A. Absence of the genetic locus CLEC16A could account for a later age at presentation of T1D, notably LADA.

Genes previously associated with Polycystic Ovary Syndrome (PCOS) in the Asian population and variability in PCOS population from central Europe

R. Attaoua¹, S. Haydar¹, D. Fakh¹, L. Andreassen¹, M. Vintila², A. Bensalem¹, N. Baculescu², C. Normand¹, P. Poucheret³, M. Coculescu², F. Grigorescu¹;

¹Molecular Endocrinology Laboratory, UMR204 NUTRIPASS, Université de Montpellier 1 (IURC), France, ²Department of Endocrinology, University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania, ³Pharmacology and Experimental Physiology Laboratory, Faculty of Pharmacy, Montpellier, France.

Background and aims: Recent investigations by genome-wide association approach in an Asian population identified many genes associated with polycystic ovary syndrome (PCOS), as LHCGR (luteinizing hormone/choriogonadotropin receptor), DENND1A (DENN/MADD domain containing 1A), YAP1 (Yes-associated protein 1), TOX3 (TOX high mobility group box family member 3) and insulin receptor (INSR) genes. In this context we explored variation of these genes and that of KLF14 (Kruppel-like factor 14) gene in PCOS in a population of 401 cases and 143 controls from Central Europe well characterized at the endocrine and metabolic levels, aiming to test gene association to PCOS in a population of Caucasian origin.

Materials and methods: Genetic markers used in the study were the SNPs rs2479106 A/G, rs1894116 A/G, rs4784165 T/G, rs2059807 (A/G) and rs1562398 for DENND1A, YAP1, TOX3 and INSR, respectively. Genotyping of SNPs was carried-out by KASPar technology while genetic association and genotype-phenotype correlations were calculated by logistic regression and ANOVA, respectively using StatView and GoldenHelix programs, respectively.

Results: We observed gene-dose effect of LHCGR (rs1340572) with diastolic blood pressure ($P=0.014$; GG ($n=1$) 100 mmHg, AG: ($n=33$) 73.8 ± 3.2 mmHg, AA: ($n=224$) 69.7 ± 0.8 mmHg) while DENND1 (rs2479106) displayed a trend of gene-dose effect with plasma insulin at 120 minutes during the OGTT test ($P=0.053$; AA ($n=84$): 73.8 ± 7.2 mU/L, AG ($n=101$): 102.0 ± 10.9 mU/L, GG ($n=22$) 128.3 ± 39.2 mU/L). However none of genes were associated with PCOS phenotype in our investigation.

Conclusion: This study allowed observing the association of genes with metabolic components of PCOS with some variability from data previously reported in the Asian population, which highlights one more time the necessity of considering differences between populations when studying the genetic susceptibility to complex disorders.

Haplotype mapping of GCKR gene indicates the association with PCOS and reveals the role of BCAA metabolism

S. Haydar¹, R. Attaoua¹, M. Coculescu², M. Vintila², D. Fakh¹, A. Ben Salem¹, N. Baculescu², P. Poucheret³, F. Grigorescu¹;

¹Molecular Endocrinology Laboratory, Nutrition & Genomes, UMR-204 NUTRIPASS, IURC, Montpellier, France, ²Department of Endocrinology, University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania, ³Pharmacology and Experimental Physiology Laboratory, Faculty of Pharmacy, Montpellier, France.

Background and aims: Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders characterized by reproductive and metabolic disorders including insulin resistance (IR) and metabolic syndrome (MetS). It has been shown that dysregulated branched-chain amino acids (BCAA) metabolism may be associated with IR. High plasma level of BCAA was also noted in women with PCOS. At the genetic level, some genes were correlated to BCAA plasma variation, type 2 diabetes

(T2D), IR and obesity, among which the GCKR (glucokinase regulatory protein) is one of the candidates. The aim of this work was to investigate the potential association of GCKR with PCOS and its components.

Materials and methods: We studied a population from Central Europe (401 cases and 143 controls) with PCOS diagnosed according to Rotterdam criteria, using the leader SNP (Single nucleotide polymorphism) rs1260326 (C/T) as well as 200 SNPs at this locus. The leader SNP was genotyped in all population by KASPAR technology. Haplotype mapping was performed in a nested study to determine the Linkage Disequilibrium (LD) pattern in population. The locus of GCKR gene was screened with 200 SNPs in 55 cases and 48 controls by Affymetrix technology. LD pattern and haplotypes reconstruction were carried-out by HAPLOVIEW 4.2 and PHASE 2.1, respectively while gene association and genotype-phenotype correlations were assessed by logistic regression and ANOVA using StatView and GoldenHelix.

Results: We found an association of the leader SNP rs1260326 TT genotype with protective effect against PCOS ($P<0.03$, OR 0.49 95%CI [0.25 - 0.96]). This result was specifically observed in lean PCOS women ($P=0.036$) and PCOS without metabolic complications or MetS ($P=0.045$). The nested study showed a block of LD including SNPs rs2293572, rs2293571, rs1260326 and rs3817588 while reconstruction of haplotypes in population revealed 7 haplotypes, among which 5 were more frequent: H3 (CGTT) (49%), H5 (GACT) (27.7%), H2 (CGCC) (15.0%), H1 (CGCT=ancestral haplotype) (4.9%) and H6 (GACC) (2.4%). The T variant of rs1260326 was found in the most frequent haplotype.

Conclusion: Our finding indicates that GCKR is a good candidate for PCOS and is in accordance with some previous studies albeit with some variations and reinforces the interest in BCAA and our approach in studying SNPs variation in ethnic groups in Europe.

397

Impact of known type 2 diabetes associated variants on circulating levels of branched-chain amino acids during an oral glucose tolerance test

Y. Mahendran^{1,2}, A. Jonsson¹, T. Schnurr¹, C.T. Have¹, N. Grarup¹, N.B. Johansen^{2,3}, D.R. Witte^{2,4}, T. Lauritzen⁴, M.E. Jørgensen³, O. Pedersen¹, T. Hansen¹;

¹NNF Center for Basic Metabolic Research, University of Copenhagen, ²The Danish Diabetes Academy, Odense, ³Steno Diabetes Center, Gentofte, ⁴Department of Public Health, University of Aarhus, Denmark.

Background and aims: A detailed understanding of the pathophysiology of type 2 diabetes (T2D) and identification of early metabolic alterations is essential for identifying individuals at high risk of this disease. Our aim is to investigate the branched-chain amino acids (BCAAs; that is leucine, isoleucine, valine) level in various stages of pre-diabetes and their association with known T2D risk variants.

Materials and methods: ADDITION-PRO is a population based longitudinal cohort study of individuals at low to high risk for diabetes, nested in the ADDITION-Denmark study. A stratified sub-sample of individuals were invited to a follow-up health examination (2009-2011) and 2,082 participants attended. A total of 1,490 participants without known diabetes were given a standard 75 g oral glucose tolerance test (OGTT) after an overnight fast of ≥ 8 hours. The blood samples were drawn at 0, 30 and 120 min for assessment of serum insulin, plasma glucose, and plasma BCAAs concentrations. Plasma BCAA levels were measured by NMR spectroscopy. Previously reported 68 T2D risk SNPs were genotyped using the Illumina Infinium HumanCoreExome Bead chip or imputed with high quality into a 1000 genomes phase 3 panel. Genotype-phenotype correlations were studied using the linear mixed model test implemented in the EPACTS software package.

Results: Circulating BCAA levels decreased during an OGTT (30, 120 minutes) compared to fasting (0 minutes) levels. Additionally, fasting

and stimulated BCAA levels were higher in men compared to women ($P < 0.001$), higher in obese compared to lean subjects ($P < 0.001$), and higher in individuals with impaired fasting glucose (IFG) ($P < 0.04$) and impaired glucose tolerance (IGT) ($P < 0.001$) compared to normal glucose tolerance. BCAA levels were positively correlated with sex, BMI, insulin levels, HOMA-IR and negatively correlated with Matsuda indices. Genetic association with fasting and/or stimulated BCAA levels (after adjusting for age, sex and BMI) suggested that the known T2D risk variants in *JAZF1* (rs864745, effect size -2.7%), *DUSP9* (rs5945326, effect size +2.6%), *IGF2BP2* (rs1470579, effect size +2.4%) and *GCKR* (rs780094, effect size -2.4%) were associated significantly ($P < 0.05$) with Isoleucine levels. *PPARG* (rs1801282, effect size +3.0%), *JAZF1* (rs864745, effect size +1.9%), *DUSP9* (rs5945326, effect size +2.2%), *PAM* (rs35658696, effect size +3.5%) variants were significantly ($P < 0.05$) associated with leucine levels. And the variants in *ADAMTS9* (rs4607103, effect size +7.6%), *DUSP9* (rs5945326, effect size +5.9%), *IGF2BP2* (rs1470579, effect size +2.8%), and *GRB14* (rs3923113, effect size -2.2%) were significantly ($P < 0.05$) associated with valine levels.

Conclusion: Our large population-based study shows that BCAA levels were significantly higher in individuals with impaired glucose regulation. Several T2D risk SNPs were significantly associated with BCAA levels; however, biological functions of these associated variants are largely unknown. Further investigations are needed to find the casual relation of the T2D risk variants with BCAA levels.

Genome-wide association studies of diabetic kidney disease in patients with type 2 diabetes

N.W. Rayner¹, E. Ahlqvist², H. Deshmukh³, N. Van Zuydam¹, N. Sandholm⁴, C. Ladenvall², M. Lajer⁵, L. Marcovecchio⁶, E. Rurali⁷, SUMMIT Collaborators, SUMMIT Consortium;

¹Wellcome Trust centre for Human Genetics, University of Oxford, UK, ²Lund University, Malmö, Sweden, ³University of Dundee, UK, ⁴Folkhalsan Research Center, Helsinki, Finland, ⁵Steno Diabetes Center, Gentofte, Denmark, ⁶University of Cambridge, UK, ⁷IRCCS - Istituto di Ricerche Farmacologiche, Bergamo, Italy.

Background and aims: Diabetes mellitus is associated with a range of chronic complications including diabetic kidney disease (DKD), a leading cause of end-stage renal disease (ESRD). To date few robustly associated genetic factors for these traits have been identified. As part of the SUMMIT consortium we performed a meta-analysis of genome-wide association studies (GWAS) in patients with type 2 diabetes (T2D) from European backgrounds to identify genetic determinants of DKD.

Materials and methods: GWAS were performed on 7 case control phenotypes based on the severity of diabetic nephropathy (DN). DN was characterised by micro-albuminuria, macro-albuminuria, end stage renal disease (ESRD), or chronic kidney disease (CKD; eGFR <60 ml/min) in 4 European studies with type 2 diabetes comprising up to 3,345 cases and 2,372 controls. We analysed 9,213,894 single nucleotide polymorphisms, imputed based on the 1000 Genomes (March 2012) reference panel, using EMMAX, adjusting for sex, age at onset, duration of diabetes and kinship matrix. Meta-analyses were performed using a fixed effects model and SNPs with $p < 5 \times 10^{-6}$, from any of the binary phenotypes, were selected for *in silico* replication in 2 European cohorts comprising 3,247 cases and 906 controls.

Results: From the meta-analyses we identified 139 SNPs for *in silico* replication. After joint analysis of the discovery and replication cohorts 9 SNPs showed nominal replication ($p < 0.05$ with same direction of effect), however no loci reached genome wide significance ($p < 5 \times 10^{-8}$). The strongest joint signals were rs4977388 (ESRD vs all other phenotypes, $p = 2.25 \times 10^{-7}$, near *MLLT3*), rs7916840 (DN, $p = 6.2 \times 10^{-7}$ intronic to *GPI58*), rs9942471 (DN, $p = 9.8 \times 10^{-7}$, near *GABRR1*), rs6865390

(Macro-albuminuria + ESRD, $p = 2.05 \times 10^{-7}$, near *RAI14*) and rs2206136, (CKD, $p = 5.42 \times 10^{-7}$, intronic to *PLCB4*).

Conclusion: To follow up on these findings we are now performing *de novo* genotyping in 3,867 additional individuals with T2D. In addition we are also integrating these data with T1D data from SUMMIT and the JDRF DNCRI, T2D data from FIND and other sources, as well as exome sequence data. By combining and comparing these different analyses we hope to gain a broader picture of the biology of DKD.

Supported by: IMI, European Commission's FP7 (the SUMMIT consortium, IMI-2008/115006).

The protective effect of cathepsin H on beta cell apoptosis is mediated through the Jak-STAT and NFκB signalling pathways

T. Floyel, A.H. Mirza, S. Kaur, F. Pociot; Copenhagen Diabetes Research Center, Pediatric Department, Herlev University Hospital, Denmark.

Background and aims: In type 1 diabetes (T1D) the pancreatic β -cells are specifically destroyed by the immune system. Genome-wide association studies have identified >50 loci that are associated with the risk of T1D, however, only little is known about how these variants modify disease risk. We recently showed that T1D-associated single nucleotide polymorphisms (SNPs) in *CTSH* (lysosomal protease cathepsin H) affect the expression level of CTSH. By combining *in vitro* and *in vivo* experiments with clinical studies we demonstrated that CTSH regulates β -cell function and disease progression in children with newly-diagnosed T1D. Interestingly, overexpression of CTSH protected insulin-secreting INS-1 cells against cytokine-induced apoptosis, which was associated with decreased activation of phospho-JNK and phospho-p38, reduced expression of the pro-apoptotic factors *Bcl2l1* (Bim), *Myc* and *Hrk* (DP5), and increased insulin transcription. The aim of this study was to identify the mechanisms through which CTSH mediates its protective effect.

Materials and methods: INS-1 cells ($n = 3$) stably transfected with a plasmid encoding CTSH (pCTSH) or an empty control vector (pcDNA) were left untreated or stimulated with 150 pg/ml recombinant mouse IL-1 β and 5 ng/ml recombinant rat IFN- γ for 6 h or 16 h. RNA was extracted and microarray analysis performed using the Affymetrix Rat Genome 230 array. Data was analyzed in R using the Bioconductor affy package and normalized using the RMA method. Comparisons between pCTSH and pcDNA cells were done using moderated t-statistic and p-values were adjusted to control the false discovery rate using the Benjamini-Hochberg procedure. Genes were considered differentially expressed when the adjusted p-value was below 0.05 and the fold change was below -1.2 or above 1.2.

Results: 39 genes were differentially expressed between the pCTSH and the pcDNA cells in the untreated condition, whereas 46 and 38 genes were differentially expressed between the pCTSH and the pcDNA cells after cytokine treatment for 6 h and 16 h, respectively. The top candidate genes are involved in the KEGG pathways: apoptosis, Jak-STAT signaling, NF κ B signaling, insulin signaling, and chemokine signaling. Among the most interesting candidates is *Trib3* which previously has been implicated in endoplasmic reticulum stress-induced β -cell apoptosis. The expression of *Trib3* was decreased by 1.48 fold in pCTSH cells compared to pcDNA cells after 6 h of cytokine treatment ($p = 1.68 \times 10^{-4}$).

Conclusion: The current data support our previous findings that CTSH protects against cytokine-induced apoptosis by regulating apoptotic signaling pathways in the β -cell, such as the Jak-STAT and NF κ B signaling pathways. Our data indicate that higher CTSH levels in β -cells may protect against immune-mediated damage and preserve β -cell function, thereby representing a possible target for β -cell therapy in T1D.

Generation of epigenetic and transcriptome maps for insulin-producing cells in pancreas, gallbladder and the brain

W. Wong¹, M. Joglekar¹, S. Satoor¹, S. Sahu¹, E. Stanley², A. Elefanty², T. Kay³, T. Loudovaris³, H. Thomas³, D. Liuwantara⁴, W. Hawthorne⁴, P. O'Connell⁴, D. Martin⁵, A. Hardikar¹;

¹NHMRC CTC, Sydney, ²MCRI, ³SVI, Melbourne, ⁴WMI, ⁵RPA Hospital, Sydney, Australia.

Background and aims: Islet transplantation is currently the only established cell-based therapy for treatment of diabetes. However due to the limited availability of pancreas and low yield of islets isolated - it is important to find alternate sources of potential insulin-producing cells. We're the first to identify insulin-producing cells in adult human gallbladder epithelium. Although, the levels of pro-insulin gene transcripts in gallbladder are thousand-fold less than in pancreatic islets, it is still significantly higher than the reported levels in differentiated stem cells. Insulin-producing cells have been also identified in brains of fruit-flies, mice and a clinical case of insulinoma from a patient with congenital brain malformation. The aim of this research is to generate epigenetic and transcriptome maps of the insulin-producing cells in pancreas, gallbladder and the brain. This will help understand the lineage commitment and function of insulin in different tissues.

Materials and methods: We implemented a range of molecular techniques including Next Generation Sequencing (NGS), Ultra high throughput TaqMan-based real-time mRNA and miR PCR, immunocytochemistry, single cell PCR, Chromatin IP (ChIP) and DNA methylation to map the transcriptome and epigenome expression of mouse and human islets, gallbladder and brain cells.

Results: Our analyses using NGS indicate similarities between the transcriptome in the brain, gallbladder and pancreatic islets (Figure 1). Insulin transcript is detected in the human gallbladders, but at several million-fold lower than in islets. Similar levels were found for glucagon in the gall bladder and brain in comparison to the higher levels in islets. Somatostatin is lower by an order of magnitude in the brain while expression of Pdx1 in the gallbladder is at ~50% of the abundance seen in human islets. Expression of the glucose transporter Glut1 is significantly higher in human islets than Glut2- at comparable levels in human gallbladder. Urocortin3, a recently described candidate associated with maturation of insulin -producing cells was seen at ~8-fold lower in gallbladder than human islets and around 20-fold lower in human brain. miRNAs important in islet beta-cell function were found in the human gallbladder epithelium (correlation, $R^2=0.716$). ChIP data indicates progenitors of gallbladder epithelial cells continue to retain open chromatin conformation at the insulin promoter region, with H3K4 trimethylation- significantly higher compared to the insulin promoter conformation in the negative control (cord-blood cells).

Conclusion: Similarities and differences in transcriptome and epigenome maps of human gallbladder and pancreas samples are identified through NGS, real-time PCR technologies and DNA methylation epigenetics.

PS 019 Multiple organs influence complication risk

401

Risk factors of new-onset diabetes after liver transplantation and whether the interleukin-2 receptor antagonists can reduce its incidence

M. Yu¹, M. Xue¹, X. Chen^{1,2}, X. Huang³, C. Lv¹, J. Gao⁴, J. Zhou³, J. Fan³, X. Gao¹;

¹Department of Endocrinology and Metabolism, Zhongshan hospital affiliated to Fudan University, Shanghai, ²Department of Endocrinology and Metabolism, Hainan Provincial Nong Ken Hospital, Haikou City, ³Department of Liver Surgery, ⁴Evidence Base Medicine Center, Zhongshan hospital affiliated to Fudan University, Shanghai, China.

Background and aims: To investigate risk factors for new-onset diabetes after transplantation (NODAT) in patients undergoing a liver transplantation and whether interleukin-2 receptor antagonists (IL-2Ra) can reduce the incidence of NODAT.

Materials and methods: We retrospectively analyzed the preoperative and postoperative clinical data of patients aged >18 years who underwent a liver transplantation in our hospital between April 2001 and December 2013. Patients with diabetes mellitus or taking glucocorticoids before transplantation, with incomplete data, or undergoing the second transplantation or being died within 3 months after transplantation were excluded. Finally, 705 non-diabetic patients who underwent a liver transplantation were included for analysis. The incidence of NODAT was analyzed according to the fasting plasma glucose (FPG) after live transplantation. All the patients were divided into 2 groups (NODAT and N-NODAT groups) and the possible risk factors of NODAT were analyzed with One-Way ANOVA and also with logistic regression analysis, including age, gender, hepatitis virus infection, living donor, preoperative FPG level, BMI, preoperative liver function, the severity of liver cirrhosis, acute rejection (AR), postoperative immunosuppressant regimen, metabolic factors, especially the effect of IL-2Ra on NODAT. Statistical analysis was done by SPSS 19.0.

Results: Of the 705 eligible study patients, 224 patients suffered from NODAT while 481 patients did not. The incidence of NODAT was 31.77%. One hundred and four patients (46.4%) in the NODAT group received IL-2Ra, while 276 patients (57.4%) in the N-NODAT group received IL-2Ra. Single factor analysis indicated that age, preoperative FPG were positive related to NODAT ($P < 0.05$), while living donor, IL-2Ra were negative related to NODAT ($P < 0.05$). Logistic regression analysis indicated that age (OR=1.025, $P = 0.006$), preoperative FPG (OR=1.305, $P = 0.012$) can increase the risk of NODAT, while IL-2Ra (OR=0.555, $P = 0.001$) and living donor (OR=0.121, $P = 0.041$) can reduce the risk of NODAT.

Conclusion: Age and preoperative FPG level was independent risk factors for NODAT, while the IL-2Ra and living donor can reduce the risk of NODAT after liver transplantation.

402

Low cumulative incidence of end-stage renal disease in young patients with type 1 diabetes in Sweden: a population based study

C. Toppe¹, A. Möllsten², S. Schön^{3,4}, G. Dahlquist²;

¹Department of internal medicine, Länssjukhuset Ryhov, Jönköping, ²Department of Clinical sciences, Pediatrics, Umeå University, ³Swedish Renal Registry, Jönköping, Sweden, ⁴Diaverum Renal Services Group, Lund, Sweden.

Background and aims: A previous study from our group showed a low cumulative incidence of end-stage renal disease (ESRD) in a Swedish

cohort of type 1 diabetes (T1D) patients with median duration of 20 years. We speculated that a good diabetes health care system might have postponed the peak incidence of ESRD and that young age at onset of T1D can postpone the development of diabetic nephropathy (DN) and ESRD. Moreover, diabetes onset during puberty may promote the development of diabetic complications. Our previous study also indicated differences by sex in ESRD development and a possible interaction with age at onset. Female patients who developed T1D after puberty had similar risk of ESRD as those with onset before 10 years of age. Male patients had the same high risk with onset during puberty and after puberty, those with onset before 10 years had the lowest risk. The aims of the present study are to assess the cumulative incidence of ESRD due to DN in a large prospective population-based cohort of T1D patients at maximum 36 years of diabetes duration and to study the effects of sex and age at onset of T1D.

Materials and methods: Since 1977 all incident cases of T1D in the ages 0–14 years are recorded in the Swedish Childhood Diabetes Register (SCDR). The Swedish Renal Registry (SRR) started in 1991 and collects data on all patients with active uraemia treatment, ESRD. We decided to include patients with diabetes duration ≥ 14 years. In total 9381 patients from the SCDR were included. We have recently received permission to include data from the Swedish National Diabetes Register, a national quality register, and are awaiting data to include patients with age at onset 15–34 years.

Results: For the childhood onset cases the median diabetes duration was 23.8 years, maximum 36.7 years, and 154 patients had developed ESRD due to diabetes. The cumulative incidence was 4.5%. There was no statistical difference between male and female patients with age at diabetes onset before 15 years of age, males 5.0%, females 3.8%. We confirm that onset of diabetes before 10 years of age postpones the development of ESRD when compared to onset during 10–14 years, HR 2.3 (95% CI=1.7–3.3). Further analyses will be available for presentation in September.

Conclusion: The cumulative risk of ESRD due to diabetic nephropathy in Swedish T1D patients at maximum 36 years of diabetes duration is still exceptionally low. There is no difference in the development of ESRD between male and female patients with onset of diabetes before 15 years of age.

403

Sarcopenia is associated with micro- and macro-albuminuria independently of hypertension and diabetes: nationwide surveys (KNHANES 2008–2011)

B.-S. Cha, Y.-H. Lee, G. Kim, E. Han, S. Kim, B.-W. Lee, E. Kang, C. Ahn, H. Lee;

Yonsei University College of Medicine, Seoul, Republic of Korea.

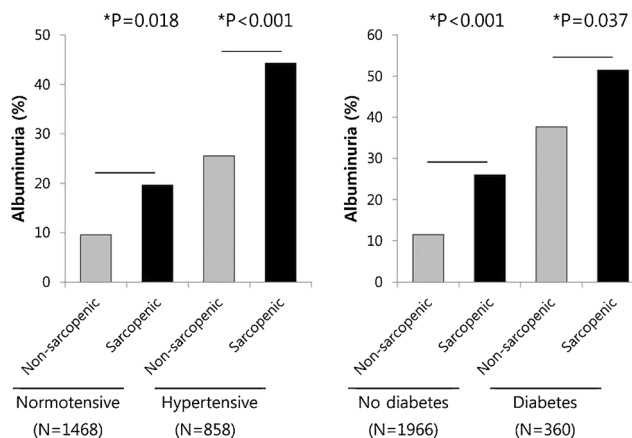

Background and aims: Sarcopenia is known to be associated with obesity-related comorbidities such as hypertension and diabetes. However, its influence on albuminuria or nephropathy has not been determined. Therefore, the aim of this study was to identify the relationship between sarcopenia and albuminuria or nephropathy in the general population.

Materials and methods: This was a population-based, cross-sectional study using nationally representative samples of 2,326 subjects aged ≥ 20 years from the Korea National Health and Nutrition Examination Surveys (KNHANES) 2008–2011. The nephropathy was defined more than 30 $\mu\text{g}/\text{mg}$ of a urinary albuminuria-to-creatinine ratio (UACR) in spot urine or more than one positive for proteinuria in urine dip stick tests. The skeletal muscle index (SMI) [$\text{SMI}(\%) = \text{total appendicular skeletal muscle mass (kg)} / \text{weight (kg)} \times 100$] measured by dual-energy X-ray absorptiometry was used to diagnose sarcopenia with cut points of 32.2% for men and 25.5% for women according to the previous study (J Clin Endocrinol Metab. 2014;99:3879–3888).

Results: A total of 385 (16.5%) subjects were classified as having a micro- or macro-albuminuria. Individuals with sarcopenia showed a

higher proportion of albuminuria compared to subjects with non-sarcopenia (22% vs. 8%, odds ratio [OR]=3.26, 95% confidential intervals [CI]=2.32–4.58, $P < 0.001$). Sarcopenic subjects had a higher risk of albuminuria, after stratification with hypertension (all ORs=2.32, all P s < 0.05) or diabetes (ORs=1.76 to 2.71, all P s < 0.05), which are known as established risk factors for albuminuria (Figure 1). Multiple logistic regression analysis also demonstrated that sarcopenia was independently associated with micro- or macro-albuminuria after adjusting for confounding factors related to albuminuria and renal function (OR=1.70, 95% CI=1.11–2.59, $P=0.014$).

Conclusion: Sarcopenia is associated with increased risks of micro- and macro-albuminuria independently of hypertension or diabetes. This suggests that sarcopenia may be considered as a novel risk factor for albuminuria.

The mortality risk in post transplantation diabetes mellitus is better predicted by glucose than HbA_{1c} based diagnostic criteria

I.A. Eide¹, T.A.S. Halden¹, A. Hartmann^{1,2}, A. Åsberg³, D.O. Dahle¹, A.V. Reisaeter^{4,1}, T. Jenssen^{5,1};

¹Department of Transplant Medicine, Oslo University Hospital, ²Institute of Clinical Medicine, ³Department of Pharmaceutical Biosciences, University of Oslo, ⁴The Norwegian Renal Registry, Oslo University Hospital, ⁵Metabolic and Renal Research Group, The Arctic University of Norway, Tromsø, Norway.

Background and aims: Current diagnostic criteria for posttransplantation diabetes mellitus (PTDM) are either a fasting plasma glucose (fPG) ≥ 7.0 mmol/L (≥ 126 mg/dL) or a 2-hour post-challenge plasma glucose ≥ 11.1 mmol/L (≥ 200 mg/dL) during an oral glucose tolerance test (OGTT). Recently the diagnostic criteria for type 2 diabetes of glycosylated haemoglobin (HbA_{1c}) $\geq 6.5\%$ (≥ 48 mmol/mol) was proposed also for PTDM. We examined HbA_{1c} based criteria compared with conventional glucose criteria in the early phase after transplantation as a predictor of mortality.

Materials and methods: In this retrospective cohort study of 1996 renal transplant recipients, transplanted between 1999 and 2011, we estimated mortality hazard ratios for patients diagnosed with PTDM. The study participants underwent weekly fPG measurements during the first 10 weeks after transplantation, followed by an OGTT and HbA_{1c} measurements at 10 weeks post-transplant.

Results: During a median follow-up of 5.4 years, 314 patients died. Both PTDM detected by an OGTT (OGTT criteria) and persistent hyperglycaemia throughout the first 2 months post-transplant (manifest PTDM) were associated with mortality (OGTT criteria: adjusted hazard ratio [HR] 1.64, 95% confidence interval [CI] 1.02 – 2.63, $p=0.04$).

Manifest PTDM: adjusted HR 2.21, 95% CI 1.40 - 3.49, $p=0.001$). PTDM detected by $HbA_{1c} \geq 6.5\%$ (≥ 48 mmol/mol) was not associated with mortality (adjusted HR 0.96, 95% CI 0.61 - 1.51, $p=0.86$).

Conclusion: Our findings confirmed that, in the early phase after renal transplantation, PTDM diagnosed by conventional glucose criteria, as opposed to the HbA_{1c} criterion, predicted mortality.

Mortality risk according to diabetes category

Diagnostic category,	Crude				Multivariate		
	n	HR	95% CI	p	HR	95% CI	p
Model 1							
PTDM by OGTT criteria	91	1.84	(1.17-2.89)	0.01	1.64	(1.02-2.63)	0.04
Manifest PTDM	73	2.44	(1.58-3.77)	<0.001	2.32	(1.49-3.67)	<0.001
Pre-transplant diabetes	365	1.63	(1.26-2.11)	<0.001	1.75	(1.31-2.34)	<0.001
Model 2							
PTDM by HbA_{1c} criterion	88	1.54	(1.01-2.36)	0.05	0.96	(0.61-1.51)	0.86
Manifest PTDM	73	2.44	(1.58-3.77)	<0.001	2.21	(1.40-3.49)	0.001

Impact of renal transplantation on glucose tolerance in Japanese recipients with impaired glucose tolerance

A. Nakamura¹, D. Iwami¹, H. Miyoshi¹, K. Morita¹, N. Shinohara¹, Y. Terauchi², T. Atsumi¹;

¹Graduate School of Medicine, Hokkaido University, Sapporo, ²Graduate School of Medicine, Yokohama City University, Japan.

Background and aims: New-onset diabetes after transplantation (NODAT) is a serious and frequent complication related with renal transplantation. Insulin resistance and impaired insulin secretion could contribute to the pathogenesis of glucose intolerance after renal transplantation, but it has been controversial which component of them is more relevant. In the current study, we investigated the natural history of glucose tolerance, insulin secretion and insulin sensitivity by analyzing the results of oral glucose tolerance test (OGTT) in Japanese recipients before and one year after renal transplantation.

Materials and methods: We performed a retrospective study of Japanese recipients without diabetes who received renal transplantation at our hospital. A 75-g OGTT was performed before and one year after renal transplantation. NODAT was defined according to the OGTT result (2-h glucose ≥ 200 mg/dL; fasting glucose ≥ 126 mg/dL). Normal glucose tolerance (NGT), impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) were defined according to the World Health Organization Expert Committee. Insulin sensitivity was estimated by the use of the Matsuda index and homeostasis model assessment of insulin resistance (HOMA-IR). Insulin secretion was evaluated based on the insulinogenic index and oral disposition index.

Results: Of the 62 recipients, 31 were diagnosed as NGT, while the remaining 31 were diagnosed as IGT before renal transplantation. In the NGT group, 9.7% of the recipients developed NODAT, 32.3% developed IFG and/or IGT, and 58.1% remained NGT one year after renal transplantation. In the IGT group, after one year, 12.9% developed NODAT and 29.0% remained IGT. Unexpectedly, 58.1% of the IGT group turned to NGT. When the patients in the IGT group were classified into an amelioration group (the changes in area under the curve of the glucose excursion during the OGTT (ΔAUC_{glu}) <0) and a non-amelioration group (ΔAUC_{glu} >0), there were no differences in parameters reflecting insulin secretion and insulin sensitivity between the two groups before transplantation. After one year of renal transplantation, Matsuda index was significantly increased, with no significant changes in insulinogenic index or

oral disposition index in the amelioration group. By contrast, insulinogenic index and oral disposition index were significantly reduced, with no significant changes in Matsuda index or HOMA-IR in the non-amelioration group. To reveal the factors influencing glucose tolerance before and after renal transplantation in the IGT group, we examined the association between ΔAUC_{glu} and the changes in parameters reflecting insulin secretion and insulin sensitivity. The changes in Matsuda index ($r=-0.5580$, $p=0.0014$), insulinogenic index ($r=-0.4674$, $p=0.0092$) and oral disposition index ($r=-0.7788$, $p<0.0001$) had a significant negative correlation with ΔAUC_{glu} .

Conclusion: More than half of Japanese recipients with IGT turned to NGT after one year follow-up of their renal transplantation. Our results suggested that the increase of insulin sensitivity without decreased insulin secretion is associated with the improvement of glucose tolerance in these recipients. Further studies are needed to elucidate the mechanism of the increase of insulin sensitivity and maintaining of insulin secretion after renal transplantation.

406

Coronary artery disease as a risk for developing type 2 diabetes mellitus

D. Zanolin¹, C. Saely^{2,3}, A. Vonbank³, P. Rein³, A. Leiberer¹, A. Muendlein¹, H. Drexel^{4,3};

¹VIVIT Institute, Feldkirch, Austria, ²Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, ³Academic Teaching Hospital Feldkirch, Austria, ⁴Drexel University, Philadelphia, USA.

Background and aims: Diabetes mellitus is a major risk factor for coronary artery disease (CAD); whether conversely CAD confers an increased risk for diabetes is unclear.

Materials and methods: We prospectively recorded incident diabetes over 6.1 ± 3.7 years in 829 consecutive non-diabetic Caucasian patients undergoing coronary angiography for the evaluation of stable CAD, covering 5057 patient years.

Results: During follow-up, diabetes was newly diagnosed in 133 patients, i.e. in 16% of the study population or in 2.6% per year. Patients with significant CAD ($n=444$) when compared to subjects who did not have significant CAD at the baseline angiography were at a strongly increased diabetes risk (20.3 vs. 11.2%; $p<0.001$). The relationship between CAD and incident diabetes was confirmed after multivariate adjustment including metabolic syndrome status (OR 1.85 [1.23-2.79], $p=0.003$).

Conclusion: We conclude that the presence of CAD indicates a strongly increased risk for incident diabetes. Repeated diabetes screening of coronary patients and targeted programs to prevent diabetes in these high-risk patients are warranted.

407

Fatal complications and causes of death in patients with type 2 diabetes mellitus comparing with general population by results of autopsies

A.L. Terekhova, A.V. Zilov;

Department of Endocrinology, I.M. Sechenov the First Moscow State Medical University, Moscow, Russian Federation.

Background and aims: To assess the frequency of fatal complications and the risks of death from different causes in patients with type 2 diabetes mellitus (DM) comparing with general population.

Materials and methods: On the basis of autopsy of 439 patients with type 2 diabetes mellitus had died in the Clinical Hospital №50 of Moscow during 2006-2009 we studied the main causes of their death and fatal complications. We compared our results with similar data from the Moscow City Statistics for the general population: autopsies of all dead

patients in hospitals of Moscow during 2007–2009. Chi-square test was used and relative risk (RR) with 95% confidence interval [95% CI] was calculated. Differences were considered statistically significant at $p < 0.05$.

Results: Patients with type 2 DM significantly were more likely to die from diseases of circulatory system compared to general population: 338 subjects (77.0%) vs. 45586 subjects (57.7%), $p < 0.001$, RR 1.33 [1.26–1.40]. Diabetics more often died from ischemic heart disease - 211 subjects (48.1%) vs. 20007 subjects (25.3%), $p < 0.001$, RR 1.89 [1.71–2.09], from myocardial infarction - 83 subjects (18.9%) vs. 10739 subjects (13.6%), $p = 0.001$, RR 1.39 [1.13–1.69], from cerebrovascular disease - 154 subjects (35.1%) vs. 20084 subjects (25.4%), $p < 0.001$, RR 1.38 [1.20–1.56] and from ischemic stroke - 89 subjects (20.3%) vs. 11725 subjects (14.8%), $p = 0.001$, RR 1.36 [1.12–1.65]. Patients with type 2 DM had a greater risk ($p < 0.001$) of death also from ischemic bowel disease 19 subjects (4.3%) vs. 1287 subjects (1.6%), RR 2.65 [1.65–4.19], cholelithiasis - 12 subjects (2.7%) vs. 469 subjects (0.59%), RR 4.60 [2.48–8.25], chronic pancreatitis - 5 subjects (1.14%) vs. 104 subjects (0.13%), RR 8.65 [3.12–21.78], and pyelonephritis - 18 subjects (4.1%) vs. 1034 subjects (1.3%), RR 4.1 [1.92–5.00]. The groups (diabetics and general population) did not differ ($p > 0.05$; RR ≈ 1) in frequency of such causes of death as hemorrhagic stroke (26 subjects (5.9%) vs. 4971 subjects (6.3%)), cancer (67 subjects (15.3%) vs. 10240 subjects (13.0%)), chronic obstructive pulmonary disease (8 subjects (1.8%) vs. 1264 subjects (1.6%)), gastric or duodenal ulcer (3 subjects (0.6%) vs. 938 subjects (1.2%)) and non-alcoholic cirrhosis (9 subjects (2.0%) vs. 1565 subjects (2.0%)). Patients with type 2 DM were more likely to develop fatal complications: pneumonia - 138 subjects (31.4%) vs. 4023 subjects (7.37%), $p < 0.001$, RR 4.26 [3.67–4.9]; pulmonary embolism - 100 subjects (22.8%) vs. 3481 subjects (6.38%), $p = 0.000$, RR 3.53 [2.93–4.21]; gastrointestinal bleeding - 36 subjects (8.2%) vs. 2801 subjects (5.14%), $p = 0.005$, RR 1.59 [1.14–2.19]; peritonitis - 28 subjects (6.37%) vs. 1462 subjects (2.68%), $p < 0.001$, RR 2.38 [1.62–3.44].

Conclusion: In comparison with general population the patients with type 2 DM more often died not only from diseases of circulatory system, but also from a number of diseases of gastrointestinal tract and pyelonephritis. Diabetics had a greater risk of severe complications such as pneumonia, pulmonary embolism, gastrointestinal bleeding and peritonitis. Along with the appropriate management of DM and the correction of cardiovascular risk factors, the timely diagnostics and treatment of non-cardiovascular comorbidities are necessary. An autopsy is an objective method of obtaining reliable information on the structure of mortality.

PS 020 Progenitor cells and pancreas differentiation

408

Use of epigenetic inhibitors to modulate endocrine differentiation

M. Fontcuberta-Pi-Sunyer¹, S. Cervantes^{1,2}, A. Garcia^{1,2}, L. Sanchez¹, R. Gomis^{1,2}, R. Gasa^{1,2};

¹Institut d' Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), ²Centro de Investigación biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Barcelona, Spain.

Background and aims: In the developing pancreas, the endocrine differentiation program is initiated in multipotent pancreatic progenitors by expression of the basic helix-loop-helix (bHLH) transcription factor Neurogenin3 (Neurog3). Posttranscriptional modifications of histones constitute an epigenetic mechanism that is closely linked to both gene silencing and activation events. A key mark in differentiation processes is the trimethylation of Histone3 at lysine 27 (H3K27me3), which is associated with transcriptional repression. Previously, we showed that ectopic Neurog3 promoted the removal of H3K27me3 marks at promoter regions of some of its target genes, suggesting a functional interaction between Neurog3 and regulators of this chromatin mark. In the present study, we aimed to specifically evaluate the contribution of these epigenetic regulators to the proendocrine activity of Neurog3. To this objective, we used chemical inhibitors for the H3K27 methyltransferase EZH2 and the H3K27 demethylases Jmjd3/UTX and studied their effects in the activation of the pancreatic endocrine differentiation program in several in vitro models.

Materials and methods: We used the mouse pancreatic duct cell line mPAC as a Neurog3-dependent endocrine differentiation model. Mouse embryonic fibroblasts (MEFs) were obtained from E12.5–E14.5 mouse embryos. To activate endocrine differentiation, we used a recombinant adenovirus expressing Neurog3 in mPAC cells and a recombinant adenovirus expressing Pdx1+MafA+Neurog3 in MEFs. Chemical inhibitors used were: EI-1/GSK-126 (EZH2) and GSK-J4 (UTX/JMJD3). Total H3K27me3 mark levels were analyzed by Western blotting, gene expression was quantitated by Real Time PCR and chromatin marks were assessed by chromatin immunoprecipitation assays (ChIP).

Results: In mPAC cells, GSK-J4 treatment led to marginal increases in total levels and enrichment of H3K27me3 marks at key endocrine gene promoters. By contrast, EI-1 treatment significantly reduced total levels and enrichment of H3K27me3 at promoter regions. Remarkably, this decrease was accompanied by enrichment in acetylated H3K27 (H3K27ac) but not by transcriptional activation of these genes. Upon ectopic expression of Neurog3, GSK-J4 dramatically blocked whilst EI-1 improved transcriptional activation of the endocrine program. However, pre-treatment with EI-1 (before Neurog3 expression) was not sufficient to impact Neurog3 function, suggesting functional interaction between EZH2 and Neurog3. Lastly, in MEFs, chemical inhibition of EZH2 also resulted in a higher level of activation of selected endocrine genes (NeuroD1, Nkx2-2, Pax6, Insulin) in response to combined ectopic expression of Pdx1, Neurog3 and MafA.

Conclusion: These results demonstrate the participation of epigenetic regulators of the H3K27me3 mark in the activation of the endocrine transcriptional cascade promoted by Neurog3. Inhibition of EZH2 activity may be a useful strategy to improve the efficiency of endocrine differentiation and beta cell transdifferentiation protocols in vitro.

Examination of sorted ALDHhi and ALDHhi/CD133+ cells in the developing human pancreasA.M. Oakie^{1,2}, J. Li^{1,2}, G. Grewal^{1,2}, G.F. Fellows², R. Wang^{1,2};¹Children's Health Research Institute, ²Western University, London, Canada.

Background and aims: The enzyme aldehyde dehydrogenase (ALDH) has been previously determined to regulate endocrine differentiation via retinoic acid signaling in the developing human pancreas. CD133, a surface membrane protein associated with the ductal cells in the fetal and adult human pancreas, has also been used in prior studies to identify and isolate stem cells. However, the separation of cells with high ALDH activity (ALDHhi) and the analysis of putative stem cell markers associated with ALDH expression has not yet been reported. This study aims to characterize transcription factors and stem cell surface markers in sorted ALDHhi cells in the human fetal pancreas, and examines the differentiation potential of ALDHhi or ALDHhi/CD133+ cells *in vitro*.

Materials and methods: Human fetal pancreata (18 to 22 weeks of fetal age), composed mainly of undifferentiated epithelial cells, were dissociated for fluorescence-activated cell sorting (FACS). Cells sorted based on ALDH activity alone (ALDHhi and ALDHlo populations) or ALDH colocalization with CD133 (ALDHhi/CD133+ and ALDHlo/CD133- populations) were examined for transcription factors (TFs), hormones, and pancreatic cell lineage markers immediately after cell sort, after *in vitro* expansion culture, or following differentiation of cluster formation using immunohistological and qRT-PCR approaches.

Results: FACS demonstrated that CD133 was highly expressed in ALDHhi cell populations, while CD34 was expressed mainly in ALDHlo cells ($p < 0.001$). The sorted ALDHhi population cells contained higher levels of islet-associated TFs (SOX9, PDX-1, and NKX6.1, $p < 0.01$) compared to ALDHlo sorted cells, as well as hormones insulin and somatostatin ($p < 0.05$), but not glucagon. It was also noted that vimentin + and CD31+ cells were predominantly observed in ALDHlo population immediately after cell sorting. Expanded culture of sorted ALDHhi or ALDHhi/CD133+ cells resulted in loss of nuclear endocrine TFs, except SOX9, and displayed mesenchymal-like structure. The loss of ductal cell phenotype in ALDHhi cells and increased vimentin+ staining in both expanded cell cultures may indicate that sorted cells enter epithelial-to-mesenchymal (EMT) transition. A similar result was observed in sorted ALDHlo or ALDHlo/CD133- cells during the expanding culture. Differentiation of expanded ALDHhi or ALDHhi/CD133+ cells led to formed islet-like clusters, restored CK19 ductal cell marker, and increased endocrine TFs gene expression; however, no endocrine hormones were detected in the clusters.

Conclusion: This study demonstrated that ALDHhi cells contain a CD133 enriched endocrine progenitor cell pool in the developing human pancreas, indicating that sorted ALDHhi/CD133+ cells may be fated towards islet cell commitment. However, future experiments require optimal culture environments for inducing progenitors to differentiate into insulin-producing islet cells.

MicroRNA expression dynamics during human induced pluripotent stem cells differentiation into insulin-producing cellsG. Sebastiani^{1,2}, M. Valentini^{1,2}, G.E. Grieco^{1,2}, G. Ventriglia^{1,2}, S. Pellegrini³, V. Sordi³, L. Piemonti³, F. Dotta^{1,2};¹Diabetes Research Unit, University of Siena, ²Fondazione Umberto di Mario ONLUS, Toscana Life Sciences, Siena, ³Diabetes Research Institute, IRCCS San Raffaele Scientific Institute, Milan, Italy.

Background and aims: In a previous study we demonstrated that human induced pluripotent stem cells (HiPSCs) are able to differentiate into

insulin-producing cells following the stages of pancreatic organogenesis. Moreover, mice transplanted with differentiated HiPSCs secreted human C-peptide in response to glucose, suggesting that these differentiated cells can engraft and secrete insulin *in vivo*. MicroRNAs (miRNAs) are a class of small non-coding RNA molecules, which control gene expression by inhibition of messenger RNA translation. MiRNAs are involved in the control of several biological processes such as cell differentiation or insulin secretion.

Here, we aim at characterizing miRNA expression profiles during differentiation of HiPSC into insulin-producing cells

Materials and methods: HiPSC were derived from fibroblast preparations from adult healthy donors and from human fetal fibroblast cell line IMR90, using a retroviral cocktail of reprogramming factors. HiPSC differentiation into insulin-producing cells lasted 18 days and was performed following Viacyte protocol with slight modifications. Total RNA was extracted using miRvana Kit at different stages during differentiation (day 0-native HiPSCs, day 4-definitive endoderm, day 10-posterior foregut, day 18-endocrine pancreas). Gene expression was analyzed by RT Real Time PCR using Taqman assays. The expression of 768 miRNAs was analyzed using Taqman human microRNA array cards PanelA+B and normalized using small RNAs RNU48 and RNU6. Differentially expressed miRNAs were further analyzed by RT-stem loop Real Time PCR. MiRNA predicted target genes were identified using Targetscan 6.2 and Gene Ontology classification was performed using online software DAVID 6.7

Results: A progressive upregulation of islet hormonal genes (insulin, glucagon, somatostatin) and of endocrine/beta-cell specific transcription factors NGN3, MAFA, MAFB, NeuroD1 and ISL-1 was detected at day-4, -10 and -18 of differentiation vs native HiPSC, paralleled by increased expression of glucose sensing apparatus genes GCK and GLUT2. MiRNA expression profiles analysis of native HiPSC during differentiation into insulin-producing cells revealed that 347/768 miRNAs were expressed at least at one time point of all samples; in addition, 19 miRNAs resulted as differentially expressed during differentiation: 12 upregulated (miR-9, miR-9#, miR-10a, miR-99a#, miR-124a, miR-135a, miR-138, miR-149, miR-211, miR-224, miR-342-3p and miR-375) and 7 downregulated (miR-31, miR-127, miR-143, miR-302c#, miR-373, miR-518b and miR-520c-3p). Following Targetscan 6.2 analysis of predicted target genes of differentially expressed miRNAs, Gene Ontology classification revealed that such target genes belong to categories of major significance in pancreas organogenesis such as cell morphogenesis at day 4, organ/tissue development at day 10 or pancreas development and exocytosis at day 18

Conclusion: We detected a specific miRNA signature in HiPSC during their differentiation into insulin producing cells and demonstrated that differentially expressed miRNAs putatively control the expression of genes involved in pancreas organogenesis

The role of miRNAs in adult cells reprogramming along the endocrine pancreatic lineageA. Osnis^{1,2}, I. Meivar-Levy², S. Ferber^{2,1};¹Human Genetics and Biochemistry, Tel Aviv University, ²Sheba Regenerative Medicine, Stem cells and Tissue engineering Center, Sheba Medical Center, Tel-Hashomer, Ramat Gan, Israel.

Background and aims: Cell replacement therapy may offer a cure for diabetes as long as new sources of insulin producing cells (IPCs) are found. Transdifferentiation of liver cells to IPCs may offer a new therapeutic source for diabetic patients. We have reported that ectopic expression of pancreatic transcription factors (pTFs) in the liver induces insulin production, both *in vivo* and *in vitro*. The key transcription factor is Pancreatic-duodenal-homeobox-1 (PDX1) which plays a dual and central role in regulating pancreas organogenesis in embryo and β -cell function

in adults. Regardless to the use of several pTFs combined with specific growth and soluble factors, transdifferentiation efficiency could be further improved. MicroRNAs (miRNAs) are short non-coding RNAs (20–25 nucleotides) that regulate gene expression. miRNAs have been shown to participate in almost every cellular process investigated so far. Several specific miRNAs involved in β -cells' development and function and also with the upkeep of insulin transcription have been identified. It was shown that miRNAs are indeed involved in the transdifferentiation process between several tissues. The present study is designed to analyze the role of miRNAs in the transdifferentiation process of extra-pancreatic tissues along the pancreatic β -cell lineage.

Materials and methods: Primary human liver and fibroblast cultures are generated from >10 separate donors. Transdifferentiation induction is performed by ectopic expression of pTFs sub-cloned in adenoviral vectors. Soluble factors are used to increase transdifferentiation efficiency. Transdifferentiation is evaluated at the molecular, cellular and functional levels.

Results: Using global analyses in miRNA arrays (QuantiMir™, NanoString) our data suggest that pTFs induced transdifferentiation is associated with alterations in the expression profile of miRNAs in both human fibroblasts and liver cells. IPCs originated from fibroblasts exhibited numerous changes in the miRNA profile, substantial activation of 9 miRNAs and the suppression of more than 100 miRNAs. Many of the β -cell specific miRNAs including miR-375 expression was not increased, possibly suggesting that not all the transcriptional repressors have been removed from the IPC cells. Ectopic complementation of miR-375, the major miRNA in the pancreas, indeed increased insulin gene expression. A potential role of miRNA in the transdifferentiation process is further exemplified by increases in Dicer expression; Pdx-1 but none of the other pancreatic pTFs used, specifically activated Dicer expression. The increased activation of Dicer expression during transdifferentiation may suggest a crucial role for miRNA biogenesis during reprogramming and the alteration in cells' fate.

Conclusion: Our data suggest that pTFs induced reprogramming alters the profile of the miRNA expression in part by increasing Dicer expression. Although it is well known that Dicer is ubiquitously expressed among many cell types, its activation during transdifferentiation potentially suggest an important role of controlling miRNA biogenesis during the reprogramming process. MiRNAs may lead profound insights into the underlying molecular and cellular pathways which regulate cell-fate transitions, to be used in regenerative medicine approaches.

Epithelial to mesenchymal transition process is a frequent event in vitro in all pancreatic endocrine cell types

J. Moreno-Amador¹, M. Nacher^{1,2}, C. García¹, N. Téllez¹, E. Montanya^{1,2},

¹IDIBELL, CIBERDEM, University of Barcelona, ²University Hospital of Bellvitge, Barcelona, Spain.

Background and aims: The concept of epithelial to mesenchymal transition (EMT) of cultured pancreatic beta cells has been carefully demonstrated by lineage tracing. In vitro, adult human beta cells transition into a highly proliferative mesenchymal cell population. The presence of EMT in other pancreatic endocrine cell populations is unknown. The aim of this study was to determine the EMT process in endocrine pancreatic cells.

Materials and methods: Human islets were isolated from pancreas of 6 multiorgan donors (age 47±7 y.o.; BMI 27±2; islet purity 67±6%). Islets were dissociated into single cells by enzymatic and mechanical disruption. Single endocrine cells (34±7% endocrine cell purity) were purified by magnetic cell sorting using PSA-NCAM antibody. The resulting cell fraction (74±6% endocrine cell purity) was seeded for monolayer culture and split 1:2 weekly. Expression of the mesenchymal marker vimentin (determined by immunofluorescence) in human endocrine cells was used

to evaluate EMT from day 0 to passage 4 (P4). Gene expression was determined by quantitative real time PCR. Beta cell apoptosis was quantified by double-staining using TUNEL assay and insulin antibody.

Results: A progressive reduction of cells expressing endocrine markers (insulin, glucagon, somatostatin and pancreatic polypeptide (PP)) was found along the four passages of culture. PP positive cells were identified up to P2 (0.3±0.2%), and the presence of insulin (0.6±0.2%), glucagon (0.2±0.1%), and somatostatin (0.2±0.1%) positive cells was residual at P4. The percentage of apoptotic beta cells was low (day 0: 0.56±0.26%; day 4: 0.04±0.01%; day 8: 0.03±0.02%; day 12: 0.05±0.04%; P2: 0.06±0.06%) suggesting that the reduction in insulin expressing cells was not due to increased beta cell death. Co-expression of endocrine and mesenchymal markers was detected after 4 days in culture and increased subsequently (insulin+vim+ 6±4% at P1; 58±4% at P4). Other endocrine populations were also found to co-express vimentin (glucagon+vim+ 62±4% and 93±4%, somatostatin+vim+ 18±6% and 95±5%, at P1 and P4 respectively; PP+vim+ 81±9% at P1 and 92±8% at P2). Changes in gene expression were also suggestive of EMT process with a significant increased expression of mesenchymal markers (cdh2, snai2, vim, nt5e and acta2) and reduction of cdh1.

Conclusion: All four types of adult human pancreatic endocrine cells underwent EMT in vitro. Lineage tracing will be used to quantify the contribution of the different endocrine cell populations to the proliferative mesenchymal pool.

Haematopoietic CD34+ stem-cell differentiation to insulin-producing cells: possible role of betatrophin

R. Lupi¹, E. Selvaggi², S. Del Guerra², S. Del Prato²;

¹Medical Area, ²Clinical and Experimental Medicine, Metabolic Unit, Pisa, Italy.

Background and aims: Though human pancreatic islet transplantation has raised great expectation, the shortage of pancreas donors remains a main limitation. Stem cell therapy is, therefore, being a matter of continuous investigation. We have investigated the potential of betatrophin to improve generation of insulin-producing cells (IPCs) from circulating haematopoietic CD34+ stem-cell of normal subjects as well as type 1 (T1DM) and type 2 diabetic (T2DM) patients.

Materials and methods: Haematopoietic CD34+ stem cells were isolated by immunomagnetic technique from the blood of 15 non-diabetic (ND: 46±4 yrs; 5 M/10 F; BMI 24.7±1.5 Kg/m²), 10 T1DM (45±5 yrs; 7 M/3 F; 23.7±1.6 Kg/m²) and 15 T2DM (62±4 yrs; 8 M/7 F; 26.5±1.4 Kg/m²) subjects. Differentiation into insulin-producing cells was obtained by a protocol, modified in our laboratory, in presence or absence of betatrophin (10 μ mol/l). Insulin-producing cells were identified by colorimetric staining and immune-fluorescence technique. Real-Time R-PCR was used for assessment of insulin gene expression and telomere length (TL) as a marker of cell senescence. Insulin was measured in culture media by IRMA assay.

Results: The number (ND: 2.71E+4±5.19E+3; T1DM: 3.26E+4±1.43E+4; T2DM 4.21E+4±1.16E+4 cell/ml) and viability (ND 42.38±6.68%; T1DM 43.29±6.18%; T2DM 44.55±7.09%) of CD34+ stem cells was similar in the 3 groups and was not affected by age. After 10-day culture in vitro expansion (ND 1.12E+5±2.03E+4, T1DM 3.08E+5±9.22E+4, and T2DM 1.31E+5±1.92E+4 cell/ml; all p<0.05 vs. day 1) and viability remained comparable among the 3 groups. TL was lower in T2DM (4.62E+1±3.44 bp) as compared to ND (2.78E+7±1.15E+7 bp) and T1DM (9.58E+7±6.18E+7 bp; both p<0.05) at baseline and it did not change after 10 day cell replication. Insulin gene expression in CD34+ stem cells increased in all groups being higher in T2DM (15.91±4.44 2^{- Δ Ct}) than in ND (2.30±1.25 2^{- Δ Ct}) and T1DM (1.84±0.77

$2^{-\Delta\text{Ct}}$; both $p < 0.05$). The increase in insulin mRNA expression was associated with a mild increase in insulin concentration in the medium. Addition of betatrophin to the culture medium further increased insulin mRNA expression in all groups (ND 13.9 ± 2.93 $2^{-\Delta\text{Ct}}$, T1DM 9.12 ± 3.41 $2^{-\Delta\text{Ct}}$, and T2DM 50.63 ± 2.17 $2^{-\Delta\text{Ct}}$; all $p < 0.05$ vs. no betatrophin) with no effect on insulin release in the medium.

Conclusion: Although circulating stem cells from normal and diabetic subjects can be manipulated to increase insulin mRNA expression, insulin release remains insufficient. Betatrophin enhances mRNA expression without affecting insulin release. Although our results support a hypothetical generation of insulin producing cells from circulating stem cells, the relevance of this approach remains questionable.

Elucidating the role of Pancreatic Stellate Cells (PaSCs) during islet cell development in the human foetal pancreas

J. Li¹, B. Chen¹, G.F. Fellows², R. Wang¹;

¹Physiology & Pharmacology, ²Obstetrics and Gynecology, Western University, London, Canada.

Background and aims: Pancreatic stellate cells (PaSCs) are non-endocrine, mesenchymal-like cells that reside within the peri-pancreatic tissue of the rodent and human pancreas. PaSCs regulate extracellular matrix (ECM) turnover in maintaining the integrity of pancreatic tissues architecture. Although there is evidence indicating that PaSCs are involved in islet cell survival and function, its role in islet cell differentiation during pancreatic development remains unclear. In the present study, the expression pattern and functional role of PaSCs was examined in the early to mid-gestation human fetal endocrine pancreas.

Materials and methods: The presence of PaSCs in the human fetal (8–22 weeks fetal age) pancreas was characterized by quantitative RT-PCR, western blotting, and ultrastructural and immunohistological approaches. Isolated human fetal islet-epithelial cell clusters (17–21 weeks fetal age) were directly and indirectly co-cultured with active or inhibited PaSCs to examine the developmental effects of PaSC on islet cell differentiation in vitro.

Results: Using microarray, qRT-PCR, and western blot approaches, we found PaSCs to be highly proliferative, with significantly higher gene and protein levels for PaSC markers during the 1st trimester of pregnancy compared to the 2nd. Ultrastructural and immunofluorescence analysis of PaSCs demonstrated a population of PaSCs near ducts and newly formed islets. A subset of PaSCs co-localized with transcription factors (PDX-1, SOX9, and NKX6.1) that are critical for maintenance of the pancreatic progenitor pool and endocrine differentiation. Human fetal PaSCs were isolated from pancreata collected during the 2nd trimester of pregnancy and identified by expression of stellate cell markers and associated products. Inhibition of PaSC activation using ATRA resulted in reduced PaSC proliferation and production. Co-culture of human fetal islet-epithelial cell clusters directly on PaSCs or indirectly using Millicell® Inserts showed a significant reduction in NGN3, NKX6.1, and insulin expression, while PDX-1 and SOX9 expression remained unchanged. Interestingly, high levels of Notch signalling, significantly increased PTF1A mRNA and the number of amylase+ cells were observed during the co-culture.

Conclusion: We have investigated the expression and potential function of PaSCs in the early to mid-gestation human fetal pancreas, and have determined that PaSCs are abundant during early stages of pancreatic development around ductal and islet structures. Direct and indirect co-culture of islet-epithelial cell clusters with PaSCs suggests that PaSCs are required for maintaining pancreatic progenitor pool. However, over-activation of PaSCs plays a negative role with respect to endocrine cell differentiation in the developing human fetal pancreas.

The core trithorax protein Wdr5 is essential for specification of pancreas progenitors into endocrine and exocrine cell lineages

S.A. Campbell^{1,2}, B.R. Tennant^{1,2}, C.J. Whiting², B.G. Hoffman^{1,2};

¹Cell and Developmental Biology, University of British Columbia, ²Surgery, Child and Family Research Institute, Vancouver, Canada.

Background and aims: All cells of the pancreas arise from Pdx1+Sox9+ pancreas progenitors that begin differentiation into endocrine, exocrine and ductal cells starting at around embryonic day 12.5 (E12.5). Various transcription factors are critical for this process; for example, Ngn3 is essential for specification of endocrine cells, which will mature into the islet cell types, including insulin-producing beta-cells. However, exactly how these transcription factors are appropriately regulated during pancreas development is still largely unknown. We have previously compared the chromatin state of mouse pancreatic islets and ES cells using chromatin immunoprecipitation sequencing data and found that cis-regulatory regions associated with pancreas critical transcription factors need to gain activating marks to become expressed; however, when and how this occurs is still not clear. Trithorax group (TrxG) complexes promote gene activation by catalyzing histone methylation via Mll/Set1 methyltransferases and we hypothesized that these complexes are necessary for induction of factors critical to progenitor cell specification during pancreas development.

Materials and methods: To test this hypothesis, we used lentiviral short hairpin RNA-mediated knockdown of the core TrxG protein Wdr5 (shWdr5) in an in vitro model of mouse pancreas development where E13.5 Pdx1+Sox9+Ngn3- progenitor cells are expanded into spheroids and then differentiated for seven days.

Results: We first examined the expression of select TrxG complex proteins, Wdr5, Dpy30, Mll1 and Mll3, at E12.5 and E14.5 of mouse development by immunohistochemistry. These proteins were widely expressed in the mouse embryonic pancreas and were co-expressed with both Pdx1+ and Ngn3+ cells. Suppressing Wdr5 using our in vitro pancreas progenitor sphere differentiation model, we found that shWdr5 treatment significantly reduced the number of spheres generated per pancreas ($n=4$, $p < 0.001$) as well as the diameter of the spheres produced ($n=4$, $p < 0.01$). Interestingly, shWdr5 also almost completely prevented expression of markers of endocrine cell lineages, including Ngn3, Ins1, Ins2 and Gcg ($n > 4$, $p < 0.01$). This effect was confirmed by experiments in mouse insulin promoter-GFP spheres, which had significantly reduced production of GFP+ cells in shWdr5-treated spheres ($n=4$, $p < 0.01$). To determine the effect of shWdr5 on the other pancreas lineages, we performed RNA-seq on pancreas spheres treated with shScramble and shWdr5. Consistent with our gene expression data, the RNA-seq results confirmed that knockdown of Wdr5 impairs endocrine cell specification. To our surprise, exocrine cell specification was also impaired, but development of ductal cells was not.

Conclusion: These results suggest that the core TrxG complex protein Wdr5 is essential for pancreas progenitors to be specified into endocrine and exocrine, but not duct, cell lineages. This implies that in pancreas progenitors, factors necessary for duct cell specification and differentiation have already attained histone methylation at their cis-regulatory regions, while factors necessary for endocrine and/or exocrine specification, such as Ngn3, have not.

Induction of selective unresponsiveness to glucose but not nutrient secretagogues in general by depolarisation in the absence of nutrients
T. Schulze, K. Schumacher, M. Morsi, U. Panten, I. Rustenbeck;
Institute of Pharmacology and Toxicology, Braunschweig, Germany.

Background and aims: The mechanisms underlying the metabolic signals which amplify glucose-induced insulin secretion while circumventing plasma membrane depolarization are still poorly understood in spite of considerable research efforts. Here, an experimental protocol is presented which may prove useful to identify the relevant metabolites.

Materials and methods: All parameters were measured in freshly isolated mouse islets. Insulin secretion was measured by ELISA of the fractionated perfusion efflux, the oxygen consumption rate (OCR) was measured by a fluorescence quench technique, and the ATP/ADP ratio by the luciferase technique.

Results: A 60 min perfusion of isolated islets with 500 μM tolbutamide in the absence of glucose abolished the insulinotropic effect of 30 mM glucose but not of 10 mM alpha-ketoisocaproic acid (KIC). The same dissociation was seen when 15 mM K^+ was used instead of 500 μM tolbutamide. When the perfusion period prior to the glucose stimulation was 40 min instead of 60 min, the loss of the insulinotropic efficacy of 30 mM glucose was incomplete. Similarly, when the K_{ATP} channel activity was only partially inhibited by 50 μM tolbutamide, a gradual increase of secretion resulted in response to 30 mM glucose. This pattern resembled the effect of glucose after 60 min perfusion in the absence of glucose (control). In SUR1 KO islets the moderate insulinotropic efficacy of glucose and KIC remained unaffected by 60 min perfusion with 500 μM tolbutamide in the absence of glucose. The loss of the insulinotropic efficacy of glucose was paralleled by the inability of glucose to raise the OCR. Under the same condition KIC increased OCR in parallel with secretion. Under control condition glucose increased the OCR, even faster than it increased secretion. The discrepancy between the preserved insulinotropic efficacy of KIC and the loss of efficacy of glucose was not due to different ATP/ADP ratios.

Conclusion: These observations suggest that the combination of moderate depolarization, either by K_{ATP} channel closure or 15 mM K^+ , and the absence of basal nutrient supply decreases the concentration of one or several metabolites critical for glucose-induced secretion, but leaves the exocytotic machinery of the beta cell unimpaired. This situation should facilitate the identification of the relevant amplifying metabolites.

Beta cell action potentials and Ca^{2+} currents during K^+ depolarisation

N. Görgler¹, M. Willenborg¹, K. Schumacher¹, A. Welling², I. Rustenbeck¹;

¹Institute of Pharmacology and Toxicology, University of Braunschweig,

²Institute of Pharmacology and Toxicology, University of Munich, Germany.

Background and aims: The concept of the amplifying pathway of insulin secretion is mainly based on experimental observations where the nutrient-induced depolarization via K_{ATP} channel closure is replaced by K^+ depolarization. Additionally, diazoxide is used to clamp the K^+ conductance at a constant level, thus precluding insulinotropic effects via changes in the activity of voltage-dependent ion channels. Earlier,

diazoxide was described to exert direct effects on the mitochondrial membrane potential; recently, discrepancies were described that exist between depolarization via K_{ATP} channel closure and K^+ depolarization.

Materials and methods: Using mouse islets insulin secretion was measured by batch perfusion and ELISA and the free cytosolic Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) by the Fura technique. Primary mouse beta cells were used for electrophysiological experiments. The membrane potential was measured by utilizing the perforated patch mode. Simultaneous measurements of $[\text{Ca}^{2+}]_i$ were performed by loading with Fluo 4. To specifically investigate currents through voltage-dependent Ca^{2+} channels in voltage-clamp experiments using the conventional whole cell configuration K^+ channel blockers were added to the bath solution and intracellular KCl was replaced by CsCl in the pipette solution.

Results: Raising the extracellular K^+ concentration of perfused islets to 15 and 40 mM led to a strong further increase of the insulin secretion even if the beta cells were already depolarized by K_{ATP} channel closure. This effect of high K^+ was accompanied by an increase of $[\text{Ca}^{2+}]_i$, which could be shown by simultaneous measurements of the plasma membrane potential. It could completely be antagonized by application of L-type Ca^{2+} channel blockers. In voltage-clamp experiments the Ca^{2+} influx appeared as nifedipine-inhibitable inward action currents when outward K^+ currents were blocked. Under these conditions 15 mM K^+ induced prolonged action currents and 40 mM K^+ transformed the action current pattern into a continuous inward current. Under current-clamp conditions the increase of the K^+ concentration to 15 mM in the presence of 500 μM tolbutamide led to a broadening of the action potentials. This was due to the fusion of several action potentials, separated by prolonged phases of electrical silence. A similar pattern of fused action potentials was caused by 1 μM BayK8644, an opener of L-type Ca^{2+} channels. In contrast to BayK8644 high extracellular K^+ did not affect the current-voltage relation when conditions were used to selectively measure currents through voltage-dependent Ca^{2+} channels.

Conclusion: High extracellular K^+ concentrations do not simply activate Ca^{2+} influx via voltage-dependent Ca^{2+} channels, they also affect the pattern of Ca^{2+} influx as becomes visible in the presence of K^+ channel blockers. In contrast to the action of Ca^{2+} channel openers this effect does not result from a direct interference with channel function.

Pancreatic beta cell dedifferentiation involves the voltage-gated calcium channel subunit gamma4

C. Luan¹, E. Ganic², I. Artner², E. Zhang¹, E. Renström¹;

¹Lund University, Malmö, ²Lund University, Sweden.

Background and aims: Voltage-gated Ca^{2+} channels (CaV) are fundamental for insulin secretion. They are heteromeric complexes comprised of the pore-forming α_1 subunits, and the accessory modulatory subunits beta, $\alpha_2\delta$ and gamma. The impact of gamma subunits in the pancreatic beta-cell is unexplored, especially the gamma4 ($\text{CaV}\gamma_4$) isoform, which has been widely detected in many tissues. Importantly, $\text{CaV}\gamma_4$ exhibits differential down-regulation in human diabetic islets and was therefore investigated in detail. The aim of this study is to investigate the physiological mechanism through which $\text{CaV}\gamma_4$ influences beta-cell function.

Materials and methods: Roles of $\text{CaV}\gamma_4$ in INS-1 cells, rat islets, human islets and beta-cell specific MafA knockout mice ($\text{MafA}\Delta\beta\text{cell}$) islets were identified by systems biology approaches in combination with physiological validation experiments: microarray, siRNA silencing, real-time quantitative PCR, western blot, patch clamp, immunostaining and radioimmunoassay.

Results: In human diabetic islets, $\text{CaV}\gamma_4$ exhibits differential 15% down-regulation (by microarray collected from 113 donors, $P < 0.05$). The gene and protein expression of $\text{CaV}\gamma_4$ were also reduced by gluco-/lipotoxic

conditions (35% and 34% respectively, $n=3$). CaV γ 4 exerted surprisingly strong effects on beta-cell Ca $^{2+}$ signaling, by an action specific to L-type CaV channels. Silencing of CaV γ 4 reduced expression of L-type Cav1.2 and Cav1.3 (28% and 32% respectively, $n=3$), and also suppressed voltage-gated Ca $^{2+}$ entry (888.5 ± 49.8 A.U.C. vs. 1084.5 ± 48 A.U.C. (negative control); $n=3$) and insulin exocytosis (389 ± 35 fF $n=14$ vs. 997 ± 206 fF (negative control); $n=15$). This is reminiscent of a dedifferentiated diabetic beta-cell phenotype. Interestingly, microarray analysis of co-regulated genes identified the transcription factor MafA that is responsible for the final steps of beta-cell differentiation, as a potential regulator of CaV γ 4 ($r=0.649$, $P<0.001$, from 128 donors). This was verified by MafA silencing and in MafA Δ beta cell (55% reduction of CaV γ 4 protein levels, $n=3$).

Conclusion: In conclusion, gamma4 affects beta-cell function stronger than expected. CaV γ 4 is important for maintaining a normal differentiated beta-cell phenotype, and is down-regulated by glucose, palmitate and in human diabetes. Treatment aiming at restoring CaV γ 4 may contribute to correcting the dedifferentiated beta-cell phenotype in diabetes.

The type 2 diabetes associated K $^{+}$ channel TALK-1 modulates pancreatic beta cell electrical excitability and 2 nd -phase insulin secretion

N. Vierra, P.K. Dadi, I. Jeong, D.A. Jacobson;

Molecular Physiology and Biophysics, Vanderbilt University, Nashville, USA.

Background and aims: Glucose-stimulated insulin secretion (GSIS) requires Ca $^{2+}$ influx through voltage-dependent Ca $^{2+}$ channels (VDCCs). VDCC activity is modulated by the plasma membrane potential (V_m), which is tuned by K $^{+}$ channels. The two-pore domain K $^{+}$ (K2P) channel TALK-1 is linked to type-2 diabetes risk through a non-synonymous polymorphism (TALK-1 A277E), however, its physiological function has remained elusive. The aim of this study was to assess the role of beta-cell TALK-1 channels on electrical excitability, Ca $^{2+}$ influx, GSIS, and glucose homeostasis.

Materials and methods: Whole-cell or single channel electrophysiological recordings were used to assess TALK-1 currents and electrical excitability of mouse and human beta-cells. TALK-1 currents were inhibited by expression of a dominant negative (DN) TALK-1 channel variant or eliminated via a knockout mouse model (TALK-1 KO). Islet Ca $^{2+}$ levels were determined with the Ca $^{2+}$ dye Fura-2. Insulin secretion was measured from pancreatic islets and serum. Blood glucose was monitored for changes in glucose tolerance.

Results: Genetic ablation of TALK-1 reduces mouse beta-cell K2P currents (11.7 ± 1.0 pA/pF, $n=25$) compared to controls (18.3 ± 1.2 , $n=23$). Human beta-cells also express functional TALK-1 channels (36.7 ± 4.5 pA/pF, $n=10$) and their K2P currents are significantly attenuated following expression of a TALK-1 DN (22.1 ± 2.3 pA/pF, $n=11$; $P=0.008$). Interestingly, we find that TALK-1 A277E channels show increased open probability (P_o ; 0.15 ± 0.01 , $n=6$) compared to TALK-1 A277 (0.09 ± 0.01 , $n=5$; $P<0.05$), suggesting that TALK-1 A277E may hyperpolarize the beta-cell V_m and limit GSIS. This is supported by our finding that TALK-1 KO beta-cells are depolarized by 6.2 ± 1.4 mV in low glucose (2 mmol/l) and 5.2 ± 1.1 mV in high glucose (14 mmol/l) compared to controls ($n=7$ /genotype; $P<0.03$). The plateau fraction (the fraction of time spent in the electrically active phase) is also increased in TALK-1 KO beta-cells by 0.13 ± 0.02 compared to controls ($P=0.03$; $n=7$ /genotype). Furthermore, we observe a 0.28 ± 0.06 peak/minute increase in the frequency of Ca $^{2+}$ oscillations in TALK-1-deficient islets relative to controls ($n>125$ islets/genotype; $P<0.005$). Consistent with these findings, we observe augmented 2 nd -phase insulin secretion from TALK-1 KO islets, which secrete more insulin (4.02 ± 1.07 ng/100 islet equivalents) than control islets stimulated with 11 mmol/l glucose ($P<0.05$; $n=4$ islet preparations/genotype). Ablation

of TALK-1 channels modestly increases serum insulin levels in chow-fed mice but does not alter glucose tolerance. However, after three weeks on a high-fat diet, fasting blood glucose is significantly reduced in TALK-1 KO mice (169.5 ± 5.6 mg/dl) relative to control mice (221.3 ± 8.4 mg/dl; $n=10$ mice/genotype; $P<0.0005$), revealing that beta-cell TALK-1 plays a critical role in adapting to metabolic stress.

Conclusion: TALK-1 channels hyperpolarize the beta-cell V_m , modulating 2 nd -phase GSIS by limiting the plateau fraction and reducing the frequency of Ca $^{2+}$ oscillations. Furthermore, TALK-1 channels impact glycemia under environmental conditions that promote diabetes. As we find that TALK-1 A277E channels have increased activity, this suggests that TALK-1 A277E may exacerbate hyperglycemia and accelerate diabetes pathogenesis under metabolically stressful states.

Ca $^{2+}$ -dependent expansion of cortical ER in insulin-secreting beta cells

B. Xie, O. Idevall-Hagren;

Medical Cell Biology, Uppsala University, Sweden.

Background and aims: The endoplasmic reticulum (ER) is responsible for protein and lipid synthesis and Ca $^{2+}$ homeostasis. Dysfunctional ER is associated with beta-cell failure and death in diabetes. The ER morphology is complex with numerous domains making contacts with other membranous organelles, including the plasma membrane (PM). It is becoming increasingly clear that such membrane contact sites are important for the normal function of the ER. The ER-PM contacts are generated by the ER-localized protein family Extended-Synaptotagmins (E-Syts), which contains multiple C2-domains with Ca $^{2+}$ and lipid-binding properties. The aim of this study was to investigate the distribution and dynamics of E-Syt-generated ER-PM contacts in beta-cells.

Materials and methods: TIRF and confocal microscopy was used to study subcellular distribution kinetics of fluorescently tagged E-Syt1, E-Syt2, E-Syt1 mutants and the cytosolic fragment of Synaptotagmin-1 (Syt-1) together with the cytosolic Ca $^{2+}$ concentration in intact or permeabilized MIN6 cells. An optogenetic approach was used to rapidly deplete the PM of the lipid PI(4,5)P $_2$ by light-induced PM recruitment of a 5 th -phosphatase.

Results: Immunoblotting showed high expression of both E-Syt1 and E-Syt2 in MIN6 beta cells and mouse islets. Fluorescence-tagged E-Syt1 localized to the reticular ER and was rapidly recruited ($t_{1/2}$ 21 ± 2 s) to the PM upon depolarization-induced Ca $^{2+}$ influx. When overexpressed alone, E-Syt2 was constitutively bound to the PM but showed depolarization-induced PM binding after co-expression with E-Syt1, demonstrating E-Syt1/2 heterodimer formation. Elevation of the glucose concentration from 3 to 20 mM resulted in oscillatory binding of E-Syt1/2 heterodimers to the PM and expansion of cortical ER. Both responses were completely inhibited by the omission of extracellular Ca $^{2+}$ and by blocking L-type Ca $^{2+}$ channels with 100 μ M verapamil. Experiments in permeabilized cells revealed half-maximal binding of the E-Syt1/2 heterodimer to PI(4,5)P $_2$ in the PM at 1.3 ± 0.2 μ M Ca $^{2+}$. Deletion studies showed that the central C2C domain and the C-terminal C2E domain of E-Syt1 function as an intramolecular coincidence detector. Both domains were thus required for efficient PM binding within the physiological Ca $^{2+}$ range (1–10 μ M). E-Syt1 and the cytosolic fragments of Syt1, which is the Ca $^{2+}$ -sensor for insulin granule exocytosis, showed nearly identical Ca $^{2+}$ -induced PM-binding with half-maximal effects at 7.6 ± 0.9 μ M and 10.2 ± 0.7 Ca $^{2+}$, respectively, in permeabilized MIN6 beta cells. The PM binding of the proteins was reduced by 95 \pm 4% (E-Syt1) and 79 \pm 9% (Syt1) after light-induced PI(4,5)P $_2$ depletion, demonstrating a role of this lipid for PM-binding of both ER and insulin granules.

Conclusion: The ER undergoes expansions in the cortical regions during glucose-stimulation of insulin secreting cells. The expansion is driven by

Ca²⁺-induced interactions between the ER-localized proteins E-Syt1/2 and PI(4,5)P₂ in the PM. The lipid- and Ca²⁺-binding properties of E-Syt1/2 strongly resembles those of granule-localized Syt1, indicating ER expansion at sites for insulin granule exocytosis.

421

Activation-dependent translocation of Epac2 to granule docking sites at the beta cell plasma membrane

I. Alenkvist, N.R. Gandasi, S. Barg, A. Tengholm;

Department of Medical Cell Biology, Uppsala University, Sweden.

Background and aims: Epac2 is an important mediator of cAMP-dependent processes in pancreatic β -cells. Activation of Epac2 results in its translocation from the cytoplasm to the β -cell plasma membrane, but it is not known how the membrane interaction is mediated. Epac2 consists of multiple domains organized in a regulatory and a catalytic region. The regulatory region contains a low- and a high-affinity cAMP-binding domain (CNB1 and CNB2) and a DEP (disheveled, Egl-10 and pleckstrin) domain. The catalytic region contains, apart from the catalytic domain, a Ras association domain that previously has been found to interact with the plasma membrane. The aim of the present study was to elucidate how different domains in the regulatory region contribute to membrane localization of Epac2 in β -cells and to investigate how localization of Epac2 is related to insulin secretory granule docking and exocytosis.

Materials and methods: Epac2 binding to the plasma membrane was monitored with total internal reflection fluorescence (TIRF) microscopy of intact or α -toxin-permeabilized MIN6 β -cells co-expressing wildtype and mutant versions of Epac2 tagged with the fluorescent proteins GFP and mCherry, respectively. Secretory granules and exocytosis were visualized by TIRF imaging of cells expressing fluorescent protein-tagged neuropeptide Y (NPY) as granule marker along with Epac2.

Results: Addition of cAMP to permeabilized β -cells evoked concentration-dependent translocation of Epac2 to the plasma membrane with half-maximal and maximal translocation at ~ 30 μ M and >100 μ M, respectively. Removal of the CNB1 domain reduced the maximal translocation amplitude to 45% of the wildtype control, but markedly increased the cAMP sensitivity (half-maximal translocation at 5.6 μ M). After removal of the DEP domain, a protein module often involved in membrane targeting, the cAMP-induced translocation was reduced by more than 90%. Epac2 translocation was also investigated in intact cells during stimulation with the cAMP-elevating hormone glucagon-like peptide-1 (GLP-1). At 1 nM, GLP-1 triggered pronounced translocation of wildtype Epac2 to the plasma membrane. The translocation response was significantly increased by CNB1 deletion (274% of wildtype), or a point mutation preventing cAMP-binding to the CNB1 domain (133%). In contrast, translocation was decreased by a point mutation preventing cAMP-binding to the CNB2 domain (28%), as well as by DEP deletion (46%). The cAMP-increasing agent forskolin induced clustering of Epac2 at sites of docked insulin secretory vesicles in 40% of the β -cells and this clustering required an intact CNB1 domain. When cells were depolarized with 75 mM K⁺, exocytosis events were seen as disappearance of granular NPY-mCherry fluorescence immediately after onset of the stimulation. The Epac2 signal was significantly elevated at granules undergoing exocytosis, but indistinguishable from background at granules that failed to release.

Conclusion: cAMP-induced translocation of Epac2 to the plasma membrane requires nucleotide binding to the high-affinity CNB2 domain and presence of an intact DEP-domain. The low-affinity cAMP-binding CNB1 domain is not required for membrane targeting, but modulates the cAMP-sensitivity of the membrane interaction and contributes to the specific association of Epac2 with granule docking sites. The data indicate that Epac2 translocation to the plasma membrane promotes secretory granule priming and exocytosis.

Eriodictyol stimulates insulin secretion through cAMP/protein kinase A signalling pathway in mice pancreatic islets

A. Hameed¹, R. Hafizur¹, S. Raza¹, N. Hossain², I. Choudhary²;

¹Dr. Panjwani Center for Molecular Medicine and Drug Research, ²H. E. J. Research Institute of Chemistry, University of Karachi, Pakistan.

Background and aims: Very recently our group has undertaken a long-term program to identify new insulin secretagogue(s) using in-house compounds available at a 'Compound Bank'. Among 179 tested compounds, eriodictyol (ED), a flavanoid, isolated from *Lyonia ovalifolia* was found as a potent insulin secretagogue in in-vitro assay. In the present study, we explored possible mechanism(s) of insulin secretory activity of ED in isolated mice islets and MIN6 cells.

Materials and methods: Islets were isolated from BALB/c mice pancreas by collagenase digestion followed by hand picking. Batches of three size matched islets or MIN6 cells (passages 23 - 26) were incubated in KRB buffer containing 3 or 16.7 mM glucose in the presence or absence of test substance(s). Secreted insulin from islets and MIN6 cells were measured by mouse insulin ELISA kit.

Results: ED stimulated insulin secretion from mice islets and MIN6 cells only at stimulatory glucose concentrations distinctly different from sulfonylurea. At 16.7 mM glucose, ED significantly induced insulin secretion from isolated islets at 50-200 μ M concentrations, maximum effect at 200 μ M. At 3 mM glucose when islets were incubated with 200 μ M ED and 50 μ M diazoxide to keep K-ATP channels open, ED-induced insulin secretion was not affected; however, at 16.7 mM glucose ED-induced insulin secretion was inhibited significantly by diazoxide (ng/islet/h; M \pm SEM; 1.75 \pm 0.32 vs. 39.76 \pm 2.71, P<0.001). When islets were depolarized by 25 mM KCl in the presence of diazoxide, insulin secretory ability of ED was enhanced at both 3 mM (ng/islet/h; M \pm SEM; 21.5 \pm 1.42 vs 7.37 \pm 1.6, P<0.001) and 16.7 mM (ng/islet/h; M \pm SEM; 70.51 \pm 1.83 vs. 24 \pm 1.64, P<0.001) glucose. In the presence of 200 μ M verapamil, an L-type Ca²⁺ channels blocker, ED-induced insulin secretion was not affected at 3 mM but inhibited at 16.7 mM (ng/islet/h; M \pm SEM; 5.2 \pm 0.54 vs. 50.55 \pm 3.61, P<0.001) glucose. In the Ca²⁺ free media, ED-induced insulin secretion was significantly inhibited at 16.7 mM (ng/islet/h; M \pm SEM; 10.13 \pm 0.88 vs 50.62 \pm 3.61, P<0.001) glucose. IBMX, a phosphodiesterase inhibitor, at 100 μ M significantly (P<0.001) enhanced ED-induced insulin secretion (70.22 \pm 2.91 ng/islet/h) at 16.7 mM glucose in comparison to ED (41.61 \pm 2.06 ng/islet/h) and IBMX (50.22 \pm 2.04 ng/islet/h) alone. H-89, a protein kinase A (PKA) inhibitor, at 30 μ M almost completely inhibited ED-induced insulin secretion at 16.7 mM glucose (ng/islet/h; M \pm SEM; 13.81 \pm 0.61 vs. 41.13 \pm 1.96, P<0.001). Calphostin-C, a protein kinase C (PKC) inhibitor, at 2.5 μ M partially inhibited ED-induced insulin secretion at 16.7 mM glucose (ng/islet/h; M \pm SEM; 29.74 \pm 1.37 vs. 41.13 \pm 1.97). When islets were pretreated with pertussis toxin (100 ng/ml), ED-induced insulin secretion was not affected at both 3 and 16.7 mM glucose.

Conclusion: ED, a novel insulin secretagogue, exerts an exclusive glucose-dependent insulinotropic effect in isolated mice islets and MIN6 cells. ED-induced insulin secretion seems to be mediated through cAMP/PKA signaling pathway, distal to the K-ATP channels and L-type Ca²⁺ channels, coupled with stimulatory glucose.

Chronic exposure to fructose exaggerates glucose-stimulated insulin secretion in INS-1E beta cells and human isletsT. Brun¹, C. Bartley¹, D. Bosco², T. Berney², P. Maechler¹;¹Cell Physiology and Metabolism, University of Geneva, ²Surgery, Cell Isolation and Transplantation Center, Geneva University Hospital, Switzerland.

Background and aims: Fructose massively appeared as an additive in the Western diet in the late 70's, preceding high incidences of obesity and type 2 diabetes and raising questions regarding putative mechanistic links. Upon fructose administration, energy sensing mediated by AMPK activation is impaired in the hypothalamus, increasing feeding behaviour in rodents. In pancreatic beta-cells, AMPK is activated in conditions of nutrient deprivation and renders the beta-cell more sensitive to glucose. Although fructose does not acutely stimulate insulin secretion, we decided to investigate the effects of chronic exposure to fructose on beta-cell function.

Materials and methods: INS-1E cells and freshly isolated human islets from different donors (n=10, each donor provided written informed consent) were exposed for 4 days to 5.5 mM fructose. Culture at standard 11.1 mM (INS-1E) and 5.6 mM glucose (human islets) served as control culture condition. At the end of the 4-day pre-treatment period, we performed immunodetections of Kir6.2 and P2Y1, measured AMPK phosphorylation, ATP levels, and insulin secretion.

Results: Chronic exposure of INS-1E cells and human islets for 4 days to fructose potentiated insulin secretion in response to intermediate 8.3 mM glucose (1.6-fold, p<0.05). Paradoxically, fructose pre-treatment reduced intracellular ATP levels by 20% and induced AMPK phosphorylation (1.3-fold, p<0.05). The latter effect was mimicked by the stable cell permeant ADP analogue 2-methyl-S-ADP, although not additive to fructose. Correlating with intracellular energy deprivation and AMPK activation, fructose caused translocation of K⁺-ATP Kir6.2 channels to the cell membrane, exhibiting starving-like phenotype. Upon glucose stimulation, ATP and ADP are co-secreted with insulin and may activate purinergic receptors on the plasma membrane. Western blot and immunofluorescence analyses showed the presence of the calcium-mobilizer P2Y1 receptor in INS-1E cells. Accordingly, in the fructose-treated cells, higher intracellular calcium oscillations were observed. Addition of P2Y1 agonists potentiated insulin secretion stimulated by 8.3 mM glucose on control INS-1E cells and human islets, mimicking the effects of fructose pre-treatment. Conversely, the P2Y1 antagonist MRS2179 reversed the potentiated secretory response induced by fructose exposure. Moreover, clearance of extracellular ATP and ADP by apyrase also inhibited fructose-potentiating effects.

Conclusion: Fructose treatment induced starving-like phenotype in INS-1E cells and human islets, resulting in the potentiation of glucose-stimulated insulin secretion. This effect was mediated by activation of purinergic P2Y1 receptor through increased release of cellular ATP/ADP.

Of mice and men: a comparative analysis of G-protein coupled receptor expression in mouse and human islets of Langerhans

R.G. Hawkes, P. Atanes, G. Huang, S.J. Persaud, S. Amisten;

Diabetes Research Group, King's College London, UK.

Background and aims: G-protein coupled receptors (GPCRs) have proven to be very successful drug targets and are responsible for the actions of approximately 30% of all prescribed therapeutics. The attractiveness of GPCRs as drug targets can be attributed to their involvement in numerous biological processes including the regulation of islet function. However, despite the large pool of potential GPCR targets only a small proportion of these are the targets of current type 2 diabetes clinical projects (GLP1R, GPR119, FFAR1). This can partly be attributed to the lack of knowledge of GPCR expression homology in translation models required to assess the suitability of such potential targets. The aim of this study was to compare the expression of GPCR mRNAs in mouse and human islets to evaluate to what degree studies on mouse islet GPCR function are translatable to human islet physiology.

Materials and methods: GPCR mRNA expression in isolated mouse and human islets was quantified relative to GAPDH using quantitative SYBR green based real-time PCR (qPCR). Human islets were isolated from heart beating donors at the islet isolation centre at King's College London. Mouse islets were isolated from 8 week old male ICR mice using collagenase digestion and handpicked. mRNA was extracted from islets using the TRIzol method and reverse transcribed into cDNA for qPCR screening.

Results: 327 functional GPCRs present in both human and mouse genomes were included in the study. GPR56 was the most abundant GPCR mRNA in human islets (15.6±1.6% of GAPDH, n=3), while the most highly expressed GPCR in mouse islets was Cckar (78.4±12.4% of Gapdh, n=4). 99 GPCRs (30.3%) were absent or expressed at trace levels in both mouse and human islets. 114 GPCR mRNAs (34.9% of GPCRs studied) were expressed above trace levels in both mouse and human islets. 62 of these (54.4%) showed >200% higher mRNA expression relative to Gapdh in mouse islets compared to their human counterparts, including 9 GPCRs (S1PR3, GALR1, OXTR, VIPR2, TACR3, CCKAR, GABBR2, TAAR1, PTGER3) whose mRNA expression was greater than 5000% more abundant in mouse islets than in human islets. On the other hand, mRNAs encoding 18 GPCRs were at least twice as abundant in human islets compared to mouse islets, including 3 GPCRs (SCTR, GPR135 and C5AR1) which were over 500% more abundant in human islets compared to mouse islets. The remaining 34 GPCRs were expressed at similar levels in both human and mouse islets. Of particular interest, 80 GPCRs (25.2%) were expressed only in human islets (e.g. HTR1F, GPR63) and 34 GPCRs (10.3%) were present only in mouse islets (e.g. GALR3, LPAR6). Additionally, 4 GPCRs (GPR148, OXER1, CCRL1, P2RY8) which are not present in the mouse genome, were expressed above trace levels in human islets.

Conclusion: This study found that approximately one third of GPCR mRNAs are expressed at similar levels in mouse and human islets, while the rest show significant differences in expression between mouse and man. These clear species differences in GPCR expression are relevant to appropriate interpretation of functional studies using mouse islets, as they indicate whether results obtained using mouse islets are relevant to human physiology.

Insulin secretion from human and rodent islets is modulated by adrenergic alpha2A receptor-selective antagonists

K. Bokvist¹, X. Peng¹, D. Scheuner¹, D.B. Wainscott¹, X.-S. Wang¹, F.F. Willard¹, N. Calvert¹, N. Diaz², A. Castaño²;

¹Eli Lilly & Co, Indianapolis, USA, ²Eli Lilly & Co, Alcobendas, Spain.

Background and aims: Insulin secretion from the pancreatic islet is regulated by a plethora of neurotransmitters and hormones including catecholamines such as adrenaline. Recently, the adrenergic alpha 2A receptor (AdrA2A) has been associated to type 2 diabetes risk with a phenotype of reduced insulin secretion and receptor overexpression at cellular levels in human islets. In this study we therefore evaluated to which extent an AdrA2A-selective antagonist modulates insulin secretion from human and rodent islets in the absence or presence of catecholamines.

Materials and methods: The in vitro pharmacology of a novel carboxamide (Cpd250) was first evaluated in functional and binding assays that assess its AdrA2 receptor family subtype specificity. After confirming that Cpd250 was a >50× selective AdrA2A antagonist compared to AdrA2B and AdrA2C, we evaluated its effects on insulin secretion in human and rat islets in the presence of catecholamines as well as its pharmacokinetic properties.

Results: Cpd250 reversed receptor activation by 300 nM noradrenaline in a cell line overexpressing human AdrA2A with a relative IC₅₀ of 57 nM. In binding assays using membranes from cells overexpressing human AdrA2A, AdrA2B or AdrA2C, Cpd250 bound to AdrA2A with 64× higher affinity than the closest family member. Binding K_is were 23 nM, 9220 nM and 1480 nM for AdrA2A, AdrA2B and AdrA2C receptors, respectively. Binding K_is for human AdrA1A or AdrA1B were both >25000 nM. Cpd250 had a slight affinity for human 5HT2B (K_i=3390 nM) but the K_is for all other 5HT receptors tested were >5000 nM. In rat islets 300 nM noradrenaline inhibits insulin secretion elicited by 11.2 mM glucose by 50-70%, an inhibition that is fully reversed by Cpd250 at doses of 3000 nM or higher. Similar observations were made in human islets; inclusion of 1000 nM noradrenaline suppressed insulin secretion induced by 11.2 mM glucose by 60%, an effect which was fully reversed by Cpd250 with an approximate EC₅₀ of 1000 nM Cpd250. We next evaluated the pharmacokinetics of Cpd250 in rats; however, we failed to observe any measurable plasma exposure. Cpd250 had very poor stability in rodent plasma, suggesting that Cpd250 is a useful in vitro tool but cannot be used to evaluate AdrA2A receptor function in vivo.

Conclusion: Here we show that adrenergic inhibition in rodent and human islets can be reversed by an AdrA2A specific antagonist which further validates previously published data on the importance of the AdrA2A receptor in the regulation of insulin secretion. We have also shown that it is possible to identify compounds that show selectivity for AdrA2A. However, Cpd250 will require further optimization to be a useful tool for in vivo studies.

426

G-protein coupled receptor dynamics in insulin secreting cells

E.I. Kay, S. Barg;

Uppsala University, Sweden.

Background and aims: The alpha 2A adrenergic receptor (ADRA2A) is a G-protein coupled receptor (GPCR) whose activation has multiple effects on signalling processes inside the pancreatic β cell, ultimately leading to reduced insulin exocytosis. Polymorphisms in ADRA2A are also associated with reduced insulin secretion and the development of type II diabetes. We aimed to identify proteins that interact with ADRA2A and to characterise the movement of ADRA2A single molecules in the membrane of insulin secreting cells.

Materials and methods: Insulin secreting INS-1 cells were co-transfected with ADRA2A-GFP and potential interacting proteins tagged with mRFP or mCherry and imaged using TIRF microscopy. For single particle tracking, INS-1 cells were transfected with ADRA2A-PATagRFP and imaged using PALM microscopy.

Results: ADRA2A-GFP was observed as bright spots in the INS-1 cell membrane which did not associate with docked secretory granules expressing NPY-mCherry. However, membrane associated ADRA2A-GFP did colocalise with caveolin-1-mRFP, a marker of caveolae. ADRA2A-GFP colocalisation with caveolin-1-mRFP was reduced following stimulation of INS-1 cells with the ADRA2A agonist norepinephrine (10 μM). ADRA2A-PATagRFP was observed both as single molecules and forming larger brighter clusters in the INS-1 cell membrane. The fluorescence intensity distribution of ADRA2A-PATagRFP molecules changed following stimulation with 10 μM norepinephrine, with two peaks observed for stimulated cells compared to a single peak for unstimulated control cells. Mean squared displacement analysis of ADRA2A-PATagRFP tracks revealed that fractions of ADRA2A-PATagRFP molecules exhibited normal, anomalous or corralled diffusion. This indicates that while some ADRA2A-PATagRFP molecules move freely in the membrane, others are impeded in their range of motion. Overall ADRA2A-PATagRFP single molecules moved rapidly, with a median speed of 0.075 μm²/s, however the peak speed was 0.025 μm²/s, indicating the presence of a slower moving receptor population. Following stimulation with 10 μM norepinephrine, ADRA2A-PATagRFP speed was slightly increased to a median value of 0.083 μm²/s.

Conclusion: ADRA2A exhibits a range of dynamics in the membrane of insulin secreting cells, which we predict are under the control of agonist stimulation and/or interaction with other membrane proteins, such as caveolin-1. ADRA2A association with caveolae may stabilise the receptor and influence its ligand stimulated interactions with G-proteins and downstream effectors. Norepinephrine stimulates ADRA2A movement away from caveolae, most likely into the cell via endocytosis, which would control the amount of membrane bound receptor available for further stimulation.

GPR75 stimulation to insulin secretion: identification of a signalling pathway in beta cells

Z. Hassan, P.M. Jones, S.J. Persaud;

Diabetes Research Group, Kings College London, UK.

Background and aims: We have previously identified that the atypical chemokine G-protein coupled receptor GPR75 is the most abundantly expressed chemokine receptor in mouse and human islets, is localized to beta cells, and is activated by the pro-inflammatory chemokine ligand 5 (CCL5). Furthermore, we have also found that the conventional CCL5 receptors, CCR1, CCR3 and CCR5, are expressed at very low levels in islets. We have previously demonstrated that CCL5-induced elevations in intracellular calcium ([Ca²⁺]_i) and insulin secretion are significantly diminished upon GPR75 down-regulation. However, identification of further downstream GPR75 signalling pathways in rodent beta cells remains unknown. Therefore, this study aimed to identify components of this pathway in MIN6 beta cells.

Materials and methods: Changes in [Ca²⁺]_i were measured by single cell microfluorimetry of Fura-2 (5 μM) loaded MIN6 beta cells (50,000 cells per coverslip). Insulin secretion from MIN6 beta cells (30,000 cells per well) was determined in static incubation experiments and quantified by radioimmunoassay.

Results: Phospholipase C (PLC) inhibition in MIN6 beta cells diminished CCL5-induced elevations in [Ca²⁺]_i (0.25 nM CCL5: 149±33% of tolbutamide response; +10 μM U73122: 65±16%, n=29, P<0.05) and

insulin secretion (20 mM glucose: 6.75 ± 0.58 ng/30,000cells/hr; +10 nM CCL5: 8.88 ± 0.57 ; +10 nM CCL5+10 μ M U73122: 6.90 ± 0.11 , $P > 0.2$ vs 20 mM glucose). Blockade of L-type Ca^{2+} channels with nifedipine abolished CCL5-induced elevations in $[\text{Ca}^{2+}]_i$ in MIN6 beta cells ($P > 0.2$ vs basal), and inhibited CCL5-induced insulin release (20 mM glucose: 3.57 ± 0.25 ng/30,000cells/hr; +10 nM CCL5: 6.35 ± 0.37 , $P < 0.001$; +10 nM CCL5+10 μ M nifedipine: 4.93 ± 0.43). Depletion of DAG-sensitive PKC isoforms by 24 hour exposure to 200 nM 4-beta PMA inhibited the stimulation of insulin secretion by CCL5 (Control: 20 mM glucose: 7.54 ± 0.41 ng/30,000cells/hr; +25 nM CCL5: 9.12 ± 0.50 , $P < 0.05$; PKC-depleted: 20 mM glucose: 3.13 ± 0.11 ; +25 nM CCL5: 3.42 ± 0.12 , $P > 0.2$ n=6-8). Furthermore, CCL5-induced insulin secretion was also inhibited upon CAMK II inhibition (20 mM glucose: 6.75 ± 0.58 ng/30,000cells/hr; +10 nM CCL5: 8.88 ± 0.57 ; +10 nM CCL5+10 μ M KN62: 5.07 ± 0.43 , $P < 0.001$ vs 10 nM CCL5).

Conclusion: These data indicate that activation of the GPR75 signalling pathway by CCL5 in MIN6 beta cells permits Ca^{2+} influx via L-type voltage operated Ca^{2+} channels by activating PLC and subsequent activation of DAG-sensitive PKC isoforms. Furthermore, the identification of a calcium influx component upon GPR75 activation likely promotes the exocytosis of insulin secretory granules by activating CAMK II. This novel role for CCL5 in improving beta cell function via the GPR75 signalling pathway provides further insight into its therapeutic potential for improving insulin secretion in type 2 diabetes.

The adhesion receptors GPR56 and GPR126 and their ligands are expressed by islets and regulate beta cell function

O.E. Olaniru, P.M. Jones, S.J. Persaud;

Division of Diabetes and Nutritional Sciences, King's College London, UK.

Background and aims: GPR56 and GPR126 are members of the adhesion class of G-protein coupled receptors that play key roles in organ development. Collagen III is the agonist of GPR56 and we have shown that GPR56 is one of the most abundant GPCRs in human islets. Collagen IV increases cAMP in GPR126 transfected HEK293 cells and stimulates an increase in $[\text{Ca}^{2+}]_i$ in tumour cells. The roles of GPR56 and GPR126 in islets is not known, so the aim of this study was to investigate their expression and functions in islets.

Materials and methods: Expression of GPR56, GPR126, collagens III and IV was determined by RT-PCR, Western blotting, and immunohistochemistry of mouse and human pancreases. The effects of 100 nM collagens on insulin gene expression and β -cell adhesion were determined by qPCR and adhesion assay respectively. Insulin secretion was quantified by radioimmunoassay after 3 days exposure of mouse islets to collagens III and IV. Changes in $[\text{Ca}^{2+}]_i$ of Fura-2 loaded MIN6 β -cells on exposure to 100 nM collagens III and IV were measured by single cell microfluorimetry.

Results: GPR56, GPR126, collagens III and IV were detected in mouse and human islets. GPR56 was abundantly expressed by β -cells but was absent from glucagon-secreting α -cells of mouse islets. Unlike collagen IV, collagen III was not expressed by β -cells, but was confined to islet capillaries. Collagens III and IV significantly increased insulin gene expression (by $178.7 \pm 5.9\%$ and $211.5 \pm 5.3\%$ respectively, $p < 0.001$) and enhanced β -cell adhesion (control: 0.08 ± 0.01 absorbance units; +Col III: 0.13 ± 0.02 ; +Col IV: 0.23 ± 0.03 , $p < 0.01$, n=5). Pre-exposure of isolated mouse islets to 100 nM collagens III and IV for 3 days led to significantly enhanced glucose-induced insulin secretion (20 mM glucose: 5.91 ± 1.22 ng/islet/h; +Col III: 10.30 ± 0.94 ; +Col IV: 13.26 ± 0.99 , $p < 0.01$, n=7-8). Chronic exposure to collagen III did not increase basal insulin release (2 mM glucose: 0.24 ± 0.02 ng/islet/h; +Col III: 0.20 ± 0.01 , $p = 0.1$, n=7), but islets exposed to collagen IV for 3 days did show significantly increased basal insulin release (2 mM glucose: 0.24 ± 0.02 ng/islet/h; +Col

IV: 0.38 ± 0.05 , $p < 0.05$, n=7). Collagen IV induced elevations in β -cell $[\text{Ca}^{2+}]_i$ at 2 mM glucose (100 nM Col IV: $60 \pm 4\%$ tolbutamide response, n=24) and it also had a small stimulatory effect at 20 mM glucose (100 nM Col IV: $133 \pm 10\%$ 20 mM glucose response). Collagen III was without effect on $[\text{Ca}^{2+}]_i$ in Fura 2-loaded β -cells at 2 mM glucose (n=32).

Conclusion: Mouse and human islets express the adhesion receptors GPR56 and GPR126 and their ligands, collagen III and IV, suggesting that these receptors may be activated in a paracrine/autocrine manner. Our data further suggest that these receptors may be the mechanism through which extracellular matrix collagens regulate β -cell adhesion, insulin synthesis and insulin secretion.

Characterisation of the sweet taste receptor electrophysiology in pancreatic beta cells

J.V. Sanchez-Andres¹, W.J. Malaisse²;

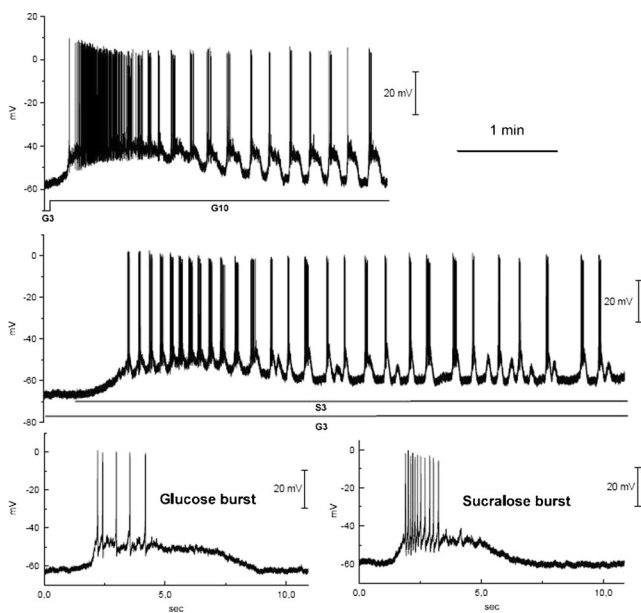

¹Medicine, Universitat Jaume I, Castellon, Spain, ²Medicine, Brussels Free University, Brussels, Belgium.

Background and aims: According to the so-called "fuel hypothesis" the stimulation of insulin release by glucose and other nutrient secretagogues may be attributed to their catabolism resulting inter alia in an increased generation of ATP. However, recent work based among others on the effects in beta cells of non-metabolizable agents, such as sucralose, has revived interest on a "receptor hypothesis", apparently involving the activation of the sweet taste receptor T1R3. The present study aimed at characterizing the electrophysiological effects of sucralose in mouse insulin-producing cells.

Materials and methods: The beta cell membrane potential was recorded in isolated mouse pancreatic islets fixed with micropins to the bottom of a perfusion chamber. The superfusion medium contained, as required, glucose and/or sucralose.

Results: When tested in the absence of glucose, sucralose (5 to 10 mM) did not affect membrane potential. At a substimulatory glucose concentration (3 to 5 mM), sucralose evoked a biphasic electrophysiological response. The first phase lasted for a few minutes and consisted of a depolarizing wave with overimposed bursting activity. No obvious difference was found between bursting induced by either glucose or sucralose. Incidentally, the response to sucralose displayed some heterogeneity. Thus, 15% of the cells were unresponsive. Moreover, in the 85% responsive cells, a second phase of electrical activity was only apparent in 11 out of 17 cells. Interestingly, when the sucralose concentration was increased during the second phase initially evoked by a lower concentration of the artificial sweetener, the cells displayed an unresponsive behavior, suggesting an apparent desensitization. At a suprastimulatory glucose concentration (5 to 10 mM), sucralose also excited the cells in a dose-dependent manner. Lower sucralose concentrations increased bursting duration at the expense of hyperpolarized periods. Higher glucose concentrations are able to drive the cell into continuous activity. The effect reverted immediately after sucralose withdrawal even for high sucralose concentrations (30 mM).

Conclusion: The present findings reveal that sucralose exerts a stimulatory effect on beta cell electrical activity. This effect is closely related to the glucose concentration. Thus, sucralose is inefficient in the absence of glucose, while potentiating the electrical response recorded in the presence of the latter hexose. These data support the view that the activation of a sweet taste receptor may stimulate and modulate glucose responses. The similarities between glucose and sucralose actions may suggest a distal convergence in their mode of action. The data presented constitutes a strong evidence of the receptor hypothesis as far as sucralose, an agonist of the homodimeric T1R3 taste receptor in the pancreatic beta cell, is able to induce an excitatory effect of the pancreatic beta cell electric activity.

Palmitate stimulates insulin secretion by enhancing mitochondrial respiration via intracellular metabolism and FFAR1 signalling

H. Kristinsson, P. Bergsten, E. Sargsyan;
Medical Cell Biology, Uppsala University, Sweden.

Background and aims: Free fatty acids (FFAs) play an important role in the regulation of insulin secretion. At high glucose, FFAs enter glycerolipid/free fatty acid cycle and generate insulinotropic metabolic coupling factors such as long-chain acyl CoAs, phosphatic acids, diacylglycerol, etc. FFAs enhance insulin secretion also by interacting with G-protein coupled receptors (GPCRs) on the plasma membrane. One of the GPCRs highly expressed in beta cells is the free fatty acid receptor 1 (FFAR1 or GPR40). We have reported that palmitate potentiates insulin secretion via a synergistic action of intracellular metabolism and FFAR1 signalling. Given the importance of mitochondria in insulin secretion, we investigated the effects of fatty acid metabolism and FFAR1 signaling on mitochondrial function.

Materials and methods: Study was performed on mouse insulinoma MIN6 cells. Cells were treated for 1 hour with XF assay media containing 25 mM glucose and 0.5 mM palmitate in the absence or presence of FFAR1 antagonist, ANT203. Cells were also exposed to FFAR1 agonist TAK875. During treatment, insulin secretion and mitochondrial oxygen consumption rate (OCR) were measured. Insulin was measured by ELISA whereas OCR was measured by Extracellular Flux Analyzer XF96e. Palmitate oxidation and glucose utilization were determined by including during culture [3H]palmitate and d-[5-3H]glucose, respectively.

Results: MIN6 cells cultured in the presence of palmitate secreted 50% more insulin than in the absence of the fatty acid. This was accompanied by a 35% rise in OCR. Inhibition of the FFAR1 pathway with ANT203 prevented the palmitate-induced rise in insulin secretion. The effect was associated with a significant reduction in OCR to levels close to those observed in control cells. Stimulation of another Gαq-coupled receptor, M3 muscarinic acetylcholine receptor, with agonist carbachol in the presence of ANT203 reverted OCR back to levels observed in the presence of palmitate alone. Stimulation of FFAR1 with TAK875 in the absence of extracellular palmitate did not enhance OCR. By inhibiting fatty acid or glucose oxidation we showed that the increase in OCR in palmitate-treated cells was largely due to increased glucose oxidation. In line with

this, glucose utilization in the presence of palmitate was increased compared to control cells. However, FFAR1 antagonist did not reduce palmitate-induced glucose utilization. Also, FFAR1 agonist TAK875 in the absence of extracellular palmitate did not elevate glucose utilization.

Conclusion: During short-term exposure palmitate stimulates insulin secretion by enhancing mitochondrial respiration via complementary action of intracellular metabolism and Gαq-dependent signaling of FFAR1

Kisspeptin and the adaptation of islets to pregnancy: a role for islet serotonin

T.G. Hill, P.M. Jones, J.E. Bowe;
Diabetes and Nutritional Sciences, King's College London, UK.

Background and aims: During pregnancy, the pancreatic islets of Langerhans undergo adaptive changes in order to compensate for the normal progression of insulin resistance that occurs during gestation. These adaptive changes include both increased glucose-stimulated insulin release and increased beta-cell mass. The signals underlying these changes are not fully understood, however it is established that prolactin and placental lactogen play an important role. Recently beta-cell serotonin (5-HT) has been found to mediate the effects of lactogenic hormones on beta-cell proliferation and glucose-stimulated insulin release via autocrine or paracrine effects at the Htr2b receptor. We have previously shown that placental kisspeptin (KP), and its G-protein coupled receptor, GPR-54, may also play a key contributory role in mediating the adaptation of rodent islets to pregnancy. However, the downstream mechanism by which KP causes these compensatory changes is not understood. We therefore investigated a possible role of the islet serotonin system, as well as the involvement of key pro-proliferative genes, in mediating the effects of KP.

Materials and methods: Islets were isolated from female ICR mice and cultured in either 2 mmol/L or 20 mmol/l glucose RPMI, with or without KP-10 (1 μmol/l) for 48 hrs. Islet samples were then taken and mRNA expression of key genes investigated using quantitative RT-PCR analysis.

Results: KP treatment dramatically increased the mRNA expression of the 5-HT synthesis enzyme *Tph-1* within islets cultured in stimulatory glucose concentrations (20 mmol/l glucose: $0.4 \pm 0.06 \times 10^{-3}$, 20 mmol/l glucose + 1 μmol/l KP-10: $1.5 \pm 0.2 \times 10^{-3}$; relative to *Gapdh*; n=4; p=0.063), but no change was observed for *Tph-2* expression (20 mmol/l glucose: 0.032 ± 0.004 , 20 mmol/l glucose + 1 μmol/l KP-10: 0.053 ± 0.006 ; relative to *Gapdh*; n=4). Additionally no change in expression of the 5-HT receptor *Htr2b* was observed in islets treated with KP-10 at either glucose concentration (20 mmol/l glucose: $0.2 \pm 0.01 \times 10^{-3}$, 20 mmol/l glucose + 1 μmol/l KP-10: $0.2 \pm 0.009 \times 10^{-3}$; relative to *Gapdh*; n=4). Exposure of isolated mouse islets to KP-10 had no effect on mRNA expression levels for the proliferative gene markers *Cyclin E1*, *Cyclin D1*, and *Ki67* (20 mmol/l glucose: 3.27 ± 0.74 , 69.1 ± 4.35 , $1.3 \pm 0.2 \times 10^{-3}$; 20 mmol/l glucose + 1 μmol/l KP-10: 5.21 ± 0.97 , 94.0 ± 1.48 , $1.4 \pm 0.2 \times 10^{-3}$; expression levels of *Cyclin E1*, *Cyclin D1* and *Ki67* relative to *Gapdh* respectively; n=3) or the pro-survival gene marker, *Birc5* (20 mmol/l glucose: $0.8 \pm 0.3 \times 10^{-3}$, 20 mmol/l glucose + 1 μmol/l KP-10: $0.8 \pm 0.2 \times 10^{-3}$; relative to *Gapdh*; n=3).

Conclusion: These results suggest that in addition to an established role mediating the effects of the lactogenic hormones, KP signalling may also be mediated through beta-cell 5-HT. Specifically KP increases the expression of the 5-HT synthesis enzyme *Tph-1*, but not *Tph-2*, suggesting an increase in 5-HT production. However, contrary to previous studies, there was no change in expression levels of the 5-HT receptor *Htr2b*. Furthermore, at present these data do not show which proliferative or pro-survival genes may be involved in mediating effects of KP on beta-cell mass, further measurements are required to determine the downstream signalling pathways involved in these effects.

432

Foetal endocannabinoids orchestrate the organisation of pancreatic islet microarchitectureK. Malenczyk^{1,2}, V. Di Marzo³, A. Dobrzyn⁴, T. Harkany^{1,2};¹Center for Brain Research, Wien, Austria, ²Medical Biochemistry & Biophysics, Karolinska Institutet, Stockholm, Sweden, ³Endocannabinoid Research Group, Institute of Biomolecular Chemistry, Naples, Italy, ⁴Nencki Institute of Experimental Biology, Warsaw, Poland.

Background and aims: 2-Arachydonoylglycerol (2-AG) and anandamide, major endocannabinoids are implicated in the control of glucose utilization and energy homeostasis by orchestrating pancreatic hormone release. Moreover, in many cell niches, endocannabinoids regulate cell proliferation, fate determination and migration. Nevertheless, endocannabinoid contributions to the development of the endocrine pancreas and, consequently, to long-lasting changes in hormone release postnatally remain unknown.

Materials and methods: To dissect the role of endocannabinoid signaling during endocrine pancreas development we combined the genetic ablation of main components of endocannabinoid signaling, (e.g., CB₁ cannabinoid receptor (CB₁R), monoacylglycerol lipase (MAGL) or transient receptor potential vanilloid 1 channels (TRPV1) knock-out models), modifications to the maternal diet during pregnancy (enrichment in ω -3 polyunsaturated fatty acids) and pharmacological probing of endocannabinoid signaling in 'pseudoislets', α/β cell aggregates that model cell sorting in pancreatic islets *in vitro*.

Results: Our results show that α cells produce 2-AG in mouse fetuses and human pancreatic islets, which primes the recruitment of β cells by CB₁R engagement. By using subtractive pharmacology we extend these findings since exogenous anandamide, a promiscuous endocannabinoid/endovanilloid ligand, impacts both the determination of islet size by cell proliferation and α/β cell sorting by differential activation of transient receptor potential TRPV1 channels and CB₁Rs. Accordingly, genetic disruption of TRPV1 channels increases islet size, while CB₁R knockout augments cellular heterogeneity by inducing α/β cell 'mixing' and favors insulin over glucagon release. Dietary enrichment in ω -3 fatty acids during pregnancy and lactation in mice, which permanently reduces endocannabinoid levels in the offspring, phenocopies CB₁R^{-/-} islet microstructure and improves coordinated hormone secretion. This is significant since both CB₁R^{-/-} and ω -3 fatty acid-exposed offspring are lean.

Conclusion: Our study identifies fundamental roles for endocannabinoids acting at CB₁R and TRPV1s in determining cellular diversity, structural complexity and life-long plasticity of the endocrine pancreas. Furthermore, it highlights that maternal dietary choices during pregnancy can program fetal pancreas development by altering endocannabinoid bioavailability which prospectively determines the offspring's sensitivity to metabolic stressors.

PS 023 Mechanisms of insulin secretion

433

The PIN protein participates in and modulates exocytosis of insulin secretory granules in the INS-1 cell lineJ. Leroy¹, K. Mezghenna¹, P. Yin², S. Barg², M. Séveno³, C. Assaillit³, J. Azay-Milhau¹, S. Péraldi-Roux¹, R. Gross¹, A.-D. Lajoix¹;¹Faculte de Pharmacie, EA 7288, Montpellier, France, ²Medical Cell Biology, University of Uppsala, Sweden, ³Functional proteomics platform, Institute of Functional Genomics, Montpellier, France.

Background and aims: PIN (Protein Inhibitor of Neuronal NO synthase) or LC8 (Light Chain 8) is a hub protein able to interact with multiple partners including neuronal NO synthase (nNOS) and cytoskeletal proteins like myosin V and dynein. We have previously shown that PIN is a positive modulator of glucose-induced insulin secretion. In order to better understand the role of PIN, we developed an inhibitory peptide, able to block interactions between PIN and its proteic partners and rendered cell-permeant by coupling with the Tat-peptide.

Materials and methods: Glucose-induced insulin secretion was measured in INS-1 β -cells in the presence of the Tat-peptide alone (GRKKRRQRRR), - the inhibitory peptide (GRKKRRQRRRGGIDVGIQVDWD) or - an irrelevant one (GRKKRRQRRRGKAVDLSHQPS). For Western blotting, monoclonal anti- α -tubulin (Sigma Aldrich) or anti-PIN (BD Biosciences) antibodies were used. Immunoprecipitation was performed using a polyclonal anti-PIN (Santa Cruz) or the monoclonal anti- α -tubulin antibody. GST-pull down was performed using recombinant GST-PIN as bait on INS-1 extracts. Potential partners of PIN were identified by Orbitrap XL mass spectrometry thanks to the Functional proteomics platform of Montpellier. For TIRF microscopy experiments, cells were transfected with NPY-EGFP reporter and continuously perfused at 32°C with KRB buffer containing 75 mM KCl to stimulate insulin secretion. Cells were imaged using a custom-built lens-type TIRF microscope based on an Axiovert 135 microscope with a 100 \times /1.45 objective (Carl Zeiss).

Results: In the INS-1 cell line, the inhibitory peptide decreased insulin secretion induced by 2.8, 5.6 and 8.3 mM glucose, by 33% at 20 μ M, and by 58% at 40 μ M ($p < 0.001$). Such an inhibitory effect has also been observed using a PIN siRNA, which decreased PIN expression and reduced 5.6 and 8.3 mM glucose-insulin secretion by respectively 16 and 20% in response to ($p < 0.001$). Surprisingly, in the presence of the inhibitory peptide, we observed, by Western blotting, a decreased level of soluble α -tubulin (-22% at 20 μ M and -95% at 40 μ M), suggesting an increased polymerization of tubulin. Interestingly, using GST-pull down with PIN as bait, revealed an interaction of PIN with α 1C-tubulin and β 5-tubulin. Direct interaction of PIN and α -tubulin was confirmed by immunoprecipitation experiments. Finally, in TIRF microscopy experiments, we found the average release time of insulin granules, during single exocytosis event, increased by 3.5 fold in the presence of the inhibitory peptide.

Conclusion: Interaction of PIN with cytoskeletal proteins appears to be involved in the control of insulin granules exocytosis, possibly via modulation of α -tubulin polymerization.

LKB1 is required for normal glucose-signalling, but not insulin secretion, in pancreatic beta cellsS. Sayers¹, D.J. Hodson¹, P. Spegel², H. Mulder², A. Swisa³, Y. Dor³, G.A. Rutter¹;¹Imperial College London, UK, ²Lund University Diabetes Center, Sweden, ³School of Medicine-IMRC, Hebrew University of Jerusalem, Israel.

Background and aims: Liver kinase B1 (LKB1/STK11), a tumour suppressor inactivated in Peutz-Jeghers syndrome, exerts its biological

effects largely by the direct phosphorylation of AMP-activated protein kinase (AMPK) and AMPK-related kinases. Deletion of LKB1 from pancreatic beta cells using a variety of Cre deleter strains has previously been shown to improve insulin content and secretion in mice. Here, we explore the impact of LKB1 deletion in beta cells on glucose-induced changes in mitochondrial metabolism and Ca^{2+} signalling using islet imaging approaches.

Materials and methods: Mice deleted selectively in the beta cell for LKB1 were generated by breeding animals bearing flox'd alleles at exons 3-6 with the novel and highly beta cell-selective Ins1Cre deleter line. Total and released insulin was measured by radioimmunoassay. Changes in intracellular ATP/ADP ratio ($[\text{ATP}/\text{ADP}]_{\text{cyt}}$) and Ca^{2+} ($[\text{Ca}^{2+}]_{\text{cyt}}$) were measured by confocal microscopy of whole islets expressing the recombinant GFP-based probe Perceval, or loaded with the fluorescent Ca^{2+} dye, fluo-2, respectively. An LKB1-encoding adenovirus (Vector Biolab), titred using qPCR to assess LKB1 overexpression, was used to rescue the effects of LKB1 deletion. Metabolite profiling was performed on isolated islets after extraction in 16.7 mM glucose on an Agilent 6890 N gas chromatograph coupled with a Leco Pegasus III TOFMS electron impact time-of-flight mass spectrometer.

Results: Whereas insulin secretion in response to elevated glucose (11 vs 3 mM) was largely unaffected (4 mice/genotype, 6 size matched islets/well, $p > 0.05$), glucose-stimulated increases in $[\text{ATP}/\text{ADP}]_{\text{cyt}}$ (12 islets/genotype, $p < 0.05$) and $[\text{Ca}^{2+}]_{\text{cyt}}$ (12 islets/4 mice/genotype, $p < 0.01$) were severely impaired in islets from LKB1 KO mice, as was the percentage of islets responsive to glucose-stimulation ($n = 12$ islets, $p < 0.05$, $p < 0.01$, respectively). $[\text{Ca}^{2+}]_{\text{cyt}}$ signalling was largely rescued after LKB1 over-expression in Ins1Cre::LKB1^{flox/flox} islets (12 islets, 3 mice/genotype, $p > 0.05$), excluding developmental effects of LKB1 deletion as responsible for the observed signalling abnormalities. Metabolomic profiling showed that fatty acids (C12, C16, C18), glycerol and glycerol-3-phosphate were lowered in LKB1 null islets, as were lactate and fumerate ($n = 3$ mice/genotype, $P < 0.05$).

Conclusion: Despite the improvement of glucose tolerance previously observed in this model, and preserved insulin secretion, deletion of LKB1 significantly impairs normal glucose-induced $[\text{ATP}/\text{ADP}]_{\text{cyt}}$ and $[\text{Ca}^{2+}]_{\text{cyt}}$ signalling in beta cells. Our findings suggest that LKB1 deficiency stimulates metabolic changes in beta cells which activate a robust amplifying pathway. This appears to override defects in the classical triggering mechanisms of insulin secretion that rely on oxidative metabolism of glucose towards ATP.

S561f cdkal1 variant, identified by whole exome sequencing of congenital hyperinsulinism patients, affects insulin content and release in ins1-e cells

C. Cosentino^{1,2}, E.S. Di Cairano³, M.C. Proverbio⁴, E. Mangano⁵, S. Moretti³, C. Perego³, C. Battaglia^{2,5};

¹Molecular and translational medicine, Milan, Italy, ²Department of Medical Biotechnology and Translational Medicine, ³Department of Pharmaceutical and Biomolecular Sciences, ⁴Department of Pathophysiology and Transplantation, ⁵Institute of biomedical technologies, National Research Council (ITB-CNR), Milan, Italy.

Background and aims: Congenital hyperinsulinism (CHI) is a rare disorder (MIM#256450), characterised by inappropriate insulin secretion that is responsible of hypoglycaemia, which can lead to neurological damage. In a previous work conducted in our laboratories 17 patients of Congenital Hyperinsulinism were recruited for a Whole Exome Sequencing (WES) study. We selected all the genes presenting rare or novel potentially damaging single nucleotide variants to perform candidate gene prioritization analysis. We found that CDK5 Regulatory Subunit

Associated Protein 1-Like 1 (CDKAL1) was one of the most significantly enriched genes by the bioinformatics analysis. CDKAL1 is a methyltransferase anchored to the endoplasmic reticulum membrane, that modifies the tRNALys (UUU) ensuring the correct translation of the codons AAA, AAG into Lysine residue. A Lysine residue is crucial for the correct cleavage of pro-insulin and the folding of mature insulin protein. Different studies have previously associated CDKAL1 to type 2 diabetes development risk and to impaired glucose homeostasis phenotype in knock-out (cdkal1^{-/-}) mice. The S561F-CDKAL1 variant identified in our study results in the substitution of a residue of serine by a phenylalanine, more hydrophobic residue at the level of the transmembrane domain. The aim of this work is to understand the consequences of the CDKAL1 variant S561F on the protein itself and on the insulin content and release of pancreatic beta cells.

Materials and methods: Clonal INS1-E cells expressing Wild Type (WT) or S561F CDKAL1 were generated and used as model to characterise S561F-CDKAL1 impact on beta cell function. The localisation of the mutated protein was monitored by immunofluorescence and insulin content and release was measured with ELISA assays.

Results: Wild type CDKAL1 overexpressed in INS1-E cells localized as expected in the reticular compartment, diffused in the cell cytoplasm. The genetic variant S561F was similarly confined in the reticular compartment, although its localization was enriched in vesicular-like structures distributed in the perinuclear region. Insulin content was increased by overexpression of WT CDKAL (2 fold over INS1E, $p < 0.05$) while it was decreased by S561F-CDKAL1 variant, thus suggesting a different insulin processing in the mutant CDKAL1. Insulin release measured in overnight culture medium in basal conditions showed that S561F-CDKAL1 overexpression increased the constitutive insulin release (2 to 4 fold over INS1E in clones 3 and 7, respectively; $p < 0.05$, $p < 0.005$ vs WT).

Conclusion: The S561F-CDKAL1 variant leads to an abnormal localisation of the protein. An increase of insulin release was observed as consequence of the overexpression of the mutated CDKAL1 protein. Our findings support the importance of CDKAL1 in insulin release and propose novel mechanisms leading to beta cells dysfunction that can participate to the development of congenital hyperinsulinism.

Protein disulfide isomerase ameliorates beta cell function in pancreatic islets overexpressing human islet amyloid polypeptide

J. Montane^{1,2}, M. Obach^{1,2}, L. Cadavez^{1,2}, S. De Pablo^{1,2}, C. Castaño^{1,2}, G. Alcarraz-Vizán^{1,2}, J. Rodríguez-Comas^{1,2}, J. Servitja^{1,2}, A. Novials¹;
¹Diabetes and Obesity Laboratory, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), ²Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas ASociadas (CIBERDEM), Barcelona, Spain.

Background and aims: Human islet amyloid polypeptide (hIAPP) is the major component of amyloid deposits in pancreatic islets of patients with type 2 diabetes. The process of hIAPP misfolding and aggregation is one of the factors that may lead to beta-cell dysfunction and death. Endogenous chaperones have been described to be important for the folding and proper function of proteins. Here, we examine the effect of the endoplasmic reticulum chaperone protein disulfide isomerase (PDI) on insulin and IAPP secretion in hIAPP Tg mouse islets.

Materials and methods: Human islet lysates were immunoprecipitated for hIAPP and interaction with major chaperones was analyzed. hIAPP Tg islets were transduced with an adenovirus encoding for the chaperone PDI and cultured with 16 mM glucose and 400 μM palmitate (HG+PA) for 24 hours. Islet function was determined by glucose-stimulated insulin and IAPP secretion and gene expression and protein levels of PDI and apoptosis marker caspase 3 were determined by real-time RT-PCR and immunohistochemistry, respectively.

Results: Immunoprecipitation of human islet lysates indicated that, among the most important chaperones of the ER (BiP, CCT4, TCP1a and PDI), only PDI was interacting with hIAPP. Islet transduction with an adenoviral vector encoding for chaperone PDI demonstrated that PDI could be overexpressed in mouse pancreatic islets. PDI overexpression at a dose of 20 MOI had no effect in glucose-stimulated insulin secretion in untreated wild-type islets. When PDI was overexpressed in hIAPP Tg islets, PDI was able to restore beta cell dysfunction associated with hIAPP overexpression by increasing insulin secretion levels. Furthermore, treatment of islets with HG+PA for 24 hours decreased glucose stimulated insulin and hIAPP secretion in hIAPP Tg mice. Nevertheless, PDI overexpression was able to counteract the decrease in insulin and hIAPP secretion in hIAPP Tg islets.

Conclusion: Overexpression of chaperone PDI was able to rescue HG+PA-induced beta cell dysfunction. This approach could reveal a new therapeutic target and aid in the development and evaluation of strategies to decrease beta cell dysfunction in type 2 diabetic patients.

Generation of the transgenic INS-SNAP (SOFIA) pig for the high-throughput high-content study of insulin granule biogenesis and turnover in isolated islets

A. Ivanova-Cederström¹, N. Klymiuk², E. Kemter², C. Andree³, A. Wuensch², M. Kurome², B. Kessler², D. Richter¹, A. Müller¹, T. Kurth⁴, M. Bickle³, E. Wolf², M. Solimena¹;

¹Paul Langerhans Institute Dresden of the Helmholtz Center Munich at the Univ. Clinic of TU Dresden, ²Inst. Molecular Animal Breeding and Biotechnology LMU, Munich, ³Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, ⁴BIOTEC, TU Dresden, Germany.

Background and aims: Age-distinct pools of insulin secretory granules (SGs) display different propensity for exocytosis, with newly synthesized SGs being preferentially secreted. Recently we exploited an insulin-SNAP chimera (Ins-SNAP) as a reporter for conditional fluorescent labelling and imaging of SGs generated at different times in insulinoma cells and *mINS2-SNAP* knocked-in SOFIA (Study OF Insulin Aging) mice. With this approach we provided formal evidence for the preferential exocytosis of young SGs and their progressive loss of mouthability with ageing. These findings are relevant for the understanding of type 2 diabetes, in which reduction of the 1st phase of insulin secretion and increased proinsulin release point to deficits in SG biogenesis and turnover. Here we report the generation of an *INS-SNAP* transgenic pig (SOFIA pig) as a large animal model for studying in greater detail the biogenesis and turnover of insulin SGs through the performance of high-throughput high-content (HTHC) screenings of compounds affecting these processes.

Materials and methods: Pools of stably *INS-SNAP* transfected porcine kidney cells were used for somatic cell nuclear transfer (SCNT), and reconstructed embryos were transferred to recipient gilts. The resulting progeny was examined for transgenic status by PCR and southern blotting and then for INS-SNAP protein expression in β -cells by immunocytochemistry on pancreatic tissue sections. Correlative light-electron microscopy (CLEM) was performed on pancreatic tissue sections of a mature founder pig. Pseudoislets obtained from *hINS-SNAP* insulinoma INS-1 cells were used to optimize a semi-automated HTHC pipeline in a 384-well format. Neonatal islet-like cell clusters (NICC) isolated from newborn SOFIA pigs were used for a pilot HTHC screening for compounds affecting SG biogenesis and turnover.

Results: A 2-year-old SOFIA founder pig was sacrificed to verify the expression of INS-SNAP protein in situ and the β -cell ultrastructure. Electron microscopy did not reveal morphological alterations of the ER, SGs or other β -cell compartments. The restricted expression of INS-SNAP protein in β -cells and its correct targeting to SGs were confirmed

by CLEM. Optimization of the HTHC platform allowed for the homogenous dispensing of ~50 *hINS-SNAP* INS-1 pseudoislets or NICC/well in 384-well plates and their retention throughout the SNAP labelling and immunolabelling procedures. Parameters for automated confocal imaging, recognition and analysis of fluorescently labelled INS-SNAP⁺ SGs were validated, thus enabling a first pilot screen for compounds affecting the turnover of age-defined SGs.

Conclusion: The successful generation of a transgenic SOFIA pig shall enable for the first time the performance of HTHC studies on the biogenesis and age-dependent turnover of insulin SGs within islets, hence providing novel insight into the biology of β -cells and treatment opportunities for type 2 diabetes.

ERK7: a novel regulator of insulin secretion and lipid metabolism in *Drosophila*

K. Hasygar, R. Hynynen, V. Hietakangas;

Department of Biosciences/Institute of Biotechnology, University of Helsinki, Helsinki, Finland.

Background and aims: Mitogen Activated Protein Kinases (MAPKs) are Ser/Thr kinases which regulate a wide variety of cellular processes. Although this family is very well studied, some of the members like ERK7 (ERK8/MAPK15) are poorly characterized. ERK7 is an atypical MAP kinase which was shown to be activated by amino acid and serum starvation in *Drosophila* S2 cells. We have developed *in vivo Drosophila* models to further characterize its physiological functions.

Materials and methods: dILP2-Gal4; UAS-GFP driver line was used for Insulin Producing Cells (IPC) specific genetic manipulations. CG-Gal4 was used for fat body specific experiments. RNAi lines and p53 overexpression lines were obtained from VDRC, Austria and Bloomington Stock Center, USA. qRT-PCR assays were used to measure mRNA levels of insulin like peptides and lipogenic genes. Immunostainings using anti-dILP2 antibody were used to assess secretion of insulin like peptides. Gas chromatography was used for quantitative lipidomics.

Results: We hereby show that ERK7 is an important regulator of growth and lipid metabolism in *Drosophila*. We observed that upon starvation, ERK7 is expressed in median neurosecretory cells (IPCs) which regulate larval growth by secreting insulin-like peptides (dILPs) in diet-dependent manner. We demonstrate that overexpression of ERK7 in IPCs strongly inhibits dILP secretion which consequently leads to reduced body size and a delay in larval development. We also identify p53 as an upstream activator of ERK7 in IPCs. Further, we establish that ERK7 function in IPCs is necessary for efficient starvation response. Finally, we also show that ERK7 has important metabolic functions outside IPCs. We show that ERK7 function in lipogenic tissues of *Drosophila* is important for normal lipid homeostasis. Overexpression of ERK7 in these tissues caused qualitative and quantitative changes in lipid levels. We are currently generating ERK7 mutants to try and decipher the pathways it regulates by using RNA-seq analysis.

Conclusion: ERK7 regulates starvation response by inhibiting insulin secretion from insulin producing cells. It also has a role outside IPCs in regulation of lipid homeostasis.

Reciprocal changes in glucose tolerance after pancreatic beta cell selective deletion or over-expression of *Slc30a8/ZnT8* in miceR.K. Mitchell¹, M. Hu¹, G. Meur¹, E.A. Bellomo¹, P.L. Chabosseau¹, R. Carzaniga², L.M. Collinson², D.J. Hodson¹, G.A. Rutter¹;¹Section of Cell Biology & Functional Genomics, Imperial College London, ²Electron Microscopy Unit, London Research Institute, UK.

Background and aims: The incorporation of two zinc (Zn^{2+}) ions into the insulin hexamer is fundamental for insulin maturation. Zinc Transporter 8 (*ZnT8*, encoded by *SLC30A8*) is highly, and almost exclusively, expressed within pancreatic beta and alpha cells where it facilitates the importation of cytosolic zinc into secretory granules. Co-secretion of Zn^{2+} from secretory granules is an important paracrine regulator of islet hormone secretion and has also been shown to regulate insulin bioavailability. Moreover, a common polymorphism (R325W) within *SLC30A8*, which lowers transporter activity, is associated with higher risk of developing type 2 diabetes (T2D). Recently, however, rare inactivating mutations in *SLC30A8* have been described which appear to protect against T2D development. Here, we explore the effects of either *ZnT8* deletion or over-expression specifically in the beta cell in mice.

Materials and methods: Beta cell specific deletion of *ZnT8* was achieved by crossing mice harbouring LoxP sites either side of exon 1 of *Slc30a8* with an *Ins1Cre* deleter strain. Transgenic mice were generated by pronuclear injection of DNA encoding c-myc tagged *ZnT8* downstream of a tetracycline regulated promoter. Beta cell overexpression of *ZnT8* was achieved by crossing transgenic mice with mice containing the tetracycline transactivator gene under the control of the insulin promoter. Glucose tolerance was assessed using glucose tolerance tests and insulin granule structure by electron microscopy.

Results: Beta cell selective deletion: Male *Ins1Cre^{+/+}::ZnT8^{fl/fl}* mice displayed significant impairments in glucose tolerance at 10 weeks of age vs *Ins1Cre^{-/-}::ZnT8^{fl/fl}* littermate controls (13.6 ± 0.74 mmol/L vs 11.5 ± 0.59 mmol/L at 30 min, respectively; $P < 0.05$; $n = 8/11$). Granule morphology was dramatically altered following *ZnT8* deletion, with an increased percentage of granules from *Ins1Cre^{+/+}::ZnT8^{fl/fl}* mice lacking dense cores (36.3 ± 2.48 vs 85.6 ± 1.37 , *Ins1Cre^{+/+}::ZnT8^{fl/fl}* vs *Ins1Cre^{-/-}::ZnT8^{fl/fl}*, $P < 0.001$, $n = 8$ beta-cells/genotype) or having ‘rod-like’ structures (31.9 ± 3.42 vs 0.6 ± 0.28 , *Ins1Cre^{+/+}::ZnT8^{fl/fl}* vs *Ins1Cre^{-/-}::ZnT8^{fl/fl}*, $P < 0.001$, $n = 8$ beta-cells/genotype), insulin granule diameter was also increased in *ZnT8* null mice (377.467 ± 5.12 nm vs 328.09 ± 5.46 nm, *Ins1Cre^{+/+}::ZnT8^{fl/fl}* vs *Ins1Cre^{-/-}::ZnT8^{fl/fl}*, $P < 0.001$, $n = 204/226$ granules). Beta cell selective overexpression: Female mice overexpressing *ZnT8* (*Rip7rTTA^{+/+}::ZnT8Tg^{+/+}*; doxycycline treated from 5 weeks) showed significant improvements in glucose tolerance compared to *Rip7rTTA^{+/+}::ZnT8Tg^{-/-}* littermate controls at both 10 (12.2 ± 0.51 mmol/L vs 13.9 ± 1.1 mmol/L; respectively; $P < 0.05$; $n = 6$) and 14 weeks of age (8.84 ± 0.59 mmol/L vs 11.7 ± 1.01 mmol/L; respectively; $P < 0.01$; $n = 6$). Overexpression of *ZnT8* also caused a significant reduction in glucose-stimulated insulin secretion in isolated islets (0.40 ± 0.05 ng/mL vs 0.94 ± 0.21 ng/mL, *Rip7rTTA^{+/+}::ZnT8Tg^{+/+}* vs *Rip7rTTA^{+/+}::ZnT8^{-/-}* respectively; $p < 0.05$; $n = 10-13$).

Conclusion: Using *in vivo* models to manipulate gene expression we show that down- or up-regulation of *ZnT8* in the beta cell respectively worsens and improves glucose tolerance in the mouse. These studies support the view that *ZnT8* activation may be therapeutically useful in T2D treatment.

A pre-obese state accelerates beta cell dysfunction in patients with type 2 diabetes: a glucagon stimulation test-based cross-sectional studyY. Kondo^{1,2}, S. Satoh², U.N. Osada³, Y. Terauchi¹;¹Endocrinology and Metabolism, Yokohama City University, ²Endocrinology and Metabolism, Chigasaki Municipal Hospital, ³Endocrinology and Diabetes, Saiseikai Yokohama-shi Nanbu Hospital, Kanagawa, Japan.

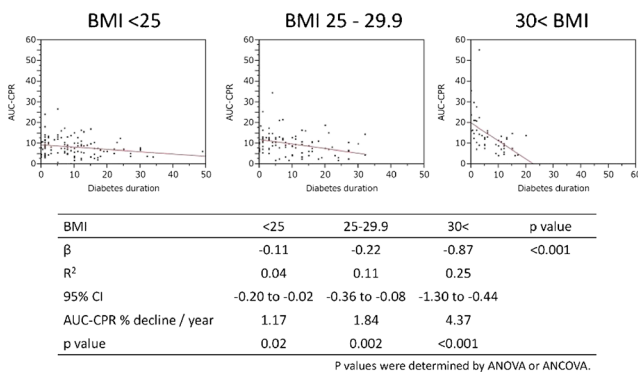

Background and aims: Type 2 diabetes (T2D) is a progressive disease in which β -cell function declines. The loss of β -cell function results in poor glucose control in T2D patients, and it accelerates the progression of diabetic complications. Some preclinical studies have shown links between obesity and β -cell dysfunction. Therefore, we aimed to investigate the relationship between obesity and the progress of β -cell dysfunction in T2D patients.

Materials and methods: We conducted a cross-sectional study on T2D patients whose β -cell function were assessed using 1-mg intravenous glucagon stimulation test (GST) from June 2010 through March 2015. Their BMI and known diabetes duration were also collected. After reviewing their medical records, the onset of diabetes was primarily defined as the time of a new T2D diagnosis after a 75-g oral glucose tolerance test (75 g-OGTT) was performed. In cases with missing 75 g-OGTT data, we defined the onset as the first finding of an HbA1c level ≥ 48 mmol/mol. The β -cell function was assessed using the area under the curve for serum C-peptide immunoreactivity (AUC-CPR) during the GST. Patients were stratified into the following groups: non-obese (BMI, < 25 kg/m²), pre-obese (BMI, $25-29.9$ kg/m²), and obese (BMI, ≥ 30 kg/m²). Univariate regression analysis was performed to determine the relationship between the AUC-CPR and diabetes duration for each group. The primary endpoint was to assess the effect of obesity on the annual declining rate of the AUC-CPR.

Results: After screening, 256 consecutive T2D patients were included in our analysis. Of those, 120 patients (47%) were non-obese, 88 (34%) were pre-obese, and 48 (19%) were obese. The obese group showed the highest AUC-CPR levels (non-obese: 8.25 ± 4.48 ng/mL·min, pre-obese: 9.81 ± 5.48 ng/mL·min, obese: 13.83 ± 9.11 ng/mL·min; $p < 0.001$). Each group had a negative regression between the AUC-CPR and diabetes duration (non-obese: $\beta = -0.11$, 95% confidence interval [CI]: -0.20 to -0.02 , $p = 0.02$; pre-obese: $\beta = -0.22$, 95% CI: -0.36 to -0.02 , $p = 0.002$; obese: $\beta = -0.87$, 95% CI: -1.30 to -0.44 , $p < 0.001$). However, as shown in figure 1, the annual declining rate of the AUC-CPR was significantly accelerated in the pre-obese group (-1.84% per year, $p = 0.02$ vs. non-obese group) and the obese group (-4.37% per year, $p < 0.001$ vs. non-obese group) compared to the non-obese group (-1.17% per year).

Conclusion: In this cross-sectional study, negative regression was confirmed between β -cell function and diabetes duration according to the AUC-CPR. The annual declining rate of β -cell function was already accelerated in the pre-obese state prior to reaching the obese state. These findings suggest that antidiabetic therapy aimed at body weight reduction should be chosen from the pre-obese state in order to preserve β -cell function in T2D patients.

Deletion of PKC ϵ in islet-associated macrophages improves beta cell function

L. O'Reilly, J. Cantley, V. Turner, R. Brink, C. Schmitz-Peiffer, T.J. Biden;

Garvan Institute of Medical Research, Darlinghurst, Australia.

Background and aims: Islet inflammation is an increasingly accepted contributing factor to β -cell dysfunction in the context of Type 2 Diabetes. This is thought to involve the actions of macrophages which are increased in islets of animals fed a high-fat diet (HFD), as well as multiple models of diabetes. Whole body deletion of the serine/threonine kinase PKC ϵ in HFD mice improves β -cell function in vivo. PKC ϵ is important in toll-like receptor signalling, and is involved in macrophage function and activation. We hypothesise that PKC ϵ is an important regulator of macrophage function in islet-associated macrophages and is a target to alleviate macrophage-mediated β -cell dysfunction in HFD mice.

Materials and methods: To study the specific actions of PKC ϵ we developed a floxed PKC ϵ mouse (PKC ϵ f). This was crossed with Pdx-cre or Rip-cre mice for β -cell specific deletion and LysMcre mice for macrophage specific deletion. Control mice were the corresponding cre alone, or PKC ϵ f mice. Bone marrow chimeras were generated by irradiation of congenic donor mice, which then received bone marrow cells from PKC ϵ WT or null mice.

For all models mice were fed normal chow or HFD for varying times and glucose tolerance tests (GTTs) and insulin tolerance tests (ITTs) were performed. Insulin and c-peptide excursions were also monitored during GTTs, using ELISA. Circulating cytokines, islet gene expression, and islet morphology were characterised in LysMcrePKC ϵ f mice. Additionally, primary peritoneal and bone marrow-derived macrophages from PKC ϵ WT and null mice were isolated to characterise the role of PKC ϵ in macrophage function and activation in vitro.

Results: β -cell specific PKC ϵ deletion did not improve glucose tolerance or β -cell function in HFD mice compared to controls. Bone marrow chimera mice reconstituted with PKC ϵ null bone marrow exhibited improved glucose tolerance ($p < 0.05$, two-way ANOVA), and insulin and c-peptide excursions ($p < 0.05$, two-way ANOVA) during the GTT at 20 weeks of high fat feeding, but not before. At 12 weeks of high fat feeding LysMcrePKC ϵ f mice exhibited significantly improved glucose tolerance ($p < 0.05$, two-way ANOVA), an elevated insulin profile ($p < 0.05$, two-way ANOVA) and significantly improved c-peptide response ($p < 0.05$, t-test) during the GTT. This effect was not seen in chow-fed mice. Islets from HFD fed LysMcrePKC ϵ f mice showed improved glucose-stimulated insulin secretion ex vivo ($p < 0.05$, one-way ANOVA). Insulin resistance as measured by an ITT was not altered, and no gross changes in circulating cytokines or inflammatory gene expression were observed. β -cell area was not changed in LysMcrePKC ϵ f mice. In vitro stimulation of primary PKC ϵ null macrophages with common activators (e.g. LPS, IFN γ , palmitate) showed no obvious alteration in macrophage activation as measured by production of nitric oxide and release of IL-1 β , IL-1 α , TNF α , IL-6, MCP-1, IL-12, IL-23, IL-10 and PGE2.

Conclusion: Deletion of PKC ϵ in the haematopoietic compartment, and more specifically macrophages, improves β -cell function in HFD mice. This improvement occurs after increased macrophage accumulation and does not appear to be due to any gross alterations in canonical activation pathways. These results suggest that a subtle alteration in macrophage biology independently of currently known mediators can preserve β -cell function under a HFD stress.

TLR4 triggered inflammation involves an interplay between macrophages, alpha and beta cells in human pancreatic isletsW. He¹, J. Kerr-Conte², K. Maedler¹;¹Centre for Biomolecular Interactions, University of Bremen, Germany, ²U859 INSERM University of Lille 2, France.

Background and aims: Inflammatory signals are strong mediators of metabolic failure in fat, liver, brain, muscle as well as in pancreatic islets. Toll-like receptor-4 (TLR-4) signaling is one of the major pro-inflammatory pathway; its ligands as well as downstream products, i.e. cytokines and chemokines are increased systemically in patients with T2D as well as in at-risk individuals. TLR4 knockout mice are protected from the metabolic consequences of a high fat diet. In the present study we investigated the mechanism of TLR4 induced inflammation in isolated human islets.

Materials and methods: Isolated human islets from healthy donors were plated onto ECM-coated dishes and exposed to the natural TLR4 ligand Lipopolysaccharide (LPS) for 3 days. Depletion of islet resident macrophages was achieved by treatment with clodronate liposome. Expression and secretion of pro-inflammatory cytokines/chemokines was evaluated by qRT-PCR and ELISA. Glucose-stimulated insulin secretion (GSIS) from islet supernatants and insulin content from human islets were examined by insulin ELISA. Beta cell apoptosis and IL-8 localization were determined by double labeling for the TUNEL assay or by anti-IL-8 and anti-insulin or anti-glucagon antibodies. Human monocytes were enriched from human PBMCs and used for the migration assay through a Boyden chamber.

Results: Treatment of isolated human islets with LPS reduced GSIS by 71.6% and insulin content by 76.6% and increased beta cell apoptosis by 2.5-fold, compared to untreated control. In parallel, mRNA levels of pro-inflammatory cytokines/chemokines, including IL-1alpha, IL-1beta, IL-6, TNFalpha, CCL2 and IL-8, were elevated by LPS. Depletion of resident macrophages in human islets by clodronate showed that LPS-induced IL-1beta and IL-1alpha expression was macrophage dependent, while IL-6, TNFalpha, CCL2 and IL-8 expression remained unchanged, suggesting the endocrine cells themselves were the major source of these cyto-/chemokines. Immunohistochemical staining showed intra-islet production of IL-8 from alpha cells. In contrast, human macrophages differentiated from human primary monocytes produced high levels of IL-8 as well as IL-1beta in response to LPS. Migration of primary human monocytes was induced by supernatants from LPS-treated human islets; this was highly dependent on IL-8, since an IL-8 neutralizing antibody completely blocked the migration.

Conclusion: Our results show that TLR4 activation leads to beta cell dysfunction, beta cell apoptosis and islet inflammation. This depends on the interplay between islet-associated resident macrophages, alpha cells and beta cells, while recruited islet macrophages may exacerbate inflammation and amplify islet damage.

An emerging role for autophagy in the regulation of beta cell survival by glucagon-like peptide-1

F.P. Zummo, K.S. Cullen, P.E. Lovat, J.A. Shaw, C. Arden;

Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK.

Background and aims: Loss of pancreatic beta-cell mass is central to the development of Type 2 diabetes. Autophagy is a self-degradative process, important for recycling cell components in response to stress and, under most conditions, is considered a cell survival mechanism. However, deregulation of autophagic flux can lead to cell death. Whether beta-cell autophagy has a protective or detrimental role in the

development of T2D is contentious. Glucagon-like peptide-1 (GLP-1) improves glycaemic control through multiple actions including preventing beta cell loss, although the mechanisms are not well understood. The aim of the current study was to determine whether the protective effect of the GLP-1 analog exendin-4 on glucolipotoxic-induced cell death is due to alterations in autophagic flux.

Materials and methods: INS-1E cells were treated with glucolipotoxic stress (25 mM glucose, 0.5 mM palmitate) in the absence or presence of 100 nM exendin-4 and/or 10 μM BAPTA, 10 μM ESI-09 for 6–16 h. Immunohistochemical staining of p62 both in fixed INS-1E and pancreas sections from control and T2DM donors was used to assess autophagy impairment. Autophagic flux was assessed by LC3-I to LC3-II conversion and by using a mCherry-GFP-LC3 construct.

Results: Treatment of INS-1E cells with glucolipotoxic stress increased cell death as evident by increased PI staining (3.7-fold±0.4 n=3, p<0.001) and also increased LC3-I to LC3-II conversion (2.5-fold±0.1 n=3, p<0.01), a distinct marker of autophagy. Glucolipotoxicity increased p62 puncta accumulation (2.0-fold±0.2 n=6, p<0.01), which indicates defective autophagy. In accordance, further studies using mCherry-GFP-LC3 showed that treatment of INS-1E with glucolipotoxic stress led to accumulation of autophagosomes and impaired autophagic flux. An increase in p62 puncta accumulation was also found in pancreatic beta cells from Type 2 diabetic donors, indicating that autophagy may also be impaired in human diabetes. Co-treatment with exendin-4 protected INS-1E cells from glucolipotoxic induced cell death (37.3% decrease n=3, p<0.01). Exendin-4 further exacerbated LC3-I to LC3-II conversion (4.1-fold±0.2 n=3, p<0.01), while reducing p62 puncta accumulation (17.9% decrease n=6, p<0.05) suggesting further stimulation and, at least partial, restoration of autophagic flux. The Ca²⁺ chelating agent BAPTA and ESI-09, an Epac inhibitor, suppressed the increase in LC3-I to LC3-II conversion driven by exendin-4 (59.0% decrease n=3, p<0.05 and 64.7% decrease n=4, p<0.05, respectively), suggesting a role for calcium in the exendin-4 regulation of autophagy.

Conclusion: Glucolipotoxicity causes impairment in autophagic flux in beta cells, resulting in accumulation of autophagosomes inside the cells. Co-treatment with exendin-4 causes partial restoration in autophagosome clearance through an EPAC/calcium-dependent mechanism.

Modulation of beta cell function by the atrial natriuretic peptideS. Undank¹, P. Krippeit-Drews¹, M. Düfer², G. Drews¹;¹Pharmacology, University of Tuebingen, ²Pharmacology, University of Muenster, Germany.

Background and aims: Recent studies suggest that the cardiac hormone ANP (atrial natriuretic peptide) is an important regulator of metabolism. It may provide a link between cardiovascular and metabolic dysregulation in obesity and (pre)diabetes. The aim of the present study was to investigate the effect of ANP on beta-cell stimulus-secretion coupling.

Materials and methods: Ion currents and the membrane potential (V_m) of mouse beta-cells were measured with the patch-clamp technique. Mitochondrial membrane potential ($\Delta\Psi$) was determined with Rh-123 fluorescence. Protein expression in pancreatic islet lysates was assessed by Western blotting. For insulin secretion measurements, batches of 5 islets were incubated for 60 minutes at 37°C with the indicated substances. Insulin was determined by radioimmunoassay.

Results: ANP (10 nM) decreased the open probability of the K_{ATP} channel in beta-cells of GC-A^{flox/flox} mice to 29±11% (n=6, p≤0.01). This effect was absent in mice with specific deletion of the GC-A receptor in beta-cells (Rip-Cre^{+/-} GC-A^{flox/flox}) (119±15%, n=6, n.s.). A membrane-permeable analog of the second messenger cGMP, 8-Br-cGMP (250 μM), mimicked the effect of ANP on the K_{ATP} channel in beta-cells of GC-A^{flox/flox} mice (reduction to 72±8% open probability vs.

100% control, $n=7$, $p\leq 0.05$), indicating that ANP acts in a cGMP-dependent manner. Determination of specific current density (GC-A^{flox/flox}: 21 ± 2 pA/pF, $n=33$ vs. Rip-Cre^{+/-} GC-A^{flox/flox}: 23 ± 1 pA/pF, $n=34$, n.s.) as well as Western blotting ($n=6$, n.s.) revealed no significant difference in the number of K_{ATP} channels or protein expression in beta-cells of Rip-Cre^{+/-} GC-A^{flox/flox} mice and their wild type littermates. ANP (10 nM) did not influence mitochondrial membrane potential (15 mM glucose: 1232 ± 35 a.u. vs. +ANP: 1240 ± 32 a.u., $n=60$, n.s.), indicating that it does not affect ATP production. In accordance with closure of K_{ATP} channels, ANP increased glucose-induced electrical activity measured as fraction of plateau phase (FOPP=percentage of time with spike activity) (ANP: $65\pm 5\%$ vs. glucose 10 mM: $47\pm 5\%$, $n=6$, $p\leq 0.05$). Insulin secretion was increased by ANP at a subthreshold glucose concentration (6 mM glucose) in islets of GC-A^{flox/flox} mice (ANP: 0.33 ± 0.07 ng insulin/(islet*h) vs. 6 mM glucose: 0.24 ± 0.06 ng insulin/(islet*h), $n=4$, $p\leq 0.05$), whereas the effect was absent in islets of Rip-Cre^{+/-} GC-A^{flox/flox} mice (ANP: 0.23 ± 0.06 ng insulin/(islet*h) vs. 6 mM glucose: 0.24 ± 0.04 ng insulin/(islet*h), $n=4$, n.s.).

Conclusion: These results provide evidence that ANP exerts cGMP-dependent specific actions in the endocrine pancreas via activation of the GC-A receptor and that the hormone is involved in the regulation of beta-cell function.

445

Ghrelin has a direct inhibitory effect on insulin secretion in human islets from both healthy subjects and type 2 diabetic patients

R.G. Fred, L. Shcherbina, M. Abels, N. Wierup;

Lund University Diabets Centre, Lund University, Malmö, Sweden.

Background and aims: Ghrelin is an insulinostatic hormone expressed in the gastro-intestinal tract and in islet ghrelin cells. In rodents most of the circulating ghrelin originates from the fundus but in humans a larger portion originates from the islets and intestine, demonstrating the necessity of experimental data from humans in addition to other experimental models. The effect of ghrelin is well documented in several experimental models, as well as *in vivo* in humans. However, the direct effect of ghrelin on human islets is not well known. Although IVGTTs have shown decreased insulin-, as well as C-peptide release after ghrelin infusion it has hitherto not been clarified if this is a primary response. Thus, our aim was to perform *in vitro* secretion assays to study the direct effect of ghrelin on human islet insulin secretion in islets from normoglycemic and type 2 diabetes (T2D) donors. Furthermore it is not known how islet expression of ghrelin and its receptor GHS-R1a are affected by T2D. We aimed to investigate ghrelin and GHS-R1a expression levels to establish the effects of prolonged hyperglycemia on ghrelin signaling. This was to be done using microarrays on islets from healthy subjects and T2D patients.

Materials and methods: Human islets from the Nordic Network for Clinical Islet Transplantation, delivered through the Human Tissue Lab (LUDC), were considered being from normoglycemic ($HbA_{1c}<6.0$) or T2D (diagnosed or $HbA_{1c}>6.0$) donors. The islets were incubated in 2.8 or 16.7 mM glucose for 1 hour with or without different concentrations of ghrelin. Insulin secretion was determined by ELISA (Mercodia). Microarray data was collected from 128 donors using the Affymetrix GeneChip Human Gene 1.0 ST array.

Results: 1 hour incubation of human islets from T2D donors ($HbA_{1c}>6.0$ with 1, 10 and 100 nM ghrelin at 16.7 mM glucose dose-dependently decreased insulin secretion with a $31.2\pm 15.7\%$ reduction at 10 nM ($p=0.042$ for $n=3$). At 2.8 mM glucose ghrelin did not effect insulin secretion. In islets from normoglycemic donors the same pattern was seen with a dose dependent decrease in insulin secretion at 16.7 mM glucose with $31.5\pm 7.27\%$ at 100 nM ($p=0.022$ for $n=6$). Thus indicating that the *in vivo* effect of ghrelin on insulin secretion is predominantly due to a direct effect on the beta-cells. The micro-array data from human islets revealed that islet ghrelin expression was negatively correlated with

HbA_{1c} ($p=0.007$ for $n=128$) and that ghrelin expression was lower in T2D islets ($p=0.03$). Islet ghrelin also correlated positively with insulin, glucagon and somatostatin expression ($p=1*10^{-10}$, $p=0.001$ and $p=2*10^{-5}$ respectively for $n=128$). The ghrelin receptor (GHS-R) expression did not correlate significantly with known diabetes risk-factors such as BMI, insulin secretion index or HbA_{1c} . Nevertheless, GHS-R correlated with PDX-1 expression ($p=3*10^{-13}$ for $n=128$) and somatostatin ($p=1.6*10^{-16}$ for $n=128$) indicating a previously unknown connection to both beta-cell transcription and delta-cell function.

Conclusion: We conclude that: 1) ghrelin directly inhibits insulin secretion in islets from both healthy subjects and T2D patients. 2) ghrelin expression levels correlate negatively with both HbA_{1c} and diagnosed T2D and positively with insulin, glucagon and somatostatin. 3) the ghrelin receptor also correlates positively with somatostatin. These findings suggest that inhibition of ghrelin signaling may be a therapeutic avenue for treatment of T2D.

The role of Epac2 in bile acid-mediated modulation of insulin secretion

E. Heider¹, P. Krippel-Drews¹, M. Düfer², G. Drews¹;

¹Pharmacology, University of Tuebingen, ²Pharmacology, University of Muenster, Germany.

Background and aims: We have shown recently that bile acids enhance glucose-stimulated insulin secretion via activation of the farnesoid X receptor (FXR). FXR activation leads to closure of K_{ATP} channels, however, the underlying mechanism is still unknown. The aim of the present study was to test whether Epac2 (exchange protein directly activated by cAMP 2) plays a role in the bile acid-mediated regulation of glucose homeostasis via FXR.

Materials and methods: Experiments were performed with beta-cells from wild-type (WT) and Epac2-knockout (KO) mice. Ion currents were measured with the patch-clamp technique; the cytosolic Ca²⁺ concentration [Ca²⁺]_c was determined by fura-2.

Results: Chenodeoxycholate (CDC, 500 nM) and the synthetic FXR agonist GW4064 (500 nM) enhanced [Ca²⁺]_c in beta-cells of WT mice to $130\pm 12\%$, $n=12$, $p\leq 0.05$ and $119\pm 5\%$, $n=18$, $p\leq 0.01$, respectively. Interestingly, both substances did not alter [Ca²⁺]_c in beta-cells of Epac2-KO mice (CDC: $n=41$, GW4064: $n=22$). The Epac-selective cAMP analog Sp8 (1 μM) evoked an elevation of [Ca²⁺]_c in WT beta-cells ($122\pm 4\%$, $n=22$, $p\leq 0.001$) but not in Epac2-KO beta-cells ($n=17$) indicating that Epac activation augments [Ca²⁺]_c in beta-cells. We further tested whether the K_{ATP} channel density is altered in beta-cells of Epac2-KO mice. Whole-cell K_{ATP} current measurements were performed without ATP in the pipette solution to induce maximum K_{ATP} current. The experiments revealed a significant decrease in K_{ATP} channel density in beta-cells lacking Epac2 (WT: 26 ± 2 pA/pF, $n=15$ vs. Epac2-KO: 18 ± 2 pA/pF, $n=22$, $p\leq 0.05$). To investigate whether the ATP sensitivity of the K_{ATP} channel is modified by FXR activation, we tested different ATP concentrations in the pipette solution in the absence and presence of GW4064. The FXR agonist increased ATP sensitivity of the channels in WT beta-cells by about 40% (14 ± 1 pA/pF $n=7$ vs. 8 ± 1 pA/pF, $n=6$, $p\leq 0.01$ for 1 mM ATP and 11 ± 1 pA/pF, $n=9$, vs. 6 ± 1 pA/pF, $n=9$, $p\leq 0.01$ for 2 mM ATP with and without GW4064, respectively). The FXR agonist did not affect ATP sensitivity of K_{ATP} channels in Epac2-KO beta-cells ($n=5-8$).

Conclusion: The experiments provide evidence for a link between bile acid signaling and the activation of Epac2 which seems to increase K_{ATP} channel sensitivity towards ATP. It is suggested that FXR stimulation activates Epac2 which in turn decreases K_{ATP} channel activity.

Decorin: A new positive component of skeletal muscle to beta cell communication?

T. Haider, C. Arous, A. Zoso, P.A. Halban, K. Bouzakri; GEDEV, centre médical universitaire, Genève, Switzerland.

Background and aims: Inter-organ crosstalk including possible communication between skeletal muscle and beta cells is an important component of normal physiology that may contribute towards the pathophysiology of type 2 diabetes. Indeed, skeletal muscle cells secrete different sets of soluble proteins (myokines) which could act positively or negatively (in health and disease respectively) on the function of distant tissues including pancreatic islets. We have observed that conditioned medium from skeletal muscle of healthy individuals has positive effects on beta cell function. Decorin, a chemokine that has been shown to be a component of the extracellular matrix of a variety of connective tissues, was identified as a myokine regulated by muscle fiber type. The major aim of this study was to explore the impact of decorin on primary sorted beta cells under control conditions and after exposure to TNF- α or cytomix.

Materials and methods: All studies were performed using sorted rat primary beta cells exposed to decorin for 24 h. Glucose-stimulated insulin secretion (GSIS) was measured by radioimmunoassay after 1 h at 2.8 mmol/l (basal) and 1 h at 16.7 mmol/l (stimulated) glucose. Confocal immunofluorescence microscopy was used to study focal adhesion and actin remodeling (after 15 min glucose stimulation). Cell death and proliferation were measured by TUNEL assay and BrdU incorporation respectively. To study the potential beneficial/protective effects of decorin, beta cells were exposed to decorin for 24 h alone or with addition of cytomix (20 ng/ml each TNF α , IFN γ , IL1- β) or 20 ng/ml TNF- α alone. Data are mean \pm SE for 5–8 independent experiments.

Results: Decorin treatment of rat primary beta cells for 24 h increased GSIS (control: 12.4 \pm 3.2% content/h; 1 μ g/ml decorin: 15.08 \pm 3.8%*; 10 μ g/ml decorin: 14.1 \pm 1.8%*; * p <0.05 vs. control) and decreased cell death (TUNEL-positive beta cells control: 0.7 \pm 0.2%; 1 μ g/ml decorin: 0.38 \pm 0.1%*; 10 μ g/ml decorin: 0.4 \pm 0.1%*; * p <0.05 vs. control). Decorin had no effect on beta cell proliferation. Confocal microscopy showed a modification of glucose-induced formation of focal adhesions containing paxillin and actin after 24 h decorin (1 μ g/ml). Decorin (100 μ g/ml) induced a slight increase of paxillin phosphorylation and presented a denser actin network in both basal and stimulated conditions depending on the decorin concentration (1 μ g/ml–100 μ g/ml). Decorin protected against the adverse effects of TNF- α on GSIS (control: 10.20 \pm 0.8% content/h; TNF- α : 8.6 \pm 0.8%*; TNF- α + 1 μ g/ml decorin: 11.03 \pm 0.9%*; * p <0.05 vs. control; ** p <0.05 vs. TNF- α alone) and blocked the effects of cytomix on apoptosis (control: 0.75 \pm 0.1% TUNEL-positive beta cells; cytomix: 5.9 \pm 0.12%; cytomix + 1 μ g/ml decorin: 0.95 \pm 0.35%).

Conclusion: We demonstrate for the first time that decorin has a positive effect on beta cells, increasing glucose-stimulated insulin secretion and decreasing cell death in the basal state. The myokine affects also beta cell focal adhesion and actin remodeling. Moreover, decorin protects beta cells from the adverse effects of TNF- α and cytomix, indicating the potential for a specific impact of decorin on cytokine signaling pathways in beta cells.

Impact on beta cells of myokines secreted by skeletal muscle of differing insulin sensitivity and fiber type

K. Bouzakri¹, P. Plomgaard², C. Howald¹, E.T. Dermizakis¹, B.K. Pedersen², P.A. Halban¹;

¹Department of Genetic Medicine and Development, CMU, Geneva, Switzerland, ²Department of Infectious Diseases and CMRC, University of Copenhagen, Denmark.

Background and aims: Decreased beta-cell functional mass and insulin resistance are hallmarks of type 2 diabetes (T2D). We have studied crosstalk between skeletal muscle of different insulin sensitivity and beta-cells, and suggested that myokines secreted by insulin-resistant skeletal muscle could contribute towards decreased beta-cell function/mass in T2D. In obese and T2D individuals, the distribution of muscle fiber types is shifted toward faster, more glycolytic fibers. We have now explored the impact on beta-cells of secreted products from human myotubes of different fiber type with varying insulin sensitivity.

Materials and methods: Human skeletal muscle biopsies of different fiber type were collected from soleus (S; slow twitch fiber) and triceps (T; fast twitch fiber); cells were expanded in culture and differentiated into myotubes. mRNA expression were measured by unbiased RNA sequencing on biopsies and corresponding cell preparations. Human myotubes were treated for 24 h with or without (control) 20 ng/ml TNF- α to induce insulin resistance. Glucose uptake was measured in response to insulin. Conditioned media (CM) from the fiber types (test: TNF- α -CM-S or T; control: C-CM-S or T) were collected and analyzed to identify their myokine composition by protein arrays. Sorted rat and human primary beta-cells were used to test effects of exposure to CM for 24 h on death (TUNEL), proliferation (BrdU) and glucose-stimulated insulin secretion (GSIS). Data are mean \pm SE with p <0.05 considered significant for all indicated differences.

Results: Biopsies from soleus and triceps revealed a unique gene signature with 2497 genes (S vs. T; p <0.01) differentially expressed in these 2 groups, while primary cells derived from soleus and triceps showed 1682 differentially expressed genes (S vs. T; p <0.01). Moreover, cells isolated from triceps and soleus secreted a different panel of myokines in control condition and after treatment with TNF- α allowing for identification of fiber specific, TNF- α and fiber/TNF- α dependent myokines. Interestingly, TNF- α failed to induce insulin resistance in cells isolated from triceps. CM-S and -T increased whereas TNF- α -CM-S but not -T decreased GSIS. Beta-cells treated with TNF- α -CM-S showed increased death (11 \pm 2-fold increased TUNEL-positive cells) and decreased proliferation (1.1 \pm 0.4 vs. 7.3 \pm 1.7% BrdU positive cells vs. C-CM-S) whereas TNF- α -CM-T treatment had no impact on these parameters vs. C-CM-T treatment. Finally, CM from either fiber type without prior exposure to TNF- α increased beta-cell proliferation (Control: 4.7 \pm 0.3; CM-S: 7.3 \pm 0.6%; CM-T: 8.6 \pm 1.1% BrdU positive cells; * p <0.05 vs. Control).

Conclusion: Taken together these results show that skeletal muscle cells from biopsies with different fiber composition present unique gene expression and myokine signatures. Moreover the impact on pancreatic beta-cells of human skeletal muscle cells is fiber specific, with both positive and negative effects depending on different insulin sensitivity. The identification of the fiber specific myokines and their molecular targets on beta-cells may lead to new therapeutic strategies for preservation of functional beta-cell mass in T2D.

Identification of novel targets of the miR-212/132 cluster involved in Wnt-signalling and regulation of insulin secretion in the pancreatic beta cell

H.A. Malm, J.L.S. Esguerra, M. Orho-Melander, L. Eliasson, I.G. Mollet;
Dept Clinical Sciences in Malmö, Lund University Diabetes Centre, Malmö, Sweden.

Background and aims: We have recently shown the miR-212/132 cluster to be highly overexpressed in diabetic Goto-Kakizaki (GK) rat islets. In the present study we aimed to validate targets of miR-212 and miR-132 and investigate their effects on insulin secretion.

Materials and methods: Conservation of microRNA 3'UTR target predictions was evaluated using TargetScan. Rat miR-212 and miR-132 were overexpressed using mirVana Mimics in INS-1 832/12 clonal beta-cells by transfection and analysed with RT-qPCR and Western Blot.

Results: In silico analysis of 249 predicted miR-212 and miR-132 target genes conserved in human, rat and mouse revealed several genes of interest to the study of type-2 diabetes mellitus (T2DM). Among these were MAPT and two transcription factors (TFs) targets of Wnt-signalling, ISL1 and SOX6. ISL1 binds to the enhancer region of the insulin gene and is a primary target of TCF7L2; SOX6 is known to function in transcriptional regulation through interaction with beta-catenin and is down-regulated in human islets from donors with high HbA1c; and MAPT, which is understood to be hyper-phosphorylated in neurofibrillar tangles in insulin deficient mice, to a large extent by glycogen synthase kinase 3 beta (GSK-3beta), a central kinase that is inactivated by canonical Wnt-signalling. Moreover, clustering of miR-212/miR132 predicted targets showed enrichment within the Wnt-signalling pathway. We have confirmed down-regulation of MAPT ($p=0.0118$, $N=3$), ISL1 ($p=0.0057$, $N=3$) and SOX6 ($p=0.0287$, $N=3$) at the mRNA level in the insulin secreting cell line INS-1 832/13 when miR-212 are overexpressed. Likewise, after overexpression of miR-132 mRNA expression of SOX6 ($p=0.0008$, $N=3$), ISL1 ($p=0.0009$, $N=3$) and MAPT ($p=0.0001$, $N=3$) was reduced. We have also obtained preliminary Western blot data showing down regulation of MAPT at the protein level.

Conclusion: These results give evidence that MAPT, SOX6 and ISL1, all three genes relevant to type-2 diabetes, are likely to be targets of miR-212 and miR-132. In addition, these results indicate that these microRNAs are involved in the translational regulation of genes affected by canonical Wnt-signalling. We are currently aiming to investigate the effect of these targets on insulin secretion and to verify additional targets of miR-212/132 involved or affected by Wnt-signalling by using an Argonaute-2/RIP (Ago2-RIP) approach.

Circulating levels of microRNAs predict residual beta cell function and glycaemic control the first 12 months after diagnosis in children with type 1 diabetes mellitus

N. Samandari, S. Pörksen, L.B. Nielsen, M.M. Andersen, S. Fredheim, J. Johannesen, J. Svensson, H.B. Mortensen, F. Pociot;
Paediatrics, Herlev University Hospital, Denmark.

Background and aims: MicroRNAs have gained intensive research focus in order to explain pathophysiological processes leading to many complex disorders including autoimmune diseases. Type 1 diabetes mellitus is the final result of T-cell driven beta-cell loss leading to lifelong insulin treatment and regular control of metabolic status. In this study it is

hypothesized that miRNA expression profile over time predicts residual beta-cell function and metabolic control in newly diagnosed children with type 1 diabetes mellitus.

Materials and methods: Children and adolescents with newly diagnosed type 1 diabetes mellitus from The Danish Remission Cohort ($N=129$) were intensively followed with blood samples the first 12 months after diagnosis. A subset of 40 children from this cohort were followed up 5 years after diagnosis. In this subgroup RNA was extracted from serum samples obtained at 1, 3, 6, and 12 months. At the same time points meal stimulated C-peptide and HbA1c were measured and IDAA1c calculated. miRNA profiling was performed using a predefined panel of 179 human miRNAs. Normalization is based on the global mean of all expressed miRNAs. Statistical analysis of miRNA prediction on disease progression with stimulated C-peptide, HbA1c and IDAA1c as endpoint was performed by multiple linear regression analysis adjusted for age and sex. Comparisons were further adjusted for multiple testing by the Benjamini-Hochberg approach for the 172 miRNAs at all time points.

Results: miRNA profiling was performed in a total of 182 serum samples. 172 different miRNAs were identified and further analyzed. Stimulated C-peptide at 12 months was predicted by hsa-mir-197-3p at 3 months. A doubling in miRNA level corresponded to a 3.5 fold higher stimulated C-peptide level ($p=0.03$). In addition a doubling of hsa-mir-24-3p and hsa-mir-146a-5p levels at 3 months corresponded to a 4.2% and 3.5% decrease in IDAA1c 12 months after diagnosis, ($p=0.01$) ($p=0.02$) respectively. A doubling in hsa-mir-375 at 3 months corresponded to a 0.75 fold lower stimulated C-peptide level at 6 months ($p=0.02$). Furthermore a doubling of hsa-mir-301a-3p at 3 months corresponded to a 1.1% decrease in HbA1c at 6 months ($p=0.02$).

Conclusion: A combination of circulating novel miRNAs expressed in sera from children newly diagnosed with type 1 diabetes mellitus can predict beta-cell function and metabolic control 12 months after disease onset. miRNAs could potentially be used as predictive biomarkers in attempt to individualize the beta-cell regenerative treatment at a crucial timepoint in this group of patients.

Modulation of long non-coding RNAs in islets of high fat diet induced obesity mice

A. Motterle¹, S. Gattesco¹, M.L. Peyot², M. Prentki², R. Regazzi¹;
¹Department of Fundamental Neuroscience, University of Lausanne, Switzerland, ²University of Montreal, Montreal Diabetes Research Center, Canada.

Background and aims: The genome transcribes a great number of long non-coding RNAs (lncRNAs). Despite being involved in diverse gene-regulatory mechanisms and their dysregulation being implicated in many diseases, only few lncRNAs have been functionally characterized and little is known about their contribution to type 2 diabetes. Type 2 diabetes is characterised by a combination of beta-cell failure and insulin resistance. The mechanisms leading to beta-cell dysfunction are complex and still largely unknown. The aim of this project is to identify novel lncRNAs, study their deregulation in the islets of mice fed a high fat diet and to investigate their role in the regulation of beta-cell functions.

Materials and methods: Islets were isolated from 13 weeks old C57Bl/6 mice after being fed a standard (SD) or a high fat (HFD) diet for 8 weeks. 100 nucleotide pair end sequencing was performed on cDNA libraries prepared from rRNA-depleted islet RNA using the Illumina platform. Reads were mapped with TopHat software version 2.0.8 to UCSC mm9 mouse genome. *Ab initio* transcript reconstruction was performed using Cufflinks version 2.1.1 and novel lncRNAs transcripts were classified from known lncRNAs and protein-coding mRNAs using Cuffmerge version 2.1.1. Differential lncRNAs of selected novel lncRNAs was confirmed by quantitative real-time PCR.

Results: RNA sequencing yielded around 500,000,000 reads per sample of which on average 75% were mapped to the mouse genome. We identified a total of 14874 protein-coding transcripts of which 1366 were upregulated and 396 downregulated in HFD mice. Functional annotation of the differentially expressed protein-coding genes showed a strong enrichment for endoplasmic reticulum, mitochondrion, protein biosynthesis and transport processes. We also detected 1761 previously annotated lncRNAs, of which 23 were upregulated and 104 downregulated. Finally, *de novo* annotation identified around 1805 novel lncRNAs, 39 of which were upregulated and 107 downregulated. Amongst the 1805 novel lncRNAs, only 237 overlapped with previously published transcripts. In agreement with previous studies, the expression of lncRNAs was lower than that of protein-coding genes, with the majority displaying an expression below an FPKM of 5. Amongst the differentially expressed genes, we confirmed in additional samples the upregulation and downregulation of two selected lncRNAs. XLOC_010971 was 35±21 ($p=0.0205$) fold higher in HFD versus SD while XLOC_013310 was 50% lower ($p=0.0051$) in HFD versus SD.

Conclusion: We used high throughput sequencing to study the differences in gene expression in islets of a well characterized model of diet-induced obesity and glucose intolerance. We detected many changes in protein-coding genes and previously annotated lncRNAs. Furthermore, we identified a new set of novel lncRNAs, a group of which displayed changes in expression between islets of lean and diet induced obesity mice, suggesting that lncRNAs could play an important role during the pathogenesis of type 2 diabetes. These data provide the basis for future studies on the contribution of lncRNAs to beta-cell dysfunction during the development of type 2 diabetes.

Influence of environmental factors on the repression of "disallowed" genes in mouse islets

K. Lemaire, M. Granvik, L. Goyvaerts, L. Van Lommel, A. Schraenen, F. Schuit;
Cellular and Molecular Medicine, KU Leuven, Belgium.

Background and aims: The concept of "disallowed" genes - a special group of housekeeping genes that is expressed in all tissues except one - was introduced in the context of low Km hexokinases and monocarboxylate transporters, genes that would interfere with normal glucose-induced insulin release when expressed in the beta cell. Subsequent mRNA analysis using freshly isolated islets and a panel of tissues from the same mice indicated that a small set of "disallowed" genes is part of the phenotype of adult mouse islets as a result of repressive changes of chromatin structure and the finetuning influence of microRNA's. This phenotype is established during the neonatal period when beta cells mature. It is unknown to what extent environmental factors can reverse this epigenetic signature so that "disallowed" genes are induced in beta cells. The aim of the present study was to examine the potential influence of important environmental factors (age, diet, pregnancy) on the expression of the "disallowed" genes in mouse islets.

Materials and methods: For the ageing experiment, we compared mRNA signals in collagenase isolated islets from male C57B16/J mice (Janvier) of 1 month, 2 months, 6.5 months, 16.5 months and 26 months of age. We next studied mRNA from islets of male mice fed a high fat diet (45% fat) or standard diet (9% fat) for 16 weeks, starting at 6 weeks of age. Islets from female mice (age 10-12 weeks) were analysed at day 0, 9.5 and 15.5 of pregnancy. Via quantitative RT-PCR (N=4 per tested condition) we quantified islet mRNA expression signals of a signature of 14 genes considered "disallowed" in islets. Chromatin immunoprecipitation was used to test histone-3 epigenetic markers for activation (H3K9ac) and repression (H3K27me3) of gene expression.

Results: Age-dependent repression of the 14 "disallowed" genes follows two patterns with significant correlations between genes within each group (e.g. $R^2=0.98$ between *Zyx* and *Ldha*; $R^2=0.96$ between *Pdgfra* and *Itih5*). Expression of the largest group (*Arghdib*, *Cat*, *c-Maf*, *Ldha*, *Lmo4*, *Smad3*, *Zfp361l* and *Zyx*) was independent of age in animals of 1 month or older. In the second group (*Itih5*, *Oat*, *Pdgfra*, *Cxcl12*, *Igf1bp4* and *Slc16a1*) mRNA expression signals decreased significantly in function of age (e.g. 1 vs 6.5 months, *Pdgfra*: 0.91 ± 0.22 vs 0.09 ± 0.03 ; $p=0.004$; *Itih5*: 1.1 ± 0.34 vs 0.2 ± 0.02 , $p=0.04$). For none of the 14 "disallowed" genes, the repression was weakened when comparing 2 yrs old with 1 month old mice. In line with this result, the epigenetic H3K9ac H3K27me3 marks were well preserved in function of age. High fat diet feeding for 16 weeks led to small alterations of expression of three genes: *Itih5* (0 vs 16 weeks HFD; 1.43 ± 0.32 vs 2.1 ± 0.36 , $p=0.03$) and *Zyx* (0.97 ± 0.11 vs 1.3 ± 0.19 , $p=0.02$) and *Ldha* (1.01 ± 0.32 vs 0.57 ± 0.1 , $p=0.04$). At day 15.5 of pregnancy we observed between 1.5 and 2.4 times more repression of *Cxcl12* ($p=0.01$), *Igf1bp4* ($p=0.003$), *Itih5* ($p=0.01$) and *Oat* ($p=8.10\cdot 10^{-5}$); genes associated with the control of proliferation of cells.

Conclusion: With some minor exceptions, the phenotypic islet signature of 14 "disallowed" islet genes appears stable during ageing, after high fat diet and during pregnancy indicating that maintenance of an epigenetic repressive signature is very effective in islets against the influence of environmental factors.

DBP and Nfil3/E4BP4 play pivotal roles in circadian regulation of beta cell function

Y. Tanizawa¹, Y. Ohta¹, A. Taguchi¹, M. Akiyama¹, H. Nakabayashi¹, T. Matsumura¹, R. Suetomi¹, A. Yanai², K. Shinoda²;

¹Department of Bio-Signal Analysis, ²Department of Neuroscience, Yamaguchi University, Graduate School of Medicine, Ube, Japan.

Background and aims: Disturbances in circadian rhythm regulation have been implicated in the development of metabolic disorders, including diabetes mellitus. The most convincing evidence has emerged from the study in mice with tissue-specific ablation of *Bmal1*, one of the core clock components. However, the detailed links between circadian regulators and downstream targets are poorly understood. Recently, we reported that the expression level of *Dbp* was decreased and *E4bp4* was increased simultaneously in the islets of *Wfs1*^{-/-} *Ay/a* mice, a model of diabetes. *Dbp* and *E4bp4* are clock-controlled output genes. *DBP* activates, whereas *E4BP4* reciprocally suppress downstream target genes by competing the same binding site, D-box. Here, we investigated the roles of *Dbp* and *E4bp4* in the circadian regulation of β -cell function.

Materials and methods: We investigated the circadian expression of *Dbp* and *E4bp4* in pancreatic islets under normal, and restricted feeding (RF). We generated transgenic mice with beta-cell specific *E4bp4* overexpression (MIP-E4BP4), and examined islet morphological changes and β -cell function.

Results: RF caused 6-h phase advances in *Bmal1* and *Clock* expression and a 12-h phase advance in *Dbp* expression and the bathyphase of *E4bp4* expression. The higher sensitivity of the *Dbp* and *E4bp4* to RF compared with *Bmal1* and *Clock* suggests a role of the *Dbp* transactivity in the adjustment in pancreatic β -cells to changes in food availability. In MIP-E4BP4 β -cells, *E4BP4* should suppress the expression of targets of the *DBP*. We generated 2 MIP-E4BP4 lines, TG-C and TG-D. TG-C and TG-D have 10 and 3 transgene copies, respectively. Real-time RT-PCR confirmed 150- or 50- fold up-regulation of *E4bp4* in the isolated islets, with increased corresponding nuclear protein levels. Circadian expression of *Bmal1* and *Clock* was not altered. Glucose tolerance test revealed markedly impaired glucose tolerance in both of the TG mice with severely diminished insulin secretion. Glucose excursion in TG-C was higher than

that in TG-D, suggesting gene-dose dependent effect. We then analyzed insulin secretion in perfused pancreas. TG-C had markedly reduced and delayed insulin secretion to 17 mM glucose. MIP-E4BP4 mice were indistinguishable in body weight from control littermates. We confirmed a 50% reduction in insulin content in TG-C. The ratio of beta to alpha cells was significantly decreased and the proportion of islets with alpha-cells in center was obviously increased in TG-C. Electron microscopy revealed the total number of insulin granules to be reduced in TG-C β -cells. RNA expression of several genes involved in insulin secretion rises around the beginning of the feeding period and sustains during that period. In contrast, circadian RNA expression of these genes was diminished in TG-C islets during the same period. Increase in those RNA transcription might get beta-cells ready to rapidly release insulin preceding feeding time.

Conclusion: Findings from this genetic model support the premise that DBP/E4BP4, downstream of the core clock genes, plays essential role in the regulation of beta-cell function, and therefore occupies a pivotal position in beta-cell failure following circadian misalignment.

Glucose-dependent expression of Alx3 in alpha cells inhibits glucagon gene expression via interactions with Pax6

M. Vallejo, M. Mirasierra;

Instituto de Investigaciones Biomedicas Alberto Sols, Madrid, Spain.

Background and aims: The regulation of glucose homeostasis to maintain normoglycaemia requires the coordinated activity of insulin and its counter regulatory hormone glucagon. Defects in insulin synthesis, secretion and/or function resulting in hyperglycaemia have been at the centre of diabetes research since its discovery. However, the notion that abnormally increased glucagon production and secretion may play an important role in the etiopathogenic mechanisms of this disease has gained recognition in recent years. Although glucagon secretion in response to fluctuations in the concentrations of glucose has been widely studied, relatively less attention has been paid to investigate how changes in glucose levels regulate glucagon gene transcription. The regulation of glucagon gene expression in alpha cells involves the binding of several transcription factors to at least four regulatory elements, named G1-G4, located in the proximal promoter. Among these transcription factors the paired-like homeoprotein Pax6 plays a prominent role as a key factor for alpha cell function. In addition, Alx3, another paired-like homeoprotein known to be important for glucose homeostasis, appears to regulate glucagon gene transcription because glucagon expression is decreased Alx3-deficient mice. In the present study, we aimed to determine the mechanism by which Alx3 regulates glucagon gene expression in alpha cells.

Materials and methods: Isolated mouse islets and alphaTC1 cells were used. Protein-DNA binding was tested by chromatin immunoprecipitation (ChIP) and electrophoretic mobility shift assays (EMSA). Quantitative RT-PCR and siRNA were used for expression studies. Student's t test was used for statistical analysis.

Results: ChIP assays and EMSA demonstrated that Alx3 binds the glucagon promoter at the G3 but not at the G1 element, whereas Pax6 binds both elements as previously reported. Immunoprecipitations from alphaTC1 cells as well as GST-pull down assays showed that Alx3 interacts and forms heterodimers with Pax6 via the homeodomain. Alx3-Pax6 heterodimers bind G3, although Alx3 alone is unable to bind this site. In contrast, Alx3-Pax6 heterodimers cannot bind G1, so that Alx3 inhibits Pax6 binding to this site. Consistent with this, overexpression of Alx3 in transfected alphaTC1 cells resulted in decreased glucagon promoter activity and inhibition of Pax6-dependent transactivation. Expression of Alx3 in mouse islets and alphaTC1 cells increased after raising the concentration of glucose. This was accompanied by decreased binding of Pax6 to G1. In cultured islets from wild type mice, glucagon expression

was lower in the presence of 16 mM glucose than in the presence of 2.8 mM glucose. In contrast, changes in glucose concentration had no effect on glucagon expression in islets from Alx3-deficient mice. In alphaTC1 cells in which Alx3 expression was silenced by siRNA, expression of glucagon in the presence of 2.8 mM glucose was lower than in controls, but in the presence of 16 mM glucose the effect was reversed so that glucagon mRNA levels were higher than in controls, reflecting availability of Alx3-free Pax6 for binding to G1.

Conclusion: Our data indicate that glucose stimulates the expression of Alx3 in alpha cells, resulting in glucose-dependent inhibition of glucagon gene expression via Alx3-Pax6 interactions on the G1 element. Thus, Alx3 contributes as a key component to the mechanisms that regulate glucose-dependent glucagon expression in pancreatic islets.

Regulation of glucose-stimulated TXNIP expression by histone acetyltransferase (HAT) p300 and histone deacetylases (HDACs) in pancreatic islet cell

Y. De Marinis^{1,2}, P. Bompada¹, J. Wright³, D. Atac¹, L. Groop¹;

¹Dept of Clinical Sciences Malmö, ²Diabridge, Malmö, Sweden, ³The Broad Institute of Harvard and MIT, Cambridge, USA.

Background and aims: Uncontrolled hyperglycemia has been considered a main reason for beta-cell deterioration over time and referred to as glucotoxicity. It has been suggested that glucose through epigenetic mechanisms, i.e. effect on histone marks, influences gene expression. Here we have used the TXNIP gene as a candidate to study such mechanisms as it is known to be upregulated by glucose in islets where it can induce beta cell apoptosis. We tested whether glucose induced TXNIP expression by stimulating activating histone mark but also if these effects of glucose on TXNIP expression could be prevented by a HAT inhibitor or by mutating the HAT by CRISPR.

Materials and methods: We applied qPCR to determine Txnip mRNA expression and chromatin immunoprecipitation (ChIP) to study acetylation at histone 3 lysine 9 (H3K9ac). We also used CRISPR with sequence-specific gRNAs to mutate HAT p300 in an insulin-producing rat beta cell line INS1 832/13 cells as an attempt to prevent the effect of glucose on histone acetylation.

Results: Treatment of INS1 832/13 cells with high glucose (25 mM) for 24 hours resulted in a 30-fold increase in Txnip mRNA expression, and accordingly a 20% increase of H3K9ac at the 5'-coding region of Txnip. We then tried to prevent the effect of glucose on Txnip expression by using the HAT p300 inhibitor C646 to reduce acetylation. Txnip expression was significantly inhibited by C646 at both 5 mM (by ~40%) and 25 mM glucose (by ~75%). The involvement of HAT p300 in Txnip expression was further confirmed by ChIP-qPCR using primers flanking the 5'-coding region of Txnip and showed a 70% down-regulation of H3K9ac by C646 at 5 mM glucose. However, no reduction in H3K9ac by C646 was detected at 25 mM glucose. This suggests that high glucose may also elevate H3K9ac by inhibiting HDACs. To confirm this hypothesis, we mutated p300 in INS1 832/13 cells by creating an indel deletion at exon1 of the p300 gene (Ep300) using CRISPR/Cas9. Compared to the wild-type INS1 cells, the Ep300 knockout cells showed almost abolished Txnip expression (96% reduction) at 5 mM glucose (see Fig), which correlated with a 70% reduced acetylation at H3K9ac Txnip, indicating direct involvement of p300 in glucose-induced Txnip expression and histone acetylation. Furthermore, in these cells Txnip expression was partially recovered by the HDAC inhibitor C1994 or high glucose with elevated H3K9ac to the same levels as in wildtype cells. This suggests that in the absence of p300, glucose-stimulated H3K9ac and thereby Txnip expression can also be achieved by inhibition of HDACs.

Conclusion: We demonstrate that glucose can stimulate Txnip expression in beta-cells by stimulating an activating histone mark, H3K9ac, involves

activity of both HAT p300 and HDAC. This study thus points at the potential of reversing adverse effects of glucose on gene expression by treatments that can modify these histone effects.

Beta cell serotonin during pregnancy: Fact or artifact?

L. Goyvaerts¹, K. Lemaire¹, J. Van Schoors², G. Vojdani³, I. Smolders², P. in 't Veld⁴, A. Schraenen¹, F. Schuit¹;

¹Cellular and Molecular Medicine, KU Leuven, ²Pharmaceutical Chemistry and Drug analysis, VUB, Brussels, Belgium, ³Centre de Recherche de l'Institut du Cerveau et de la Moelle épinière, CNRS, INSERM, Université Pierre et Marie Curie, Paris, France, ⁴Diabetes Research Center, VUB, Brussels, Belgium.

Background and aims: In pregnant mice, placental lactogen induces Tph1, the rate-limiting enzyme of serotonin biosynthesis, in a subpopulation of pancreatic beta cells. This physiological process is recapitulated in non-pregnant mice by the artificial expression of the human growth hormone (hGH) minigene in many commonly used transgenic driver lines for islet and diabetes research. hGH has lactogenic effects in the mouse, by binding to prolactin receptors on beta cells. The physiological process during pregnancy and the common artifact in genetically modified mouse models raises the question what the function is of beta cell serotonin. It was suggested (but not confirmed) that serotonin acts locally on beta cell proliferation and insulin release. In order to find an answer, we examined the phenotype of Tph1-deficient mice.

Materials and methods: Beta cell-specific Tph1 knockout mice (Tph1betaKO) were generated by crossing Tph1fl/fl mice (Dr. Yadav, Cornell University, US) with Rip-creERR26LacZ mice that do not express hGH. Second, we re-analysed the total body Tph1KO mice which have serotonin-negative islets during pregnancy. Quantitative PCR was performed for islet transcripts encoding Ki-67 and for the 12 most induced genes during pregnancy ("islet pregnancy gene signature"). Islet serotonin was measured using HPLC and normalized for islet GABA content. Pancreas sections were used for serotonin immunohistochemistry and quantification of Ki-67/insulin double positive cells as an index for beta cell proliferation.

Results: To our surprise, the Tph1betaKO line maintained high islet [serotonin]/[GABA] ratios during pregnancy (Tph1betaKO versus Cre-control p=0.74, Flox-control p=0.27), despite an efficient and islet-specific recombination of the gene. The underlying mechanism is that genetic recombination in islets removes exons 2 and 3 of the gene, but leaves a downstream methionine codon in the correct reading frame for initiation of translation. Thus, Tph1betaKO beta cells produce a truncated but catalytically active TPH1. Taking a step back, we therefore used total Tph1KO mice for further studies. mRNA analysis in pregnant mice showed that Tph1 was not induced during pregnancy and there was no compensatory increment in Tph2 in WT mice. All but one of the genes of

the islets pregnancy gene signature remained unchanged in islets from pregnant Tph1KO mice, the exception being the gene encoding isovalerate dehydrogenase (Ivd) an enzyme needed for the catabolism of leucine. Importantly, neither Ki-67 mRNA signal, nor the percentage Ki-67 positive beta cells was decreased in pregnant Tph1KO mice.

Conclusion: The Tph1betaKO mouse which has already been used in literature, still has islet serotonin production during pregnancy and therefore cannot be used to investigate a serotonin-deficient islet phenotype during pregnancy. Total body Tph1KO mice with complete disappearance of islet serotonin production during pregnancy were statistically the same as WT mice in terms of islet Ki-67 mRNA signal and number of Ki-67-positive beta cells. Together, our data do not support the idea that islet serotonin stimulates beta cell proliferation during pregnancy.

Proinflammatory cytokines disrupt islet gap junction channels and calcium homeostasis early in development of diabetes in NOD mice
R.K.P. Benninger¹, N.L. Farnsworth², J. St.Clair¹;

¹Bioengineering, University of Colorado, ²University of Colorado, Aurora, USA.

Background and aims: Pro-inflammatory cytokines mediate β -cell decline and islet dysfunction in type1 and type2 diabetes. Cytokines disrupt islet Ca^{2+} , and disruption to islet Ca^{2+} , are observed in models of type 1 diabetes. In addition, there is a strong Ca^{2+} dependence to apoptosis mechanisms. Gap junction channels between islet β -cells regulate Ca^{2+} , and studies in models of type2 diabetes have indicated their disruption during disease progression. The goal of this study was to understand the role of altered Cx36 gap junction coupling in islet dysfunction during the progression of type1 diabetes and how pro-inflammatory cytokines may disrupt coupling.

Materials and methods: Ca^{2+} signaling, insulin secretion, cell viability and Cx36 gap junction coupling and Cx36 phosphorylation were measured in mouse and human islets treated with a cocktail of pro-inflammatory cytokines (10 ng/mL TNF- α , 5 ng/mL IL-1 β , 100 ng/mL IFN- γ), or in islets from NOD and NOD-RAG1ko mice at >6 weeks of age. Glucose tolerance tests (GTT) were administered in these mice. Genetic modulators of Cx36 and pharmacological modulators of Cx36, KATP, PKC δ , iNOS and NO donors/scavengers were also applied. Statistical significance was determined using ANOVA with Tukey's post-hoc analysis ($\alpha=0.05$).

Results: Low levels (up to 1/100 dilution) of pro-inflammatory cytokines disrupted Ca^{2+} signaling in terms of disrupted oscillations and increased basal activity ($p<0.005$). Cx36 gap junction coupling was also reduced under these conditions in mouse and human islets ($p<0.05$). This disruption was dependent on nitric oxide generation, PKC δ activation and phosphorylation of Cx36 (all $p<0.005$). Altered Ca^{2+} signaling ($p<0.05$) and decreased Cx36 gap junction coupling ($p<0.05$) was similarly observed as early as 6 weeks of age in NOD mice prior to the emergence of diabetes but in the presence of disruptions to glucose tolerance. Gap junction coupling, Ca^{2+} dynamics and glucose tolerance further declined with increasing age, prior to the onset of diabetes. Increased gap junction coupling in mouse and human islets reduced cytokine-induced disruptions to insulin release and β -cell death ($p<0.05$). Decreased gap junction coupling in mouse islets increased cytokine-induced disruptions to insulin release and β -cell death ($p<0.05$). This increase was reversed through inhibiting depolarization-induced Ca^{2+} elevations by KATP activation ($p<0.05$).

Conclusion: This study shows that gap junction coupling and Ca^{2+} regulation is highly-sensitive to disruption by conditions associated with the development of type1 diabetes, and discovers the mechanisms underlying its disruption in mouse and human models. This study also suggests this loss of gap junctions exacerbates cytokine-induced islet dysfunction and β -cell death later in disease progression through Ca^{2+} dependent mechanisms. As elevated gap junctions protects against this, this may provide a therapeutic target for delaying the onset of diabetes. Defining the mechanisms underlying gap junction disruption, may provide a means to modulate gap junctions for such a therapeutic strategy.

Overexpression of Fis1 leads dose-dependently to alterations of mitochondrial morphology and impairment of glucose-stimulated insulin secretion in INS1E beta cells

J. Schultz, T. Kantowski, R. Waterstradt, S. Baltrusch;

Institut of Medical Biochemistry and Molecular Biology, Rostock, Germany.

Background and aims: Mitochondria in living cells exist as a dynamic network that continuously cycle through fusion and fission events. Mitochondrial fission is mainly regulated by three proteins, the fission protein 1 (Fis1), the dynamin-related protein 1 (Drp1) and the mitochondrial fission factor (Mff). Numerous studies indicate that Fis1 is the key regulator for mitochondrial dynamics and, thus, essential to maintain mitochondrial function. Recent data questioned the need of Fis1 for mitochondrial network integrity and eventually proper insulin secretion in pancreatic beta cells. Therefore, the aim of this study was to investigate changes in the mitochondrial network structure and cellular function after overexpression of Fis1 in INS1E cells.

Materials and methods: Overexpression of Fis1 in INS1E cells was achieved by the pLUX lentiviral vector system. Scrambled lentiviral particles were used as control. Gene expression of Fis1 was carried out by quantitative Real-Time PCR and the protein level of Fis1 was determined using western blot and immunofluorescence analyses. The ATP content was measured using the ATPlite assay and glucose-stimulated insulin secretion by ELISA. The mitochondrial membrane potential and mitochondrial morphology was analyzed by means of TMRE and MitoTracker Green, respectively.

Results: Lentiviral Fis1 overexpression resulted in significantly enhanced gene and protein expression of Fis1 compared to control infected cells. We observed an impairment of ATP content and Glucose-stimulated insulin secretion was significantly impaired after enhancement of Fis1 in INS1E cells, whereas the control cells respond to the glucose stimulus. The ATP content was markedly reduced in Fis1 overexpressing cells compared to control infected cells. Likewise, the mitochondrial membrane potential and glucose content was significantly reduced in cells overexpressing Fis1 compared to control infected cells. INS1E cells as well as control infected cells showed an interconnected mitochondrial network with a homogenous structure. In contrast, a 10-fold overexpression of Fis1 resulted in fragmentation of mitochondria. Higher level of overexpression evoked dose-dependently formation of mitochondrial perinuclear clusters. In addition, we observed enhanced loop formation of mitochondria in cells with overexpression of Fis1.

Conclusion: Our results suggest that Fis1 is certainly important for beta cell metabolism and proper glucose-stimulated insulin secretion. Because the enhanced expression of Fis1 evoked a strong change in the mitochondrial morphology of INS1E cells, we propose to further characterize the role of Fis1 in regulation of mitochondrial dynamics and function in pancreatic beta cells in healthy and type 2 diabetic subjects.

Oxidative stress induced-autophagy might involve in pancreatic beta cells remodelling during neonatal mice through p53/pAMPK/mTOR/Beclin1 pathway

X. Wu¹, L. Gao¹, H. Zhang¹, H. Shi¹, J. Zhao¹, X. Zhao¹, K. Xu¹, M. Woo²;

¹Department of Endocrinology, First Affiliated Hospital with Nanjing Medical University, China, ²Division of Endocrinology, Department of Medicine, Toronto General Hospital, Toronto General Research Institute, Canada.

Background and aims: Pancreatic beta cells undergo dynamic remodeling during neonatal period to meet the increased physiological demands after weaning, with decreased proliferation, neogenesis and enhanced

apoptosis. Autophagy, a catabolic process of the lysosomal degradation of cellular components, has been found to be crucial in beta cell survival/function and body metabolism. However, whether autophagy involves in neonatal beta cells remodeling is unknown. This study was designed to explore the function and related molecular mechanisms of autophagy in beta cells remodeling during neonatal period.

Materials and methods: Mice islets at 1-, 3-, 8-week after birth were isolated by collagenase. The morphological structure of autophagosome was observed by electron microscope. Double immunofluorescence staining was performed for insulin with LC3. The expression of autophagy-related genes were detected by real-time quantitative PCR. The expression of the p53/pAMPK/mTOR/Beclin1/LC3-II proteins was detected by Western blotting. The expression of malondialdehyde (MDA) and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase subunits p22phox of islet cells were detected by lipid oxidation kit and immunohistochemistry respectively. Hydrogen peroxide (H₂O₂)-stimulated INS-1 cells were applied as a cell model of oxidative stress on beta cells. INS-1 cells were treated with PFT- α (the inhibitor of p53), the change of protein expression of p53/pAMPK/mTOR/Beclin1/LC3-II was detected by Western blotting.

Results: (1) Compared with 1 w and 8 w, the typical double-membrane autophagosome appeared within cytoplasm of islet cells at 3 w, the expression of p22phox, MDA and insulin+/LC3+ cells was significantly increased ($P < 0.01$) (2) The mRNA level of p53 was higher at 3 w than that at 1 w and 8 w ($P < 0.05$), while mTOR was lower than that at 1 w and 8 w ($P < 0.01$). The mRNA expression of the autophagy-related genes dynamically changed. Compared with 1 w and 8 w, the mRNA levels of ULK1, Becn1 and Map1lc3b markedly increased at 3 w ($P < 0.05$). Compared with 1 w, the levels of pik3c3, Atg5, Map1lc3a and Atg16l1 increased at 3 w ($P < 0.05$); the mRNA level of Atg4d was significantly increased at 3 w and 8 w ($P < 0.05$). At 3 w, the mRNA expression of Atg4c was higher than that at 8 w ($P < 0.05$). (3) Western blot showed that compared with 1 w and 8 w, the protein levels of p53, pAMPK, Beclin1 and LC3-II were markedly increased at 3 w ($P < 0.01$), while mTOR protein significantly decreased at 3 w ($P < 0.01$). (4) The MDA level of INS-1 cells after H₂O₂ stimulation was markedly increased in a dose dependent manner ($P < 0.01$), along with the markedly increased expression of LC3-II and p53. With the inhibitor of p53 to block the signaling pathway, the protein expression of p53/pAMPK/Beclin1/LC3II were significantly decreased, but the expression of mTOR increased in H₂O₂-stimulated INS-1 cells ($P < 0.05$).

Conclusion: Both autophagy and oxidative stress increase in islet cells at 3-week after birth. Oxidative stress induced-autophagy might involve in pancreatic beta cells remodeling during neonatal mice through p53/pAMPK/mTOR/Beclin1 pathway.

Evidence of beta cells dedifferentiation in human type 2 diabetes

F. Cinti¹, R. Bouchi², J. Kim-Muller², L.E. Ratner², M. Suleiman³, M. Masini³, L. Marselli³, P. Marchetti³, D. Accili²;

¹UnivPM-Department of Experimental and Clinical Medicine, Ancona, Italy, ²Columbia University, New York City, USA, ³University of Pisa, Italy.

Background and aims: Diabetes is associated with a deficit of insulin-producing β cells. Animal studies show that β cells become dedifferentiated in diabetes, reverting to a progenitor-like stage, and partly converting to other endocrine cell types. To determine whether similar processes occur in human type 2 diabetes, we surveyed pancreatic islets from 15 diabetic and 15 non-diabetic organ donors.

Materials and methods: We scored dedifferentiation, by immunohistochemistry, using markers of endocrine lineage (Synaptophysin and Chromogranin A), β cell-specific transcription factors (NKX6.1,

FOXO1, MafA), and a newly identified endocrine progenitor cell marker, aldehyde dehydrogenase 1A3 (ALDH1A3).

Results: Dedifferentiated cells, defined as Synaptophysin-positive/hormone-negative cells, accounted for 31.9% of β cells in type 2 diabetics vs. 8.7% in controls ($p < 0.001$). The expression and localization of transcription factors required for maintenance of β cells in rodents (FOXO1, NKX6.1, and MAFa) were altered in 84% of insulin positive cells in diabetics ($p < 1 \times 10^{-5}$) and associated with the expression of the progenitor cell marker ALDH1A3. Interestingly, insulin secretion in response to glucose was inversely correlated with the dedifferentiation score ($r = 0.55$, $p < 0.05$). Moreover, β cell-specific transcription factors were ectopically found in glucagon- and somatostatin-producing cells of diabetic subjects.

Conclusion: The data support the view that pancreatic β cells become dedifferentiated and convert to α - and δ -“like” cells in human type 2 diabetes. We envision dedifferentiation as a mechanism to protect β cells from apoptosis by stealth, preserving them for re-differentiation under more favorable metabolic conditions. The findings should prompt a reassessment of goals in the prevention and treatment of β cell dysfunction.

Palmitate-induced impairment of glucose-stimulated insulin secretion by pancreatic beta cells is disconnected from concomitant mitochondrial respiratory defects

C. Affortit¹, J. Barlow¹, V. Hirschberg Jensen¹, M. Jastroch²;

¹Plymouth University, UK, ²Institute for Diabetes and Obesity, Helmholtz Zentrum Muenchen, Germany.

Background and aims: Pancreatic beta cell mitochondria couple the oxidative breakdown of glucose to the synthesis of ATP and are essential for glucose-stimulated insulin secretion (GSIS). Indeed, mitochondrial respiratory activity might prove a good indicator of functional beta cell integrity, and insight in islet respiration may thus benefit transplantation protocols. With this study we aimed to clarify the connection between mitochondrial function and GSIS in pancreatic beta cells subjected to glucolipotoxic conditions.

Materials and methods: Islets isolated from C57BL/6 mice and INS-1E insulinoma cells were exposed for 24 or 48 hr to BSA-conjugated palmitate (free concentration 20–40 nM) in the presence of 11 mM glucose. Glucose sensitivity of oxidative phosphorylation was derived from absolute oxygen uptake rates measured in a Seahorse XF24, and insulin was quantified by ELISA. Respiratory activity and insulin secretion were normalised to islet DNA or INS-1E cell number determined from PicoGreen and DAPI fluorescence, respectively. Significance of palmitate effects was evaluated with Student's t-tests.

Results: Islets exposed to palmitate for 48 hr consume oxygen at a rate of 3.9 ± 0.5 pmol oxygen \times min⁻¹ \times ng DNA⁻¹ when incubated at 5.5 mM glucose. This respiratory rate is corrected for non-mitochondrial oxygen uptake and is indistinguishable from that exhibited by control islets exposed to BSA alone. Basal mitochondrial respiration increases to 8.2 ± 1.5 and 6.4 ± 0.8 pmol oxygen \times min⁻¹ \times ng DNA⁻¹ in control and palmitate-exposed islets, respectively, when glucose is raised to 28 mM. Normalised to basal mitochondrial oxygen uptake, palmitate lowers the islets' respiratory response to glucose from 2.5- to 1.7-fold ($P < 0.05$). This respiratory defect is echoed by GSIS impairment: 48-hr palmitate exposure lowers the islet insulin secretory response to glucose from 10.5-fold \pm 1.8 to 3.4-fold \pm 0.6 ($P < 0.001$). GSIS impairment results from an inhibitory palmitate effect ($P < 0.01$) on absolute insulin secretion at 28 mM glucose and a stimulatory effect ($P < 0.001$) on absolute basal insulin release at 5.5 mM glucose. GSIS impairment is also apparent after 24-hr palmitate exposure when the islet insulin secretory response to glucose has been lowered from 6.5-fold \pm 0.5 to 3.5-fold \pm 0.6 ($P < 0.01$). Importantly, after this relatively short exposure, palmitate has not yet significantly affected islet mitochondrial respiration. A disconnect between palmitate-induced

respiratory defects and GSIS impairment is also seen in INS-1E cells. After 24-hr exposure, palmitate lowers the insulin secretory response (secretion at 28 mM glucose normalised to insulin release by nutrient-starved cells) from 4.4-fold \pm 1.1 to 1.2-fold \pm 0.1 ($P<0.05$). This GSIS annulment results from palmitate stimulation of basal insulin release ($P<0.05$) and a small non-significant inhibition ($P=0.45$) of insulin secretion at 28 mM glucose. Concomitantly, palmitate lowers the normalised mitochondrial respiratory response to glucose of nutrient-starved INS-1E cells from 1.7 \pm 0.1 to 1.2 \pm 0.1 ($P<0.05$). This respiratory defect is exclusively caused by an inhibitory effect ($P<0.01$) of palmitate on absolute respiration at 28 mM glucose.

Conclusion: Palmitate-induced GSIS impairment in pancreatic beta cells is disconnected from mitochondrial respiratory defects.

Improved human type 2 diabetes beta cell function and survival by autophagy induction

M. Bugliani¹, M. Masini¹, F. Syed¹, S. Mossuto¹, M. Suleiman¹, L. Marselli¹, U. Boggi¹, F. Filipponi¹, D.L. Eizirik², M. Cnop², V. De Tata¹, P. Marchetti¹;

¹University of Pisa, Italy, ²Université Libre de Bruxelles, Belgium.

Background and aims: Cells degrade and recycle their components by autophagic processes. Autophagy alterations have been proposed to also cause beta cell dysfunction that lead to type 2 diabetes (T2D). We evaluated the effects of autophagy modulation in islets prepared from T2D and non-diabetic (ND) human donors, studied under several different experimental conditions.

Materials and methods: Islets were isolated from 5 T2D (age: 77 \pm 7 yrs; gender: 3 M/2 F; BMI: 23.9 \pm 3.7 Kg/m²) and 17 non-diabetic (ND; age: 65 \pm 21 yrs; gender: 5 M/12 F; BMI: 23.4 \pm 3.3 Kg/m²) organ donors. T2D and/or ND islets were then cultured for 1–5 days with 10 ng/ml rapamycin (autophagy inducer), or 5 mM 3-methyl-adenine (3MA) and 1.0 nM concanamycin-A (ConcA) (autophagy blockers), either in the presence or absence of metabolic (0.5 mM palmitate) or chemical (0.1 μ g/ml brefeldin A) inducers of endoplasmic reticulum (ER) stress.

Results: Compared to untreated T2D islets, rapamycin exposed (24 h) diabetic islets showed improved insulin secretion (glucose-induced insulin stimulation index from 1.6 \pm 0.8 to 2.1 \pm 1.1, $p=0.05$), reduced percentage of β cells showing signs of apoptosis (from 6.6 \pm 1.7 to 2.0 \pm 0.8% by electron microscopy, $p<0.05$) and better preserved insulin granules, mitochondria and ER ultrastructure. This was associated with significant reduction of PERK, CHOP and Bip gene expression (qRT-PCR). As expected, in ND islets palmitate exposure (5 days) induced a 4–5 fold increase of beta cell apoptosis (from 0.4 \pm 0.2 to 2.0 \pm 0.8%, $p<0.01$); this deleterious action was prevented by rapamycin (0.3 \pm 0.3%) and significantly exacerbated by 3-MA (7.0 \pm 1.1%) and ConcA (3.1 \pm 1.1%). Substantially similar results were observed with brefeldin treatment (24 h). Glucose-stimulated insulin secretion from ND islets was reduced by palmitate (40–50%) and brefeldin (60–70%); rapamycin prevented palmitate cytostatic action, but affected brefeldin effects marginally. Both palmitate and brefeldin induced PERK, CHOP and Bip gene expression, which was partially, but significantly prevented by rapamycin.

Conclusion: This study emphasizes the importance of autophagy in human beta cell function and survival, particularly in situations of ER stress. Modulation of autophagy could be a tool for beta cell protection strategies.

Mitochondrial dysfunction and diabetes predisposition

A. Kogot-Levin, I. Raz, S.W. Zangen;

Diabetes Unit, Hadassah University hospital, Jerusalem, Israel.

Background and aims: Pancreatic β -cells couple mitochondrial oxidation of glucose to ATP with insulin secretion. The Cohen diabetic sensitive rat (CDs), a genetic model of diet-induced diabetes, develops hyperglycemia when fed a diabetogenic, high sucrose diet (HSD) but maintains normoglycemia on regular-diet (RD). We previously demonstrated in CDs rats reduced glucose stimulated insulin secretion (GSIS) in association with altered mitochondrial morphology. We aim to examine islet-mitochondrial function and biogenesis in CDs and its role in diabetes development in CDs rats.

Materials and methods: Pancreatic islets were isolated from CDs and non-diabetic control rats fed 30 days RD, or a HSD. Activity of islet-mitochondrial respiratory chain enzyme, cytochrome-c oxidase (COX, complex IV), normalized to activity of citrate-synthase (CS) was determined spectrophotometrically. Gene expression was analyzed by qRT-PCR. Protein level was determined by Western-blot analysis. ATP content was measured by the luciferin-luciferase luminescence assay.

Results: Complex IV activity was ~50% reduced ($P<0.01$ vs. control) in islets isolated from normoglycemic-CDs fed RD, maintaining only small residual activity (~15%) in islets of hyperglycemic-CDs rats fed HSD. ATP content was 20% lower ($P<0.01$ vs. control) in islets of normoglycemic-CDs markedly reducing on HSD (60%, $P<0.01$ vs. control). Expression of complex IV subunits; COX2, COX4 and COX5b was decreased ($P<0.01$) in islets of normoglycemic-CDs-rats, decreasing furthermore on the diabetogenic-diet. Gene-expression of complex IV assembly chaperones (COX10, COX11, COX17 and SCO1) was unaltered in islets of normoglycemic-CDs rats. COX17 expression was 50% reduced in islets of hyperglycemic-CDs while the expression of the other the COX assembly factors were unchanged. COX1 protein levels was lower in islets of normoglycemic-CDs decreasing furthermore in islets of hyperglycemic-CDs rats. CDs-islet expression of mitochondrial biogenesis activators (NRF1, NRF2 and TFAM) was decreased; while PGC-1 α expression and protein levels as well as islets mtDNA content were unchanged.

Conclusion: We found a tight association between the significant reduction in islets-COX activity and GSIS in normoglycemic-CDs rats. Our data suggest that combination between reduced COX activity and mitochondrial biogenesis sets a congenital low mitochondrial threshold in islets of CDs rats. The low islet-COX threshold probably plays a critical role in the inability of the β -cells to secrete sufficient insulin to maintain the plasma glucose concentrations within the normoglycemic-range when exposed to a diabetogenic diet. The Cohen diabetic rat represents an interesting model to study molecular pathways underlying reduced GSIS and provides a good model to examine novel therapeutic intervention aimed at improving β -cell function.

464

Coxsackievirus B5 infection and CVB5 proteases 2A and 3C both increase caspase 3/7 activity independently from apoptosis and reduce insulin granule cargoes in beta cells

A. Petzold¹, K.-P. Knoch¹, A. Sönmez¹, C. Wegbrod¹, C. Münster¹, A. Friedrich¹, M. Roivainen², M. Solimena¹;

¹Paul Langerhans Institute Dresden of the Helmholtz Center Munich, at University Clinic and Faculty of Medicine, TUD, Germany, ²National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: Type 1 Diabetes (T1D) results from the autoimmune destruction of pancreatic beta cells. Major cargoes of the beta cell secretory granules (SGs), namely proInsulin/Insulin, ICA512/IA-2 and ZnT8/SLC308A are dominant autoantigens of T1D, but the reason(s)

for their preferential targeting by autoimmunity is unknown. Human Enteroviruses (HEVs), like Coxsackievirus B (CVB) are among the candidate environmental agents triggering and/or accelerating the development of T1D. However, the relationship between HEV infection and loss of self-tolerance toward SG cargoes is unclear. We previously showed that CVB5 infection of rodent islets and insulinoma cells inhibited the glucose-induced rapid up-regulation of total protein biosynthesis, but not that of SG precursor proteins, including proInsulin, proICA512, proPC1/3, proPC2 and proChromograninA. The corresponding mature SG cargoes and Insulin release were instead dramatically reduced. Thus, we investigated if and how HEV infection affects the expression of SG autoantigens that may favor their targeting by the immune system.

Materials and methods: Mouse insulinoma MIN6 cells were infected with Faulkner (F) or MIN6 cell adapted (MCA) CVB5 serotypes and compared to non-infected cells 96 h post-infection. Mouse pancreatic islets were harvested 72 h post-infection with CVB5 strains. MIN6 cells transfected with CVB5 proteases 2A and 3C were compared to mock transfected cells 96 h post-transfection. Proteasome activities were measured by luminescence assays and protein expression by immunoblotting.

Results: The reduction of mature SG proteins upon CVB5 infection was insensitive to proteasome inhibitors MG-115 and MG-132. However, in CVB5-infected cells the increased Caspase-, Trypsin- and Chymotrypsin-like proteolytic activities associated with the proteasome were insensitive to these inhibitors. CVB5-infection increased also Caspase 3/7 activity, which however was mostly insensitive to Caspase 3/7 inhibitor and not associated with enhanced apoptosis, as assessed by TUNEL and Annexin V staining, while necrosis was increased. Accordingly, cleavage of apoptotic markers Caspase 3/7 and Poly (ADP-ribose) polymerase (PARP) was not detected. Finally, the levels of Major Histocompatibility Complex class I molecules (MHC class I) were unchanged in CVB5 infected insulinoma cells, but increased in CVB5-infected mouse islets. Remarkably, expression of CVB5 proteases 2A and 3C, similarly to CBV5 infection, was sufficient to reduce the levels of mature SG proteins in MIN6 cells. Likewise, in proteases 2A and 3C transfected cells Caspase-, Trypsin- and Chymotrypsin-like activities associated with the proteasome as well as Caspase 3/7 activity were increased, albeit not apoptosis.

Conclusion: Our findings suggest that CVB5 proteases 2A and 3C target SG cargoes to massive degradation in conditions of reduced translation of housekeeping proteins, thus poisoning infected beta cells for preferential presentation of SG protein-derived peptides on MHC class I.

Role of PIAS1 in palmitate mediated beta cell dysfunction

A.I. Chowdhury¹, K. Hömaeus², J. Bergquist², P. Bergsten¹;

¹Medical cell biology, ²Chemistry Biomedical centre and SciLifeLab, Uppsala University, Sweden.

Background and aims: Elevated circulating free fatty acid levels, in particular palmitate, have been connected with development of type 2 diabetes mellitus (T2DM). The notion is supported by observed beta-cell dysfunction in islets after long-term treatment with palmitate. The protein inhibitor of activated STAT (PIAS) family consists of four members. Initially identified as negative regulators of STAT mediated signaling, they have since been implicated in regulating many transcription factors by blocking DNA binding activity, recruiting transcriptional co-repressors or co-activators and promoting protein sumoylation through SUMO E3 ligase activity. In a recent study PIAS1 suppressed the transcriptional activity of liver X receptor (LXR) in hepatocytes. LXR is involved in integrating lipid metabolism and the potential role of PIAS1 in lipid metabolism made us investigate the role of PIAS1 in islet dysfunction induced by chronically elevated palmitate levels.

Materials and methods: Human islets were cultured in the presence or absence of palmitate for 7 days. After culture, glucose-stimulated insulin secretion was measured by ELISA and levels of various proteins by western blot. PIAS1 interacting proteins were pulled down and identified using LTQ-Orbitrap mass spectrometer.

Results: Glucose-stimulated insulin secretion was decreased by 50% and apoptosis increased by 40% in human islets after long-term palmitate treatment. PIAS1 was present at the protein level in control islets and the level almost doubled after treatment with the fatty acid. PIAS1 interacting proteins included ATP citrate lyase (ACLY) and ATP synthase subunit 5 beta (ATP5B). In islets treated with palmitate the two proteins were significantly reduced. Overexpressing PIAS1 in beta-cells significantly reduced ACLY and ATP5B. Consistent with reduced ACLY levels in islets exposed to palmitate, levels of acetyl-CoA carboxylase (ACC) and fatty acid synthase (FAS) were also reduced in islets treated with the fatty acid.

Conclusion: Long-term palmitate treatment of islets increased levels of PIAS1, which in turn decreased ACLY and ATP5B protein levels implicating decreased lipogenesis as well as ATP synthesis. Elevated PIAS1 levels may thus contribute to altered lipid and energy metabolism reducing GSIS and increasing apoptosis.

Eukaryotic translation initiation factor 2A (eIF2A) protects pancreatic beta cells from ER stress-induced apoptosis by selective regulation of translational initiation

E. Panzhinskiy¹, F. Taghizadeh¹, Y. Yang¹, B. Hu¹, J.D. Johnson¹, E. Jan²;

¹Cellular and Physiological Sciences, ²Biochemistry, University of British Columbia, Vancouver, Canada.

Background and aims: Endoplasmic reticulum (ER) stress plays important role in beta cell death in diabetes. ER stress leads to activation of the unfolded protein response (UPR), which inhibits protein translation via phosphorylation of eIF2 α , and if unresolved induces apoptosis. eIF2A has been implicated in the translation of specific mRNAs under stress conditions, such as viral infection, when general translation is suppressed. Therefore, our specific hypothesis was that eIF2A plays a key role in regulation of mRNA translation during UPR in beta cells.

Materials and methods: Thapsigargin (Tg, 1 $\mu\text{mol/l}$), palmitate (PA, 0.5 mmol/l in BSA) were used to induce ER stress in mouse insulinoma cells (MIN6), primary mouse and human islets. Real-time RT-PCR and Western Blot were used to assess gene expression. Spinning disc confocal microscopy and ER tracker Blue-White DPX (Molecular Probes) were used for subcellular localization studies. Plasmid encoding GFP-tagged eIF2A was transfected using electroporation and cells were FACS sorted 72 hr later for the experiments. Apoptosis was assessed by live cell imaging of propidium iodide stained cells. Insulin secretion assay was performed using RIA. To assess protein synthesis cells were treated with 35S Met/Cys DMEM for 30 min, protein samples were collected and separated using SDS-PAGE, and radiation quantified.

Results: We showed that mRNA (3.7 \pm 0.5-fold, n=3) and protein (2.3 \pm 0.3-fold, n=6) expression of eIF2A was up regulated in MIN6 beta cells treated with Tg, suggesting an association with the UPR. PA also increased protein expression of eIF2A by 2.1 \pm 0.1 fold (n=3). The findings were confirmed using isolated mouse and human islets treated with Tg and PA. We found that eIF2A was predominantly localized in the ER under basal and UPR conditions (67.1 \pm 13% n=10). We showed 94.3 \pm 5.1% (n=3) reduction in thapsigargin-induced apoptosis in MIN6 cells overexpressing eIF2A (4-fold). On the protein level reduced death of beta cells was associated with 90.5 \pm 6.1% (n=3) decrease in protein expression of UPR pro-apoptotic marker CHOP. However eIF2A overexpression had no effect on induction of transcription of CHOP mRNA during UPR, indicating specific role of eIF2A in the inhibition of stress-induced translation of CHOP mRNA. Tg decreased insulin secretion by 54 \pm 11% (n=3) in MIN6 cells, however it was only decreased by 21 \pm 17% in cells overexpressing eIF2A. MIN6 cells showed decreased protein synthesis rate by 80.2 \pm 10% (n=3) after 2 hours of Tg treatment. However protein synthesis rate was unchanged in cells overexpressing eIF2A, despite normal induction of eIF2 α phosphorylation after Tg treatment. Immunoprecipitation of eIF2A showed increase in the interaction of eIF2A with eIF2 α during UPR in MIN6 cells with the maximum of 5.9 \pm 1.1 fold increase (n=3) after 24 hr of Tg treatment, which might explain uncoupling of translational initiation from eIF2 α phosphorylation in cells overexpressing eIF2A.

Conclusion: We conclude that eIF2A improves function of beta cells and prevents UPR-induced apoptosis. We identified a novel protective role for eIF2A in the context of ER-stressed beta cells via the selective inhibition of CHOP mRNA translation and prevention of global translation attenuation. Thus, eIF2A may potentially serve as a new therapeutic target in diabetes.

Lipotoxic stress induces pancreatic beta cell apoptosis through modulation of BCL-2 proteins by the ubiquitin-proteasome system

E.N. Gurzov, S.A. Litwak, J.A. Wali, E.G. Pappas, H. Saadi, W.J. Stanley, L.C. Varanasi, T.W.C. Kay, H.E. Thomas; Immunology and Diabetes Unit, St Vincent's Institute, Melbourne, Australia.

Background and aims: Previous studies have shown induction of endoplasmic reticulum (ER) stress, increased levels of ubiquitinated proteins, and deregulation of the Bcl-2 protein family in the pancreas of type 2 diabetic patients. Here, we evaluated the role of the saturated free fatty acid (FFA) palmitate in modulation of the ubiquitin-proteasome system (UPS) and β -cell apoptosis.

Materials and methods: UPS activity was assessed by immunohistochemistry in lean and obese human and mouse samples. Real time PCR, Western blot, and viability assays were performed to study the molecular mechanism of palmitate-induced β -cell death in human and mouse islets and MIN6 cells. β -cell function and islet apoptosis triggered by diabetogenic conditions were analysed in Bcl-2 transgenic mice (RIP-Bcl-2).

Results: To examine the effect of obesity on the UPS in islets, we stained pancreatic sections of lean and obese [body mass index (BMI) $>$ 25 kg/m²] humans with anti-ubiquitin antibody. In obese human samples, there was an increased prevalence of ubiquitinated proteins in pancreatic islets when compared to lean controls. Similar results were obtained in pancreata from mice fed a high fat diet for 24 weeks. To determine whether exposure to increased FFAs had a role in the increased ubiquitin staining observed in obese subjects, human islets were treated with palmitate and levels of ubiquitinated proteins were measured by Western blot analysis. We observed an increase in the levels of ubiquitinated proteins after palmitate treatment in human islets. Similar results were obtained in mouse islets and MIN6 cells (1.5 fold increase in ubiquitination, n=4, p<0.05). Moreover, after 24 h treatment with either palmitate or the UPS inhibitor MG132, there was a significant increase in cell death (15% cell death in palmitate-treated cells, 28% cell death in MG132-treated cells, 1–2% cell death in control cells, n=5, p<0.001). Palmitate or MG132 treatment induced ER stress in β -cells (ATF4, Chop and Bip activation), resulting in decreased expression of the pro-survival proteins Bcl-2 and Bcl-XL, and upregulation of the pro-death BH3-only protein PUMA. On the other hand, pharmacological activation of the UPS by sulforaphane (SFN) ameliorated ER stress, upregulated anti-apoptotic Bcl-2 proteins and protected β -cells from palmitate-induced cell death (21% cell death in palmitate-treated cells, 7% cell death in palmitate and SFN-treated cells, 3–4% cell death in control cells, n=5, p<0.05). Furthermore, transgenic overexpression of Bcl-2 protected islets from apoptosis in vitro (45% cell death in palmitate-treated wild-type islets, 32% cell death in palmitate-treated RIP-Bcl-2 islets, 16–22% cell death in control islets, n=4, p<0.05) and improved glucose-induced insulin secretion in vivo.

Conclusion: Our results suggest that the FFA palmitate inhibits the UPS, causing β -cell apoptosis, and that this effect could be reversed by activation of the proteasome. The mechanism of β -cell death involves the deregulation of Bcl-2 proteins via activation of ER stress signaling. In this context, overexpression of the pro-survival protein Bcl-2 improved β -cell function in a mouse model of obesity. Overall, our data clarify the mechanism by which FFAs induce β -cell death and provide therapeutic targets to improve glucose homeostasis in type 2 diabetes.

Role of Sirtuin 3 (Sirt3) in the regulation of pancreatic beta cell function

Y. Zhou¹, A.C.K. Chung^{1,2}, H. Lee¹, G. Xu^{1,3}, J.C.N. Chan^{1,4}, A.P.S. Kong^{1,4};

¹Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Shatin, ²Partner State Key Laboratory of Environmental and Biological Analysis, The Hong Kong Baptist University, Kowloon Tong, ³School of Chinese Medicine, The Hong Kong Baptist University, Kowloon Tong, ⁴Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Shatin, Hong Kong.

Background and aims: Pancreatic beta cells play an important role in the pathogenesis of type 2 diabetes (T2D). Beta cells are extremely vulnerable to pathological conditions such as hyperglycemia and hyperlipidemia. Sirt3 is a mitochondrial deacetylase which regulates a series of cell metabolic pathways including glucose and fatty acid oxidation. We aimed to investigate the role of Sirt3 in the regulation of beta cell function.

Materials and methods: Sirt3 mRNA and protein expression levels of MIN6 pancreatic beta cell line and isolated mouse islets were measured after free fatty acid (FFA) treatment. Sirt3 was overexpressed or knocked down in MIN6 cells and primary islets to evaluate its role on beta cell function. Sirt3 knockout (KO) mice and wild type (WT) mice were treated with high fat diet (HFD) or standard diet (STD) for 3 months (n=7 for each STD feed group, n=8 for each HFD feed group). Body weight and blood glucose levels were measured every week. Oral glucose tolerance test

(OGTT) and insulin tolerance test (ITT) were performed after mice were fed with STD or HFD. During OGTT, blood samples were collected for insulin level determination in addition to blood glucose measurements.

Results: Exposure of MIN6 cells and primary islets to FFA decreased Sirt3 expression and impaired glucose stimulated insulin secretion (GSIS). However, overexpression of Sirt3 partially rescued FFA induced impairment on insulin secretion. This protective effect was abolished after intervention with protein kinase A (PKA) specific inhibitor H89. Knock down of Sirt3 in MIN6 cells attenuated glucose stimulated ATP generation (7.00 ± 0.49 vs. 4.71 ± 0.38 pmol/ μ g protein, $p < 0.001$), CREB phosphorylation and PPAR γ expression. Besides, the GSIS of MIN6 cells was also decreased after Sirt3 siRNA transfection (1.13 ± 0.32 vs. 0.58 ± 0.15 ng/ μ g protein, $p < 0.05$). Similar changes were observed in islets isolated from Sirt3 KO mice. However, these impairments in beta cells function were ameliorated after re-expression of Sirt3 in Sirt3 KO islets via Sirt3 adenovirus infection. After 3 months of HFD feeding, glucose tolerance of both Sirt3 KO and WT mice were impaired with a higher magnitude observed in Sirt3 KO mice (glucose AUC: HFD feed WT vs. KO = 1102 ± 88.42 vs. 1328.25 ± 52.22 mmol \cdot L $^{-1}\cdot$ min $^{-1}$, $p < 0.05$). In addition, the fasting serum insulin level was decreased in Sirt3 KO mice compared with WT mice after both STD and HFD feeding (STD feed WT vs. KO = 0.033 ± 0.012 vs. 0.0042 ± 0.00060 ng/ml, $p < 0.05$. HFD feed WT vs. KO = 0.042 ± 0.015 vs. 0.0039 ± 0.00023 ng/ml, $p < 0.05$). The GSIS of Sirt3 KO mice was also significantly reduced compared with WT mice after both STD and HFD feeding (STD feed WT vs. KO = 0.160 ± 0.029 vs. 0.031 ± 0.023 ng/ml, $p < 0.01$; HFD feed WT vs. KO = 0.240 ± 0.040 vs. 0.130 ± 0.027 ng/ml, $p < 0.05$).

Conclusion: Sirt3 is involved in the regulation of insulin secretion in pancreatic beta cells under physiological condition and after HFD. Over-expression of Sirt3 protects pancreatic beta cells from FFA induced dysfunction possibly through a PKA/CREB dependent pathway.

Downregulation of TxNIP under glucolipotoxic conditions in insulin secreting cells

M. Panse¹, G. Kaiser^{1,2}, F. Gerst^{1,2}, H.-U. Häring^{1,2}, S. Ullrich^{1,2}; ¹Internal Medicine IV, Endocrinology, Diabetology, Angiology, Nephrology and Clinical Chemistry, University Hospital Tübingen, ²Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tübingen (IDM of the DZD e.V.), Germany.

Background and aims: Glucose dependent stimulation of TxNIP is speculated to play a role in glucotoxicity, by inhibiting the ROS scavenger thioredoxin, thereby, increasing oxidative stress. Upregulation of TxNIP by glucose occurs via ChREBP dependent transcriptional activation. This activation is negatively regulated by the transcription factor FOXO1. The glucose dependent stimulation of TxNIP is counteracted by fatty acids. We have previously observed that palmitic acid lowers TxNIP mRNA levels both in a FFAR1 dependent and independent manner. Although the FFAR1 dependent pathway does not involve PKC δ or FOXO1, INS-1E cells overexpressing PKC δ contain significantly lower TxNIP mRNA levels than control INS-1E cells. The present study attempts to identify the detailed mechanisms of TxNIP mRNA regulation. **Materials and methods:** INS-1E cells were cultured under standard culture conditions (11 mmol/l glucose, 10% FCS) and protein expression was downregulated by siRNA. After 48 h of culture, cells were treated with palmitic acid (60 and 600 μ mol/l) or the FFAR1 agonist TUG-469 (3–10 μ mol/l). Inhibitors were added 1 h prior to palmitic acid. Changes in expression were analysed by qRT-PCR and western blot.

Results: To examine the role of FOXO1 in TxNIP mRNA regulation, INS-1E cells were incubated with the pan protein kinase B (Akt/PKB) inhibitor Akti-1/2, which triggers dephosphorylation and nuclear accumulation of FOXO1. Akti-1/2 (10 μ mol/l) did not lower but rather increased glucose (11 mmol/l) induced TxNIP mRNA levels. In

accordance, in PKC δ overexpressing INS-1E cells, which have low TxNIP mRNA levels, phosphorylation of Akt/PKB and nuclear phospho-FOXO1 was significantly higher than in control INS-1E cells. These observations suggest that glucose induced TxNIP expression might be antagonized by phosphorylated but not by dephosphorylated FOXO1. Since palmitic acid transiently reduced Akt/PKB phosphorylation, palmitic acid induced TxNIP downregulation is probably mediated by other pathways. FFAR1 induced enhancement of insulin secretion depends on the stimulation of phospholipase C (PLC) and protein kinase D1 (PKD1) and therefore, we examined whether these enzymes exert effects on TxNIP mRNA levels. While the PLC inhibitor U73122 (1 μ mol/l) counteracted FFAR1 dependent reduction of TxNIP mRNA levels, the downregulation of PKD1 by siRNA had no effect. In addition, the inhibition of ERK1/2 by PD98059 (10 μ mol/l) did not affect TxNIP mRNA levels. Finally, the stress kinase JNK, which plays a crucial role in palmitic acid induced β -cell death, was inhibited by SP600125 (10 μ mol/l). The inhibitor did not counteract the effect of palmitic acid but itself reduced TxNIP mRNA levels.

Conclusion: In insulin secreting cells, TxNIP mRNA levels are rapidly and reversibly regulated by a variety of pathways including Akt/PKB, JNK and PLC.

Role of very long chain fatty acid elongase 2 (Elovl2) in the regulation of pancreatic beta cell dysfunction induced by gluco-lipotoxicity

L. Bellini¹, M. Campana¹, A. Machel¹, J. Véret¹, M. Chacinska², N. Kassis¹, A. Blachnio-Zabielska², M. Ibberson³, C. Bernard⁴, B. Thorens³, C. Cruciani-Guglielmacci¹, C. Magnan¹, H. Le Stunff¹; ¹BFA team 2, University Paris Diderot, France, ²Medical University of Bialystok, Poland, ³University of Lausanne, Switzerland, ⁴Institut de Recherches Servier, Suresnes, France.

Background and aims: The IMIDIA program (<http://www.imidia.org/>) aims to identify new targets involved in β cell dysfunctions induced by obesity. To achieve this goal, RNAseq analyses have been performed on isolated islets of Langerhans from mice under high fat diet and controls. Using bioinformatical analysis, we found that expression of Elovl2 was correlated with glucose intolerance. This enzyme is involved in the production of poly-unsaturated fatty acids, such as decosahexaenoic acid (DHA). Therefore, our project aimed to determine the role of Elovl2 in β cell dysfunction induced by saturated fatty acids and high glucose concentrations, a phenomenon defined as gluco-lipotoxicity.

Materials and methods: Pancreatic cell lines (INS-1 and MIN6) or islets of Langerhans have been incubated with 0.4 mM of palmitate and 30 mM of glucose. Elovl2 expression has been determined by real-time PCR and Western-Blot. The role of Elovl2 has been determined using a stable cell line over-express it or by adding its product, DHA, on the β cells. Insulin secretion (ELISA test) and apoptosis (detection of caspase 3/7 activity and PARP cleavage by western blot) of pancreatic β cells have been determined. Ceramide production has been quantified through a DAG kinase test and lipidomics.

Results: We found that gluco-lipotoxicity inhibits Elovl2 expression in β cells. Addition of DHA to the incubation medium can partially restore insulin secretion induced by glucose. DHA also inhibits caspases-3/7 activation and PARP cleavage induced by gluco-lipotoxicity. Interestingly, stable Elovl2 over-expressing cells are partially protected from apoptosis induced by gluco-lipotoxicity. We also found that adding DHA and over-expressing Elovl2 inhibit ceramides production induced by gluco-lipotoxicity.

Conclusion: Our results show that Elovl2, through DHA production, can counteract the deleterious effects induced by gluco-lipotoxicity by blocking ceramide synthesis.

Enhancer of Zeste Homolog 2 (EZH2) is a molecular switch in HDAC3-mediated glucolipotoxicity in beta cells

T. Dahlby¹, M.B. Backe¹, M.S. Dahllof¹, C. Simon², E. Holson³, B. Wagner³, M. Lundh², T. Mandrup-Poulsen¹;

¹Department of Biomedical Sciences, University of Copenhagen, ²University of Copenhagen, Denmark, ³Broad Institute, Cambridge, USA.

Background and aims: Type 2 diabetes (T2DM) is caused by relative insulin deficiency arising when pancreatic β -cell insulin secretion fails to compensate for insulin resistance. Elevated blood free fatty acids and later glucose are mediators of progressive β -cell failure in T2DM. Posttranslational modifications by acetylation and methylation of the histone backbone in chromatin are important epigenetic modulators of gene transcription. We previously showed that inhibition of histone deacetylase (HDAC) 3 reverts deleterious effects of β -cell glucolipotoxicity (GLT), but the molecular mechanisms are unclear. The aim of this study was to investigate the mechanisms by which β -cell dysfunction and apoptosis by HDAC3-mediated glucolipotoxicity (GLT) can be reverted by HDAC3-inhibition.

Materials and methods: mRNA microarray was performed on samples from the rat β -cell line INS-1E exposed to a diabetic milieu (25 mM glucose and 0.5 mM palmitate) in the presence or absence of the HDAC3-selective inhibitor BRD3308 and validated by RT-qPCR. Microarray data was analyzed by fold-change and the 400 top scoring genes from each set and the intersecting gene sets were analyzed to find enriched transcription factors (TF) by employing the ENCODE ChIP-Seq Significance Tool. EZH2 inactivation was performed by overexpression of four different EZH2 shRNAs in INS-1E cells, confirmed by real-time PCR and Western blotting. Empty vector (EV) served as control (ctrl). EZH2 knock-down cells were exposed to 25 mM glucose and 0.5 mM palmitate, and β -cell apoptosis was analyzed by quantitative in vitro determination of cytoplasmic histone-associated DNA fragments (Roche). Data was analyzed by two-tailed, paired Student's t-test.

Results: The mRNA microarray data revealed 52 genes differentially regulated by nutrient overload (glucolipotoxicity, GLT) with or without specific HDAC3-inhibitor. The microarray was validated by qRT-PCR of 6 genes selected for their differential expression pattern which was confirmed in 5/6 cases. By unbiased bioinformatics analysis of the mRNA microarray data we found that the histone methyltransferase (HMT) and TF Enhancer of zeste homolog 2 (EZH2) is a key transcriptional regulator in HDAC3 inhibitor treated insulin-producing cells exposed to GLT. We achieved ~70% knock down of EZH2 with sh-1 and ~40% knock down with sh-4 and somewhat lower knock-down by sh-2 and -3. Pronounced shRNA mediated knock-down of EZH2 (sh-1) aggravated whereas partial knock-down (sh-4) protected against GLT-induced β -cell apoptosis (p-value of n=4: ** p<0.01, * p<0.05, Figure 1).

Conclusion: Our results identified EZH2 as a novel molecular switch regulating glucolipotoxicity-induced β -cell dysfunction and apoptosis. The possibility that the bimodal role of EZH2 on β -cell viability is conferred by the dual action of EZH2 as HMT and TF is under investigation.

PKCdelta is a key regulator of palmitate-induced beta cell death

M. Shiozaki¹, K. Fujimoto¹, T. Sasaki², K. Yoshida³, K. Utsunomiya¹;
¹Division of Diabetes, Metabolism and Endocrinology, Department of Internal Medicine, ²Institute of Clinical Medicine and Research, ³Department of Biochemistry, The Jikei University School of Medicine, Tokyo, Japan.

Background and aims: High glucose and fatty acid (FA) levels induce beta cell dysfunction and cell death, leading to a condition known as glucolipotoxicity. Both FAs and glucose are metabolized to diacylglycerol which activates novel protein kinase C (PKC), including PKCdelta. Although activated PKCdelta is implicated in cell death, the molecular mechanisms involved in the role of PKCdelta in beta cells are yet to be fully defined. The aim of this study was to elucidate PKCdelta's molecular mechanism during glucolipotoxicity in beta cell death.

Materials and methods: Mouse insulinoma (MIN6) cells were incubated with 25 mmol/l glucose with or without 0.4 μ mol/l palmitate for 72 h. Phosphorylation of PKCdelta and protein expression of Pdx1 were analyzed by Western blotting. Translocation of PKCdelta was studied by PKCdelta staining and Western blotting. Cell death was assessed with Annexin V and propidium iodide. PKCdelta knockdown was performed using a lentiviral vector followed by a cell death assay. To study the molecular mechanism in vivo, we created beta cell specific *Pkcd*^{-/-} mice (bPKCDKO) and treated them with 50 mg/kg streptozotocin (STZ) in the neonatal period (type 2 diabetes model). These mice were fed either a normal diet (ND) or a high fat diet (HFD). Intraperitoneal (i.p.) glucose tolerance tests were performed after a 16-h fast. Alpha/beta cell architecture and mass were assessed by insulin/glucagon staining, and beta cell death was assessed by TUNEL staining.

Results: Palmitate phosphorylated PKCdelta, with no change in whole PKCdelta protein expression in MIN6 cells, suggested PKCdelta activation. Although in the normal state, PKCdelta was localized in the cytoplasm, palmitate induced a nuclear translocation of a full length and a catalytically active fragment of PKCdelta. During palmitate treatment, the number of Annexin V positive cells significantly increased. Furthermore, palmitate phosphorylated Pdx1 at T11, and reduced the expression of Pdx1 protein, implicating PKCdelta induced MIN6 cell death via Pdx1 down regulation. To confirm the involvement of PKCdelta in palmitate induced MIN6 cell death, PKCdelta was knocked down. PKCdelta deficiency prevented the development of palmitate induced Annexin V-positive cells by 28% (p 0.05). bPKCDKO mice treated with STZ and HFD showed improved glucose tolerance compared with mice fed ND, accompanied by improved insulin secretion. Although HFD-fed control mice treated with STZ showed reduced beta cell mass and disturbed alpha/beta cell architecture, PKCdelta deficiency in beta cells ameliorated beta cell mass to about 70% (p<0.05) and disturbed alpha/beta cell

architecture. PKCdelta deficiency in beta cells also showed a reduction in beta cell apoptosis by 46% ($p < 0.05$).

Conclusion: Under glucolipotoxic conditions, PKCdelta is activated, followed by the downregulation of Pdx1, which results in beta cell death. In vivo, beta cell specific PKCdelta deficiency ameliorates beta cell mass and insulin secretion, as a result of reduced beta cell apoptosis. Our results suggest that palmitate induces beta cell death via a PKCdelta/Pdx1 dependent pathway. It may serve as fundamental knowledge pertaining to novel approaches toward diabetes, by targeting the PKCdelta/Pdx1 pathway.

PS 028 Beta cell injury: apoptosis

473

NPY Y1 receptor stimulation protects against cytokine-induced apoptosis in mouse islets

Z.J. Franklin, S.J. Persaud, G.A. Bewick;

Diabetes and Nutritional Sciences, King's College London, UK.

Background and aims: NPY receptor stimulation has proliferative actions and protective effects against programmed cell death in a number of tissues, but little is known about the protective effects of NPY receptor activation on beta cell survival. We have identified Y1 receptors as the most abundant sub-type in mouse islets. Therefore, we investigated the potential protective role of Y1 receptor activation in mouse islets.

Materials and methods: Isolated mouse islets were treated for 24–48 h with the Y1 receptor agonist Leu³¹Pro³⁴-NPY (1 nmol/l–1 μmol/l) alone or in combination with the Y1 antagonist BVD10 (100 nmol/l–1 μmol/l) or the PLC inhibitor U73122 (10 μmol/l) in the absence or presence of a cytokine cocktail (IL-1β, 50 U/ml; TNF-α, 1000 U/ml, IFN-γ, 1000 U/ml) for the last 24 h of incubation. Apoptosis was measured by caspase glo 3/7 activity and insulin secretion by RIA.

Results: Treatment of mouse islets for 48 hours with Leu³¹Pro³⁴-NPY (1 nmol/l–1 μmol/l) protected against cytokine-induced apoptosis (mixed cytokine response: 100%; 60±2%, 67±5%, 54±2%, 69±7% with 1 nmol/l, 10 nmol/l, 100 nmol/l and 1 μmol/l Leu³¹Pro³⁴-NPY respectively, $p < 0.01$ – $p < 0.001$, $n = 8$). Furthermore, pre-treatment with 1 nmol/l Leu³¹Pro³⁴-NPY for 24 h followed by cytokine exposure alone and 1 nmol/l Leu³¹Pro³⁴-NPY treatment in the presence of cytokines for 24 h without pre-treatment significantly protected mouse islets against cytokine-induced apoptosis (mixed cytokine response: 100%; pre-treatment: 61±5%, $p < 0.001$; no pre-treatment: 71±5%, $p < 0.01$, $n = 8$). The selective Y1 receptor antagonist BVD10 did not inhibit islet apoptosis induced by cytokines when administered alone (100 nmol/l BVD10: 98±22%; 1 μmol/l BVD10 139±27% of the mixed cytokine response, $p > 0.2$, $n = 8$), but reversed the anti-apoptotic effect of Leu³¹Pro³⁴-NPY (1 nmol/l Leu³¹Pro³⁴-NPY + 100 nmol/l BVD10: 78±13%; 10 nmol/l Leu³¹Pro³⁴-NPY + 1 μmol/l BVD10: 109±14% of the mixed cytokine response, $p < 0.05$ – $p < 0.01$, $n = 8$), indicating the protective effect is likely via Y1 receptors. Inhibiting PLC activity with U73122 reversed the anti-apoptotic effects of Leu³¹Pro³⁴-NPY (10 μmol/l U73122+1 nmol/l Leu³¹Pro³⁴-NPY: 110±13% of the mixed cytokine response, $p < 0.01$, $n = 6$), whilst having no protective effect on cytokine-induced apoptosis when administered alone (10 μmol/l: 109±17% of the mixed cytokine response, $p > 0.2$, $n = 6$), suggesting that the anti-apoptotic properties of Y1 receptor activation may be mediated through a PLC signalling cascade. As expected, acute exposure to Leu³¹Pro³⁴-NPY inhibited glucose-induced insulin secretion when used at 1 μmol/l (2 mmol/l glucose: 0.6±0.05 ng islet⁻¹ h⁻¹; 20 mmol/l glucose: 2.5±0.5; 1 μmol/l Leu³¹Pro³⁴-NPY: 0.9±0.3, $p < 0.05$, $n = 8$), but it had no effect at 1 nmol/l–100 nmol/l (all $p > 0.2$, $n = 8$). In addition, 48 h exposure to Leu³¹Pro³⁴-NPY (1 nmol/l–100 nmol/l) had no significant effect on glucose stimulated insulin secretion (all $p > 0.2$, $n = 8$).

Conclusion: These results indicate that NPY Y1 receptor stimulation can protect against cytokine-induced apoptosis in mouse islets at low concentrations without inhibiting glucose-stimulated insulin secretion.

Hypoxia induces beta cell death by inhibiting the adaptive UPR

M. Bensellam¹, E. Maxwell¹, J.-C. Jonas², J. Chan¹, D.R. Laybutt¹;
¹Diabetes and Obesity, Garvan Institute of Medical Research, Sydney, Australia, ²Pôle d'endocrinologie, diabète et nutrition, Université catholique de Louvain, Brussels, Belgium.

Background and aims: Hypoxia is implicated in the loss of functional beta cell mass in type 2 diabetes and with islet transplantation, although the mechanisms are unknown. The adaptive unfolded protein response (UPR) is required for endoplasmic reticulum (ER) homeostasis and beta cell integrity. Here we investigated the influence of hypoxia on the adaptive UPR and the role it plays in apoptosis.

Materials and methods: Isolated mouse islets and MIN6 cells were exposed to various O₂ tensions. Ddit3 (Chop) and Hif1 α were inhibited using siRNA. Hspa5 (Bip) was overexpressed using a plasmid vector. JNK was inhibited using SP600125. UPR and hypoxia-response gene expression was assessed in islets from prediabetic and diabetic db/db mice and age-matched lean control mice. mRNA and protein levels were measured by real-time RT-PCR and western blot. Apoptosis was measured by DNA fragmentation ELISA.

Results: Deprivation of O₂ (1% vs 20%) for 4–24 h markedly reduced the mRNA and protein levels of adaptive UPR genes, including Hspa5, Hsp90b1 and Fkbp11 as well as the activation of Xbp1 (splicing) and PERK (phosphorylation). Opposing effects were observed in MEF cells suggesting that hypoxia specifically inhibits the adaptive UPR in beta cells. This was accompanied by upregulation of integrated stress response (ISR) genes, including Ddit3, Atf3 and Trb3 along with increased phosphorylated EIF2A. Interestingly, Ddit3 knockdown significantly increased adaptive UPR gene expression in association with partial protection against hypoxia-induced apoptosis ($p < 0.05$). Moreover, Hspa5 overexpression alone partially protected against hypoxia-induced apoptosis ($p < 0.01$). JNK inhibition, but not Hif1 α knockdown, partially prevented the hypoxia-mediated loss of adaptive UPR gene expression and protected against hypoxia-induced apoptosis ($p < 0.01$). Finally, mRNA levels of hypoxia-response genes, including Hyou1, Tpi1, Gapdh and Eno1, were markedly upregulated in vivo in the islets of diabetic db/db mice, but not in prediabetic db/db mice, suggesting that islet hypoxia correlates with beta cell failure. Interestingly, the upregulation of hypoxia-response genes further correlate with downregulation of adaptive UPR gene expression in diabetic db/db islets.

Conclusion: Hypoxia inhibits the adaptive UPR in beta cells partially via Ddit3 and JNK activation, but independently of Hif1 α . Downregulation of the adaptive UPR contributes to hypoxia-induced beta cell apoptosis and may play a role in the loss of functional beta cell mass in type 2 diabetes. *Supported by: SFD (Paris, France) and NHMRC and ARC of Australia*

The L-type calcium channel beta1 subunit is essential for preventing apoptosis in beta cells

A. Kazim, E. Zhang, E. Renström;
 Lund University, Malmö, Sweden.

Background and aims: Voltage-gate calcium channels (Cav) play a pivotal role as triggers of insulin secretion. Genetic variants in genes encoding the pore-forming Cav α 1 subunits determine the human beta-cell phenotype and affect the risk of type 2-diabetes. The functions of the auxiliary Cav β subunits are only patchily explored, but they are proposed to modulate of translocation and stability of the α 1 subunits. Supporting this idea, Cav β 3 was previously shown to suppress Ca²⁺-oscillations in mouse beta-cells. Furthermore, Cav β 2 is subject to palmitoylation, which could serve as a regulatory signal for α 1 function. To clarify this we have investigated gene co-expression with Cav β in human islets and explored the effects of all Cav β subunits (1–4) in beta-cell function.

Materials and methods: Insulin secretion. Calcium imaging. Immunoblotting. Viability assay.

Results: Microarray analysis of gene expression in human islets revealed that the different Cav β subunit genes (CACNB1, CACNB2, CACNB3, CACNB4) significantly correlated primarily with genes encoding other Cav subunits, structural proteins, as well as apoptosis-regulating proteins. For example, CACNB1, -2, -4 correlated with EIF3E that was recently demonstrated to control translocation of Cav α 1. These results support the idea that Cav β may interfere with beta-cell function and viability. In addition, CACNB1 and CACNB2 both exhibited a negative correlation vs. HbA1c of the islet donors. Next, we investigated the effects of silencing the different Cav β subunits on glucose-stimulated insulin secretion in INS(832-13)cells. Gene silencing (72 h) was efficient as verified on the protein level by immunoblotting and for e.g. Cav β 1 it amounted near >95%. Interestingly, silencing of Cav β 2, Cav β 3 and Cav β 4 failed to affect insulin release under either basal or stimulatory conditions. By contrast, reduced Cav β 1 expression resulted in increased insulin release under both basal and stimulated conditions. Based on these results, we next focused on Cav β 1 and explored depolarization-evoked increases in cytoplasmic Ca²⁺ concentration ([Ca²⁺]_i) in Cav β 1-silenced cells. Surprisingly, this resulted in a 76% decrease in [Ca²⁺]_i evoked by high K⁺ (9.8 \pm 1.09 vs. 2.3 \pm 0.23 fluorescence intensity; $P < 0.001$), whilst not affecting basal [Ca²⁺]_i. This result contrasts with the observed increased insulin release. In an attempt to explain this we next investigated cell viability (EthD-1 & Calcein AM) and found that this was severely compromised in Cav β 1-silenced cells (0.46 \pm 0.21 vs. 7.8 \pm 0.098 percentage cells; $P < 0.001$). This was due to increased apoptosis as assessed by immunoblotting of cleaved caspase 3, which increased by 300% in Cav β 1-silenced cells.

Conclusion: Cav β 1 affects Ca²⁺-homeostasis in the beta-cell, but is essential for beta-cell viability. Silencing of Cav β 1 results in increased apoptosis in a non-Ca²⁺ dependent fashion.

A dual approach with Siglec-7: it inhibits macrophage infiltration into human islets and restores beta cell function and survival

M. Hauke¹, G. Dharmadhikari¹, K. Stolz¹, S. Kelm¹, J. Kerr-Conte², K. Maedler¹;

¹Centre for Biomolecular Interactions, University of Bremen, Germany, ²Thérapie Cellulaire du Diabète, University of Lille 2, France.

Background and aims: In both, type 1 and type 2 diabetes mellitus cytokine and chemokine production and infiltrating immune cells are hallmarks of islet inflammation. Siglecs (Sialic-acid binding immunoglobulin like lectins) are cell surface receptors expressed on haematopoietic cells, they balance immune responses by immunoreceptor tyrosine-based inhibitory motifs (ITIMs), which recruit tyrosine phosphatases and eventually inhibit activation signals transduced from pattern recognition receptors. Siglec-7 was found to be downregulated in diabetic islets as well as in activated PBMCs. Here, we aimed to investigate whether such changes in Siglec-7 expression directly modulate islet immune cell infiltration, β -cell function and survival.

Materials and methods: To investigate the role of Siglec-7 in β -cell function and survival, over-expression was carried out in isolated human islets with or without diabetic stimuli (glucose/palmitic acid, cytokine mixture IL-1 β /IFN γ /TNF α), followed by glucose stimulated insulin secretion (GSIS) and TUNEL assay. Cytokine secretion was analyzed by the Meso Scale Discovery[®] multi array technology. To ascertain its role in immune cells, Siglec-7 expression was analyzed by RT-PCR and FACS in freshly isolated PBMCs from non-diabetic individuals cultured with the same diabetogenic conditions or 100 ng/ml Lipopolysaccharide (LPS) for 12 hours.

Results: Siglec-7 mRNA was markedly down-regulated in islets isolated from patients with T2D and in pancreases from autopsy from patients with T2D. Over-expression of Siglec-7 improved β -cell function and survival in human islets isolated from patients with T2D. The overexpression also prevented glucolipotoxicity- and cytokine-induced β -cell apoptosis. In isolated human islets from patients with T2D, Siglec-7 overexpression caused a reduction in basal IL-1 β (40%) and TNF α (50%) expression. In human monocytes, LPS, glucose/palmitic acid, as well as the cytokine mixture IL-1 β /IFN γ /TNF α induced their activation as seen by the induction of IL-6 mRNA and CD25 expression; a simultaneous decrease was observed in Siglec-7 mRNA levels. Induced migration of enriched monocytes was observed under conditions of elevated glucose/palmitate as well as by islets from patients with T2D. This demonstrates the triggering of inflammation in islets under diabetogenic conditions. Conditioned media from islets overexpressing Siglec-7 majorly inhibited cell migration of immune cells.

Conclusion: Our data suggest that Siglec-7 is regulated in islets and immune cells under diabetogenic conditions and influences immune cell migration, β -cell function and survival.

Reduced expression of the transcription factor, STAT6, in beta cells may contribute to their loss in human type 1 diabetes

M.A. Russell, K. Taniguchi, S.J. Richardson, N.G. Morgan;
University of Exeter Medical School, UK.

Background and aims: It is widely accepted that immune cells infiltrate the pancreatic islets in human type 1 diabetes and contribute to beta-cell loss by releasing pro-inflammatory cytokines. In addition, the production and influence of anti-inflammatory cytokines (e.g. IL-4 or IL-13) is correspondingly down-regulated in this disease, which may also contribute to beta cell loss. IL-4 and IL-13 each signal via their cognate cell surface receptor to induce the phosphorylation and activation of the transcription factor, STAT6; which then mediates their effects. In the current study we have evaluated the extent to which STAT6 acts as a regulator of beta-cell viability and have studied whether islet STAT6 expression is altered in human type 1 diabetes.

Materials and methods: An archival collection of formalin fixed paraffin embedded (FFPE) pancreas samples from both healthy controls and individuals with type 1 diabetes was interrogated using STAT6 antisera. Both immunofluorescence (IF) and immunohistochemical (IHC) staining approaches were employed. Cell culture studies were also undertaken to explore STAT6 phosphorylation and beta-cell viability by Western blotting and flow cytometry respectively.

Results: IF staining of FFPE human pancreas tissue revealed a robust expression of STAT6 within the endocrine pancreas in non-diabetic individuals. Importantly, STAT6 was found at high levels in insulin-containing beta-cells but expression was negligible in other islet endocrine cell types. To assess the role of STAT6 in the beta-cell, IL-4 and IL-13 were employed as stimuli in INS-1E cells and isolated human islets. Treatment of these with IL-4 or IL-13 induced a rapid, time-dependent rise in STAT6 phosphorylation at Tyr641, indicating increased STAT6 activation. In accord with this, the anti-inflammatory cytokines potently protected the cells against a range of cytotoxic insults including serum starvation, saturated fatty acids and pro-inflammatory cytokines (10% foetal calf serum: 11.3 \pm 0.9%; no serum: 35.5 \pm 1.3% cell death; no serum plus 20 ng/ml IL-13: 23.8 \pm 0.8%; p <0.001). Pharmacological inhibition of Janus kinases (which act immediately upstream of STATs) prevented cytokine-induced STAT6 phosphorylation and reversed the improved cell viability caused by IL-4 or IL-13 (no serum: 30.0 \pm 1.3% cell death, IL-13: 16.9 \pm 0.8%, IL-13+P6: 30.3 \pm 1.3%; p <0.001). Finally, we investigated whether the expression of STAT6 is altered within the islets of pancreases of patients with type 1 diabetes compared to controls. Pancreas sections

from six healthy and six age- and sex-matched patients with recent-onset type 1 diabetes were immunostained for STAT6 and islet hormones. Images of five islets per section were captured at identical microscope and camera settings. The mean fluorescence intensity of STAT6 expression within each islet was calculated and analysis of these data revealed that total STAT6 levels were significantly decreased in the islets of individuals with recent-onset diabetes (MFI for STAT6; healthy control 14.22 \pm 1.23, T1D 2.31 \pm 0.64; p <0.001).

Conclusion: STAT6 is expressed in human beta-cells and its activation improves the viability of these cells in response to various cytotoxic insults. Expression of STAT6 is reduced in the beta cells of individuals with type 1 diabetes and this may contribute to the enhanced vulnerability of these cells in the face of the pro-inflammatory milieu found in inflamed islets.

478

Robust amyloid deposition with M1 macrophage infiltration in the islets in super-elderly Japanese type 2 diabetic subjects

H. Mizukami, W. Inaba, A. Xing, T. Yoshida, Y. Takeuchi, S. Yagihashi;
Pathology and Molecular Medicine, Hiroasaki University, Japan.

Background and aims: Dramatic increase in elderly type 2 diabetic patients (T2DM) is a serious problem in modern society. Although pathogenesis of elderly T2DM can be distinct from that in younger ones based on their different energy metabolism, differences in the islet pathology between elderly and less old diabetic patients are yet to be addressed. In this study, we attempted to characterize the islet changes in elderly T2DM patients.

Materials and methods: Pancreata from 13 young non-diabetic (Y-ND) (mean 25.8 y.o.), 22 middle-aged non-diabetic (M-ND) (61.3), 23 middle-aged diabetic (M-DM) (59.4; onset of DM 48.8), 30 super-elderly non-diabetic (SE-ND) (89.5), and 10 super-elderly diabetic subjects (SE-DM) (88.5; onset of DM 80.3) were investigated. On the tetra immunostained sections, morphometric analysis was conducted on each endocrine cell as to their volume density, mass and occupancy in the islet. Immunohistochemical expressions of insulin transcriptional factors (TFs) such as PDX1 and MafA or in situ hybridization for (pro)insulin mRNA, and infiltration of macrophages positive for CD68 (M1-M) and CD163 (M2-M) were assessed for insulin transcriptional activity and inflammatory changes, respectively.

Results: Pancreas weight (PW) was comparable among groups except for SE-DM which showed 50% decrease compared to SE-ND. In accord with this result, pancreatic parenchyma of SE-DM displayed severe atrophy. In addition, we found a high frequency of amyloid deposition (amyloid volume density>0.1%) in SE-DM (70%) compared to M-DM (27%) and SE-ND (3%). Compared to M-ND, volume density of β cells ($V\beta$) was reduced ca 30% in M-DM. In contrast, there was a significant increase in volume density of α cells ($V\alpha$ in M-DM. $V\beta$ in SE-ND was increased to 130% of M-ND accompanied by an increase in islet volume density (V_i). $V\beta$ in SE-DM was dramatically reduced 35% compared to SE-ND (p <0.01). There were no significant changes in either δ or PP cell volume densities among all cohorts. The expressions of PDX1 and MafA were the most prominent in Y-ND and preserved in M-ND, whereas those in M-DM, SE-ND, and SE-DM were all suppressed to similar extents to those in M-ND, together with reduced insulin mRNA expression (p <0.05). Both M1-M and M2-M infiltrated into the islets of M-DM and further M1-M infiltrates were conspicuous in SE-DM, while M2-M infiltrates in SE-DM were less marked compared to that of M-DM.

Conclusion: This study disclosed that the islet pathology in SE-DM is distinct from those in M-DM, characterized by pancreas atrophy, amyloid deposition, macrophage infiltrates, and less implication of TFs. Thus, environmental insults may more strongly be implicated in the onset of SE-DM compared to usual M-DM.

479

A role for the Nrf2-antioxidant pathway in intrinsic beta cell repair after resolution of hyperglycaemia

R. Robertson¹, T. Abebe¹, S. Hahn¹, J. Mahadevan², E. Oseid¹, F. Urano²;

¹Medicine, Pacific Northwest Diabetes Research Institute, Seattle, ,

²Medicine, Washington University, St. Louis, USA.

Background and aims: It is well established that sustained hyperglycemia causes beta cell necrosis and apoptosis. However, very little information exists about whether damaged beta cells can undergo intrinsic repair once treatment resolves the hyperglycemic state, and if so, what mechanisms might be involved. To address these issues, we studied euglycemic ZDF rats that become hyperglycemic when fed a high fat diet (HFD). Observations were made during a baseline non-HFD period, during a HFD, and after returning to a non-HFD with particular emphasis on Nrf2, a protein that binds to the promoter elements of genes involved with synthesis of antioxidant proteins.

Materials and methods: 3 groups (n=12 each) of normoglycemic ZDF female rats were fed non-HFD (16.5% fat) for 2 weeks. Thereafter, one group each was fed the HFD (48% fat) for 9, 18, and 28 days, respectively. Animals (n=4) from each of the groups were sacrificed for pancreatectomy at 3 time periods: at baseline; on the 9th, 18th, and 29th day of HFD; and at the end of a 3 week return to non-HFD. Non-fasting blood samples were taken throughout the study for glucose and insulin. Pancreases were used for insulin immunostaining and beta cell mass as well as for immunofluorescent staining for Ki67, apoptosis, PDX-1, superoxide dismutase (SOD-1), catalase (CAT), glutathione peroxidase-1 (GPx-1), hemoxygenase-1 (HO-1) and nuclear factor erythroid-derived 2-related factor (Nrf-2).

Results: 9 days HFD caused hyperglycemia (348 +/- 16 mg/dl) and during the remaining weeks after return to non-HFD, elevated glucose levels returned to baseline levels (147 +/- 10 vs 135 +/- 3 baseline, mg/dl; p=ns). After 18 days HFD and hyperglycemia (513 +/- 34), elevated glucose values partially returned to baseline levels (215 +/- 37 vs 144 +/- 6 baseline; p=ns). After 28 days HFD and hyperglycemia (546 +/- 63) and during the remaining weeks after return to non-HFD, elevated glucose levels failed to return to baseline levels 294 +/- 69 vs 133 +/- 9; p< 0.03). Corresponding insulin levels failed to respond to the higher glucose levels by the end of the experiments: 18 day study=20 +/- 4 vs. 38 +/- 4 microU/ml baseline; 28 day study=14 +/- 2 vs. 26 +/- 4 baseline. Insulin immunostaining revealed beta cell damage after 9, 18, and 28 days of HFD. However, islets were healthy-appearing after a return to non-HFD in the 9 day HFD study. Nonetheless, there was a lesser improvement in beta cell imagery during return to non-HFD after 18 days HFD and very little improvement in beta cell imagery after return to non-HFD after 28 days HFD. Nrf2, HO-1, and SOD-1 were prominent in the nucleus during HFD in the 9 day study compared to pre-HFD images, although less so in the 18 and 28 day experiments. No changes in apoptosis, Ki67, GPx-1, or catalase were observed.

Conclusion: These data demonstrate that HFD in female ZDF rats causes hyperglycemia and associated beta cell damage that is reversible after a return to non-HFD in a time-related fashion wherein longer exposure to HFD is accompanied by lesser recovery of beta cell mass. The immediate appearance of intranuclear Nrf2 and antioxidant proteins that accompany the recovering beta cell morphology after the shortest but not the longest exposure to HFD suggests an early response role of the Nrf2-antioxidant pathway in beta recovery from hyperglycemia-induced damage.

Protection against inflammatory beta cell damage by lysine deacetylase inhibition and microRNA expression

A.L. Vestergaard¹, E.M.H. Pallesen¹, G. Novotny¹, D.N. Rasmussen¹, R. Regazzi², M. Lundh¹, T. Mandrup-Poulsen¹;

¹Department of Biomedical Sciences, University of Copenhagen, Denmark, ²Department of Fundamental Neurosciences, University of Lausanne, Switzerland.

Background and aims: Pro-inflammatory cytokines contribute to pancreatic β -cell apoptosis in type 1 and 2 diabetes mellitus. The detrimental effects resulting from cytokine-induced signaling in the β cell can be reduced by inhibition of class I classical lysine deacetylases (KDACi), especially HDAC1 or HDAC3, and is associated with down-regulation of inflammatory gene expression, only in part through hyperacetylation of NF κ B. We therefore hypothesize that HDACi-mediated hyperacetylation of histones and/or other proteins upregulate expression of microRNAs (miR), which repress translation of oxidative stress proteins responsible for β -cell death. The aim of the study is to identify novel and specific therapeutic targets for β -cell protection by mapping the miR profile of β cells rescued from inflammatory assault by inhibition of lysine deacetylation, thereby identifying miR that repress cytokine-induced mitochondrial and oxidative β -cell stress.

Materials and methods: Stable INS-1 knockdown (KD) clones of HDAC1, -2, and -3 (class I KDACs) or empty vector were generated by Lentiviral shRNA transduction. The cells were incubated 6 h with or without cytokines (150 pg/mL IL-1 β + 5 ng/mL IFN γ), and RT-qPCR-based miR array was performed. Regulation of several miR was verified by TaqMan RT-qPCR, and medium nitrite was determined with Griess' reagent.

Results: Following systematic analysis using NormFinder, miR-103 was chosen for normalization of the qPCR array data. Constitutive expression of 103 miR, and cytokine-induced expression of 84 miR were up- or down-regulated more than 3-fold by KD of HDAC1, -2, and/or -3 (see figure). MiR-146a, -146b, -21 and -34a were chosen for further analysis, and their expression was assessed by RT-qPCR normalized to U6. Cytokine exposure induced a 15-fold expression of miRNA-146a, which was reduced by 65% in HDAC1- but not in HDAC2- or HDAC3-deficient INS-1 cells (p<0.05, n=5). Expression of miRNA-146b, miR-21 and miR-34a were unaffected by HDAC1-3 deficiency, while cytokine-induced NO production was reduced by 27% and 44% in the HDAC1 (n=8) and HDAC2 (n=5) but not HDAC3 deficient clones respectively. The qPCR array analysis revealed several additional novel miR potentially important for understanding the beneficial effects of KDAC inhibition, which are currently being functionally validated.

Conclusion: The interesting association between HDAC1 KD-mediated protection against cytokine-induced INS-1 cell destruction, and the inhibitory effect of HDAC1 knockdown on the β -cell pro-apoptotic miR-146a and other miR under investigation, warrants further investigations aiming to show a causal role of miR in HDAC inhibitor-mediated protection of pancreatic β cells. The perspective of this study is to develop novel anti-diabetic drugs targeting HDAC1 and/or associated miR.

PS 029 Beta cell mass imaging and regulation

Graft revascularisation is essential for non-invasive monitoring of transplanted islets with radiolabeled exendin

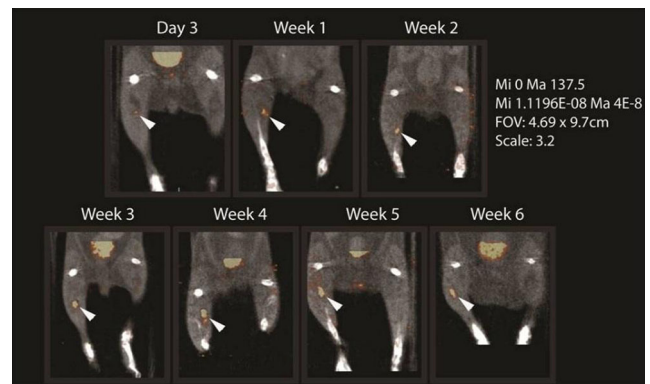

W.A. Eter, D. Bos, C. Frielink, O.C. Boerman, M. Brom, M. Gotthardt; Radiology and Nuclear Medicine, Radboud University Medical Center, Nijmegen, Netherlands.

Background and aims: Pancreatic islet transplantation provides insulin independence for type 1 diabetes patients. However, the clinical outcome is still poor due to decline of islets survival in response to inflammatory and non-inflammatory processes. Clearly, development of non-invasive imaging tools visualizing islet transplants would improve the therapy by predicting islets survival. ¹¹¹In-exendin-3 is a promising tracer to non-invasively visualize β -cells by SPECT (Single Photon Emission Computed Tomography). However, after isolation, islet vasculature is disrupted and therefore, delivery of the radiotracer to islet grafts early after transplantation may depend on their revascularization. Here we investigated the role of islet revascularization dynamics in promoting exendin-3 delivery to islet grafts and to image them after transplantation by SPECT.

Materials and methods: Syngeneic transplantation was performed in calf muscle of C3H mice with 800 islets. Mice were injected intravenously with 15 MBq of ¹¹¹In-exendin and scanned 1 h post-injection. SPECT was acquired at 3 days, 1, 2, 3 or 4, 5, 6 weeks. Exendin uptake was determined by SPECT quantitative analysis and immunostaining was performed against insulin and VEGFR-2 to confirm presence of β -cells and to quantify intra-islet vascular density, respectively. Data were expressed as means \pm SEM.

Results: After 3 days, 0.013 ± 0.003 kBq of the tracer accumulated in the transplants, which significantly increased up to 0.06 ± 0.005 kBq at 4 weeks ($p < 0.001$) and remained similar up to 6 weeks after transplantation (0.07 ± 0.003 and 0.07 ± 0.002 kBq, for week 5 and 6, respectively). First signs of revascularization coincided with low exendin-3 uptake by 3-day old grafts and increase in islets vascular density between 3 days and 3 weeks ($p < 0.001$) correlated with the uptake of exendin-3 by the islets (Pearson Correlation coefficient $r = 0.85$)

Conclusion: Islet revascularization is a key physiological process when monitoring islet transplants after in-vivo targeting of the β -cells with radiotracers. Stable and reproducible uptake of exendin was achieved starting 4 weeks post-transplantation, indicating that longitudinal assessment of islet survival by SPECT can reproducibly be performed after this time point.

Re-routing of insulin signalling in response to knockdown of PI3K-C2 α promotes pancreatic beta cell proliferation

B. Leibiger¹, T. Moede¹, M. Paschen¹, N.-O. Yunn², J.-H. Im², S.H. Ryu², P.-O. Berggren¹, I.B. Leibiger¹;

¹The Rolf Luft Research Center for Diabetes and Endocrinology, Karolinska Institutet, Stockholm, Sweden, ²Pohang University of Science and Technology, Republic of Korea.

Background and aims: Signaling via insulin receptor B-type (IR-B) and PI3K-C2 α is required for glucose-stimulated insulin secretion and keeps the beta cell in a glucose-sensitive, differentiated state. We have recently observed that knock-down of PI3K-C2 α in pancreatic beta cells, in contrast to most other cells, leads to increased proliferation and survival. The aim of this study was to evaluate the mechanism underlying the increased beta cell proliferation and survival after knockdown of PI3K-C2 α .

Materials and methods: MIN6 cells, primary mouse and human beta cells were treated with control siRNA or siRNA against PI3K-C2 α . Cell proliferation was measured by incorporation of labeled DNA precursors into nuclei. Protein expression and phosphorylation were evaluated by Western blot. Apoptosis rate was determined by triple staining with Hoechst 33342, propidium iodide and AlexaFluor488-annexinV. IR-B/Shc interaction was evaluated by FRET analysis and co-immunoprecipitation.

Results: Knockdown of PI3K-C2 α led to increased cell proliferation of MIN6 cells (1.48 \pm 0.11 fold), mouse (1.88 \pm 0.24 fold) and human (1.92 \pm 0.21 fold) primary beta cells. Cells treated with PI3K-C2 α siRNA were more resistant to apoptotic stimuli (48.4 \pm 4.9% less apoptotic MIN6 cells when treated with 20 μ M H₂O₂ and 32 \pm 2.9% less apoptotic MIN6 cells when treated with 6 μ M staurosporine). The positive effect of PI3K-C2 α knockdown on cell proliferation was insulin-dependent and was abolished both by IR-B-blocking antibodies ($p \leq 0.01$) and IR-B-blocking aptamers ($p \leq 0.01$). Knockdown of PI3K-C2 α led to increased IR-B/Shc interaction (1.8 \pm 0.3 fold). Knockdown of PI3K-C2 α led to decreased signaling via the IR-B/PKB α -pathway resulting in a less glucose-sensitive/differentiated phenotype and to increased signaling via the IR-B/Shc/ERK-pathway resulting in enhanced proliferation.

Conclusion: Insulin resistance in the signaling cascade via IR-B/PI3K-C2 α leads to partial loss of the differentiated, glucose-responsive state of the beta cell but at the same time promotes beta cell proliferation via a different signaling cascade involving Shc/ERK. PI3K-C2 α represents a key regulatory element allowing the beta cell to switch between IR-B signaling leading to differentiation respective proliferation in response to insulin.

Beta cell amount, function and turnover in non-diabetic obese vs lean subjects

L. Marselli, M. Suleiman, M. Occhipinti, F. Olimpico, F. Syed, M. Bugliani, P. Marchetti;

Department of Clinical and Experimental Medicine, Islet Cell Laboratory, University of Pisa, Italy.

Background and aims: To better understand the relative roles of beta cell amount, function and turnover in the maintenance of glucose homeostasis in non-diabetic (ND) obese subjects (OB), we compared several beta cell characteristics in 13 OB (age 66 \pm 13 yrs; 4 M/9 F; BMI: 32.0 \pm 3.3 kg/m²) and 14 lean [LEAN; 64 \pm 15 yrs; 4 M/10 F; 22.5 \pm 1.8 kg/m² ($p < 0.01$ vs OB)] ND organ donors.

Materials and methods: Immunofluorescence staining was performed with pancreatic sections; glucose stimulated insulin secretion was assessed from isolated islets by the batch incubation method; laser capture

microdissection (LCM) was used to acquire beta cell enriched samples from frozen specimens.

Results: Pancreatic insulin (INS) and glucagon (GLUC) areas were 0.71 \pm 0.34% and 0.27 \pm 0.25% in OB, and 0.85 \pm 0.50% and 0.22 \pm 0.15% in LEAN, with the respective INS/GLUC values of 3.0 \pm 1.1 and 4.1 \pm 1.3 ($p = 0.06$). Cells positive for both INS and GLUC were 10.5% in OB and 7.0% in LEAN islets. Beta cell clusters (<4 cells) per mm² were 7.8 \pm 4.9 in OB and 7.6 \pm 7.0 in LEAN (>90% in acinar tissue, the remaining in/close to ducts); similar proportions of OB and LEAN clusters contained only INS+ (around 60%) or GLUC+ (around 35%) cells; contained INS+ and GLUC+ cells were seen in 7.6 and 3.9% of clusters in OB and LEAN, respectively. TUNEL or Ki67 positive beta cells were similarly rare in the two groups. Glucose stimulated (16.7 mM glucose) INS release (μ U/islet/min) was 0.093 \pm 0.048 from OB and 0.058 \pm 0.031 from LEAN (both $p < 0.01$ vs basal) islets; INS stimulation index was higher with OB islets (3.4 \pm 1.2 vs 2.3 \pm 1.1, $p = 0.03$), with a similar effect also seen with glibenclamide (3.4 \pm 1.1 vs 2.5 \pm 1.2) but not with arginine (2.4 \pm 0.9 vs 2.2 \pm 1.0). LCM was applied to islets and acinar or duct clusters. RIN values were >6 for islet beta cells and >4 for cluster beta cells, with respective concentrations of >4 ng/ μ l and approximately 100 pg/ μ l.

Conclusion: Beta cells in ND OB show greater insulin secretion to glucose and glibenclamide, but not arginine; the morphometric features of OB vs LEAN beta cells requires further studies; LCM use could allow detailed molecular investigation of OB beta cell properties.

In vitro imaging of GLP-1R as an approach to non-invasive in vivo pancreatic islet imaging

V. Chellakudam, K. Janikowska, A. Babic, E. Allémann, N. Lange; Pharmaceutical Technology, School of Pharmaceutical Sciences, University of Geneva - University of Lausanne, Geneva, Switzerland.

Background and aims: Recently, exendin-4 derivatives targeting glucagon like peptide -1 receptor (GLP-1R) are emerging as promising candidates for the imaging of pancreatic β cell mass. Our project aims at developing and evaluating 1) multimodality imaging probes with exendin as the targeting ligand; 2) multivalent probes with 1 to 4 exendin to increase the avidity of the probe to receptor; and 3) inclusion of short and long PEG linkers to reduce the kidney uptake and enhance circulation half-lives for in vivo studies. In our studies, a defined cyclopeptidic scaffold was selected as delivery vehicle for these probes. All probes were labeled with Cy5 for fluorescence imaging.

Materials and methods: Dose response assays were carried out to determine the binding affinity (IC₅₀) of exendin derivatives. Then, competition binding assays were designed to study the specificity to the GLP-1R. Finally, cell imaging experiments at 37°C and 4°C were conducted to visualize internalization of the probes. Assays were performed in CHL/hGLP-1R cells that ectopically express hGLP-1R and compared to the GLP-1R negative native CHL cell line.

Results: Dose response assays: All compounds showed affinities in the nanomolar range to CHL/hGLP-1R cells. The cyclopeptide carrying 2 exendins and short PEG linker showed the lowest IC₅₀ values (1.0 \pm 0.1 nM) in CHL/hGLP-1R cells (see table below) No binding was observed in GLP-1R negative CHL cell line or other human control cell lines (HeLa, Panc-1). Competition binding assays: At high concentrations of unlabeled exendin, tagged exendin derivatives were unable to displace the untagged ligand. Cell imaging experiments: At 37°C internalization of the probes into the cytoplasm was observed. However, at 4°C was mostly confined to the cell membrane indicating an active transport of the probes.

Conclusion: GLP-1R targeting cyclopeptide carrying multiple exendin copies show high binding affinities to the GLP-1R similar to exendin-4 (39aa). The competition assays and fluorescence imaging confirm the specificity of the probes to the receptor for receptor-mediated internalization

Exendin-4 derivatives with Cy5	IC ₅₀ (nM)
Exendin	2.6 ± 0.2
Cyclopeptide + 1 Exendin short PEG	7.1 ± 0.5
Cyclopeptide + 1 Exendin long PEG	2.9 ± 1.5
Cyclopeptide + 2 Exendins short PEG	1.0 ± 0.1
Cyclopeptide + 2 Exendins long PEG	2.3 ± 0.6
Cyclopeptide + 4 Exendins short PEG	2.8 ± 1.7
Cyclopeptide + 4 Exendins long PEG	3.0 ± 1.4

Cathelicidin antimicrobial peptide: a novel regulator of islet function and beta cell regenerative capacity

L.D. Pound, C. Patrick, C.E. Eberhard, G.-S. Wang, R.N. Vandenbeek, F.W. Scott;
Ottawa Hospital Research Institute, Ottawa, Canada.

Background and aims: Cathelicidin antimicrobial peptide (CAMP) is a naturally-occurring secreted peptide primarily expressed in immune cells and in epithelia that are in contact with the environment. CAMP has numerous pleiotropic roles in immunomodulation, wound healing and cell growth. We have previously demonstrated that Camp expression is up-regulated in the gut when type 1 diabetes (T1D)-prone BBdp rats are protected from diabetes development. Unexpectedly, we identified CAMP expression in the pancreatic β -cell, a previously unreported finding. Thus, we sought to characterize the novel roles of CAMP in the pancreatic islet and investigate its potential as a novel therapeutic for the treatment of diabetes.

Materials and methods: Immunohistochemistry was used to detect CAMP expression in the pancreatic islet. Changes in Camp gene were analysed by qRT-PCR in diabetes-prone BBdp and control BBc rats. Dispersed islets were loaded with an intracellular calcium indicator, FURA-2 AM, to assess calcium mobilization following treatment with the CAMP peptide (LL-37). Glucose-stimulated insulin secretion and glucagon secretion were evaluated under high or low glucose conditions, respectively, in the presence or absence of the CAMP peptide. Finally, a cohort of BBdp rats was treated daily for one week with either the CAMP peptide or saline control and duct-associated insulin+ cells were quantified to assess β -cell regenerative processes.

Results: CAMP expression colocalizes with insulin+ but not glucagon+ cells, indicative of the novel expression of CAMP in the β -cell but not the α -cell. Camp gene expression was significantly down-regulated in the islets of young diabetes-prone BBdp rats compared with control BBc rats prior to the onset of insulinitis, suggesting early involvement in T1D pathogenesis. CAMP treatment of dispersed islets from both BBc and BBdp rats resulted in a significant increase in intracellular calcium levels. This effect was both delayed and blunted in the absence of extracellular calcium, indicating that CAMP promotes the mobilization of both extracellular and intracellular calcium stores. Consistent with the critical role of calcium mobilization in islet hormone secretion, CAMP treatment similarly promoted both insulin and glucagon secretion from islets isolated from BBc and BBdp rats. Daily treatment with the CAMP peptide for 7 days resulted in enhanced β -cell neogenesis. In addition, we identified changes in the gut microbiota in BBdp rats compared with BBc rats. In vivo CAMP treatment alleviated this gut microbiota dysbiosis and resulted in a shift in abundance in specific bacterial populations towards control BBc levels.

Conclusion: Our data indicate for the first time that CAMP is expressed in the islet β -cell and demonstrate a novel role for CAMP in pancreatic islet function and β -cell regenerative capacity. Importantly, by stimulating both insulin and glucagon secretion, CAMP may be promoting islet paracrine signalling thereby enhancing overall islet function and glucoregulation. Furthermore, changes in expression in diabetes-prone

BBdp rats indicate that CAMP could play an important role in T1D pathogenesis. Taken together, these findings strongly suggest that CAMP could be used as a novel therapeutic target for diabetes.

GCN2, a type 2 diabetes mellitus susceptibility gene, is associated with the regulation of pancreatic beta cell mass

K. Masuda¹, A. Kanno², S.-I. Asahara², R. Yoshitomi¹, T. Matsuda², M. Kimura-Koyanagi², Y. Shibutani², N. Yokoi³, M. Kasuga⁴, S. Seino³, Y. Kido¹;

¹Kobe University Graduate School of Health Sciences, ²Division of Diabetes and Endocrinology, ³Division of Molecular and Metabolic Medicine, Kobe University Graduate School of Medicine, ⁴Research Institute National Center for Global Health and Medicine, Tokyo, Japan.

Background and aims: Single-nucleotide polymorphism (SNP) analysis of Japanese diabetes patients has revealed a significant correlation between a general control nonderepressible 2 (*GCN2*) SNP and type 2 diabetes mellitus (T2DM). *GCN2* is a molecule activated by amino acid deficiency. Amino acid deprivation leads to accumulation of uncharged transfer RNAs (tRNAs), which induce the activation of *GCN2*. A comparison of *GCN2* expression in different mouse tissues showed that *GCN2* was prominently expressed in pancreatic islets. We analyzed the role of *GCN2* in pancreatic β -cells and its involvement in the onset of T2DM.

Materials and methods: We generated generalized *GCN2* knock-out mice (*GCN2*^{-/-} mice), analyzed their metabolic parameters and histology. We also investigated changes in intracellular signaling by using islets from *GCN2*^{-/-} mice and INS-1 cells. Using isolated islets from wild-type mice fed a normal-chow diet (NCD) and a high-fat diet (HFD), we analyzed amino acid levels and relative charging levels of tRNAs.

Results: *GCN2*^{-/-} mice fed a NCD did not exhibit any changes in glucose tolerance or pancreatic β -cell mass. However, *GCN2*^{-/-} mice fed an HFD exhibited significant aggravation in glucose tolerance and reduction in pancreatic β -cell mass. Islets isolated from *GCN2*^{-/-} mice showed significant increase in mTORC1 activity and decrease in insulin signaling. We also found elevated phosphorylation of TSC2 in islets from *GCN2*^{-/-} mice, considered that chronic activation of mTORC1 resulted in reduction of insulin signaling through the negative-feedback mechanism, which is consistent with our previous findings on *TSC2*^{-/-} mice. As *GCN2*^{-/-} mice displayed reduction in pancreatic β -cell mass only when fed an HFD, we compared the activity of *GCN2* in islets from wild-type mice, and found that *GCN2* was markedly activated in islets from mice fed an HFD. Next, we investigated the conditions which activate *GCN2* in pancreatic β -cells. In INS-1 cells, *GCN2* was activated by glucose load, but not by other insulin secretagogues. Because insulin translation was enhanced in islets of mice fed an HFD, we constructed a hypothesis that amino acids were decreased by its consumption and *GCN2* was activated when translation of insulin is enhanced. To verify our hypothesis, we compared amino acid levels in islets from wild-type mice fed a NCD with those fed an HFD, and found that a lot of amino acids are decreased in islets from mice fed an HFD. Moreover, we found decreases in charging level of tRNAs in islets from mice fed an HFD.

Conclusion: Our results showed that chronic activation of mTORC1 activity is one of the causes of reduction in pancreatic β -cell mass in *GCN2*^{-/-} mice. During HFD load, insulin translation is enhanced, amino acids are decreased, and uncharged tRNAs accumulate in islets, which leads to the activation of *GCN2*. From our data, we consider that activated *GCN2* contributes to the maintenance of pancreatic β -cell mass. We expect that *GCN2*^{-/-} mice could be one of the models of the pathogenesis of T2DM in patients who have a SNP in *GCN2*.

Calculation of radiation doses to the islets of Langerhans due to radionuclide imaging with exendin

I. van der Kroon¹, W. Woliner-van der Weg¹, M. Brom¹, C. Frielink¹, L. Joosten¹, M.W. Konijnenberg², E.P. Visser¹, M. Gotthardt¹;

¹Radiology and Nuclear Medicine, Radboud university medical center, Nijmegen, ²Nuclear Medicine, Erasmus Medical Center, Rotterdam, Netherlands.

Background and aims: Recently, radiolabeled exendin was developed to non-invasively image the beta cells in the islets of Langerhans by Single Photon Emission Computed Tomography (SPECT) or Positron Emission Tomography (PET), aiming at increasing our insight into the pathophysiology of diabetes. The use of radiolabeled exendin could lead to concern about radiation-induced damage to the islets because it is known from literature that high doses of radiation (>10 Gy) can lead to islet death. Estimation of the potential radiation-induced damage requires a method for calculation of the radiation dose to the islets. Commonly used whole organ dosimetry methods do not contain the islets of Langerhans as a separate compartment and therefore do not provide the radiation dose to single islets. Due to high accumulation of the radiolabeled tracer in the islets as compared to the exocrine pancreas, whole pancreas radiation dose estimation will underestimate the actual radiation dose to single islets, while overestimating the dose in the exocrine pancreas. Therefore, the islets of Langerhans need to be treated as a separate compartment. In our work, whole organ dosimetry is combined with the islets of Langerhans as a separate compartment to calculate the islet radiation dose resulting from imaging of beta cells with radiolabeled exendin. Using this model, the islet radiation dose was calculated for different conditions (i.e. different radionuclides, healthy and diabetic patients, different islet sizes).

Materials and methods: The model includes the compartments that contribute to the islet radiation dose. The contribution of the pancreas and kidneys to the islet radiation dose was S-value based, while the self-dose of the islets was calculated using Monte Carlo simulations for a small sphere model (diameter: 50–400 μm). As input for the model both data from a clinical study (organ distribution of the tracer) and data from a preclinical study with Biobreeding Diabetes Prone (BBDP) rats (endocrine-exocrine uptake ratio, intra-pancreatic tracer distribution and beta cell mass), was used.

Results: The islet radiation dose was found to be small with a maximum of 74.3 mGy for the SPECT tracer ¹¹¹In-exendin (150 MBq injected activity per patient) and a maximum of 2.35 mGy for the PET tracer ⁶⁸Ga-exendin (75 MBq injected activity per patient). The activity in the islets contributes up to 45% to the total islet radiation dose for ¹¹¹In-exendin and up to 22% for ⁶⁸Ga-exendin. Due to the high accumulation of radiolabeled exendin in the kidneys, the kidneys have the largest contribution to the total islet radiation dose (49–81%).

Conclusion: The resulting islet radiation doses suggest that even repeated exendin imaging will not lead to islet death, since the maximum islet radiation dose is smaller by a factor of 130 - 4000 than the one known to cause serious islet damage (>10 Gy). Further reduction of the total islet radiation dose may be achieved by reducing the activity in the kidneys, for example by co-injection with gelofusin or injection of lower amounts of activity.

Effects of obesity and diabetes on alpha and beta cell mass in surgically removed human pancreas

J. Inaishi¹, Y. Saisho¹, K. Kou¹, S. Sato¹, R. Murakami¹, T. Yamada², M. Kitago³, Y. Kitagawa³, H. Itoh¹;

¹Department of Internal Medicine, ²Department of Pathology, ³Department of Surgery, Keio University School of Medicine, Tokyo, Japan.

Background and aims: The physiological and pathophysiological changes in beta cell mass (BCM) and alpha cell mass (ACM) in humans in the face of obesity and diabetes (DM) remain unclear. We have previously reported that there was no increase in BCM in Japanese obese individuals compared with lean subjects, however, the study was based on autopsy pancreas where we were not able to exclude the possibility of various confounding factors. The aim of this study was that, by using surgically removed pancreas samples, to clarify 1) effect of obesity or duration of obesity on ACM and BCM, 2) relationship between the glycemic markers (HbA1c and glycated albumin (GA)), beta cell function and ACM or BCM, and 3) relationship between postoperative glycemic control and ACM or BCM in humans.

Materials and methods: We obtained human pancreas samples from 69 individuals (41 men, body mass index (BMI) 22.2±2.9 kg/m², age 66±12 years (mean±S.D)) who underwent pancreatic surgery between the years 2000 and 2012. Twenty-nine patients were diabetic before operation. Pancreatic sections were stained for insulin or glucagon, and fractional beta (%BCA) or alpha cell area (%ACA) was measured, respectively. In addition, we evaluated the history of obesity by questionnaires to the patients.

Results: 1) In the non-diabetic (NDM) group (N=40), there was no significant correlation between BMI and %BCA or %ACA. Cases in NDM were divided into lean and obese groups (mean BMI 21.6±2.0 vs. 26.4±1.3 kg/m²). Either %BCA or %ACA in obese group was not significantly increased compared with lean group. Cases in NDM were also divided into two groups according to the duration of obesity (less than 10 years and 10 years or more). However, there was no significant difference in %BCA or %ACA between the two groups. 2) In the patients with DM (type 2 or pancreatic DM, N=29, 66±8 years, BMI 21.6±3.1 kg/m²), %BCA was significantly decreased by 56% compared with age- and BMI-matched NDM group (P<0.01), while there was no change in %ACA. %BCA, but not %ACA was significantly negatively correlated with HbA1c or GA (r=-0.44, P=0.04 and r=-0.46, P<0.01, respectively). Furthermore, there was a significant positive correlation between %BCA and serum C-peptide to plasma glucose ratio before operation (r=0.37, P=0.03). 3) To clarify the relationship between postoperative glycemic control and %ACA or %BCA, five cases who underwent total pancreatectomy were excluded. There was no significant correlation between HbA1c at 6 months after operation and either %BCA or %ACA. However, %BCA, but not %ACA was significantly negatively correlated with GA at 3 and 6 months after operation (r=-0.60, P<0.01 and r=-0.59, P=0.01, respectively).

Conclusion: We confirmed that there was no increase in either BCM or ACM in Japanese nondiabetic obese individuals who undertook pancreas surgery, supporting the hypothesis that beta cell regenerative capacity is limited in Japanese population. BCM was decreased by 56% in patients with diabetes, while there was no change in ACM in those individuals. BCM, but not ACM was associated with preoperative and postoperative glycemic control. These findings further support the concept that BCM rather than ACM has a major role in regulating blood glucose level.

The importance of Zinc transporter 8 autoantibody (ZNT8A) in the diagnosis of type 1 diabetes in the Brazilian population

K.F.B. Gomes, C. Semzezem, R.T. Fukui, A.S. Santos, R.F. Santos, M.E.R. Silva;

Laboratório de Carboidratos e Radioimunoensaio–LIM18. Hospital das Clínicas da Faculdade de Medicina, University of São Paulo, Brazil.

Background and aims: Recently, the Zinc transporter-8 (ZnT8), an islet cell secretory granule membrane protein, was identified as an autoantigen in T1D. Autoantibodies to ZnT8 (ZnT8A) complement the established antibodies to insulin (IAA), to GAD65 (65 glutamic acid decarboxylase, GAD65A), and to protein tyrosine phosphatase (insulinoma-2 antigen, IA2A) in Caucasians, but there are few data in Latin-America and in the very heterogeneous Brazilian population, with diverse patterns of admixture.

Materials and methods: For this purpose, we analyzed 479 T1D patients (12.3±7.7 yrs., diabetes duration 10.9±11.5 yrs.) and 329 controls (27.2±10.6 yrs). Serum levels of GAD65A and IA2A were determined by radioimmunoassay (RSR limited, UK; CV <7%). Serum levels of Znt8A were obtained by ELISA (Kronus, USA CV <7). Chi-square test, Fisher exact test and Mann-Whitney test were used in statistical analysis. P < 0.05 was considered significant.

Results: The Znt8A frequency of all patients analyzed (48.3%) was similar to that of GAD65A (47.7%) and IA2A (45.4%), but GAD65A frequency was slightly greater than that of IA2A (OR=1.25; CI: 1.016–1.559; p=0.04). All three autoantibodies frequencies declined in a similar way following years after diagnosis, being more intense after the first year. The three autoantibody titers also declined with diabetes duration, being much more faster to ZnT8A. There was a negative correlation among ZnT8A titers with age of blood collection (r=-0.369; p<0.0001) and diabetes duration (r=-0.439; p<0.0001), but not with age at diabetes onset (r=-0.006; p=0.91), even when considering only those patients with new onset T1D (less than two years of diagnosis). Titers and frequency of ZnT8A and IA-2A did not differ with respect to gender and ancestry, whereas GAD65A titers were greater in females (12.0±23.9×6.8±14.9 IU/mL; p=0.003) and in those of European ancestry (10.6±22.2×6.4±12.6 IU/mL; p=0.01). Among patients with only one islet autoantibody, ZnT8A, GAD65A and IA-2A corresponded to 10.1%, 10.1% and 4.3% respectively. So, the determination of ZnT8A allowed the additional diagnosis of DM1 in 10.1% of patients and, only 3.8% of recent-onset T1D patients, (until 2 year after diagnosis) remained three autoantibodies negative. The CTLA4 +46A/G was slightly associated with greater frequency of ZNT8A (80.4%×66.7; OR 2.048, CI=1.138–3.685; p=0.023). ZnT8A was rare in controls, being the only autoantibody observed in seven control subjects (1.5%) who were GAD65A and IA-2A negative, and its frequency was similar to that GAD65A (1.6%) and IA2-A (1.6%) in controls.

Conclusion: The prevalence of Znt8A in a Brazilian population (Sao Paulo city) was higher than previously reported in Asiatic patients with T1D, but similar to that reported in Caucasians. Therefore, ZnT8A can be considered a marker for T1D autoimmunity even in heterogeneous populations.

In situ detection of components of innate immune response in human insulinitis

L. Nigi¹, F. Mancarella¹, G. Ventriglia¹, G. Sebastiani¹, A. Pugliese², G.W. Burke², M. Battaglia³, F. Dotta¹;

¹Diabetes Unit, Department of Medicine, Surgery and Neuroscience, University of Siena, Italy, ²Diabetes Research Institute, Depts. of Medicine and Surgery, University of Miami-Miller School of Medicine, USA, ³Diabetes Research Institute (DRI), IRCCS San Raffaele Scientific Institute, Milan, Italy.

Background and aims: Type 1 diabetes (T1D) is an autoimmune disease in which both adaptive and innate immune responses are involved in target organ destruction and dysfunction. The aim of the present study was to analyze pancreatic expression of components of innate immune system (neutrophils; CCL2 and its receptor CCR2; CXCL10 and MICA) in human T1D.

Materials and methods: We analyzed pancreatic specimens obtained from 4 T1D, 4 autoantibody-positive non-diabetic (AAb+) and 6 autoantibody-negative non-diabetic (CTR) organ donors from the nPOD cohort, as well as from pancreatic biopsies obtained from 4 T1D transplanted patients from the nPOD-Transplantation (nPOD-T) cohort. Formalin-fixed and paraffin embedded sections were used in immunohistochemical investigations to analyze the expression of neutrophils, CCR2 and CXCL10. In addition, triple and/or double immunofluorescence with confocal microscopy analysis, was performed to identify islet cells subset(s) expressing CCL2 chemokine and MICA protein (a ligand for NK and CD8 T-cells). Colocalization between CCL2 and MICA with insulin and glucagon was performed by using Las AF software.

Results: Immunohistochemical experiments revealed that neutrophils were detectable in pancreatic exocrine tissue at higher frequency in T1D and in AAb+ vs CTR (p:0.0095 and p:0.038 respectively). Neutrophils were also found in pancreatic exocrine tissue of T1D transplanted patients. CCR2+ cells were scattered in exocrine tissue with the following trend: T1D > AAb+ > CTR. The expression of CXCL10 was found in all insulin containing islets of T1D patients and in several islet cells from AAb+ donors, while was virtually undetectable in CTR islets. In nPOD-T donors the expression of CXCL10 was found in several islets. Immunofluorescence analysis revealed that CCL2 was expressed almost exclusively by beta cells in islets of T1D, AAb+ and CTR, as well as of nPOD-T subjects. The same result was detected in islets of transplanted pancreata of nPOD-T subjects. Finally, MICA was expressed in few insulin containing islets with inflammatory infiltrates, exclusively in beta cells in pancreata from transplanted patients of the nPOD-T cohort but not of other nPOD organ donors.

Conclusion: Our findings strengthen the hypothesis that: 1 Innate immunity is indeed involved in T1D pathogenesis. 2 Residual presence of insulin containing cells is associated with ongoing islet inflammation. 3 Immune infiltration affects the whole pancreas and not only pancreatic islets.

Increased leucocytic infiltration of islets and exocrine tissue in organ donors with prolonged duration of life support

S. Smeets, G. Stangé, L. Zhidong, P. in't Veld;

Diabetes Research Center, Vrije Universiteit Brussel (VUB), Brussels, Belgium.

Background and aims: Leucocytic infiltration of the human endocrine pancreas is considered to be the hall-mark of recent onset type 1 diabetes in young patients. Recently, it has been proposed that a more general infiltration of both endocrine and exocrine pancreas can be found in most type 1 and type 2 diabetic patients. To interpret these findings, it is

important to have insight into the variability of leucocytic infiltration in the normal pancreatic gland in function of the clinical characteristics of the patient. This study assesses the correlation between the duration of life support and the presence of a leucocytic infiltrate in human donor pancreas. It extends our previous observations, using immunophenotyping to identify and quantify the infiltrating leucocytes, study the kinetics of the infiltration in a series of organ donors with increasing duration of life support, and differentiate between infiltration in the exocrine tissue and in the endocrine pancreas.

Materials and methods: Pancreas biopsy specimens from non-diabetic organ donors with different duration of life support (0, 3, 6, 9 and ≥ 12 days) were used ($n=10$ per time point). Sections were double-stained for CD68, CD45, CD3, CD8 and CD20 in combination with insulin and digitally imaged to quantify the number of leucocytic cells in total pancreas and islets of Langerhans.

Results: Donor pancreata from patients with a short duration of life support (0–3 days) showed low levels of infiltrating leucocytic cells. Infiltration levels strongly increased from 6– ≥ 12 days of life support onwards: CD68+ cells were found to increase 10-fold between day 0 and day 6 ($p < 0.0125$), remaining at elevated levels at day 9 and ≥ 12 ($p < 0.0025$), with up to 9% of total cells found to be CD68+ in some donors (Figure 1). CD45+, CD3+, CD8+ and CD20+ cells were less markedly increased, with a significant ($p < 0.0125$) 5-fold increase for CD45 and a significant ($p < 0.0125$) 2-fold change for CD8 and CD20 between day 0 and day 9. The number of CD68+ cells in the islets showed a significant 2.5-fold increase between 0 and ≥ 12 days ($p < 0.05$), whereas other leucocyte cell types were present in low numbers and did not show significant changes between the two groups.

Conclusion: These results show that increased duration of life support is associated with increased leucocytic infiltration in the endocrine and exocrine human donor pancreas from day 6 of life support onwards, affecting 15–33% of pancreatic organ donors. The effect is strongest for CD68+ cells. Clinical conditions around the time of organ retrieval should therefore be taken into account when studying inflammatory lesions in the diabetic pancreas and necessitate adequate matching of patient samples.

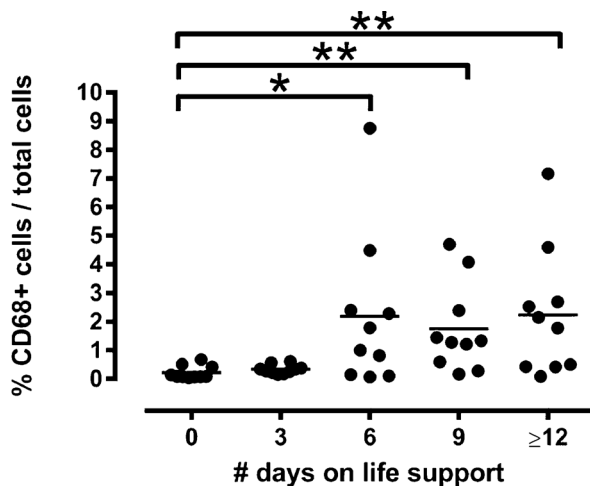

Figure 1. The percentage of infiltrating CD68+ cells in the pancreas, expressed in function of the number of days on life support. (Mann-Whitney U test; * = $P < 0.05/k$ and ** = $p < 0.01/k$; with $k = \#$ independent comparisons = 4 (Bonferroni correction))

492

STZ treatment causes immediate depletion of immune cells in sciatic nerve and dorsal root ganglion

T. Fleming, A. Hidmark, S. Vittas, P.P. Nawroth;

Internal Medicine I and Clinical Chemistry, University of Heidelberg, Germany.

Background and aims: Streptozotocin (STZ) treatment is common method for the induction of type 1 diabetes in rodent models. However, it has been shown that STZ induces thermal hyperalgesia in mice, independently of hyperglycemia, and is neurotoxic in vitro by induction of oxidative stress. These findings bring into question the limitations of STZ-induced diabetes as a model for diabetic neuropathy. Tissue resident macrophages constitute the first line of response to toxic challenges by clearing debris from apoptotic cells via their scavenger receptors. In this study, the effect STZ treatment on macrophages resident in sciatic nerve (SN) and dorsal root ganglions (DRG) and determine whether the observed thermal hyperalgesia was associated with neuronal inflammation.

Materials and methods: Healthy, wild-type mice were sacrificed 5 days after three consecutive treatments of STZ (50 mg/kg/day; i.p., $n=5$) or after 1 week, 3 weeks or 3 months after five consecutive treatments. Following sacrifice, peritoneal cavity lavage was collected, along with the DN and DRGs, which were digested and stained with antibodies against CD45, MHC class II, CD68, CD11b, Ly-6C, mannose receptor CD206 and activated NFkB and analyzed by flow cytometry. Thermal hyperalgesia was measured by Hargreaves. Statistical significance was tested with two-tailed student's T-test.

Results: Transient hyperalgesia was detected 4 days after initiation of treatment with STZ (response times was decreased by 1.3 secs, $p < 0.01$) before significant difference in blood glucose levels had developed. Thermal hyperalgesia was also evident at 6 days (-0.9 secs, $p < 0.01$) but had disappeared by 3 weeks. The number of CD68+ macrophages in the DRG was significantly reduced at 5 days after treatment (from 9% of all nucleated cells to 2%, $p < 0.001$). The number of CD68+ macrophages were not significantly reduced in the SN at this point, but SN macrophages displayed increased activation of NFkB (1.9 fold increase of fluorescence intensity $p < 0.01$ and 1.7. fold increase of number of positive cells $p < 0.05$). At 1 and 3 weeks, CD68+ cells in SN of STZ-treated mice were reduced to 54% and 39% respectively, as compared to control ($p < 0.05$), and in particular macrophages expressing CD206 were depleted (from constituting 70% to 50% of CD68+ macrophages after 1 week, $p < 0.01$). None of these changes were evident in macrophages obtained by peritoneal lavage at any of the studied time points, excluding the explanation of direct effects of STZ on macrophages. There were no signs of STZ-induced immediate inflammation in the nerve. MHC class II was at no point up-regulated on macrophages and there was no evidence of inflammatory infiltration of CD45+CD11b+LY6C+ monocytes at 1 week. As a result of the CD68+ macrophage depletion, number of intraneural CD45+ cells was significantly reduced (to 64% and 41% of control at 5 days and 1 week respectively, $p < 0.05$ and < 0.001). STZ-induced lymphopenia of peripheral nerve gradually normalized over the course of 12 weeks.

Conclusion: Our findings are consistent with a non-inflammatory innate immune response in the peripheral nervous system due to a toxic injury induced by STZ. Depletion of M2 macrophages by STZ in SN may affect the regenerative capacity of the nerve in response to further injury. Symptoms of neuropathy observed during the first three months of STZ-induced diabetes may therefore be indirectly affected by the neurotoxic effects of STZ.

Functional silencing of CD4⁺ T-cells by the modulating RIB5/2 antibody prevents islet autoimmunity and systemic prediabetic inflammation in the LEW.1AR1-IDDM rat model

T. Schoeppe, H. Weiss, S. Baltrusch, M. Tiedge;
IBIO, University of Rostock, Germany.

Background and aims: The LEW.1AR1-*idm* rat is an animal model of spontaneous autoimmune diabetes. Islet infiltration occurs within a narrow time range between 40 and 60 days after birth with proinflammatory cytokine peaks in blood PBMCs. The rat-specific anti-CD4 antibody RIB5/2 confers temporal internalization of the T-cell receptor complex without depletion of T cells. It was the aim of this study to investigate if RIB5/2 treatment can ameliorate the proinflammatory state in prediabetic LEW.1AR1-*idm* rats.

Materials and methods: Normoglycaemic LEW.1AR1-*idm* rats were treated between the age of 40 and 50 days with the monoclonal anti-CD4 antibody RIB5/2 (5 × 5 mg ab/kg b.w. i.p.). 200 µl blood were collected at day 40 (before antibody application), day 50 and day 60. RNA was purified from peripheral blood mononuclear cells (PBMCs) that were isolated by Ficoll density-gradient centrifugation. The RNA was used for gene expression analysis of proinflammatory (*TNFα*, *IFNγ*, *IL-1β*) and antiinflammatory cytokines (*IL-4*, *IL-10*), T-cell markers (*CD25*, *CTLA4*, *NRP1*), *L-Selectin*, *TGF-β* and *FoxP3* by real-time RT-PCR. Rats were monitored until the age of 120 days. Serial pancreatic sections were stained with Haematoxylin-Eosin (HE) to document the islet infiltration process.

Results: All 12 treated LEW.1AR1-*idm* rats remained normoglycaemic and developed no diabetes until age of 120 days. In the control cohort the diabetes incidence was 60% after 70 days. In comparison to untreated rats the antibody treated animals revealed by HE- and T-cell staining no lymphocytic infiltrations in pancreatic sections. Treatment with the anti-CD4 antibody RIB5/2 resulted in significantly ($P < 0.05$) reduced gene expression levels of *TNFα*, *INF-γ*, *IL-4*, *NRP1* (1.4 - 8-fold) at most 12 days after the last administration of RIB5/2 (age 60 days) compared with infiltrated animals. The treatment led to significantly higher expression of the regulatory genes *TGF-β*, *FoxP3* and *L-Selectin* (1.2 - 3-fold) but also significant high levels of the T-cell silencer signal *CTLA4* (6-fold) with an age of 50 and 60 days in compared with infiltrated animals.

Conclusion: The anti-CD4 antibody RIB5/2 treatment conferred temporal functional CD4 T-cell silencing without significant immunosuppressive side effects in the LEW.1AR1-*idm* rats. The treatment induced permanent tolerance against beta cell autoimmunity with downregulation of proinflammatory gene signatures in PBMCs. Moreover, this strategy effectively prevented islet infiltration and beta cell destruction. The data indicate that CD4⁺ T-cells play a key-role within systemic inflammatory processes of islet autoimmunity. T-cell silencing by modulating antibodies may be an attractive option for prevention of human T1DM.

The dependence of the insulin-induced cytokine levels production by basic genetic markers in the patients with autoimmune diabetes

E.A. Repina¹, E.N. Stepanova², M.N. Boldyreva³, M.V. Shestakova¹, I.I. Dedov¹;

¹Endocrinology Research Centre, ²Russian medical academy of post-graduate education, ³FGBU "Institute of Immunology" FMBA of Russia, Moscow, Russian Federation.

Background and aims: Numerous studies in different countries have been proven association of some single nucleotide polymorphisms (SNP) of the gene CTLA-4 with the development of autoimmune diabetes (T1DM). Its protein product expressed by natural T regulatory cells that control autoimmune inflammation. The aim of this study was to

investigate the dependence on the insulin-induced cytokine levels production by genotype polymorphisms options rs 231775 and rs 3087243 CTLA-4 gene.

Materials and methods: We examined polymorphisms rs 231775 and rs 3087243 CTLA-4 gene. These two SNPs of CTLA-4 gene were analyzed in 134 patients with T1DM. The control group consisted of 108 blood donors without autoimmune disease and family history on them. Allele identification was performed with Real-Time PCR technique. Association of genetic markers with pathology was considered statistically significant when p -value < 0.05 . At the same time we examined cytokines' levels in 30 patients with T1DM and 10 healthy people. Mononuclear leukocytes were isolated by centrifugation in the ficoll-verographin density gradient. The cells thus obtained were resuspended in the complete nutritive medium reducing their concentration to 2.0×10^6 /ml. Phytohemagglutinin (PHA-P) (10 mcg/ml) and insulin (insulin human) (10 mcg/ml) were added to the samples to stimulate mononuclear leukocytes; cell suspensions were further incubated for 36 hours. Initial, PHA-induced and insulin-induced levels of interleukin-1 (IL-1), IL-2, IL-4, IL-6, IL-7, IL-8, IL-10, IL-12, gamma interferon (IFN- γ) and tumor necrosis factor alpha (TNF- α) in supernatants of cell cultures were measured by solid phase immunoassay at 450 nm. Statistical analysis was performed by analysis of variance adjusted for sex and age. It was calculated the exact two-sided Fisher's test and p -value.

Results: 1) Insulin-induced levels of IL-1, IL-2, IL-4, IL-6, IL-7, IL-12 and IFN- γ were significantly higher in patients with G/G genotype of polymorphism rs 231775 CTLA-4 gene in comparison with genotypes A/A and A/G of the same polymorphism (IL-1 - $p = 0.0042/p = 0.0005$; IL-2 - $p = 0.0025/p = 0.0002$; IL-4 - $p = 0.0036/p = 0.0036$; IL-6 - $p = 0.0004/p = 0.0004$; IL-7 - $p = 0.0176/0.0070$; IL-12 - $p = 0.0573/0.0097$ and IFN- γ - $p = 0.0043/p = 0.0004$).

2) At the same time, insulin-induced levels of IL-1 and IL-6 were significantly higher in the patients with G/G genotype of polymorphism rs 3087243 CTLA-4 gene in comparison with genotype A/G of the same polymorphism (IL-1 - $p = 0.0357$ and IL-6 - $p = 0.0080$).

3) Insulin-induced levels of IL-6, IL-8, IL-10, IFN- γ and TNF- α were significantly higher in the patients with T1DM in comparison with healthy people (IL-6 - $p = 0.0215$, IL-8 - $p = 0.0002$, IL-10 - $p = 0.0033$, IFN- γ - $p = 0.0228$ and TNF- α - $p = 0.0034$).

Conclusion: The high levels of IL-6, IL-8, IL-10, IFN- γ and TNF- α testify quite aggressive autoimmune inflammation in the patients with T1DM. G/G genotypes of rs 231775 and rs 3087243 CTLA-4 gene polymorphisms are the markers of natural T regulatory cells insufficiency, which is reflected in the levels of insulin-induced cytokine production in the patients with T1DM.

495

Betatrophin in newly diagnosed type 1 and 2 patients: preliminary results

R. Maciulewski, K. Siewko, A. Zielińska, D. Lipińska, G. Kozłowska, M. Górka, M. Szelachowska;
Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Białystok, Poland.

Background and aims: Betatrophin is a factor produced in the liver and white adipose tissue, regulating the metabolism of lipids, especially triglycerides. There is limited data about this recently discovered molecule. It has been shown that in mice, betatrophin significantly improves beta cell function. Preliminary studies in humans suggest that elevated betatrophin concentration may be associated with an increased risk for type 2 diabetes (T2D) and cardiovascular diseases. Elevated concentration of this molecule was also observed in the longitudinal type 1 diabetes (T1D). The aim of the study was to compare the concentration of betatrophin in newly diagnosed patients with autoimmune diabetes (AD - type 1 and LADA), type 2 diabetes and in the control group.

Materials and methods: The study enrolled 80 patients with newly diagnosed diabetes: 28 patients with AD (mean age 36 ± 1.98 ; mean BMI 23.8 ± 0.94 kg/m²), 26 patients with T2D (mean age 37.7 ± 1.7 ; mean BMI 29.5 ± 0.93 kg/m²) and 26 healthy controls (mean age 39.5 ± 2.25 ; mean BMI 25.5 ± 0.94 kg/m²). All subjects were measured also C-peptide concentrations in the glucagon test, the presence of antibodies against beta cells (GADA, IA-2A, IAA), concentration of interleukin 15 (IL15) and lipids profile with free fatty acids (FFA). Concentrations of betatrophin, IL15, FFA, C-peptide, anti-islet antibodies were measured by ELISA and lipid profile by Cobas analyser.

Results: Serum betatrophin concentrations were higher in the newly diagnosed AD and T2D compared with healthy controls with significant difference between AD and the control group ($p=0.02$). C-peptide concentration was significantly lower in AD in comparison to the control group ($p<0.001$). We found significantly lower total cholesterol concentration in AD group vs T2D ($p=0.036$), HDL-cholesterol concentration in T2D vs control group ($p=0.04$), LDL cholesterol concentration in AD vs control group ($p=0.02$), significantly higher triglycerides concentration in T2D vs AD ($p=0.003$) and in T2D vs control group ($p=0.01$). Concentration of betatrophin in T2D correlated negatively with the patient's weight ($r=-0.4$; $p=0.04$), C-peptide ($r=-0.44$; $p=0.03$) and IL15 level ($r=-0.47$; $p=0.01$).

Conclusion: Higher betatrophin concentration in newly diagnosed AD and T2D in comparison to the control group, may suggest potential role of betatrophin in the pathogenesis of diabetes, in particular AD. Although IL-15 seems to be important in the pathogenesis of T1D, we found the association between betatrophin and IL15 in T2D. A further research are needed. For that reason, we are going to check the above-mentioned parameters in another 170 subjects soon.

496

Liquefied pancreatic ECM: a novel encapsulation platform for diabetes therapy

S. Krishtul, D. Chaimov, L. Baruch, M. Machluf;
Biotechnology and Food Engineering, Technion, Haifa, Israel.

Background and aims: Despite the large potential of beta cells encapsulation for diabetic therapy, and the extensive knowledge gained in the field, severe hurdles impede their clinical application. Those include the limited longevity of encapsulated beta cells, and the polymers used, which provide immunological and mechanical protection, but do not mimic the cell biological niche. Extracellular matrix (ECM) plays a vital role in the function of mature tissue. Not only it provides a physical niche for cellular attachments, the ECM is also responsible for transmitting signals, which affect cellular differentiation, maintenance, and biological function. Particularly, ECM based materials were demonstrated to improve beta cells culture and insulin secretion. Therefore, the aim of this study was to develop a unique cell microencapsulation platform, which is based on isolated natural pancreatic ECM hydrogel, and entraps cells that are induced to transdifferentiate into insulin producing cells and to provide a pre-clinical evidence for its applicability for diabetes therapy.

Materials and methods: Insulin-secreting human transduced mesenchymal stem cells and liver cells were encapsulated in gelled ECM—produced by enzymatic decellularization and liquefaction of porcine pancreatic tissue—and injected into diabetic mice.

Results: The newly-developed ECM-microencapsulation system provided the cells with a natural fibrous niche that supports cell viability, and significantly improves differentiation and insulin secretion (up to 5-fold increase comparing to transduced non-encapsulated cells, $p=0.001$). Moreover, the ECM-encapsulated cells were immunologically silent, as concluded from the negligible levels of pro-inflammatory cytokines in the peripheral blood, the normal values of complete blood count and the viability of the cells within ECM-capsules even four weeks following subcutaneous transplantation to mice. Most importantly, transplantation

of approximately 5.5×10^5 ECM-encapsulated transduced cells to streptozotocin induced diabetic mice significantly ameliorated hyperglycemia for up to four weeks. This was demonstrated in reduced blood glucose levels which were maintained less than 300 mg/dl through all the experiment, comparing to the blood glucose levels of the untreated group (approximately 350 mg/dl). Further, fructosamine concentration test and glucose tolerance test were performed two weeks post transplantation. The treatment with encapsulated transduced cells had reduced the fructosamine levels of the diabetic mice to levels of healthy, non-diabetic mice ($p=0.005$). Similarly, treated mice responded to glucose tolerance test with a clearance rate that paralleled that of healthy mice, whereas in the untreated group no glucose clearance was evident.

Conclusion: Our results indicate that ECM-microcapsules not only provide the transdifferentiated cells with immunological and mechanical protection, but also support cell function by mimicking their natural niche. Thus, transplantation of the ECM-encapsulated cells, even in minimal quantities, to diabetic mice results with a significant amelioration of their condition. Altogether, the advantages of this ECM-encapsulation system, clearly point at our ECM-based microencapsulation platform as a promising prospective cell-based therapy for the treatment of diabetes.

Bioactive nanocoatings: the integration of active anti-coagulant and anti-inflammatory therapeutics in multilayer nanocoatings to improve survival of pancreatic islets

A.L.F. Austin, Z.-L. Zhi, A.J.F. King, P.M. Jones;
Diabetes and Nutritional Sciences Division, King's College London, UK.

Background and aims: There are still many obstacles to successful islet transplantation, the main one being the loss of the functional beta cell mass in the early post-transplantation period, where up to 70% of the islet cells become functionally impaired due to the instant blood mediated inflammatory response (IBMIR). Conformal nanocoating may be one way in which to protect islets in this early time period by providing a nano-thin, protective shield around the islet without changing the islet volume. This would allow transplantation to the clinically relevant intraportal site whilst still providing protection against cell interactions and the hostile microenvironment. Importantly, this coating also has the advantage of being able to incorporate therapeutically active molecules which can target this IBMIR effect. We have developed a novel nanocoating scheme using incorporated anti-IBMIR agents to protect the islets and reduce islet cell destruction in the immediate post-transplantation period.

Materials and methods: Islets were isolated from ICR mouse pancreata by collagenase digestion and Histopaque®-1077 gradient. The nanocoatings were constructed using an anti-coagulant heparin polyaldehyde and glycol chitosan alternating layering scheme and incorporated the anti-inflammatory protein $\alpha 1$ -antitrypsin with differing densities of aldehyde groups to alter layering capacity. Anti-coagulant activity, islet viability and function in vitro and in vivo were assessed.

Results: By controlling aldehyde density generated on heparin at below 5%, the cell viability was greater than 99% in both groups and nanocoated islets had similar dynamic insulin secretion to non-coated islets. Mice transplanted with with nanocoated islets had comparable blood glucose concentrations compared to those transplanted with non-coated islets. The nanocoating incorporating $\alpha 1$ -antitrypsin exhibited significant anti-coagulant activities in an in vitro clotting assay (strand formation time: 276 ± 6 s vs 235 ± 15 s, control, $P<0.05$, $n=5$).

Conclusion: The anti-coagulant and anti-inflammatory activities of our nanocoating have shown that therapeutic molecules can be successfully incorporated. These results demonstrate the potential of this approach for reducing donor cell induced inflammatory responses especially at the crucial early post-transplantation time points, thus improving transplant outcome.

Levels of insulin antibodies negatively associate with insulin sensitivity in autoantibody-positive adults with newly diagnosed diabetes

V. Burkart¹, B. Nowotny¹, F. Zivehe¹, M.-C. Simon¹, K. Strassburger¹, C. Herder¹, K. Muessig¹, J. Szendroedi¹, M. Roden^{1,2};

¹German Diabetes Center, ²Department of Endocrinology and Diabetology, Medical Faculty, Heinrich-Heine University, Düsseldorf, Germany.

Background and aims: Increasing evidence indicates that the pathogenesis of type 1 diabetes (T1D) is not only driven by beta cell-directed autoreactivity but also by insulin resistance (IR). Autoimmunity in T1D is characterized by the presence of antibodies against beta cell-associated molecules, such as islet cell antigen (ICA), glutamic acid decarboxylase (GAD) and insulin, the dominant target autoantigen in T1D. Autoantibodies typically emerge in the prediabetic phase and persist after disease onset. The link between IR and autoimmunity might be relevant for monitoring diabetes progression and adaptation of therapeutic strategies, particularly in the early phase following disease diagnosis. In our current study we therefore hypothesized that IR associates positively with circulating beta cell-directed autoantibodies in patients with newly diagnosed T1D.

Materials and methods: From the German Diabetes Study, 156 patients (97 male, 59 female; mean age 36±11 years; diabetes duration 196±94 days, A1c 48.6±8.8 mmol/mol) who were positive for at least one antibody against ICA (immuno fluorescence), GAD or insulin (radioimmunoassay) were selected. Insulin sensitivity (M-value) of the patients was determined by hyperinsulinemic-euglycemic clamp tests.

Results: In the patients circulating insulin-directed antibodies (IAA) were found to be correlated with M-values. The levels of IAA had a median of 0.9 U/ml with an interquartile range of 0.2 to 7.4 U/ml. The clamp studies yielded M-values with a median of 8.2 mg * kg⁻¹ * min⁻¹ with an interquartile range of 6.4 to 10.4 mg * kg⁻¹ * min⁻¹. Correlation analyses by applying an unadjusted model revealed that doubling of IAA levels decreased the M-value by 2.6% (p=0.023). After adjustment for age, sex and body mass index (BMI), doubling the IAA level resulted in a 3.9% lowering of the M-value (p<0.001). Additional adjustment for the patients' C-peptide concentration and fasting blood glucose levels as well as for their daily insulin dose did not affect the correlation between IAA and M-value (p=0.009). In contrast, levels of antibodies against GAD or ICA did not correlate with insulin sensitivity.

Conclusion: From our results we conclude that in patients with newly diagnosed T1D expressing at least one beta cell-directed antibody, insulin sensitivity negatively relates to IAA, but not to other autoantibodies. This finding may be of clinical relevance for monitoring the course of the disease and for optimizing the treatment of T1D in the early phase after disease onset.

Autoimmune diseases in children and adults with type 1 diabetes from the type 1 diabetes exchange clinic registry

J.B. McGill¹, T.D. Riddlesworth², J. Hughes¹, L.A. DiMeglio³, K.M. Miller², R.W. Beck²;

¹Washington University School of Medicine, St. Louis, ²Jaeb Center for Health Research, Tampa, ³Indiana University School of Medicine, Indianapolis, USA.

Background and aims: Type 1 diabetes (T1D) is often associated with other autoimmune diseases (AD), but screening guidelines for these ADs in T1D patients are not well characterized or evidence based. To better

understand the factors associated with and the prevalence of AD in people with T1D, we analyzed the frequency of AD and associated factors in all individuals in the T1D Exchange Clinic Registry database.

Materials and methods: Diagnoses of AD, represented as ordinal categories: 1) no AD, 2) 1 AD, or 3) >1 AD based on the list of diseases in the Table, were obtained from medical record review of 25762 T1D Exchange Clinic Registry participants diagnosed with type 1 diabetes (50% female, 82% non-Hispanic white, mean age 23 yrs, mean duration of diabetes 11 yrs). Ordinal logistic regression was used to identify demographic and clinical factors associated with the diagnosis of AD.

Results: Of 25762 people diagnosed with T1D, 6588 (26%) were diagnosed with at least 1 additional AD: 5054 (20%) with 1 AD and 1534 (6%) with >1 AD. The Table displays the percent diagnosed by specific AD. Of the most common ADs, 4871 (19%) were thyroid diseases, with Hashimoto's disease /hypothyroidism being the most common of the thyroid diseases, and 1428 (6%) were celiac disease. When comparing >1 AD with one AD and no AD, subjects with >1 AD were more likely to be slightly older (mean 29 yrs vs 28 yrs vs 21 yrs; p<0.001), female (71% vs 62% vs 45%; p<0.001), non-Hispanic White (89% vs 88% vs 80%; p<0.001), and have a longer T1D duration (mean 15 yrs vs 14 yrs vs 9 yrs; p<0.001). Mean HbA1c was similar between AD groups: 8.1% for >1 AD, 8.2% for 1 AD and 8.3% for 0 AD.

Conclusion: In the T1D Exchange Clinic Registry, diagnosis of one or more AD in addition to T1D is common, particularly in women, older participants, and non-Hispanic whites. Autoimmune thyroid disease and celiac disease are the most common associated ADs. Further studies are needed to better understand contributing factors and the prevalence of new diagnosis of AD to aid in the development of AD screening recommendations for patients with T1D.

Table. Frequency of Diagnosis of Autoimmune Disease Overall and by Gender*

The role of IL-7 and IL-7/IL-2 receptor isoforms in the development of the autoimmune T cells of children with type 1 diabetes

K. Förtsch, T. Meissner, B. Ueberberg, C.M. Reinauer, E. Mayatepek, M. Jacobsen;

Department of General Pediatrics, Neonatology, and Pediatric Cardiology, University Children's Hospital, Heinrich Heine University, Düsseldorf, Germany.

Background and aims: Autoantigen specific CD4+ T cells of a TH1 phenotype support the development of autoimmune diseases and play a

key role in the pathogenesis of type-1 diabetes. Regulatory T cells can prevent development and progress of type 1 diabetes. IL-7 has multifaceted effects on T cells including induction of effector T cells of a TH1 phenotype and suppressing the development of regulatory T cells. The crucial role of IL-7 and its receptor for type 1 diabetes was shown in type 1 diabetes animal models and by functional analyses of IL-7 receptor signalling in patient's material. Association of a polymorphism in the IL-7 receptor with type-1 diabetes indicated a role of genetic components. In contrast to IL-7, IL-2 primarily supports the development of regulatory T cells, which in principle can prevent the development of type 1 diabetes. Notably, both IL-7 and IL-2 receptors are strongly regulated during early T cell activation and polarization. The influence of IL-2 and IL-7 receptor expression pattern on the T cell response to IL-7 and IL-2 and how this affects T cell polarization remains unclear. The aim of this study was to determine cellular and soluble IL-7 and IL-2 receptor expression and to examine the influence of IL-7/IL-2 in vitro on the generation, polarization, and regulation on T cell immunity and to identify possible dysregulation of T cell functions in type 1 diabetes.

Materials and methods: Children with type 1 diabetes were recruited and classified according to the manifestation age (below or above 5 years) and disease duration. T cell activation in the presence or absence of IL-7 dependent T cell response is characterized in vitro. Flow cytometry was applied to determine activation markers, cytokine profile, and IL-7/IL-2 receptor expression. Concomitantly soluble IL-7 and IL-2 receptor isoform expression was quantified in plasma and culture samples using cytometric bead array technology. Immunological results were correlated with clinical data (including autoantibody status and HLA type).

Results: Initial results showed significant differential IL-7 and IL-2 receptor expression during T cell activation with and without IL-7. In addition, we detected increased proportions of IFN γ /TNF α expressing T cells in the presence of IL-7 and remarkably IL-10 expression was also enhanced by IL-7. Notably, IL-7 and IL-2 receptor concentrations in serum samples varied markedly between individual patients with newly diagnosed diabetes.

Conclusion: Functional in vitro analyses of IL-7/IL-2 receptor expression during T cell activation and effector cytokine expression may provide insight into relevant events in the development of type 1 diabetes autoimmunity. Soluble cytokine receptors in serum are biomarker candidates for disease manifestation and severity.

Relationship between Hashimoto's thyroiditis, autoimmune and metabolic markers in adult onset autoimmune diabetes

L. Duvnjak^{1,2}, D. Majić Milotić¹, M. Senta³, K. Blaslov^{1,2}, J. Knežević Čuča¹;

¹University Hospital Merkur, Zagreb, ²School of Medicine, University of Zagreb, ³University Hospital Center Zagreb, Croatia.

Background and aims: Hashimoto's thyroiditis and juvenile type 1 diabetes mellitus (T1DM) are the most common combination of autoimmune (AI) disorders. It was recently proposed that besides genetic susceptibility central obesity might contribute to unknown mechanisms underlying the thyroid-antibody production. Latent AI diabetes in adults (LADA) is characterized by clinical presentation resembling type 2 diabetes but with T1DM autoimmune markers, primarily glutamic acid autoantibody (GAD Ab). Little is known about the presence of Hashimoto's thyroiditis in LADA and adult onset T1DM. We aimed to investigate the relationship between Hashimoto's disease presence, AI markers and metabolic features in patients with LADA and adult-onset T1DM.

Materials and methods: Four hundred and seven patients diagnosed with AI diabetes over the age of 30 years were divided according to Ab positivity into three groups: GAD single positive group (representing

LADA); islet cell Ab (ICA)+GAD positive and ICA+GAD+protein tyrosine phosphatase Ab (IA2) positive group representing adult-onset T1DM. ICA Ab was measured by indirect immunofluorescence. GAD and IA2 Abs were detected by enzyme like immunoadsorbent assay (ELISA). Hashimoto's thyroiditis was diagnosed by thyroid ultrasound guided needle biopsy and serologic tests for thyreoglobulin and tissue peroxidase Abs by chemiluminescent immunoassay (CLIA). Body mass index (BMI), waist circumference, arterial hypertension (AH), THS, FT3, FT4, triglycerides, HDL cholesterol and statin use were also evaluated.

Results: Patients characteristics are shown in Table 1. LADA group showed significantly higher Hashimoto's thyroiditis presence compared to the groups of adult-onset T1DM. Although all patients had TSH and peripheral thyroid hormone levels within the normal range, TSH was significantly higher in the LADA group compared to other two groups. Higher BMI, waist circumference, statin use and AH presence were more common in the LADA group. In the regression analysis including Ab status, BMI, waist circumference, the use of statins and the presence of AH adjusted for gender and age at diagnosis, single GAD positivity was significantly associated with Hashimoto's thyroiditis (OR 1.977 (1.174-3.328), p=0.001). The association was also significant for waist circumference and statin use (OR 1.038 (1.003-1.072), p=0.031; OR 1.525 (1.171-1.716), p=0.008).

Conclusion: Hashimoto's thyroiditis is more prevalent in patients with LADA compared to other forms of AI diabetes in adults. The possible association of both GAD positivity and waist circumference with the presence of Hashimoto's thyroiditis in LADA patients was found. These results might indicate the potential contribution of central obesity in Hashimoto's pathogenesis which needs to be clarified in further studies.

Islet cell associated autoantibodies in Ethiopians with diabetes mellitus

E.S. Siraj¹, M. Gupta², H. Yifter³, A. Ahmed³, T. Kebede³, A. Reja³;
¹Temple University School of Medicine, Philadelphia, ²Cleveland Clinic, Cleveland, USA, ³Addis Ababa University, Faculty of Medicine, Ethiopia.

Background and aims: Our understanding of the role of autoimmunity in the pathogenesis of diabetes in African population is limited. This study aims to evaluate the prevalence of 4 different islet cell associated antibodies in Ethiopian patients with diabetes as well as non-diabetic controls. In addition, the study intends to assess the utility of a combi-assay for the simultaneous detection of antibodies against glutamic acid decarboxylase (GADA) and the protein tyrosine phosphatase like IA-2 (IA-2A) as a first-line screening test for antibodies.

Materials and methods: A total of 187 subjects from a Diabetic Clinic at an Ethiopian Hospital were evaluated in a cross sectional study. Fifty five patients had type 1 diabetes mellitus (T1DM), 86 patients had type 2 diabetes mellitus (T2DM) and 46 were non-diabetic controls. In addition to clinical information, blood samples well collected. Islet cell associated

antibodies were measured by using 4 different assays for: islet cell antibodies (ICA), GADA, insulin autoantibodies (IAA) and the IA-2A.

Results: The mean age of studied subjects was 29 years in T1DM, 51 years in T2DM and 29 years in controls. The mean duration of diabetes was 7 years in T1DM and 9 years in T2DM. The results of the antibody studies [no. positive/no. tested (% positive)] are shown in the Table below. Testing with individual assays revealed that the combi-assay positivity was entirely due to GADA and none due to IA-2A. The GADA assay had a concordance rate of 95% when compared with ICA assay. In subjects with T2DM, GADA positivity was associated with insulin requirement ($P=0.022$), lower BMI ($P=0.039$) and lower basal C-peptide levels ($P=0.005$).

Conclusion: 1- Ethiopian patients with T1DM have a higher prevalence of islet cell associated autoantibodies than patients with T2DM. 2- GADA seems to be significantly present in Ethiopians whereas IA-2A seems to be absent. 3-Because of its simplicity and its good diagnostic accuracy, GADA should replace the ICA as the assay of choice. 4-Subjects with T2DM, who are GADA+, have some features of T1DM, supporting the notion that a subset of T1DM patients may exist within the group of Ethiopians with T2DM.

Proinsulin peptide immunotherapy in type 1 diabetes: safety data of a first in new-onset type 1 diabetes phase 1b trial

M. Alhadj Ali¹, Y.-F. Liu², R. Stenson¹, G. Clifford¹, L. Adams³, J. Powrie³, D. Kyne⁴, N. Leech⁴, K. Green⁵, R. Andrews⁵, M. Peakman², C. Dayan¹;

¹Cardiff University School of Medicine, ²Department of Immunobiology, King's College London, ³Department of Diabetes and Endocrinology, Guy's and St. Thomas' Foundation Trust, London, ⁴Department of Diabetes and Endocrinology, Victoria Royal Infirmary, Newcastle upon Tyne, ⁵Joint Clinical Research Unit, Bristol Royal Infirmary, UK.

Background and aims: In Type 1 Diabetes, nonclinical studies have shown that Antigen Specific Therapy (ASI) strategies have been highly effective in disease prevention, and some of them have worked in the much more stringent setting of close to, or at, disease onset. Furthermore, they have demonstrated that the ASI strategies may be effective when the relevant autoantigen is delivered as a short peptide, representing a key target (termed an epitope) of the pathological T lymphocyte response that is characteristic of the disease. Clinical trials of ASI as applied to Type 1 Diabetes have predominantly focused on insulin as the autoantigen, administered by a variety of routes, in the setting of secondary prevention. Aims and objectives: We aimed to examine the safety of intradermal administration of the naturally processed proinsulin peptide C19-A3 (PPI C19-A3) at a dose of 10 µg every 14 days or every 28 days for a total of 12 doses (Group B) and 6 doses (Group C), respectively, to patients with new-onset Type 1 diabetes.

Materials and methods: The trial was a multi-centre, randomised; double-blind, placebo-controlled, 3-arm study of 10 µg of PPI C19-A3 peptide administered every 14 or every 28 days, with follow-up for 48 weeks. 27 patients aged 18-45 with new-onset Type 1 Diabetes, HLA-

DRB1*0401 genotype, antibody positivity and a stimulated c-peptide level >0.2 pmol/ml were recruited to the trial within 100 days of diagnosis. All subjects received injections at bi-weekly intervals, and in the case of the placebo group (Group A) ($n=8$) this was normal saline only; for the low frequency dosing group (Group C) ($n=10$) this was alternate study drug and normal saline only; and for the high frequency dosing group (Group B) ($n=9$) this was the study drug on every occasion.

Results: The trial injections have been generally well tolerated and all recruited patients completed the trial follow up with no withdrawal. No events of systemic hypersensitivity (type 1) have been reported in the trial, therefore; it has been shown that administration of Proinsulin peptide was safe. Only 5 serious adverse events (SAEs) were reported and classified as mild or moderate in severity (either unrelated or unlikely related to the randomisation drug). Local trial investigators did not report any SUSAR. More than 75% of adverse events (AEs) have been reported as hypoglycaemic episodes unlikely related to the randomisation drug, however; local skin reaction at the injection site has been reported as an AE that is likely related to the trial drug with no systemic complications.

Conclusion: Proinsulin peptide immunotherapy in the dosing regimen used is well tolerated and free from the risk of systemic hypersensitivity and serious adverse reactions. The safety from hypersensitivity reaction was clearly seen in the repeated dosing up to 12 doses in the same patient. This phase 1 trial will pave the route for future phase 2 trials in new-onset Type 1 Diabetes which aim to examine the effectiveness of Proinsulin peptide immunotherapy on T cell autoimmunity and preservation of β cell function.

Prevalence of latent autoimmune diabetes in young, non obese, adult onset diabetes patient with poor response to oral insulin secretagogues

A. Shrivastav, S. Mukhopadhyay, S. Chowdhury;
Institute of Post Graduate Medical Education & Research, Kolkata, India.

Background and aims: Latent autoimmune diabetes in adults (LADA) is defined as adult-onset diabetes with circulating islet antibodies but not requiring insulin initially. Diagnosing LADA has treatment implications because of the high risk of progression to insulin dependency. This study was done to observe the prevalence of LADA in young (25-40 years), adult onset (>20 years) and non obese ($BMI<23$) diabetic patients having poor glycaemic control with Oral insulin secretagogues

Materials and methods: Three hundred young (25-40 years), adult onset (>20 years) and non obese ($BMI<23$) diabetic with poor glycaemic control with optimal dosage of Oral insulin secretagogues (Sulphonylureas) were included in the study. None of the patient had e/o Ketoacidosis. Detailed clinical History, family history and Anthropometric measurements were taken. Ultrasound screening of pancreas was done for every patient. HbA1c, fasting C peptide, 1 hour post meal C peptide, Anti Glutamic acid decarboxylase antibodies (GADA) and Islet Cell Autoantigen 512 Antibodies (AntiIA2) were estimated for every patient.

Results: The mean age of patients was 33 years and they had diabetes for an average of 6 years. On Autoantibody screening, 134 patients came out to be Autoantibody positive. 122 patients (40.67%) were positive for GADA and 21 patients were positive for Anti IA2 antibodies. 9 of the 21 Anti IA2 positive patients were also having Anti GAD Antibodies. Patients who were Antibody positive had lower BMI, more complications and worse glycaemic control. Family history of Diabetes was most predictive of absence of Antibodies.

Conclusion: The high prevalence of LADA (44.67%) in our study is among a selected subclass of diabetic with higher pretest probability for LADA. The prevalence in general diabetics will be much lower. However we can say that Antibody screening in this select group of diabetic

(young, non obese, no family history) is warranted and will lead to better standards of care. The low positivity of Anti IA2 Antibody as compared to GADA has also been observed in other Indian studies and may be due to lower prevalence of HLA DR4. Young, non obese diabetes patients with adultonset diabetes, no family history and poor response to oral insulin secretagogues should be screened for Autoimmune Diabetes. Fasting / Stimulated C peptide is a good screening test with a poor response leading to a higher pre test probability for testing positive for LADA. A high C peptide rules out Autoimmune Diabetes.

Misclassification of outcomes of pancreas transplantation

T. Bawa¹, S. Clarke-Swaby², M. Drage², P. Choudhary³,
¹King's College London, ²Guy's Hospital, London, ³Diabetes Research Group, King's College London, UK.

Background and aims: Success rates for pancreas transplantation have been steadily improving, with 5-year survival rates over 70% for simultaneous pancreas kidney transplants. Currently, graft failure is defined as the re-introduction of insulin, which has some limitations. Different clinicians have different thresholds to introduce insulin, and some choose to start oral therapies first in some cases. Alternatively, some patients may still have residual C-peptide despite being on insulin therapy, providing important protection against hypoglycaemia. As a result, current graft survival rates may not provide an accurate picture of graft success - i.e. restoration of the patient to the non-diabetic state. Our hypothesis is that a clinically relevant proportion of patients may be misclassified. Our aim was to identify the number of patients with misclassified graft function who had had a pancreas transplant at our transplant unit between 2008 and 2012.

Materials and methods: We were able to obtain latest available HbA1c, fasting glucose [FG], C-peptide, and current therapy for 103/124 pancreas transplant recipients at Guy's hospital between 2008 and 2012, of which 90 were simultaneous pancreas kidney and 13 were solitary pancreas transplantations. We classified pancreas grafts using current definitions of function based on insulin use and compared this to a modified classification based around definitions of diabetes. We categorised grafts using the following criteria: 1] Functioning: HbA1c<6% or FG <6.1 mmol/L, and on no diabetes medication; 2] Partial function: HbA1c≥6% or FG≥6.1 mmol/L, and on basal insulin alone/oral therapy/no therapy, or having C-peptide>300pmol/L. 3] Failure: Pancreatectomy or C-peptide<300pmol/L. If C-peptide was unavailable, HbA1c≥6.5% or FG≥7.0, and full insulinisation was considered graft failure.

Results: Of the 103 transplants, there were 10 early technical failures [<1 month post transplantation]. 71 are currently classified functioning and 22 as late failure, after a mean follow up of 4.0±1.7 years. Of 71 functioning grafts, 7 met our criteria of partial function, with 2 patients on oral therapy and 5 with raised HbA1c on no therapy. Of the 22 with late failure [mean time to failure 1.7±1.4 years], 2 met our criteria of partial function; 1 had residual function with preserved C-peptide, the other on basal insulin only. In the 20 that met our criteria of failure, 45% [n=9] failed after experiencing a period of partial function. In total, 9/103 grafts [8.7%] were misclassified according to our criteria. C-peptide data was incomplete and some patients classified as having late failure may still have some measurable C-peptide.

Conclusion: Our new classification system would reclassify 8.7% of grafts as having partial function. Almost half of the grafts that developed late failure were documented as having a period of partial graft function for some time before complete graft failure, and identifying these patients early may represent an opportunity to understand mechanisms of graft failure and intervene to prolong graft survival.

Protein tyrosine phosphatase 1B is a novel target on the improvement of islet graft's revascularisation

H. Figueiredo¹, A.L. Castillo Figueroa¹, A. Garcia^{1,2}, R. Fernandez-Ruiz^{1,3}, H.S.M. Farghaly^{1,3}, R. Malpique¹, R. Gomis¹,
¹Diabetes and Obesity Research Laboratory, IDIBAPS-Hospital Clínic, University of Barcelona, ²CIBERDEM, Barcelona, Spain, ³Faculty of Medicine, Assiut, Egypt.

Background and aims: One of the main limitations encountered in pancreatic islet transplantation, leading to islet loss and graft failure is poor revascularization. Protein tyrosine phosphatase 1B (PTP1B) is known to negatively mediate several signaling pathways by maintaining phosphotyrosine levels in key proteins. Recently PTP1B was described as a negative regulator of angiogenesis through vascular endothelial growth factor (VEGF) signaling. In this sense, our main aim is to investigate if PTP1B ablation contributes to the improvement of graft revascularization and survival.

Materials and methods: Diabetic BALB/c mice (single injection of streptozotocin - 160 mg/Kg) were transplanted, with 200 islets, isolated from PTP1B^{-/-} or PTP1B^{+/+} mice, into the anterior chamber of the eye. Four groups of animals were constitute (n=12 animals/group): Non transplanted; Control - transplanted with PTP1B^{+/+} islets; PTP1B^{-/-} - transplanted with PTP1B^{-/-} islets; and not diabetic group. Animals were followed for 28 days during which weight and glycemic levels were measured. Graft revascularization was evaluated, *in vivo*, at day 7, 15 and 28. *Post-mortem* morphometric analysis was conducted on graft-containing eyes. Gene expression (qRT-PCR), and protein detection (ELISA), were performed in islet samples.

Results: After 28 days the PTP1B^{-/-} group showed normalization of glycemic levels when compared with the not diabetic group (PTP1B^{-/-}: 161±32 mg/dL vs not diabetic: 140±22, not significant) and a dramatic decrease when compared with the control (472±52 mg/dL, 66% decrease, p<0.05) and non transplanted groups (528±22, 70% decrease, p<0.01). Graft functional vascularization was assessed, *in vivo*, after 7, 15 and 28 days post-transplant. In all moments, PTP1B^{-/-} group, showed increased vascular density (day 7: PTP1B^{-/-}: 0.0187±0.002% vs Control: 0.0130±0.001%, p<0.05/ day 15: PTP1B^{-/-}: 0.0290±0.005% vs Control: 0.0188±0.002%, p<0.05/ day 28: PTP1B^{-/-}: 0.0297±0.004% vs Control: 0.0187±0.005%; p<0.05) and increased vascular area (day 7: PTP1B^{-/-}: 11.3±3% vs Control: 5.8±2%, p<0.001/ day 15: PTP1B^{-/-}: 21.4±2% vs Control: 10.8±2%, p<0.001/ day 28: PTP1B^{-/-}: 23.180±2% vs Control: 10.027±3%; p<0.001). Grafts from both groups reached maximum revascularization by day 15. Morphometric analyses of the graft-containing eyes (recovered at day 28) revealed a 5-fold increase on the percentage of β-cell expressing VEGF on PTP1B^{-/-} grafts when compared with the control (PTP1B^{-/-}: 89.9±9% vs control: 17.86±3%; p<0.001). Moreover, when compared with PTP1B^{+/+} islets, PTP1B^{-/-} islets show a 3 fold increase in VEGF expression (p<0.05) and, at the protein level, a 1.8 fold increase in relative VEGF secretion by VEGF islet content (PTP1B^{-/-}: 1.95±0.45 vs PTP1B^{+/+}: 1.05±0.1, p<0.05).

Conclusion: Our results reveal PTP1B as a particular key player on the revascularization of islet grafts, suggesting this as a potential novel target for an improved therapeutic treatment in islet transplantation. Further investigation is being conducted to decipher the signaling mechanism behind these findings.

The co-transplantation of islets with dental pulp stem cells improved survival and function of transplanted beta cells in streptozotocin-induced diabetic mice

I.-A. Takako^{1,2}, T. Shin¹, I. Atsushi¹, H. Kaori¹, N. Yasuhiro¹, M. Ryuya¹, S. Yusuke³, H. Yoji³, O. Yutaka¹;

¹Endocrinology and Diabetes, ²Oral and Maxillofacial Surgery, ³Metabolic Medicine, Nagoya University Graduate School of Medicine, Japan.

Background and aims: Pancreatic islet transplantation is an attractive treatment option for Type 1 diabetes mellitus (T1DM). Islet transplantation has some issues, however, such as the required administration of immuno-suppressant drugs and the low rate of insulin withdrawal due to a short survival rate of transplanted islets. Therefore, it is critical how to protect the viability of transplanted islets in recipient. Recent studies reported that co-transplantation of Mesenchymal Stem Cells (MSC) with pancreatic islets improved glycemic control more than that of pancreatic islets alone. Meanwhile, we have reported that secreted factors from stem cells, especially Dental pulp stem cells from human exfoliated deciduous teeth (SHED) rather than MSC, has beneficial effects in paracrine manner on viability of pancreatic islets. SHED have received considerable attention because of requiring a less invasive collection method and their applicability to autologous treatment. Therefore, we examined the effect of co-transplantation of islets with SHED on glycemic control in streptozotocin (STZ) diabetic mice.

Materials and methods: Islets were isolated from 10 week-old male C57Bl/6J. STZ (150 mg/kg body weight) was intraperitoneally injected into 10 week-old male C57Bl/6J mice one time only. Three days after this single STZ injection, the mice were divided into six transplanted groups: Sham (CTL), transplantation of SHED alone (a-SHED: 5×10^5 cells), MSC alone (a-MSC: 5×10^5 cells), islet alone (a-Is: 75 islets), islets with MSCs (co-MSC: 75 islets and 5×10^5 cells) or islets with SHED (co-SHED: 75 islets and 5×10^5 cells). The cells were transplanted into the kidney capsule of C57Bl/6J. An intraperitoneal glucose tolerance test (IPGTT) and insulin content were examined 28 days after the transplantation.

Results: Co-SHED ameliorated glucose intolerance and reduction of body weight in STZ-diabetic mice and the effects continued for 28 days after transplantation, although all other groups did not show any beneficial effect. Only Co-SHED also suppressed the elevated level of blood glucose and enhanced the insulin secretion during IPGTT. These data suggested that the improved viability of transplanted islets possibly contributed to the improvement in glycemic regulation, thus we next investigated the state of insulin preservation in transplanted islets. Co-SHED and co-MSC preserved the insulin content of transplanted islets in the kidney capsule more than a-Is, and the level of insulin content in co-SHED was much higher than in co-MSC. Interestingly, histological study showed that transplanted SHED survived for 28 days after transplantation, even though any immuno-suppressant drug was not administrated.

Conclusion: This study demonstrated that co-transplantation of islets with SHED had much more beneficial effects on the survival of transplanted islets than transplantation of islet alone and co-transplantation with MSC. Furthermore, the result of their long survival of SHED after transplantation suggested that SHED might modulate the immune reaction. The co-transplantation of islets with SHED has potential as practical strategy for T1DM treatment.

A newly developed non-haematopoietic erythropoietin analogue prevents damages to transplanted islets and inhibits macrophage activation

M. Kumagai-Braesch¹, M. Watanabe¹, A. Cerami², M. Brines², C.-G. Östenson³, T. Lundgren¹;

¹CLINTEC, Transplantation Surgery, Karolinska Institutet, Stockholm, Sweden, ²Araim Pharmaceuticals, Tarrytown, USA, ³Molecular Medicine, Karolinska Institutet, Solna, Sweden.

Background and aims: Pancreatic islet transplantation (PITx) efficiency has been hampered by islet damage during isolation and inflammatory reactions at transplantation. Erythropoietin (Epo) exerts anti-inflammatory, anti-apoptotic and cyto-protective effects in addition to its hematopoietic property. We've investigated if a newly developed non-haematopoietic epo analogue, ARA 290, would protect islets and ameliorate inflammatory responses following PITx.

Materials and methods: Effects of ARA 290 on pancreatic islets of C57BL/6J (H-2b) mice and on murine macrophage were investigated in vitro in a culture model. As a marginal PITx, 175 islets were transplanted intraportally to STZ-induced diabetic mice (H-2b). ARA 290 (120 µg/kg) was given intraperitoneally just before and at 0, 6 and 24 hours after PITx. Liver samples were obtained at 12 hours after PITx, and expression levels of pro-inflammatory cytokines were assessed.

Results: ARA 290 protected islets from cytokine-induced damage and apoptosis. Pro-inflammatory cytokine secretions (IL-6, IL-12 and TNF-α) were significantly inhibited by ARA 290. In the transplantation study, ARA 290 treatment significantly improved metabolic control of recipients after marginal mass PITx. Intra peritoneal glucose tolerance test (IPGTT) performed at day 14, showed significantly lower area under the curve (AUC) in the ARA 290 treated group (Figure 1). Up-regulation of MCP-1, MIP-1β, IL-1β and IL-6 mRNA expression within the liver were suppressed by ARA 290 treatment.

Conclusion: ARA 290 protected pancreatic islets from cytokine-induced damage and apoptosis in vitro and ameliorated the inflammatory response following PITx. It appears to be a promising candidate for improvement of PITx.

Figure 1: AUC in IPGTT (* $p < 0.05$ vs. control group; values are depicted as lower quartile, median and upper quartile (boxes) with minimum and maximum ranges.).

Quantitative imaging of intramuscular transplanted islets of Langerhans with SPECT by dopamine 2 receptor targeting

S.M.A. Willekens, I. van der Kroon, D. Bos, L. Joosten, C. Frielink, O.C. Boerman, M. Brom, M. Gotthardt;
Radiology and Nuclear Medicine, Radboud university medical center, Nijmegen, Netherlands.

Background and aims: Besides insulin therapy, islet transplantation is considered one of the most promising therapies for type 1 diabetic patients with poor glycemic control. Despite improvements in immunosuppressive therapy, islet transplantation still results in short term insulin independence. A non-invasive imaging method to, longitudinally and quantitatively, monitor the viable transplanted islets might provide insight in the faith of the islets after transplantation. Furthermore, it would offer the possibility to evaluate potential interventions that might improve long term transplantation outcome. Dopamine (D2) receptors are expressed on beta cells and are therefore a suitable target to monitor islet grafts. Here, we investigated the use of the D2 receptor antagonist [123 I]iodobenzamide ([123 I]IBZM) for the quantification of viable graft volume.

Materials and methods: Six weeks after rats were transplanted intramuscularly with 1000, 2000 or 3000 islets, they received 50 MBq [123 I]IBZM intravenously and one hour post injection SPECT images were acquired. Afterwards, animals used for ex vivo autoradiography were injected with [125 I]IBZM, euthanized 1 h post-injection, and the graft containing muscles were dissected for ex vivo SPECT, autoradiography and histological analysis. Viable graft volume was calculated histologically by multiplying insulin-positive area by interslice distance.

Results: Six weeks after transplantation, a clear signal of all grafts was observed by SPECT. Moreover, the intensity of the SPECT signal correlated linearly with the calculated viable graft volume (Pearson $r=0,73$; $p=0,005$). The SPECT signal observed in the calf muscle ex vivo correlated with the SPECT signal observed in the calf muscle in vivo. Furthermore, ex vivo autoradiography confirmed specific tracer accumulation and co-localization with the grafts location, as determined histologically. These observations confirm that the SPECT signal observed in vivo originates from specific targeting of the D2 receptor, expressed on the graft.

Conclusion: In conclusion, [123 I]IBZM can successfully be applied for non-invasive, quantitative graft observation in vivo. Especially in combination with other beta cell specific tracers, such as exendin, it might provide a strong tool to obtain detailed complementary information by non-invasive molecular imaging and to predict islet graft metabolic state and transplantation outcome.

Comparative biology of porcine and human islets in situ and after xenotransplantation in vivo

J.K. Stertmann, C.M. Cohrs, C. Chen, H. Chmelova, M. Solimena, S. Speier;
Paul Langerhans Institute Dresden of Helmholtz Centre Munich at the University Clinic Carl Gustav Carus of the Technische University Dresden, Germany.

Background and aims: Islet transplantation is a successful experimental clinical approach for the treatment of brittle diabetes. However, its wide application is limited by the shortage of human organ donors. Pig to human xenotransplantation may serve as a potential alternative approach. Sparse previous work on isolated islets and dispersed cells suggested that porcine islet endocrine cell composition and architecture differs from human islets, potentially affecting the regulation of islet cell function. However, detailed information about the physiology of porcine islets as well as the vascular network is still limited. To further increase our knowledge and to circumvent the enzymatic stress during islet isolation, we utilize acute pancreas tissue slices to compare the three-dimensional morphology of porcine and human islets *in situ*. This approach allows the analysis of endocrine cells and intact intra-islet vascular network within a conserved anatomical environment under near physiological conditions. Furthermore, we evaluated the ability of porcine and human islets to rebuild their distinct vascular network after transplantation, by three-dimensional analysis of transplanted islets *in vivo*.

Materials and methods: We here used a combinational approach of pancreas tissue slices and the anterior chamber of the mouse eye platform to assess three-dimensional islet architecture of human and porcine islets in the endogenous pancreas *in situ* and after xenotransplantation *in vivo*. *In situ* analysis of endogenous islet architecture was performed on pancreas tissue slices prepared from slaughterhouse pigs and human tissue obtained after partial pancreatectomy. The tissue was stained for insulin, glucagon for endocrine cell composition and the vascular network was visualized by fluorescently labeled lectin. *In vivo*, intra-islet vascular network was assessed in fully engrafted porcine and human islets transplanted to the anterior chamber of the mouse eye by i.v. injection of a fluorescent tracer.

Results: Three-dimensional analysis of human and porcine pancreatic tissue slices revealed cell compositional differences of the insulin (55% ± 6.95 for human vs. 67.4% ± 6.10 for porcine, p -value < 0.05) and glucagon fraction (24.7% ± 7.73 human vs. 6.2% ± 2.66 porcine, p -value < 0.01). Additionally fractional blood volume displayed significant differences between the species (7.97% ± 2.65 vs. 10.26% ± 2.94 , p -value < 0.05).

After xenotransplantation into the anterior chamber of the mouse eye, the vascular network of porcine donor islets was similar to the *in situ* situation (8.78% ± 3.63). In contrast, human islets displayed a reduced potential to revascularize under xenogenic conditions (2.32% ± 1.10).

Conclusion: In conclusion, the three-dimensional *in situ* analysis reveals interspecies differences of islet architecture which are potentially important for islet function. Additionally, our *in vivo* approach could show that porcine islets have the potential to rebuild their endogenous vascular network under xenogenic conditions which might be crucial for therapeutic islet transplantation.

The effect of transplanted pancreatic islets on recipient liver morphology: rat animal study

J. Kriz¹, E. Fabryova², Z. Papackova², D. Jirak³, E. Sticova⁴, M. Cahova², T. Koblas², F. Saudek¹;

¹Diabetes Center, ²Center of Experimental Medicine, ³MRI unit, ⁴Transplant Center, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: The permanent hyperinsulinemia in Type-2 diabetic patients is considered a likely risk factor for development of primary liver tumor. Pancreatic islets are commonly transplanted into the hepatic portal vein and the liver tissue is subsequently exposed to insulin in locally high concentration. There were published several articles pronouncing the hypothesis of a direct influence of transplanted islets on formation and subsequent progression of morphological changes in liver tissue (tumors, cysts). Therefore our study was focused on monitoring of liver changes during 10 months follow up after transplantation of pancreatic islets in rat animal model.

Materials and methods: Isolated pancreatic islets were transplanted into diabetic (streptozotocin) or healthy recipients in isogenic manner. Group A (n=5) - healthy Brown Norway recipients, transplantation of 450 islets into the portal vein; Group B (n=17) - STZ (50 mg/kg) diabetic Brown Norway recipients, transplantation of 450 islets into the portal vein; Group C (n=8) - STZ (50 mg/kg) diabetic Brown Norway recipients, transplantation of 1000 islets under the left kidney capsule; Group D (n=8) - STZ (60 mg/kg) diabetic Prague Hereditary Hypertriglyceridemic recipients, transplantation of 1200 islets into the portal vein; Blood glucose levels, weight, IVGTT was monitored in all recipients for 10 months. The morphology of liver was examined by magnetic resonance imaging (MRI) 5 and 8 weeks after islet transplantation. At the end of study all recipients liver were excised, fixed in formalin and examined by histology.

Results: Injection of streptozotocin induced severe diabetes (glycaemia over 25 mmol/l) in all animals. Transplantation of pancreatic islets in suboptimal number normalized fasting blood glucose levels but did not normalize glucose assimilation in IVGTT in all diabetic recipients. In healthy recipients transplanted islets did not modify blood glucose levels. While liver of Group A recipients remained intact, in animals of Group B and C the substantial part of liver tissue was cystically changed. Multiple voluminous cystic complexes with cholangiocyte cubic epithelium lining were detected in these animals irrespective of transplantation site. In insulin resistant animals of Group D, the transplanted islets caused just formation of focal steatosis until the end of study. The total volume of hepatic cysts detected in animals of group B by MRI was 0.42±0.92 ml and 4.68±9.57 ml five and eight months after transplantation, respectively. This represented 4.3% and 29.3% of total liver volume.

Conclusion: The injection of diabetogenic agent streptozotocin and subsequent transplantation of isogenic pancreatic islets can induce liver morphological changes, which were different in relation to the strain. Further research is needed to identify the differences in Brown Norway and hHTG rats, which are substantial for kind of liver reaction.

Human IAPP impairs the success of islet transplantation

A. Hara^{1,2}, Y. Fujitani¹, T. Oghihara¹, T. Miyatsuka¹, H. Watada^{1,2};

¹Department of Metabolism & Endocrinology, ²Center for Therapeutic Innovations in Diabetes, Juntendo University Graduate School of Medicine, Tokyo, Japan.

Background and aims: β-cell replacement by islet transplantation has been explored as a potential curative therapy for type 1 diabetes. Despite

advancements in islet manipulation and immune suppression that have increased the survival of transplanted islets, the progressive decline of graft function remains a problem, and many recipients return to being insulin dependent within a few years after the transplant. However, the molecular mechanisms underlying the loss of function of grafted islets have not been fully elucidated. Islet amyloid polypeptide (IAPP)-derived amyloid deposits were observed in approximately half of the implanted islets in a recipient with type 1 diabetes. We therefore hypothesized that human IAPP (hIAPP) in transplanted islets contributes to loss of islet function and impairs the success of islet transplantation. The aim of this study was to elucidate the role of hIAPP during islet transplantation, using knock-in mice that express a physiological level of hIAPP.

Materials and methods: Islet donors were 16-week-old hIAPP-KI male mice and C57BL/6J (control) male mice. Mice with a plasma glucose level >400 mg/kg 7 days after streptozotocin treatment that were fed a high-fat diet (60% fat) were used as recipients. Recipients were implanted under the kidney capsule with 150 hIAPP-KI or control islets. Following transplantation, blood glucose levels and body weight were measured for 8 weeks. Thereafter, metabolic parameters were measured, and the graft-bearing kidney was subjected to both histological and biochemical analysis. To assess glucose level-dependent cell death, islets were cultured for 4 days in medium containing 200, 300, or 400 mg/dL glucose, and oligonucleosomes released into the cultured cell lysate were quantified.

Results: Plasma glucose levels were significantly higher in mice implanted with hIAPP-KI islets (hIAPP group) than control islets from 3 days after transplantation. Normalized scores, which reached normoglycemic levels (<200 mg/dL) after transplantation, were lower in the hIAPP group than the control group. HbA1c levels were well controlled in the control group (4.8%) but not in the hIAPP group (6.7%) after 8 weeks of transplantation (P<0.005). The insulin content of kidneys from the hIAPP group were significantly lower than the control group. The ratio of cleaved caspase 3 (cell death marker)-positive cells to insulin-positive cells was significantly higher in the hIAPP group than in the control group. Culturing of hIAPP-KI islets for 4 days in 400 mg/dL glucose increased the production of cell death marker, oligonucleosomes was significantly increased by 1.8 times compared with control islets.

Conclusion: In summary, we showed that the physiological level of hIAPP is associated with an increase in β-cell apoptosis, and inhibits the amelioration of hyperglycemia by islet transplantation.

5 year safety and effectiveness of islet transplantation in subjects with eGFR <60: retrospective observational study

R.A. Oram, T. Olateju, Y. Ling, S. Imes, A. Malcolm, A.M.J. Shapiro, P.A. Senior;

Clinical Islet Transplant, University of Alberta, Edmonton, Canada.

Background and aims: Kidney-pancreas transplant is optimal treatment for Type 1 diabetes (T1D) with end-stage renal disease (ESRD) while islet transplantation (ITx) has been reserved for subjects with adequate renal reserve. Since renal impairment increases the risk of severe hypoglycaemia, the short term risks of severe hypoglycemia may justify the potential renal risks of ITx with calcineurin inhibitor (CNI) based immunosuppression in T1D with moderate, stable renal impairment.

Materials and methods: We compared the safety and effectiveness of ITx in T1D subjects with or without renal impairment (eGFR<60 ml/min) in a single centre, 5 year, retrospective study. The primary end points were a) safety: progression to ESRD, doubling of serum creatinine, or death from any cause; and b) effectiveness: proportion maintaining good glycemic control (a1c <7%) and protection from hypoglycemia (HYPO score<423, Clarke score<4 and LI<329) at 5 years.

Results: 118 ITx recipients with at least 5 years of follow up (transplanted between 1999-2009) were included. Maintenance immunosuppression was with sirolimus plus tacrolimus or tacrolimus plus mycophenolate. 29/118 (25%) subjects had eGFR<60 ml/min at baseline. Subjects with eGFR<60 were older (mean \pm sd: 52 \pm 10 v 44 \pm 10 years, $p=0.0001$), female gender 69 v 52% ($p=0.1$), median(IQR) eGFR was 81(71-92) v 54 (48-58). The proportion of subjects reaching the safety end point was 3/28 (11%) v 7/86 (8%) ($p=0.7$). The proportion reaching the efficacy end point was 14/29 (48%) v 37/82 (45%) ($p=0.8$). Average yearly GFR decline was slightly greater with higher starting gfrs ($r=0.15$, $p<0.0001$).

Conclusion: ITx appears to be equally safe and effective to provide good glycemic control and protection from hypoglycaemia over 5 years in carefully selected subjects with moderate renal impairment. These data help guide the risk benefit assessment for T1D subjects with both severe hypoglycemia and renal impairment.

Efficacy of autologous stem cells transplantation in patients with type 2 diabetes mellitus: a randomised placebo-controlled study

S. Bhansali¹, V. Kumar², V. Jha², N. Marwaha³, N. Khandelwal⁴, A. Bhansali¹, P. Dutta¹;

¹Endocrinology, ²Translational and Regenerative Medicine, ³Transfusion Medicine, ⁴Radiodiagnosis, PGIMER, Chandigarh, India.

Background and aims: T2DM is characterized by two major defects: insulin resistance and insulin deficiency. Current therapies in T2DM targeting β -cells are insulin, glitazones and GLP-1 analogs. These therapies have demonstrated glycemic durability over a prolonged period of time but their role in β -cells regeneration is elusive. Therefore, this has led to the emergence of novel β -cells regenerative therapies like hematopoietic stem cell (HSCs), mononucleated stem cells (MNCs) and mesenchymal stem cells (MSCs). This study evaluates the efficacy of autologous bone marrow derived-stem cell transplantation (ABMSCT) and autologous bone marrow derived-mesenchymal stem cell transplantation (ABM-MSCT) in patients with T2DM.

Materials and methods: This prospective, randomized, single-blinded placebo controlled study enrolled 30 patients with triple oral hypoglycemic drug failure and requiring insulin ≥ 0.4 Units/Kg/day for achieving euglycemia (HbA1c $\leq 7.5\%$). They were randomly assigned to MSCs group (n=10), MNCs group (n=10), who received ABM-MSCT and ABMSCT through targeted approach respectively, while control arm (n=10) underwent sham procedure and were followed for 6 months. The efficacy of intervention was assessed by gold standard method "hyperglycemic clamp" to estimate C-peptide response and insulin sensitivity index. The primary end-point was a reduction in insulin requirement by $\geq 50\%$ from baseline, while maintaining HbA1c $\leq 7\%$.

Results: Six out of 10 (60%) patients in the ABM-MSCT and 9 out of 10 (90%) patients in the ABMSCT, while one (10%) in the control group achieved the primary endpoint ($p=0.001$). There was a modest but not significant decrease in HbA1c in ABM-MSCT from 6.9% (6.6-7.0%) to 6.8% (6.4-7.3%) ($p=0.441$), ABMSCT from 6.7% (6.4-7.3%) to 6.9% (6.5-7.0%) ($p=0.575$) as well as in controls from 6.5% (6.2-6.8%) to 6.2% (6.0-6.2%) ($p=0.262$). There was a significant increase in C-peptide response in ABMSCT ($p=0.046$), while improvement in insulin sensitivity index ($p=0.04$) in ABM-MSCT group during hyperglycemic clamp. There was a significant decrease in HOMA-IR ($p=0.028$) in ABM-MSCT, while HOMA - β function were remain unaltered ($p=0.445$) in ABMSCT.

Conclusion: The ABMSCT and ABM-MSCT results in reduction in insulin dose while maintaining target HbA1c. MSCs improves insulin sensitivity index and MNCs improves β cell function. A combined therapy with these two types of stem cells remains to be explored.

Effect of pioglitazone, exenatide and combination of pioglitazone and exenatide on plasma alpha-hydroxybutyrate in type 2 diabetes

D. Tripathy, A. Chavez-Velazquez, R. Martinez, A. Hansis, R. DeFronzo;

Diabetes, Medicine, University of Texas Health Science Center, San Antonio, USA.

Background and aims: Alpha-hydroxybutyrate has been shown to be an early marker of insulin resistance in recent studies. Pioglitazone is known to reduce plasma alpha-hydroxybutyrate in IGT subjects. The aim of this study was to examine the effect of Pioglitazone, Exenatide(Byetta) and a combination of these two on plasma metabolites in subjects with T2DM.

Materials and methods: We randomized thirty T2DM subjects (age=55 \pm 3 yrs; BMI=34.9 \pm 5; FPG=167 \pm 10 mg/dl; HbA1c=8.3 \pm 0.4%) to receive the following: (i) Exenatide (EXE 10ug bid, n=11), (ii) pioglitazone (PIO, 45 mg/d, n=10), or (iii) PIO+EXE (n=9) for 24 weeks. Subjects also participated in an OGTT and 2-step hyperglycemic (+125 and +400 mg/dl) clamp followed by IV arginine (5 g) bolus prior to treatment and again at week 24 of treatment. Plasma alpha-hydroxybutyrate, linoleoyl-GPC (LGPC), and oleic acid were measured before and after treatment.

Results: At baseline there was no significant difference in the concentrations of the measured metabolites between subjects. Combined Pioglitazone+Exenatide yielded the greatest reduction in fasting plasma glucose, 2-hr glucose and HbA1c compared to treatment with individual medications (all $p<0.05$). Combined treatment increased Matsuda Index (MI) of insulin sensitivity from 2.7 \pm 0.5 to 5.9 \pm 0.6 ($p<0.05$). Pioglitazone alone improved Matsuda Index of insulin sensitivity (MI) from 4.9 \pm 0.8 to 7.9 \pm 1.5 ($p<0.05$). Pioglitazone treatment alone decreased the fasting FFA (0.643 \pm 0.06 to 0.376 \pm 0.07 μ M, $p=0.001$) and 2-hour FFA (0.252 \pm 0.09 to 0.09 \pm 0.01 μ M, $p=0.009$). Pioglitazone therapy led to a significantly lower alpha-hydroxybutyrate (6.31 \pm 0.8 vs 4.8 \pm 0.7 μ g/mL, $p=0.04$) and oleic acid (72 \pm 5.4 vs 53.7 \pm 6.8 μ g/mL, $p=0.03$), however Pioglitazone did not affect plasma LGPC levels. Alpha-hydroxybutyrate correlated with insulin secretion insulin sensitivity index in Pioglitazone treated subjects ($r=0.643$, $p=0.04$). Combined Pioglitazone+Exenatide treatment showed a trend to reduced plasma alpha-hydroxybutyrate (6.31 \pm 0.8 vs 4.8 \pm 0.7 μ g/mL, $p=0.058$). There were no significant changes in plasma metabolites seen in patients treated with Exenatide alone.

Conclusion: Pioglitazone reduces novel metabolites related to lipid metabolism and oxidative stress. This could represent a novel mechanism by which TZDs improve insulin sensitivity. Plasma alpha-hydroxybutyrate was not affected by Exenatide suggesting that the mechanism of improved glycemic control seen with Exenatide is primarily by improvement in insulin secretion.

Chronic caffeine intake restores insulin sensitivity in high-sucrose diet rats through adaptations in adipose tissue metabolism

J.C. Coelho¹, B.F. Melo¹, T. Rodrigues², P. Matafome², J.F. Sacramento¹, M.J. Ribeiro¹, M.P. Guarino^{1,3}, R. Seiça², S.V. Conde¹;

¹CEDOC, NOVA Medical School, Faculdade de Ciências Médicas, Universidade NOVA de Lisboa, ²Laboratório de fisiologia, IBILI, Faculdade de Medicina, Universidade de Coimbra, ³UIS-Unidade de Investigação em Saúde- Escola Superior de Saúde de Leiria- Instituto Politécnico de Leiria, Portugal.

Background and aims: Several epidemiological studies have described beneficial effects of chronic coffee intake on type 2 diabetes and metabolic syndrome. Our group has previously shown that chronic caffeine (caff) intake both prevents and reverses insulin resistance in prediabetes animal models, being the time needed to restore insulin sensibility inversely correlated with the caff concentration administered. It is known that obesity is associated with insulin resistance and that alterations in adipose tissue (AT) metabolism contribute to the development and maintenance of insulin resistance. Therefore, the aim of this work was to investigate if the enhancement of insulin sensitivity induced by chronic caff intake is due to alterations in AT metabolism, namely in fat deposition, lipid profile and insulin signaling pathway in this tissue.

Materials and methods: All experiments were performed in 8-13 weeks *Wistar* rats of both genders (250-450 g). Two groups of rats were used: the high sucrose (HSu) group and a control group. The HSu model was obtained by submitting animals to a 35% sucrose diet in drinking water during 28 days. After the 28 days, the 2 groups were divided and submitted to different caff concentration in drinking water: 0, 0.5, 0.75 and 1 g/L during 12 weeks. Insulin sensitivity and glucose tolerance were monitored during all the experimental period. Afterwards rats were anaesthetized with pentobarbitone (60 mg/Kg) and blood was collected by heart puncture. Abdominal fat was collected and weighted and plasma cholesterol, HDL, LDL and triglycerides were measured. Western blots of proteins involved in insulin signaling pathway in AT were performed.

Results: HSu diet did not change weight gain in relation to controls, however both visceral and total fat weight increased by 47% and 49% respectively (visceral fat control=5.29±0.86 g; total fat control=23.59±4.30 g). Chronic caff intake did not modify daily weight gain either in control or in the HSu group. Caff did not promote changes in total or visceral fat in the control group, however in the HSu group, visceral fat deposition was inhibited by caff in all concentrations tested and total fat deposition was inhibited by caff concentrations of 0.75 and 1 g/L. Hsu diet, as well as caff intake, did not significantly modify cholesterol, LDL and HDL plasma levels. Nevertheless, HSu diet increased triglycerides levels to 77.58±5.89 mg/dl (control=42.69±5.17 mg/dl) and caff showed a trend to decrease triglycerides in this group, in a dose dependent manner. Although caff did not change AT insulin receptor (IR), protein kinase B (Akt) and Glut4 total expression, it increased the expression of the phosphorylated forms of the IR and Akt in the Hsu animal model.

Conclusion: Chronic caff administration avoids visceral and total fat accumulation in a concentration dependent manner in HSu animals, without altering animal's weight. Although caff did not directly affect IR expression in the AT, it stimulated insulin signaling cascade, suggesting that this may be one of the mechanisms for caffeine-induced improvement of insulin sensitivity in HSu rats.

The rapid subcutaneous injection of heparin plus insulin lispro improved dramatically blood glucose of a patient with subcutaneous insulin resistance

T. Sumita¹, T. Hosaka², T. Iuchi¹, G. Sakai¹, S. Yasuda¹, S. Katayama¹, I. Inoue¹;

¹Saitama Medical University, ²Kyorin University, Tokyo, Japan.

Background and aims: Subcutaneous insulin resistance (SIR) is a syndrome, which is caused by increased insulin inactivation or proteolytic degradation in the dermal tissue and by impaired transport of injected insulin from subcutaneous tissue into the circulation. The blood glucose levels of 48 year-old male with type 2 diabetes, who injected insulin about 200 U per day, were still high. Interestingly, his blood glucose levels were improved near normal after direct infusion of insulin into vein. Thus, he was considered to be a state of SIR. In this report, we evaluate the successful treatment of this SIR case.

Materials and methods: The dimethyl-isopropyl-azulene ointment including 0.1% nafamostat mesilate (NAF) as a protease inhibitor was treated with the case, which is expected to prevent insulin degradation at the injection skin spot. Heparin modulates vascular endothelial growth factor and is expected to accelerate subcutaneous diffusion of insulin into the blood stream. And insulin lispro mixed with heparin (Hepalis) consisted of the concentrations of 500 U heparin and 50 U insulin per one mL respectively. And Hepalis was injected by syringe or continuous subcutaneous infusion (CSII) capillary. The blood glucose level (7 times in a day), serum C-peptide and serum insulin was examined.

Results: The blood glucose levels after lispro insulin injection at the skin spot with NAF contain ointment (310±17 mg/dL) were not significantly changed compared to those without NAF's one (351±22 mg/dL). Next, Hepalis was tried to inject as the continuous basal insulin injection by CSII. The blood glucose levels with Hepalis after replaced similar amounts of lispro insulin were a little decreased (327±16 mg/dL), but not significant (p=0.05), compared to those with lispro alone (360±12 mg/dL). And then, although the Hepalis treatment by CSII was tried as basal-bolus insulin, the blood glucose levels were still not decreased under 300 mg/dL. Finally, we tried to inject as bolus insulin by syringe at the short time. The activity of Hepalis was suspected to impair due to slowly infusion by CSII because an injection time of Hepalis by CSII was took about ten minutes. Basal heparin infusion was continued by CSII. Drastically, the blood glucose levels after Hepalis infusion by syringe were decreased significantly (P<0.001) and reached the levels under 200 mg/dL with gradual Hepalis elevation, followed by the significant increasing serum levels of insulin lispro.

Conclusion: In this SIR case, Injection of Hepalis rapidly into subcutaneous tissue was more effective to circulate the insulin lispro and to improve the blood glucose levels. Though the precise mechanism of this SIR has not been cleared, our report will be a clue to discover the pathophysiology of the SIR.

Acetic acid enhances insulin-stimulates glucose uptake by the forearm muscle in patients with type 2 diabetes

E. Petsiou¹, P. Mitrou², E. Papakonstantinou¹, E. Maratou², V. Lambadiari¹, F. Spanoudi¹, S.A. Raptis^{1,2}, G. Dimitriadis¹;

¹2nd Department of Internal Medicine, Attikon University Hospital, ²Hellenic National Center for Research, Prevention and Treatment of Diabetes Mellitus and its Complications (H.N.D.C), Athens, Greece.

Background and aims: Acetic acid, the main constituent of vinegar, has been shown to have a glucose-lowering effect in patients with glucose abnormalities. However, the mechanisms of this effect are still obscure. The aim of this randomised, cross-over study was to investigate the effect of vinegar on 1) muscle glucose uptake and blood flow rates and 2)

circulating plasma glucose, insulin and lipid levels, in patients with type 2 diabetes, using the arteriovenous difference technique across the forearm muscles.

Materials and methods: Eleven subjects with DM2 (age 53+4 years, BMI 25+1, HbA1c 6.8+0.3%) consumed vinegar (30 ml containing 6% acetic acid, 20 ml water) or placebo (50 ml water), at random order on two separate days (a week apart), before a mixed meal (557 kcal; 75 g carbohydrates, 26 g protein, 17 g fat). Plasma glucose, insulin, triglycerides, non-esterified fatty acids (NEFA) and glycerol were measured preprandially and at 30–60 min for 300 min postprandially from the radial artery and from a forearm vein. Muscle blood flow was measured with strain-gauge plethysmography. Glucose flux was calculated as the arteriovenous difference of glucose multiplied by the blood flow rates.

Results: Vinegar compared to placebo: 1) increased forearm glucose uptake (765+87 vs 579+63 $\mu\text{mol}/100\text{ ml tissue}$, $p=0.0357$) 2) decreased plasma glucose (2834+134 vs 3005+149 $\text{mM}\cdot\text{min}$, $p=0.0279$), insulin (16136+3397 vs 20473+4185 $\text{mU/L}\cdot\text{min}$, $p=0.0457$) and triglycerides (371+34 vs 409+38 $\text{nmol/L}\cdot\text{min}$, $p=0.0439$) 4) did not change muscle blood flow, plasma NEFA and glycerol.

Conclusion: In DM2 vinegar reduces postprandial hyperglycaemia, hyperinsulinaemia and hypertriglyceridaemia without affecting lipolysis. Vinegar's effect on carbohydrate metabolism may be partly accounted for by an increase in glucose uptake, demonstrating an improvement in insulin action in skeletal muscle.

Clinical Trial Registration Number: NCT02309424

The in vitro pharmacology of LY IGLar (LY2963016): a new insulin glargine product

J.S. Moyers, S.D. Kahl, X. Ruan, C. Zhang, M.W. Farnen, M.D. Michael, R.A. Owens;

Eli Lilly and Company, Indianapolis, USA.

Background and aims: Basal insulin analogs, with durations of action sufficient for coverage over the course of 24 hours, are important for the proper management of glycemic control in the patients with diabetes. LY IGLar (LY2963016, insulin glargine), an insulin analog with the same amino acid sequence as insulin glargine (Sanofi-Aventis; IGLar), differs from human insulin due to the addition of two arginine residues to the C-terminus of the B-chain and due to the replacement of asparagine at position A₂₁ with a glycine. These changes shift the isoelectric point such that the insulin glargine analog is soluble at an acidic pH but then precipitates after injection at the neutral physiological pH.

Materials and methods: The pharmacological properties of six independent lots of LY IGLar were compared to IGLar using a panel of in vitro biological assays. The receptor binding affinity of LY IGLar for the human insulin receptor isoform A (hIR-A), hIR isoform B (hIR-B), and human IGF-1 receptor (hIGF-1R) was determined by competitive radioligand binding using cell membranes prepared from HEK-293 cells overexpressing the cloned receptors. Functional activation of hIR signaling was determined in cells by quantitation of receptor phosphorylation by ELISA using 293 cells expressing hIR-A or hIR-B, de novo lipogenesis from [¹⁴C]-glucose in 3 T3-L1 adipocytes, and cell proliferation by [³H]-thymidine incorporation in human Saos-2 cells. Statistical comparisons were determined for the K_i/EC_{50} responses from each assay using the Sidak and Holm-Bonferroni multiple comparison adjustment methods with the significance level set at $\alpha=0.05$.

Results: The receptor binding affinity, K_i , of LY IGLar was determined to be 0.41±0.01, 0.45±0.03, and 16.0±0.4 nM for hIR-A, hIR-B, and hIGF-1R, respectively. The affinities were comparable to those observed for IGLar at 0.40±0.02, 0.45±0.04, and 15.5±0.6 nM, respectively. To determine whether LY IGLar and IGLar stimulated similar functional activation of hIR, we used 293 cells expressing hIR-A or hIR-B to determine

the half-maximal concentrations, EC_{50} , of each ligand required to stimulate receptor tyrosine phosphorylation. The EC_{50} values for LY IGLar were 3.7±0.2 and 2.1±0.1 nM for hIR-A and hIR-B, respectively. The EC_{50} values for IGLar were 4.5±0.2 and 2.5±0.1 nM for hIR-A and hIR-B, respectively. Using 3 T3-L1 adipocytes to assess ligand stimulation of metabolic activity, we found that LY IGLar and IGLar were maximally efficacious with comparable EC_{50} values for stimulation of de novo lipogenesis from glucose. The EC_{50} of LY IGLar was 0.97±0.09 nM and the EC_{50} of IGLar was 0.87±0.08 for stimulation of de novo lipogenesis. The mitogenic potential of LY IGLar and IGLar was determined by [³H]-thymidine incorporation in the hIGF-1R dominant human cell line, Saos-2. The EC_{50} values for stimulation of cell proliferation by LY IGLar and IGLar were 0.53±0.03 and 0.53±0.03 nM, respectively.

Conclusion: Results showed that the in vitro pharmacological properties of LY IGLar were not different from IGLar, supporting LY IGLar as an alternative therapy for patients with diabetes.

D-chiro-inositol improves metabolic control in overweight patients with type 1 diabetes

A. Maurizi, R. Del Toro, M. Menduni, A. Lauria Pantano, S. Kyanvash, S. Manfrini, P. Pozzilli;

Endocrinology and Diabetes, University Campus Bio-Medico, Rome, Italy.

Background and aims: With the increase of obesity in childhood and adolescence, insulin resistance is now occurring more frequently in patients with type 1 diabetes (T1D). Consequently, insulin doses are often increased causing weight gain and poor glycaemic control in these patients. Therefore, to achieve optimal glycaemic control and to improve insulin sensitivity, insulin sensitizing drugs such as metformin are commonly used in addition to insulin therapy in overweight and obese T1D patients. Similarly to metformin, studies in vitro and in animal models have shown that D-Chiro-Inositol (DCI), as putative mediator of intracellular insulin action can accelerate glucose disposal and act as insulin sensitizer. In recent clinical trials significant reduction of DCI plasma levels and a linear relationship between its decreased urinary excretion and the degree of insulin resistance were observed. In these conditions oral supplementation with DCI seems to improve glucose metabolism reducing insulin resistance status. The aim of this prospective, randomized controlled trial was to evaluate the efficacy of DCI oral supplementation on glycaemic control as assessed by HbA1c in patients with T1D undergoing intensive insulin therapy.

Materials and methods: A total of 25 patients affected by T1D aged 17–50 years (12 males, 13 females) with disease duration >1 year and BMI >25, were enrolled in the study. Patients were randomised to 1 g DCI plus 400 mcg folic acid once daily (treated group) or to 400 mcg folic acid only once daily (control Group). HbA1c and BMI were evaluated at entry into the trial and at 3 and 6 months follow-up. The sample size for the study has been calculated taking into account 80% power and a difference of HbA1c of 0.3% at the end of the study period. Paired t test (two tailed) and analysis of variance were used to evaluate differences in HbA1c and BMI at different time points.

Results: HbA1c at entry was 8.3%±0.14 (SD) in DCI treated group and 7.9%±0.28 (SD) in control patients (p :NS). After 3 months follow-up a statistically significant reduction of HbA1c levels were observed in DCI treated group vs. control group (7.4%±0.8 vs. 7.7%±1.0, respectively, p :<0.05). At the end of the study period HbA1c reduction in DCI treated group vs. control group was statistically confirmed. BMI at entry was 25.6±1.8 (SD) in DCI treated group and 27.1±2.2 (SD) in control patients (p :NS). After 3 and 6 months follow-up there was a tendency for a reduction in BMI in the DCI treated group vs. control group (25.2±1.5 vs. 26.9±1.5, respectively, p :NS)

Conclusion: Insulin therapy is the mainstay of treatment for patients with T1D. This trial demonstrated for the first time that the oral supplementation of DCI to insulin treatment in T1D patients improves glycaemic control as shown by a significant reduction of HbA1c levels.

521

The role of a fixed Berberis aristata/Silybum marianum combination in the treatment of type 1 diabetic patients

G. Derosa, D. Romano, A. D'Angelo, P. Maffioli;

Internal Medicine and Therapeutics, University of Pavia, IRCCS Policlinico S.Matteo, Italy.

Background and aims: Berberis Aristata is available in a fixed dose with Silybum Marianum, in order to increase its low bioavailability. Even if the effects of Berberis Aristata in type 2 diabetic patients have been already reported, nothing has been published about Berberis Aristata use in type 1 diabetic patients. For this reason, the aim of this study was to evaluate if the addition of Berberis Aristata/Silybum Marianum leads to a reduction of insulin dose and to an improvement of glycemic control in type 1 diabetic patients.

Materials and methods: We enrolled 85 type 1 diabetic patients and randomized them to add, to their usual insulin therapy, placebo or Berberis Aristata/Silybum Marianum 588/105 mg, 1 tablet during the lunch and 1 tablet during the dinner, for six months. We evaluated if there was a reduction of insulin dose necessary to reach an adequate glycemic control. We also evaluated at baseline, and after 6 months: body mass index (BMI), glycated hemoglobin, fasting plasma glucose (FPG), post-prandial glucose (PPG), total cholesterol (TC), low density lipoprotein-cholesterol (LDL-C), high density lipoprotein-cholesterol (HDL-C), triglycerides (Tg). The null hypothesis that the expected total dose of insulin used from randomization would did not differ significantly between placebo, and Berberis Aristata/Silybum Marianum was tested using analysis of variance and analysis of covariance (ANCOVA) models. Similar analyses were applied to the other variables. The statistical significance of the independent effects of treatments on the other variables was determined using ANCOVA. A 1-sample t test was used to compare values obtained before and after treatment administration; 2-sample t tests were used for between-group comparisons. Statistical analysis of data was performed using the Statistical Package for Social Sciences software version 11.0 (SPSS Inc., Chicago, Illinois, USA). For all statistical analyses, $p < 0.05$ was considered statistically significant.

Results: We observed a reduction of total insulin dose necessary to achieve an adequate glycemic control in Berberis Aristata/Silybum Marianum, both compared to baseline and to placebo ($p < 0.05$ for both). Regarding insulin administration at meals, we recorded that the group treated with Berberis Aristata/Silybum Marianum used less insulin at meals, both compared to baseline and placebo ($p < 0.05$ for breakfast, and $p < 0.01$ for lunch and dinner). The same can be said for insulin at bedtime ($p < 0.05$ for both vs baseline and vs placebo). We observed a decrease of glycated hemoglobin with Berberis Aristata/Silybum Marianum compared to baseline ($p < 0.05$), but not compared to placebo. There was a decrease of FPG, and PPG with Berberis Aristata/Silybum Marianum both compared to baseline and to placebo ($p < 0.05$ for both). We recorded a decrease of TC, Tg and LDL-C and an increase of HDL-C with Berberis Aristata/Silybum Marianum both compared to baseline and to placebo ($p < 0.05$ for both).

Conclusion: The addition of Berberis Aristata/Silybum Marianum to insulin therapy in type 1 diabetic patients leads to a reduction of the insulin dose necessary to achieve an adequate glycemic control.

Resveratrol improves glucose homeostasis in diabetic rats: Potential involvement of the hepatic glucose handling

C.Y. Yonamine, E.P. Machado, J.V.D. Esteves, H.S. Freitas, M.M. Okamoto, U.F. Machado;

Physiology and Biophysics, University of São Paulo, Brazil.

Background and aims: The polyphenol resveratrol is a powerful activator of the sirtuin 1 (SIRT1), a histone deacetylase that plays an important role in the cellular homeostasis. It has been described that resveratrol improves the metabolic profile of obese subjects; however, the mechanisms by which this effect occurs remain obscure. Glycemic homeostasis involves a balance between glucose uptake and delivery, respectively in skeletal muscle and liver. These glucose fluxes are impaired in diabetes mellitus (DM), and have been related to decreased GLUT4 protein (encoded by the Slc2a4 gene) in muscle and increased GLUT2 protein (encoded by the Slc2a2 gene) and phosphoenolpyruvate carboxykinase (Pepck) expression in liver. Despite evidence that resveratrol improves the metabolic profile, it is not established if it could contribute to improve glycemic homeostasis in DM. We hypothesized that resveratrol could revert the DM-induced alterations in the expression of glucose transporters, thus contributing to improve glycemic homeostasis. Therefore, the present study investigated, in insulin-treated diabetic rats, if resveratrol improves glycemic homeostasis, and regulates gene expression of the glucose transporters in muscle and liver as well.

Materials and methods: Male Wistar rats were rendered diabetic by streptozotocin injection (50 mg/Kg of body weight); citrate buffer-injected rats were used as non-diabetic controls (ND). Twenty days later, the diabetic rats were divided into 3 groups: placebo-treated diabetic (DP), insulin-treated diabetic (DI, 6 U/day insulin) and insulin+resveratrol treated diabetic (DIR) (6 U/day insulin + 10 mg/Kg resveratrol). After 30 days of treatment, glycemia, 24-hour glycosuria and plasma fructosamine were evaluated, and soleus muscle and liver were sampled for analysis of Slc2a4, Slc2a2 and Pepck mRNAs (qPCR), and GLUT4, GLUT2 and p-AMPK (phosphorylated AMP-activated protein kinase) proteins (Western blotting). Results were analyzed by one-way ANOVA, followed by Bonferroni post-test.

Results: As expected, DP rats showed increased glycemia, 24-hour glycosuria and plasma fructosamine. DI and DIR showed similar decrease in glycemia and glycosuria; however, only DIR restored completely the fructosamine concentration ($P < 0.01$ vs DP and DI). In soleus, diabetes decreased Slc2a4 (by 60%, $P < 0.001$), GLUT4 (by 53%, $P < 0.05$) and p-AMPK (by 48%, $P < 0.05$); and all these parameters were similarly recovered in DI and DIR rats. On the other hand, in liver, diabetes increased the Slc2a2 (by 3.6 folds, $P < 0.001$), GLUT2 (by 30%, $P < 0.05$) and Pepck (by 80%, $P < 0.01$); and insulin alone was not able to significantly alter these parameters. However, the addition of resveratrol to insulin treatment restored the Slc2a2 ($P < 0.001$ vs DP and $P < 0.05$ vs DI), GLUT2 ($P < 0.05$ vs DP and DI) and Pepck ($P < 0.001$ vs DP, $P < 0.05$ vs DI) expression to the non-diabetic values.

Conclusion: Addition of resveratrol to insulin treatment of diabetic rats improved long-term glycemic homeostasis, as evinced by plasma fructosamine levels. Resveratrol also decreased Slc2a2 and Pepck in liver, indicating reduction in hepatocyte gluconeogenic activity and glucose efflux as well. No evidence of resveratrol effect in skeletal muscle was observed. In summary, the results reveal that resveratrol, as coadjuvant in the insulinotherapy of diabetic rats, improves glycemic homeostasis, and that involves reduced hepatic glucose production.

Stearoyl-CoA desaturase and its regulation in human skeletal muscle by exercise

K. Eckardt¹, S. Lee¹, T.M. Langlete¹, T. Holen¹, J. Jensen², K.I. Birkeland^{3,4}, C.A. Drevon¹;

¹Department of Nutrition, University of Oslo, ²Norwegian School of Sport Sciences, Oslo, ³Department of Endocrinology, Oslo University Hospital, ⁴Institute of Clinical Medicine, University of Oslo, Norway.

Background and aims: Stearoyl-CoA desaturase 1 (SCD1) catalyzes the rate-limiting step in the synthesis of monounsaturated fatty acids (FA), which are required for *de novo* triacylglycerol synthesis. In this way SCD1 also converts FA with a high lipotoxic potential into FA with lower lipotoxic potential, e.g. palmitic acid (PA) to palmitoleic acid. Recently, a muscle-specific SCD1-overexpressing mouse model was described with elevated glucose uptake, FA oxidation and exercise capacity. Hence, a high SCD1 level in skeletal muscle might be beneficial for its metabolic function. Here, we investigated the regulation of SCD1 in human skeletal muscle.

Materials and methods: Healthy sedentary men categorized either as control (BMI=23.5±2.0 kg/m², normal fasting and 2 h serum glucose levels, n=13) or dysglycemic (pT2D; BMI=28.9±2.5 kg/m², fasting glucose≥5.6 mmol/L and/or 2 h serum glucose≥7.8 mmol/L, n=11) participated in a combined strength and endurance training for 12 weeks. In addition, an acute endurance test was performed before and after the intervention. Biopsies from *m. vastus lateralis* were taken before, directly after, and 2 h post exercise, before and after intervention. RNA was isolated and analyzed by high throughput mRNA sequencing followed by differential gene expression analysis. Primary human skeletal muscle cells (SkMC) were exposed to electrical pulse stimulation (EPS) to induce contraction, low dose of PA or a combination of both followed by analyses using qRT-PCR.

Results: At baseline SCD1 mRNA expression was 50% lower in skeletal muscle of pT2D compared to control group (p<0.001). After the intervention SCD1 expression was enhanced significantly both in pT2D (1.8-fold, p<0.001) and control subjects (1.5fold, p<0.001). Both groups also had increased VO₂max (13%, p<0.001) and insulin sensitivity (pT2D 29%, p<0.01; control 36%, p<0.001). At baseline acute exercise increased SCD1 mRNA expression in the pT2D group directly after the acute bout (1.3fold, p<0.05). After intervention the pT2D group exhibited a significant 1.9-fold increase in SCD1 mRNA expression p<0.001) 2 h post exercise, which then reached a similar level as in the controls. During *in vitro* differentiation of SkMC SCD1 mRNA expression increased significantly (3.7-fold, n=5-6) in parallel with up-regulation of myogenin (4-fold) and MHCIIa (10-fold). Stimulation of contraction by EPS (1 Hz, 2 ms, 11.5 V) for 24 h significantly promoted SCD1 mRNA expression (1.5-fold, p<0.05, n=7) in parallel with induction of PGC1α (1.8-fold, p<0.01) and IL-6 (2.8-fold, p<0.01). Incubation of SkMC with PA increased SCD1 mRNA expression significantly at a concentration as low as 20 μM (1.2-fold, p<0.05). Maximum induction of 2-fold was observed at 100 μM (p<0.001, n=8), and higher concentrations of PA up to 300 μM had no additional effect. The combination of EPS and PA for 24 h increased SCD1 mRNA expression 3.8-fold (p<0.001, n=7) compared to control cells.

Conclusion: Given the important role of SCD1 in lipid metabolism its lower expression in skeletal muscle of overweight dysglycemic subjects may be linked to metabolic impairments observed in similar groups of participants. Moreover, the up-regulation of SCD1 by long-term exercise may be associated with increased insulin sensitivity.

Does the energy cost of walking explain why patients with diabetic peripheral neuropathy walk more slowly?

M. Petrovic¹, F. Bowling², K. Deschamps³, S. Verschueren³, C. Maganaris⁴, A. Boulton², N. Reeves¹;

¹Manchester Metropolitan University, ²University of Manchester, UK, ³Katholieke Universiteit Leuven, Belgium, ⁴Liverpool John Moores University, UK.

Background and aims: It has previously been shown that patients with diabetes and especially those with diabetic peripheral neuropathy (DPN) choose to walk more slowly (self-selected speed) and display a number of other gait alterations compared to age-matched healthy controls. It has been suggested that patients with diabetes and DPN have a lower self-selected walking speed to lower the physical demands of walking. However, there are a number of physiological alterations with diabetes that would increase the energy cost of walking (CoW). We therefore hypothesise that the CoW will be higher in patients with diabetes and DPN compared to controls when walking at the same speed, and will dictate the choice of a slower self-selected walking speed in patients with diabetes and DPN. The aim of this study was to investigate the CoW in patients with diabetes and neuropathy at different speeds.

Materials and methods: Participants were allocated into one of the three groups: healthy controls (Ctrl; mean age: 56, n=31), patients with diabetes but no neuropathy (DM; mean age: 51, n=22) and patients with diabetes and moderate-severe peripheral neuropathy (DPN; mean age: 66, n=14). Participants walked at a range of control speeds on a treadmill while expired air was measured to determine oxygen uptake and the CoW calculated. Participant's self-selected walking speed was measured in a gait laboratory using motion analysis. Group differences were tested using an ANOVA and LSD post-hoc test.

Results: Self-selected walking speed was lower in DM and DPN patients compared to controls, albeit not reaching significance (Ctrl: 1.45; DM: 1.38; DPN: 1.35 m·s⁻¹; P>0.05) but the CoW was not different between groups. At standardised speeds, patients with DPN walked with a higher CoW compared to the Ctrl and DM group and this was mostly evident at the speeds of 0.6, 0.8, 1.0, 1.2 and 1.6 m·s⁻¹ (Figure 1).

Conclusion: When walking at the same controlled speeds, the CoW was significantly higher in people with DPN compared to controls, people with DPN chose to walk more slowly than controls, but there were no differences in the CoW between groups at this self-selected speed. There are a number of physiological mechanisms such as stiffer tendons that cause a higher CoW in people with DPN when they are 'forced' to match the walking speed of controls. We suggest that the CoW is a major factor in determining why people with DPN choose to walk more slowly, since they seek to minimise the energy CoW. This will likely have implications for the level physical activity and amount of walking people with DPN choose to perform, which might impact upon glycaemic control.

Energy expenditure from daily physical activity and risk of developing diabetes and change in cardiovascular risk factors

M. Kurita¹, T. Nakagami¹, J. Oya¹, C. Isago¹, Y. Tanaka¹, Y. Hasegawa¹, A. Ito¹, Y. Endo², Y. Uchigata¹;

¹Tokyo Women's Medical University School of Medicine, ²Health and Community Medicine, Saitama-ken Saiseikai Kurihashi Hospital, Saitama, Japan.

Background and aims: Prior studies have shown that leisure time physical activity decreased the risk of incidence of diabetes and hypertension, and increasing daily steps ameliorated lipid metabolism in Japanese. However, very few studies used the information of energy expenditure (EE) estimated from time and intensity during daily physical activity. Here, we examined the association between daily EE estimated by validated questionnaires and risk of developing diabetes and change in cardiovascular risk factors.

Materials and methods: We registered 1,532 Japanese health checkup examinees at SSK hospital who were neither previously diagnosed diabetes, or medicated hypertension or dyslipidemia. They completed the Japan Arteriosclerosis Longitudinal Study Physical Activity Questionnaire, which examined usual patterns of physical activity during the previous month. Of those, 1,096 (746 men, average age: 55±8 years) were followed for 5 years. Incidence of diabetes was defined when HbA1c ≥6.5% or fasting plasma glucose (FPG) ≥126 mg/dl was observed at least once during the follow-up period. The relation between total (tertile) or leisure time (0 or >0) EE at baseline and 5-year change in waist circumference (Wc), body mass index (BMI), FPG, blood pressures, lipids, and high-sensitivity C-reactive protein (CRP) were analyzed. Cox's proportional hazard model was used to calculate hazard ratios (HRs) and their 95% confidence intervals (CIs) for incidence of diabetes from total or leisure time EE at baseline.

Results: In men, total EE had negative relations with FPG and triglyceride (TG) at baseline, and leisure time EE had a positive relation with HDL-cholesterol (HDL-c) and negative relations with TG and CRP at baseline (all p<0.05). In women, total EE had negative relations with Wc and BMI at baseline and a positive relation with HDL-c, and leisure time EE had no relation with cardiovascular risk factors at baseline. Increasing total EE (tertile 1 → 3) increased 5-year change of HDL-c (3.0 → 5.0%, p=0.037) in men. Men with leisure time EE>0 showed lower 5-year change in TG and higher 5-year change in HDL-c compared with men with leisure time EE=0 (25 vs 14% and 1.5 vs 6.3% respectively, all p<0.05). In comparison with the 1st tertile of total EE, HRs (95% CI) for the risk of developing diabetes in the 2nd and 3rd tertiles were 0.71 (0.32-1.61) and 0.73 (0.33-1.65) for men, and 1.33 (0.30-5.96) and 0.32 (0.03-3.04) for women, respectively. The HRs (95%CI) for the risk of developing diabetes in leisure time EE>0 in comparison to leisure time EE=0 were 0.78 (0.34-1.78) for men and 0.54 (0.13-2.27) for women.

Conclusion: Increasing total EE, especially leisure time EE, ameliorated lipid metabolism during five years in Japanese men. The non-significant effect of EE on the development of diabetes may in part reflect the heterogeneity of pathophysiology of diabetes.

Reduced and adverse metabolic response to supervised 8-week endurance exercise in a group at high risk for type 2 diabetes

A. Böhm^{1,2}, G. Schnauder¹, P. Schneeweiß¹, J. Hudemann¹, A. Nieß¹, C. Hoffmann^{1,2}, C. Weigert^{1,2}, J. Machann^{2,3}, H. Staiger^{1,2}, A. Fritsche^{1,2}, N. Stefan^{1,2}, H.-U. Häring^{1,2};

¹Internal Medicine, Eberhard Karls University Tübingen, ²Institute for Diabetes Research and Metabolic Diseases (IDM) of the Helmholtz Center Munich at the University Tübingen, ³Radiology, Eberhard Karls University Tübingen, Germany.

Background and aims: Increase in physical activity is essential for the prevention of type 2 diabetes. However, there is evidence that people differ in their individual response to exercise and there is little information available about potential pathomechanisms involved.

Materials and methods: In our study center in Tübingen, a group of 20 middle-aged individuals (13 women, 7 men), at high risk for type 2 diabetes, completed an 8-week supervised endurance training (3×1h/week) on sub-maximal intensity (80% VO₂max). Individual anaerobic threshold (IAT) was determined by lactate measurements during incremental exercise, peak aerobic capacity (VO₂max) by spirometry at exhaustion. Pre and post intervention, insulin sensitivity was measured by a 75 g frequently sampled oral glucose tolerance test. Body fat mass and distribution were determined by magnetic resonance imaging, liver fat content by ¹H magnetic spectroscopy.

Results: Despite the relative short time of the intervention, an increase in VO₂max (from 22.9±5.1 to 25.4±5.8; p=0.0442) and IAT (from 1.1±0.3 to 1.3±0.3; p<0.0001), a decrease in BMI (from 32.5±4.7 to 32.2±4.8, p=0.0309), percent body fat (from 39.0±10.7 to 36.9±10.7; p=0.0320), total adipose tissue mass (from 35.4±10.4 to 34.6±10.6; p=0.0234), RR_{diastolic} (from 92±10 to 88±9; p=0.0324), heart ratio (from 76±13 to 70±9; p=0.0200), triglycerides (from 114±36 to 98±38, p=0.0176), and LDL cholesterol (from 117±28 to 111±25; p=0.0268) was observed. Unexpectedly, insulin sensitivity, did not change significantly (8.3±6.4 vs. 9.5±7.8; p=0.1). We found a high variability in the change of insulin sensitivity, ranging from 0.6 - to 2.7-fold during the intervention. Insulin sensitivity did not improve in 20 percent of the participants; in 40 percent of the subjects a negative effect on insulin sensitivity was seen. Between the two groups with the largest changes of insulin sensitivity (8 responder versus 8 non-responder) there were no differences in baseline parameters. However, after adjustment for sex, age and BMI, transaminases (GOT: 28±6 vs. 24±8, p_{adj}=0.0082; GPT: 32±13 vs. 30±16; p_{adj}=0.0080; γ-GT: 38±14 vs. 21±15; p_{adj}=0.05) and intrahepatic lipids (8.4±6.6 vs. 7.8±8.5, p_{adj}=0.03) were higher in the responders, pointing to a possible impact of intrahepatic lipids on the increase of insulin sensitivity during a supervised exercise training.

Conclusion: We found that, although mean body fat mass and cardiorespiratory fitness improved during a supervised exercise intervention, insulin sensitivity did not increase in 60 percent of these individuals. High liver fat content and elevated liver enzymes may predict a larger increase in insulin sensitivity during exercise training.

IL6 mediates the reduction of insulin secretion in exercise-trained mice

F.M.M. de Paula, N.C. Leite, P.C. Borck, C.C. Zoppi, A.C. Boschero; Structural and Functional Biology, University of Campinas, Brazil.

Background and aims: Exercise training reduces glucose-induced insulin secretion (GIIS) in lean and obese rodents. Despite higher insulin sensitivity and blood glucose clearance capacity, some intracellular mechanisms have been proposed to explain the lowered insulin secretion. However, it is still unknown how this signal reaches pancreatic beta cells

activating the intracellular pathways. IL6 is highly released by skeletal muscle cells and it was reported to mediate the crosstalk between contracting muscles and pancreatic beta cells. Thus, our aim was investigating the role of IL6 on GIIS modulation of exercise-trained mice.

Materials and methods: After weaning, 21 days old male C57BL/6 mice were randomly assigned into the control group (C) remaining untrained, limited only to cage movement and the trained group (TRE). Mice were submitted to an endurance training 5× per week, during 1 h, at 70% VO₂ max for 8 weeks. After training, pancreatic islets were isolated and the blood collected. GIIS was measured in islets from trained mice. In addition, islets from non-trained mice were incubated with serum from trained animals with or without IL6 inhibitor. It was also quantified UCP2 expression and ATP production. Insulin content was measured by radioimmunoassay.

Results: Isolated islets from TRE mice displayed 50% lower GIIS under stimulatory glucose concentration. CTL islets incubated with serum from TRE animals showed the same magnitude of insulin secretion decrease, reported in the islets from trained mice. When the islets from CTL animals were pre-incubated with IL6 inhibitor, before incubating with serum from TRE mice, the effect of exercise-induced reduction on GIIS was lost. Although UCP2 expression was increased in TRE, ATP production did not differ between the groups.

Conclusion: Exercise-induced GIIS modulation seems to be an endocrine signaling through plasma factors, being IL6 among them. Higher islets UCP2 content was associated with reduced GIIS. However, ATP production was not altered.

Synergistic mtDNA point mutations of OXPHOS complexes resulted in reduced fat mass, improved genetic fitness in a conplastic mouse strain

S. Schröder¹, J. Brenmoehl², M. Tiedge¹, S. Baltrusch¹;

¹Institute of Medical Biochemistry and Molecularbiology, Rostock,

²Leibniz Institute for Farm Animal Biology (FBN), Dummerstorf, Germany.

Background and aims: Mutations in complexes of the respiratory chain, which are encoded in the mitochondrial genome (mtDNA), can alter cellular energy metabolism during aging. Due to mitochondrial dysfunction mtDNA mutations may result in a reduced physiological fitness and metabolic diseases such as adipositas and type 2 diabetes mellitus. Previous studies indicate that multiple mutations in the OXPHOS system predispose to hepatosteatosis. It was the aim of this study to investigate the fitness, muscle and fat mass from conplastic mice carrying a single mtDNA point mutation in the cytochrome c oxidase (complex IV) or a combined mutation in the cytochrome c oxidase (complex IV) and the NADH dehydrogenase (complex I).

Materials and methods: The genetic fitness was quantified by a computer-controlled treadmill in conplastic mouse strains C57BL/6NTac-mtBPL/1J (NADH dehydrogenase mutation und cytochrome c oxidase mutation, mtBPL), C57BL/6NTac-mtNOD/LtJ (cytochrome c oxidase mutation, mtNOD) and C57BL/6NTac-mtAKR/J (control; mtAKR) at the age of 6 months. In addition, we analyzed blood glucose levels. Muscle and fat mass was quantified by weighting femoral muscle, gonadal and brown adipose tissue, respectively. Data are expressed as percentage of total body weight.

Results: At the age of 6 months mtBPL mice (7.2 mmol/l) showed significantly higher blood glucose levels compared to mtNOD mice (6.1 mmol/l) and mtAKR control mice (6.2 mmol/l). mtBPL (70 m) mice moved over longer distances on a treadmill than mtAKR control mice (28 m). Furthermore, mtBPL mice showed a significantly higher muscle mass (1.3% vs. 1.0%) and a significantly lower fat mass for both gonadal fat (2.9% vs. 4.2%) and brown fat (0.2% vs. 0.3%) compared to mtAKR control mice.

Conclusion: Double mtDNA point mutations in the NADH dehydrogenase and cytochrome c oxidase resulted in higher blood glucose levels in 6 month old mtBPL mice without manifestation of diabetes. However, mtBPL mice showed a better physiological aerobic fitness, higher muscle mass and lower fat deposition. Apparently, OXPHOS mutations induce tissue-specific adaptations of mitochondrial dynamics and energy metabolism. The reduced fat stores in adipose tissue may favor hepatic steatosis and subsequent insulin insensitivity as observed in older mtBPL mice. Thus, mtDNA mutations in humans may also play a causative role for disproportional fat distribution between fat tissue and liver in adipose patients.

Moderate intensity exercise training rapidly increases insulin stimulated intestinal glucose uptake in sedentary individuals

K.K. Motiani, A. Savolainen, J. Eskelinen, K.A. Virtanen, R. Parkkola, J. Knuuti, P. Nuutila, K.K. Kalliokoski, J.C. Hannukainen; Turku PET Center, University of Turku, Finland.

Background and aims: Recently it has been shown that insulin is a potent stimulator of glucose uptake (GU) in intestine and that intestinal insulin resistance manifests in obesity and type 2 diabetes. Exercise training improves whole body glycaemia and insulin stimulated skeletal muscle GU. Thus, we aimed to study the tissue specific effects of exercise training on insulin-stimulated intestinal GU.

Materials and methods: Healthy individuals (n=26, aged=48 [SD 5] yrs, BMI=26.1 [SD 2.4] kg·m⁻², VO₂peak=34.2 [SD 4.1] ml·kg⁻¹·min⁻¹) and patients with IFG/IGT/T2D (n=20, aged=49 [SD 4] yrs, BMI=30.1[SD 2.7] kg·m⁻², VO₂peak=28.3[SD 4.6] ml·kg⁻¹·min⁻¹) were randomized into high intensity interval training (HIT) and moderate intensity training (MIT) groups. The groups were studied before and after two weeks and six sessions of HIT (4-6×30 s all out sprints on cycle ergometer with 4 minutes of recovery) or MIT training (40-60 min cycling with ergometer at 60% of VO₂max). Intestinal GU was measured during euglycemic hyperinsulinemic clamp using positron emission tomography and ¹⁸F-FDG.

Results: In healthy individuals, VO₂peak and whole body insulin sensitivity improved and visceral fat decreased similarly in both groups (all p<0.05), following intervention. Training increased GU in colon and tended to increase in small intestine in MIT group, whereas opposite was observed in HIT group [colon: MIT 30%, HIT - 2% (p=0.02) and small intestine: MIT 10%, HIT - 9% (p=0.08), respectively]. The GU in the small intestine correlated positively with the VO₂peak [Pre: r=0.46 p=0.03; Post: r=0.45 p=0.03] and negatively with visceral fat mass [Pre: r=-0.42 p=0.05; Post: r=-0.45 p=0.03]. The results for IFG/IGT/T2D group are under analysis and will be presented in the congress.

Conclusion: This study suggests that MIT rapidly enhances insulin stimulated intestinal GU already after two weeks of training in sedentary individuals.

Effect of individualised physical activity treatment on drug naïve type 2 diabetic patients

T.N. Nguyen^{1,2}, H.T.T. Vu^{1,2}, T. Pham¹, I. Van de Ploeg³, C.J. Sundberg³;

¹National Geriatric Hospital, Hanoi, ²Hanoi Medical University, Viet Nam, ³Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Exercise is considered a corner stone of diabetes management, along with diet and medication since long. The benefits of exercise are determined by its type, duration, frequency and intensity. The aim of this study was to evaluate the health effect of physical activity on prescription in newly diagnosed type 2 diabetes (T2D) patients in Vietnam.

Materials and methods: Twenty-three newly diagnosed T2D patients were randomized in two groups: 12 patients received a 12 week - program of individualized physical activity (IPA group) (at least 30 minutes/day of moderate-to-vigorous intensity activity, face-to-face education each week, guided to use pedometer Yamax 500, physical activity diaries); 11 patients received standard care (SC group) according to WHO guidelines. Fasting plasma glucose (FPG) was measured before, every second week and after twelve weeks. HbA1c, insulinemia, liver enzymes, serum creatinine, BUN, lipid profile, oral glucose tolerance test, blood pressure, weight, waist and hip circumference were measured before and after 12 weeks.

Results: During the treatment period, all patients in IPA group kept walking: mean 5.3±0.9 days/week, 8317±1962 steps/day (67.3±25.9 minutes/day). In IPA group, FPG decreased and achieved the treatment goal after 4 weeks (from 8.8±1.0 to 7.1±0.8 mmol/L, $p < 0.001$), which was sustained during the treatment course. Over the twelve weeks, the FPG level decreased by 1.6±0.9 mmol/L in the IPA group and by 0.4±1.2 mmol/L in the SC group (from 8.7±1.9 to 8.3±1.0 mmol/L) ($p < 0.05$). HbA1c in the IPA group was reduced by 16.3±7.3 mmol/mol (from 66.8±5.1 to 50.5±5.5 mmol/mol, $p < 0.001$) and by 1.3±6.8 mmol/mol in the SC group. In addition, triglyceride levels decreased more ($p < 0.05$) in the IPA group (1.1±1.6 mmol/L) between baseline and twelfth week than in the SC group (0.6±1.1 mmol/L). There was no difference between the two groups in homeostasis model assessment of insulin resistance (HOMA - IR), blood pressure, weight, waist and hip circumference.

Conclusion: Individualized physical activity of sufficient frequency, duration and intensity shows a promising improvement of glycemia and lipid profile in drug naïve type 2 diabetes.

Insulin increases the expression of the genes associated with glycoprotein 130 signalling in human skeletal muscle and this effect is reversed by NEFAs

M. Straczkowski^{1,2}, M. Stefanowicz^{1,2}, N. Matulewicz^{1,2}, A. Nikolajuk¹, M. Karczewska-Kupczewska^{1,2};

¹Department of Prophylaxis of Metabolic Diseases, Institute of Animal Reproduction and Food Research, Polish Academy of Sciences, Olsztyn, ²Department of Metabolic Diseases, Medical University of Białystok, Poland.

Background and aims: Glycoprotein 130 (gp130) cytokines, including interleukin 6 (IL-6), act through plasma membrane receptors consisting of 2 glycoproteins: a cytokine binding subunit (like IL-6R) and gp130, responsible for signal transduction. IL-6 may induce insulin resistance, however, in some conditions it may exert insulin-sensitizing effect in skeletal muscle. The aim of the present study was to assess the effect of insulin and NEFAs on the expression of the genes associated with gp130 signaling in skeletal muscle of healthy humans and in cultured human myotubes.

Materials and methods: In experiment 1, we examined 20 healthy male subjects with normal glucose tolerance (mean age 25.2±3.2 years, mean BMI 26.5±4.6 kg/m²). The biopsy of vastus lateralis muscle was performed before and after 6-hour clamps without or with Intralipid/heparin infusion. In experiment 2, we performed muscle biopsy in 8 healthy male subjects with similar characteristics and then satellite cells were differentiated into myotubes. We treated myotubes with insulin and palmitate separately and in combination. In both experiments, the expression of IL-6R, gp130 and associated genes was analyzed with Real Time PCR.

Results: In experiment 1, serum IL-6 increased and soluble forms of IL-6R and gp130 decreased similarly during both clamps (all $p < 0.05$). Insulin infusion resulted in an increase in muscle expression of IL-6R ($p < 0.001$) and JAK2 ($p = 0.041$) in the entire group and in gp130 ($p = 0.043$) in normal-weight individuals. Concurrent Intralipid heparin infusion, which reduced insulin sensitivity by approx. 40%, abolished all these insulin's effects. In experiment 2, incubation with insulin increased the expression of IL-6R, gp130 and SOCS3 (all $p < 0.05$). Incubation with palmitate reversed all these changes and decreased JAK1 ($p = 0.041$).

Conclusion: Our data show that the regulation of genes associated with gp130 signaling in skeletal muscle may be important for lipid-induced insulin resistance.

Metformin action on cell cycle arrest and insulin resistance condition in hepatocarcinoma cells

A. Montesano¹, P. Senesi², G. Mollica¹, F. Vacante³, S. Paimi¹, L. Luzi^{1,2}, I. Terruzzi³;

¹Department of Biomedical Sciences for Health, University of Milan, ²Metabolism Research Center, San Donato Hospital and Scientific Institute, ³Diabetic Research Institute, Metabolism, Nutrigenomics and Cellular Differentiation Unit, San Raffaele Scientific Institute, Milan, Italy.

Background and aims: Nutrient overload is associated with the development of obesity, insulin resistance and type 2 diabetes (T2DM). Insulin resistance is a characteristic feature of T2DM and is characterized by defects in insulin signaling. However, the underlying mechanisms for developing insulin resistance in the presence of excess nutrients are

incompletely understood. In recent decades, global changes in dietary habits have led to an increase in added sugar consumption, which has been linked to increased trends in obesity and type 2 diabetes (T2DM). T2DM is associated with a higher risk of liver diseases frequently degenerating in hepatocellular carcinoma (HCC). Fructose (FR) has been reported to be responsible for the metabolic disturbances, liver fat deposition and HCC. Unfortunately, most HCC seem to be resistant to conventional chemotherapy and radiotherapy. The poor efficacy of antitumor agents is also due, at least in part, to the inefficient drug delivery and metabolism exerted by the steatotic/cirrhotic liver that host the tumor. Excessive IGFs signaling is a characteristic feature of liver tumors. Recent studies suggest that downregulation of IGF1 together with upregulation of IGF2 and overactivation of IGF1 receptor and insulin receptor isoform A are important events in HCC development. These alterations cause a higher cell proliferation. Metformin (METF), the most commonly prescribed drug for T2DM that inhibits hepatic gluconeogenesis and decreases glycogenolysis, has been found to lower HCC risk. We investigated molecular effects of METF on *in vitro* human hepatoma cell lines (HepG2), an useful insulin resistance cell model.

Materials and methods: HepG2 cells were treated with METF (400 μ M) in association or not with 5 mM FR for 24 or 48 hours. METF action on cell cycle progression and signaling pathways involved in metabolism regulation was evaluated by Immunofluorescence and Western Blot assay.

Results: Since assessing HepG2 cell viability, METF seemed to decrease growth cell capacity, we performed western blot and immunofluorescence studies to investigate cell cycle regulators. METF showed to induce expression of cyclin D3 and p21 protein. In addition, METF increased ratio retinoblastoma (Rb)/pRb. These data suggest that METF could arrest the cell cycle at G0/G1 phase without inducing apoptosis as supported by p53 unmodified levels. Furthermore, studying PPARs modulation, target signaling of FR action on liver fatty acid metabolism, we observed that METF seemed to increase PPAR γ levels, confirming that METF could reduce cellular lipid drops accumulation caused by FR, as showed by Red Oil staining. Besides, METF showed to improve insulin resistance increasing pIRS1tyr/pIRSser ratio, principal molecular marker of IR condition, and GSK activation.

Conclusion: In conclusion, our data shows that METF could suppress HepG2 proliferation, through induction of cell cycle arrest at G0/G1 phase. Also, METF effect on fatty acid metabolism and on insulin resistance leads to the development of new METF therapeutic use in liver diseases associated with insulin resistance.

Bone/Body Morphogenetic Proteins (BMPS) act as insulin-sensitisers via upregulation of PPARgamma expression in mature 3T3-L1 adipocytes

I. Schreiber^{1,2}, P. Knaus^{1,2}, K. Ruschke¹;
¹Biochemistry, FU Berlin, ²BSRT, Berlin, Germany.

Background and aims: Antidiabetic drugs like Metformin and thiazolidinediones improve insulin sensitivity of muscle and adipose tissue, but can cause severe side effects in type-2-diabetes patients. Therefore, the identification of new insulin sensitizers and a detailed understanding of their functionality is of great interest. Bone/Body morphogenetic proteins are secreted growth factors clinically used because of their bone healing properties. Beside their classical role in development, BMPs are now seen as metabologens. They have been found to regulate adipogenesis, iron metabolism in liver and the formation and thermoregulatory activity of BAT, but their metabolic functions in adult tissues need to be further investigated.

Materials and methods: Fully differentiated 3 T3-L1 adipocytes were stimulated with insulin, BMP-2, BMP-6 or both. To generate insulin-resistant adipocytes, the cells were kept in medium containing insulin

for 8 h prior to stimulation. Adipocytes stably expressing a GLUT-4_GFP_7myc-construct were stimulated as described, stained for myc-tag-translocation and analyzed via flow cytometry. Uptake of 3H-2-deoxyglucose was measured after short or long-term stimulations. Protein expression levels were analyzed by qRT-PCR and Western Blot or via flow cytometry.

Results: Previous work showed that overnight stimulation with BMPs in combination with a short-term insulin stimulation significantly increases glucose uptake rates compared to controls ($F=25.998$, $p<0.05$). Furthermore *in vitro* generated insulin resistant adipocytes show elevated glucose uptake upon 18 h of BMP2 treatment independent of an additional insulin stimulus ($F=9.365$, $p<0.05$). The magnitude of this effect is comparable to the known insulin sensitizer Rosiglitazone that served as positive control. The BMP-mediated effect is not caused by enhanced translocation of GLUT-4 vesicles as shown with a GLUT-4_GFP_7myc-translocation assay and time resolved glucose uptake assays. The insulin sensitizing effect of BMP-2 and BMP-6 was observed earliest 4 h after stimulation. Canonical Smad 1/5/8 as well as MAP kinase signaling was triggered by BMPs in mature adipocytes. Sequential alteration of PPARgamma, RXRalpha, GLUT-4 and GLUT-1 mRNA expression indicates a transcriptional effect of BMPs on glucose uptake.

Conclusion: Long-term BMP stimulation has an insulin sensitizing effect on mature adipocytes. We suggest that this effect is mediated by activation of PPARgamma expression and not via direct glucose transporter translocation. Phospho-Smads activating the PPARgamma promoter via known Smad-binding elements might mediate this effect on glucose metabolism. The impact of MAP kinase signaling on this effect will be further investigated using selective inhibitors. PPARgamma is a nuclear receptor and its upregulation via BMP signaling could lead to a higher sensitivity of the nuclear surface for natural ligands like polyunsaturated fatty acids. Therefore, PPARgamma together with RXRalpha can act as a transcription factor and initiate transcription of a defined set of downstream targets like GLUT-1 and GLUT-4. To investigate metabolic changes in BMP stimulated adipocytes extracellular flux measurements will be performed. Further work needs to determine if BMPs could serve as a new antidiabetic treatment strategy with reduced side effects, especially beneficial for osteoporosis patients.

Effect of the long-acting insulin analogues glargine and degludec on cardiac cell function

T. Hartmann¹, N. Wronkowitz¹, S. Greulich², M. Ouwens², P. Wohlfart³, N. Tennagels³, J. Eckel¹;

¹Paul-Langerhans Group for Integrative Physiology, ²Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Düsseldorf, ³Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: Long acting insulin analogues are designed to mimic the physiological pattern of endogenous insulin secretion resulting in a better glycaemic control while reducing the risk of hypoglycaemia. One important aspect for their long-term use is cardiovascular safety data: Insulin glargine (IGla) has proven to be safe in the cardiovascular outcome ORIGIN trial; for Insulin degludec (IDeg), the outcome trial DEVOTE is ongoing. The aim of this study was to investigate IGla, its active metabolite M1 (IGla-M1) and IDeg on signaling and contractility in three pre-clinical cardiovascular cellular models (mouse atrial cell line HL-1, primary rat cardiomyocytes (ARVM) and iPS-cell derived human cardiomyocytes (Cor.4U)).

Materials and methods: Adult rat ventricular cardiomyocytes were isolated from Lewis rats and incubated with 100 nM regular insulin (Ins), IGla, IGla-M1 or IDeg to compare the positive inotropic effect of each

insulin. To examine the role of Akt, we preincubated ARVM for 30 min with the Akt inhibitor triciribine. Additionally, ARVM and HL-1 cells were used to investigate the insulin signaling pathway by Western Blot analysis. To determine the impact of insulins on cardiotoxicity and efficacy in human Cor.4U cells, beating rate was monitored with an impedance-based device (xCelligence Cardio) for up to 24 h.

Results: In HL-1 cells, IDeg stimulation results in a significantly lower Akt (Ser473) phosphorylation compared with Ins, IGla and IGla-M1 after 5- and 10-min incubation. Nonetheless, after 60-min treatment the phosphorylation was comparable with Ins and IGla M1. In ARVM we observed similar increases in pAkt (Ser473) phosphorylation with Ins, IGla-M1 and IDeg (7.4-, 8.2- and 7.8-fold, respectively) after a single timepoint (10 min). Incubation of electrically paced ARVM with the different analogues resulted for all insulins in a significantly increased sarcomeric shortening (2.5–2.8 fold) and similarly increased contractility (2.1–2.4 fold) and relaxation velocities (2.6–3.5 fold). The positive inotropic effect of Ins and long-acting analogues could be totally abrogated by the specific Akt inhibitor triciribine. In human Cor.4U cells, all insulins displayed no obvious cardiotoxicity and slightly increased the rate of spontaneous beating 1.1–1.2-fold.

Conclusion: In conclusion, we demonstrated similar efficacy under steady-state-conditions in regard to insulin signaling, positive inotropy and beating rate for the insulin analogues tested compared with regular insulin. In HL-1 cells, IDeg exhibited a slower on-set of action on AKT phosphorylation. Whether the observed kinetic difference plays a role in more complex tissue models may need to be investigated.

Insulin glargine and (A21Gly,DiD-Arg) insulin do not promote breast cancer growth in a mouse model

E. Gallagher¹, N. Tennagels², U. Werner², D. LeRoith¹;

¹Department of Medicine, Mount Sinai School of Medicine, New York, USA, ²Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: Since it was found that the insulin analog AspB10 led to mammary tumors in rats, there have been concerns over the potential mitogenicity of insulin analogs. As insulin analogs and delivery systems continue to be developed, there is a need to understand the mitogenic mechanisms of certain analogs. Previous studies have reported that insulin analogs that activate the insulin-like growth factor receptor (IGF-1R) may be more mitogenic, while others have suggested that prolonged activation of the insulin receptor (IR) may be responsible for the tumor promoting effects. Insulin glargine has greater affinity for the IGF-1R than human insulin (HI) in vitro, but in vivo it is metabolized to an M1 metabolite that has similar affinity to the IR and IGF-1R as HI. (A21Gly,DiD-Arg) Insulin is a modified form of insulin glargine that is resistant to in vivo metabolism and has higher affinity for the IGF-1R than HI. The aim of our study was to determine if insulin glargine and the non-metabolizable insulin (NMI) glargine analog (A21Gly,DiD-Arg) promote the growth and metastasis of breast cancer in a mouse model.

Materials and methods: We used female MKR mice on an FVB/n background for these studies. The MKR mouse is a model of insulin resistance, due to muscle specific (M) overexpression of a mutant (K to R mutation) kinase dead IGF-1R. At 8 weeks of age, the 4th mammary fat pad of MKR mice was injected with murine Mvt-1 breast cancer cells, derived from a c-myc/vegf overexpressing model. Tumor bearing mice were divided into 3 groups (n=8 per group) and injected with insulin glargine (12.5 IU/kg twice daily), NMI (12.5 IU/kg twice daily) or an equal volume of vehicle for 3 weeks. Tumors were measured twice weekly for 3 weeks. At the end of the study tumors were weighed, and pulmonary macrometastases were quantified.

Results: There was no difference in tumor size (vehicle 234.3±39.5 mm³, glargine 237.4±33.8 mm³, NMI 265.5±21.8 mm³) at the

end of the study. Similarly, tumor weight and the number of metastases were not significantly different between the insulin glargine, NMI and control groups at the end of the study.

Conclusion: These data demonstrate the lack of mitogenic effect of insulin glargine or the non-metabolizable form of insulin glargine in a mouse model of breast cancer.

GLP-1 agonist induces transdifferentiation of pancreatic alpha cells dedifferentiated by FOXO signalling

M.-K. Kim^{1,2}, J. Park¹, M. Park³, H. Jung², E. Lee¹, T. Kim¹, T. Kim¹, M. Kwon¹, S. Lee¹, B. Rhee¹, J. Park^{1,2};

¹Division of Endocrinology and Metabolism, College of Medicine, ²Molecular Therapy Lab, Inje University, ³Division of Endocrinology and Metabolism, Dong-A University College of Medicine, Busan, Republic of Korea.

Background and aims: Pancreatic alpha cell has been more emphasized in pathophysiology of diabetes by glucagoncentric explanation and transdifferentiation to beta cell. One recent study reported that GLP-1 directly increased intrinsic GLP synthesis in alpha cell line and changed alpha cell specific gene transcription. FOXO signaling under glucotoxic injury is related to dedifferentiation of pancreatic beta cell and delta cell. We investigated FOXO signaling in pancreatic alpha cell under hyperglycemia and GLP-1 effect on transdifferentiation of alpha cell.

Materials and methods: α-TC1-6 cell line was cultured in hyperglycemia or FOXO inhibitor. And then GLP-1 agonist, Exendin-4 was applied to them. We measured FOXO transcription factor, Pax6 levels and MafB gene, glucagon gene (Gcg) and protein expression after hyperglycemia or FOXO inhibitor treatment. PDX1, Pax4 levels, Pax6 levels, MafA and MafB gene, glucagon gene (Gcg) and protein expression were checked after Exendin-4 treatment.

Results: Hyperglycemia induced FOXO nuclear localization in pancreatic alpha cell. Hyperglycemia and FOXO inhibitor decreased Maf B, glucagon gene and Pax 6. Exendin-4 increased Maf A, Pax 4 and PDX1 in FOXO inhibitor affected alpha cells

Conclusion: GLP-1 agonist treatment can induce transdifferentiation of pancreatic alpha cell dedifferentiated by FOXO signaling and hyperglycemia

Effects of glucose concentration on AMPK activation and activity of metformin and berberine

J. Yin, Y. Xiao, L. Wei, W. Jia;

Shanghai Clinical Center for Diabetes, Department of Endocrinology and Metabolism, Shanghai Key Labo, Shanghai Jiao Tong University Affiliated Sixth People's Hospital, China.

Background and aims: Both metformin and berberine are well-known hypoglycemic agents for treatment of type 2 diabetes. Underlying mechanisms involves activation of AMP-activated protein kinase (AMPK) pathway. However, theoretically excess nutrient such as hyperglycemia may inactivate AMPK. This study aimed to examine whether metformin and berberine were able to exert hypoglycemic effects under high glucose condition via AMPK activation.

Materials and methods: Glucose consumption was used to evaluate the glucose-lowering effect of metformin and berberine on HepG2 hepatocytes and C2C12 myotubes. AMPK phosphorylation and ACC phosphorylation were measured with western blot to assess the activity of AMPK pathway. Anaerobic glycolysis was evaluated through determining lactate concentration in the medium.

Results: In this study, we found that in HepG2 hepatocyte and C2C12 myotubes, metformin and berberine significantly increased glucose consumption in a dose-dependent manner. In different glucose concentrations, e.g. 5.6 mmol/L, 15 mmol/L and 30 mmol/L, metformin and berberine exerted similar glucose-lowering effects. On the other hand, the lactate production was largely enhanced by metformin or berberine in the cells in the same way as they affect glucose consumption. Meanwhile, AMPK and ACC phosphorylation was stimulated by 5 mmol/L metformin or 10 μ mol/L berberine in the presence of 5.6 mmol/L glucose concentration. Nevertheless, in 15 mmol/L glucose concentration, metformin and berberine failed to activate AMPK pathway. In 30 mmol/L glucose concentration, metformin and berberine even reduced phosphorylation of AMPK and ACC. Surprisingly, more phosphorylation of AMPK and ACC was observed in high glucose concentration compared with low glucose concentration.

Conclusion: These results suggest: 1) Metformin and berberine promote glucose metabolism by stimulation of glycolysis, which is independent of glucose concentration. 2) Metformin and berberine activate AMPK pathway in low glucose concentration other than in high glucose concentration. 3) High glucose concentration is able to activate AMPK pathway by itself.

Glucagon receptor siRNA is not as effective at normalising glycaemia and lipid metabolism as leptin treatment in streptozotocin-diabetic mice

U.H. Neumann¹, J.S.S. Ho¹, S. Chen², Y.Y.C. Tam², P.R. Cullis², T.J. Kieffer¹;

¹Cellular and Physiological Sciences, ²Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada.

Background and aims: The hormone leptin can reverse hyperglycemia in rodent models of type 1 diabetes. Supraphysiological levels of leptin dramatically reduce the counter-regulatory hormone glucagon which may be one mechanism by which leptin acts to reduce glycemia. However, leptin therapy can also improve hyperglycemia prior to normalization of glucagon and can reverse hyperglucagonemia without restoring normoglycemia. Therefore, the contribution of glucagon suppression to the metabolic actions of leptin remains unclear. To investigate this we compared the metabolic effects of leptin with hepatic glucagon receptor (GCGR) knockdown using GCGR siRNA encapsulated in liposomal nanoparticles (LNPs) in streptozotocin (STZ)-treated mice.

Materials and methods: To find an effective GCGR siRNA, 3 GCGR siRNAs, and factor VII (FVII) siRNA as a control, were encapsulated into LNPs and delivered via the tail-vein at a dose of 5 mg/kg to wildtype mice and subsequent glucose homeostasis was assessed for 7 days. To compare the effect of glucagon suppression in type 1 diabetes to that of leptin treatment, STZ diabetic mice were administered either 5 mg/kg GCGR siRNA or FVII siRNA as a control, then half of the animals from each group were implanted with a pump delivering 20 μ g/day leptin resulting in mice that received FVII siRNA, GCGR siRNA, leptin+FVII siRNA, or both GCGR siRNA and leptin treatments. Various metabolic parameters were assessed over 7 days to compare the therapies.

Results: Two of three GCGR siRNAs appeared to work in wildtype mice; the most effective GCGR siRNA was capable of reducing fasting blood glucose (5.6 \pm 0.1 mM vs 8.1 \pm 0.3 mM, p <0.05), enhancing oral glucose tolerance (10.8 \pm 0.6 mM vs 19.2 \pm 0.8 mM, 20 min post gavage, p <0.05), and elevating plasma glucagon levels (140 \pm 30 pg/mL vs 14 \pm 3 pg/mL, p <0.05) compared to controls given FVII siRNA. This GCGR siRNA was then used in mice with STZ-diabetes to compare with leptin treatment. As expected, glucagon levels were suppressed by leptin treatment, and increased by GCGR siRNA treatment. In addition, this dose of leptin induced supraphysiological levels of leptin that were unaltered by GCGR

siRNA treatment. Blood glucose levels were significantly reduced by GCGR siRNA treatment, however, not as dramatically as with leptin treatment (29.5 \pm 0.6 mM FVII siRNA, 19.4 \pm 1.2 mM GCGR siRNA, 9.9 \pm 0.7 mM leptin+FVII siRNA, p <0.05). Plasma β -hydroxybutyrate was similarly normalized by both treatments compared to FVII siRNA treatment (2.67 \pm 0.22 mM FVII siRNA, 0.56 \pm 0.04 mM GCGR siRNA, 0.38 \pm 0.03 mM leptin+FVII siRNA, p <0.05). Conversely, plasma cholesterol, triglycerides, fatty acids, and glycerol were all significantly reduced by leptin treatment, but were unaffected by GCGR siRNA treatment. For all parameters, the addition of GCGR siRNA to leptin treatment did not further improve metabolism compared to leptin treatment alone.

Conclusion: Compared to leptin treatment, GCGR siRNA was equally effective at reducing plasma ketones, partially effective at reducing glycemia, and ineffective at reducing cholesterol, triglycerides, fatty acids, and glycerol. Therefore our results suggest that the glucagon suppression by leptin only accounts for a portion of the metabolic actions of leptin.

Fibroblast growth factor-21 is secreted by skeletal muscle in vivo and correlates with muscle glucose uptake in humans with type 2 diabetes
P. Mitrou¹, E. Maratou¹, E. Petsiou², V. Lambadiari², S.A. Raptis^{1,2}, G. Dimitriadis²;

¹Hellenic National Center for Research, Prevention and Treatment of Diabetes Mellitus and its Complications (H.N.D.C), Athens, ²2nd Department of Internal Medicine and Research Institute, Athens University Medical School, "Attikon" University Hospital, Greece.

Background and aims: Fibroblast growth factor-21 (FGF-21) belongs to the fibroblast growth factor family, and serves as an endocrine hormone, which was originally identified to increase glucose uptake in fat cells. In rodents, FGF-21 is highly expressed in the liver and regulates hepatic glucose production. The physiological role of circulating FGF-21 in the regulation of carbohydrate metabolism *in vivo* in skeletal muscle which is the most important tissue for insulin-stimulated glucose uptake, still remains to be clarified. The aim of this study was to investigate the association of circulating FGF-21 levels with glucose uptake by the skeletal muscle in humans with type 2 diabetes (DM2), using the arterio-venous difference technique across the forearm muscle.

Materials and methods: A mixed meal (557 kcal; 75 g carbohydrates, 26 g protein, 17 g fat) was given to 11 newly diagnosed subjects with DM2 (age 53±4 years, BMI 25±1, HbA1c 6.8±0.3%) and 10 control subjects (age 48±4 yrs, BMI 24±1 kg/m²). Plasma FGF-21, glucose [G] and insulin were measured preprandially and at 60 min intervals for 300 min postprandially from the radial artery (A) and from a deep forearm vein (V). Muscle blood flow [BF] was measured with strain-gauge plethysmography. Calculations: Glucose flux: [G(A-V)]x[BF]; Glucose clearance:[G(A-V)]x[BF]/[G(A)].

Results: 1) FGF-21 concentrations were increased in the forearm vein compared to the artery throughout the whole 5-h period in both DM2 (poverall=0.0028) and control (poverall=0.0146) subjects 2) FGF-21 levels were changed after the mixed meal in both DM2 (poverall=0.0008) and control (poverall=0.0092) subjects, reaching a peak at 120 min (following the postprandial glucose and insulin increase) 3) Fasting FGF-21 was increased in patients with DM2 compared to controls (157±30 vs 82±12 pg/ml respectively, p=0.0146) (3) Fasting FGF-21 was positively correlated with muscle glucose flux (r=0.87, p=0.0004) and glucose clearance (r=0.07, p=0.0127) in patients with DM2.

Conclusion: FGF-21 is secreted by human skeletal muscle *in vivo*. In type 2 diabetes FGF-21 is increased and positively correlated with glucose flux and glucose clearance by the forearm muscle. Therefore, FGF-21 may be considered as a beneficial myokine for improving muscle glucose metabolism in type 2 diabetes.

AS160 vs Tbc1d1: cooperative determination of insulin-responsive GLUT4 trafficking activity after exercise-mimetic stimuli

H. Hatakeyama^{1,2}, M. Kanzaki²;

¹Frontier Research Institute for Interdisciplinary Sciences, ²Graduate School of Biomedical Engineering, Tohoku University, Sendai, Japan.

Background and aims: AS160 and Tbc1d1, proteins of the TBC1D Rab GTPase-activating (RabGAPs) family, emerged as the key nexus deciphering biochemical phosphorylation signals into physical processes of GLUT4 translocation. Unlike adipocytes which express only AS160, skeletal muscle cells express both RabGAPs and their relative abundances vary among different skeletal muscles. With our novel GLUT4

nanometry combined with cell-based reconstitution model, we clearly determined the respective functional roles of the RabGAPs in GLUT4 behavior (MBoC 24: 806, 2013), *i.e.* AS160 mediates insulin-responsive GLUT4 release from its static storage sites and, in contrast, Tbc1d1 temporally acquires insulin-responsiveness which triggers GLUT4 release only after exercise-mimetic stimuli (AICAR-pretreatment and transient cytosolic Ca²⁺ increases). We herein analyzed their combinatorial regulator mechanisms employing our methodology with varied relative abundances of the two RabGAPs.

Materials and methods: All experiments were performed in 3T3L1 fibroblasts exogenously expressing myc-GLUT4, HA-sortilin, AS160-enhanced yellow fluorescent protein (EYFP) and HaloTag-Tbc1d1, and relative abundances of AS160 and Tbc1d1 were estimated by relative fluorescence intensities of EYFP to those of HaloTag TMR ligand. Intracellular myc-GLUT4 was labeled with Quantum dot-conjugated anti-myc antibodies, and the movement of individual Quantum dot signals was tracked with positional precision at 6 nm.

Results: First, Tbc1d1 inhibited AS160-mediated insulin-dependent GLUT4 release in a relative abundance-dependent manner, indicating that Tbc1d1 functionally dominates AS160. Detailed functional assessments with varied relative abundances of AS160 and Tbc1d1 revealed that AS160 modulates sensitivity to external stimuli in Tbc1d1-mediated activation of GLUT4 trafficking. For example, GLUT4 release induced by transient cytosolic Ca²⁺ increases in the presence of insulin with abundant AS160 occurred much faster (~30 s) than that in cells with little or no AS160 (~10 min). In addition, acquired insulin responsiveness after AICAR-pretreatment is more obvious in cells with both Tbc1d1 and AS160 even after acute (5 min) stimulation than in cells expressing only Tbc1d1. Importantly, this modulatory action of AS160 was completely abolished by an obesity-related Tbc1d1 mutant (R125W) with an impaired phosphotyrosine-binding 1 (PTB1) domain.

Conclusion: Our GLUT4 nanometry combined with cell-based reconstitution model revealed that AS160 potentiates insulin sensitivity in Tbc1d1-mediated GLUT4 releasing activity after exercise-mimetic stimuli, apparently mediated through functional interaction with the PTB1 domain of Tbc1d1. This modulatory action could be involved in the differences in insulin sensitivity among skeletal muscles and beneficial effects of exercise on muscle insulin sensitivity. To further verify this notion, we currently examine GLUT4 behavior in isolated skeletal muscle and *in vivo* using several imaging techniques.

Alpha-lipoic acid increases "exercise-mimetic" effects of the PPARbeta/delta pathway in skeletal muscle

A.-S. Rousseau, B. Sibille, J. Murdaca, I. Mothe-Satney, J. Neels, P.A. Grimaldi;

University of Nice Sophia Antipolis/INSERM U1065/C3M, France.

Background and aims: The quality of the acute and adaptive response to physical exercise depends on exercise-induced molecular signals and signaling pathways, the activation of which varies with redox status. α -lipoic acid (α -LA), a powerful antioxidant, is independently involved in some exercise-signaling pathway activation driven by PPAR β/δ , a transcription factor known to mimic the phenotypic adaptation to aerobic exercise training. We validated the hypothesis that α -LA interacts with PPAR β/δ genic effects in skeletal muscle, identified the molecular mechanisms involved in those effects, and determined their potential physiological implications.

Materials and methods: Differentiated C2C12 myotubes and C2C12 expressing a negative-dominant form of PPAR β/δ , were treated during 48 h with various concentrations of α -LA (50 to 250 μ mol/l) and PPAR β/δ agonist GW0742 (0.3 to 300 nmol/l). Different inhibitors were used (eg. the non-competitive inhibitor of PPAR β/δ GSK3787 (1 μ mol/l) and the inhibitor of the c-Jun N-terminal (JNK) pathway, SP600125 (30 μ mol/l)).

The agonist activity of α -LA on PPAR β/δ was measured in a reporter assay. In vivo studies with 3-month C57Bl6 mice (minimum 6 per group) were conducted. Mice performed a one bout of stressful treadmill exercise (35 cm/s, 1 h) and/or one night or 7-weeks voluntary wheel running training. Analyses were done by qPCR and Western-Blot. Statistical analyses were performed using parametric or non-parametric tests depending on cases.

Results: Treatment of C2C12 with α -LA (250 μ mol/l) induces ($p < 0.05$) a pattern of gene expression (PDK4, CPT1a, Catalase, Prkag3) similar to those observed in response to GW0742 in C2C12 myotubes. In the reporter assay, treatment with α -LA did not lead to an increase in luciferase activity, suggesting that α -LA was not an agonist of PPAR β/δ . However, the inhibition of PPAR β/δ activity, in C2C12 PPAR β/δ -DN or in C2C12 treated with GSK3787, led to a loss of α -LA effect on PPAR β/δ target gene expressions, suggesting that this pathway had to be active to allow α -LA effects. Both PPAR β/δ mRNA levels and protein expression were increased in response to α -LA treatment (2-fold; $p < 0.05$). Moreover, co-treating cells with α -LA and GW0742, maximized the effect of GW0742 on PDK4 expression for lower concentration (3 nmol/l) than those usually used (300 nmol/l) to induce this effect. Under physiological conditions, PPAR β/δ expression was decreased ($p < 0.05$) in vastus lateralis in response to one bout of stressful treadmill exercise whereas it was increased ($p < 0.05$) when lowering oxidative stress exposition in response to voluntary exercise training (2-fold). We evidenced in C2C12 that the JNK pathway activity was decreased with α -LA treatment. The inhibition of the JNK pathway with SP600125 induced a 2-fold ($p < 0.05$) increase in PPAR β/δ mRNA level and protein expression and a significant response on its target-genes, similar to α -LA treatment.

Conclusion: We have evidenced a novel potential mechanism of regulation of the adaptation to stress involving the JNK pathway on the level of expression of PPAR β/δ in skeletal muscle. This mechanism could be relevant when the JNK pathway is chronically active in skeletal muscle such in diabetic or obese patients and/or in conditions where PPAR β/δ expression in skeletal muscle is known to be particularly low, such as with aging and/or physical inactivity. Furthermore, treatment with α -LA might be beneficial in these conditions.

Fractalkine (CX3CL1) a novel myokine protecting skeletal muscle from insulin resistance in humans

A. Zoso¹, P. Plomgaard², J.S. Hansen², C. Brandt², C. Howald¹, E.T. Dermizakis¹, B.K. Pedersen², P.A. Halban¹, K. Bouzakri¹;

¹Department of Genetic Medicine and Development, Geneva University, Switzerland, ²Department of Infectious Diseases and CMRC, University of Copenhagen, Denmark.

Background and aims: Fractalkine (CX3CL1) is a chemokine produced as a membrane-bound protein shed to the circulation through enzymatic cleavage by Adam 10 and 17 and regulated by exercise. Recently it has been shown to be associated with Type 2 Diabetes and we showed that its mRNA expression is increased in human primary skeletal muscle cells with TNF- α induced insulin resistance. However, the impact of CX3CL1 on primary human skeletal muscle cells exposed to TNF- α remains to be explored.

Materials and methods: CX3CL1 mRNA and protein levels were measured in plasma and muscle biopsies from healthy volunteers performing either 3 h of bicycling exercise or 2 h of one legged knee extensor exercise. Plasma CX3CL1 levels were also measured in healthy males infused for 4 h with TNF- α or placebo. Human skeletal muscle cells were obtained from abdominal muscle and cultured with CX3CL1 for 48 h alone or with TNF- α 20 ng/ml for the last 24 h to induce insulin resistance. We investigated insulin induced-deoxyglucose uptake, insulin and NFkB signaling pathways using western blot and ER and mitochondrial alterations

by immunostaining. Deeper investigation of CX3CL1 effects on myotube gene expression was conducted by RNAseq.

Results: Plasma CX3CL1 increased rapidly after the beginning of exercise, reaching a maximum by 3 h (1.4 ± 0.4 μ g/l; $p < 0.01$ vs starting condition). In the one-legged knee extensor model, mRNA content of CX3CL1 in the exercising leg (EL) was higher compared to the resting leg (RL). During exercise CX3CL1 plasma levels increased in all vessels (arterial, RL femoral vein and EL femoral vein), even if its release did not increase significantly from the EL compared to RL. 24 h post exercise, CX3CL1 protein content in the EL was decreased (1.08 ± 0.07 vs 0.31 ± 0.04 ; $p < 0.05$), while ADAM10 mRNA expression was not increased. Human volunteers infused with TNF- α showed an increase of plasma CX3CL1 with a maximum after 4 h (8.2 ± 0.8 μ g/l; $p < 0.001$ vs placebo). In vitro, myotubes treated with CX3CL1 showed an increase of basal glucose uptake (190 ± 8 vs. 120 ± 18 cpm/mg protein/min; $p < 0.05$) and were protected from the impact of TNF- α on insulin stimulated-glucose uptake (TNF- α +CX3CL1: 245 ± 9 vs. TNF- α : 146 ± 25 cpm/mg protein/min; $p < 0.05$). CX3CL1 moreover prevented the negative effect of TNF- α on Akt and AS160 phosphorylation and IRS1 expression, restoring control levels. Phosphorylation of ERK, NFkB and p38 induced by TNF- α was blunted in the presence of CX3CL1. In addition, confocal imaging highlighted that CX3CL1 in the face of TNF- α reorganized a proper structure of ER and increased considerably the number of mitochondria measured by cytochrome C staining. Although TNF- α modulated the expression of 5276 genes (CTR vs TNF- α), CX3CL1 failed to reverse the vast majority of these changes (TNF- α vs TNF- α +CX3CL1).

Conclusion: Our study demonstrates that CX3CL1 is expressed by human skeletal muscle and regulated by exercise and TNF- α infusion. We also show that this novel myokine protects human myotubes from the negative impact of TNF- α . This suggests that its autocrine role might have important implications in modulating the effects of insulin resistance on skeletal muscle function including glucose uptake. Ongoing studies are underway to determine more precisely any possible impact of CX3CL1 on human muscle gene expression.

Regulation of skeletal muscle energy metabolism and insulin action by perilipin 5

C. Laurens^{1,2}, P.-M. Badin^{1,2}, K. Louche^{1,2}, D.R. Joanisse³, D. Langin^{1,2}, V. Bourlier^{1,2}, C. Moro^{1,2};

¹Institute of Metabolic and Cardiovascular Diseases, INSERM, ²Paul Sabatier University, Toulouse, France, ³Département de Médecine et de Kinésiologie, Centre de Recherche Institut Universitaire de Cardiologie et de Pneumologie de Québec, Canada.

Background and aims: Intramuscular triglycerides lipid droplets can fuel muscle contraction during exercise but also promote insulin resistance when in excess. Recent work indicates that perilipin 5 (PLIN5) may play a gatekeeper role at the lipid droplet surface. The aim of the present work was to characterize the role of PLIN5 in the regulation of skeletal muscle lipid and glucose metabolism.

Materials and methods: We measured PLIN5 protein content in different mouse skeletal muscles and in lean sedentary, endurance trained and obese glucose intolerant (IGT) subjects. We also overexpressed PLIN5 using an adenoviral approach in human skeletal muscle cells primary culture to characterize its functional role in the regulation of energy metabolism and insulin action.

Results: PLIN5 is highly expressed in oxidative compared to glycolytic muscles. PLIN5 protein content strongly correlates with insulin sensitivity ($r^2 = 0.42$, $p < 0.0001$), is elevated in endurance-trained subjects, and reduced in obese IGT. PLIN5 overexpression in human skeletal muscle cells slows down triglyceride depletion (-53%, $p = 0.0025$), as well as lipolysis-derived fatty acids mobilization and oxidation (-46%, $p =$

0.0035). This is accompanied by an increase in glucose oxidation and glycogen synthesis, concomitant with a decrease of *pyruvate dehydrogenase kinase 4* gene expression. Finally, PLIN5 overexpressing cells are partly protected from palmitate-induced lipotoxicity and insulin resistance.

Conclusion: Collectively, our data indicate that PLIN5 plays a key role in the regulation of skeletal muscle energy metabolism. PLIN5 could contribute to maintain insulin sensitivity by modulating fatty acid trafficking in and out of the lipid droplet in skeletal muscle.

p300 is essential for the full effect of calorie restriction to enhance skeletal muscle insulin sensitivity

S. Schenk¹, S. LaBarge¹, O. Osborn², C.E. McCurdy³, C. Migdal¹, S. Nalbandian¹;

¹Orthopaedic Surgery, ²Medicine, University of California, San Diego, La Jolla, ³Human Physiology, University of Oregon, Eugene, USA.

Background and aims: The E1A binding protein, p300, is a transcriptional co-activator and acetyltransferase (KAT), that along with its paralogs, CREB binding protein (CBP), interacts physically and functionally with 2000 or more transcriptional regulators and other proteins, many of which play an integral role in regulating metabolism. Surprisingly, however, very little is known regarding the contribution of p300, and KATs in general, to skeletal muscle metabolism. Our objective was to determine the contribution of p300 to skeletal muscle insulin action, including calorie restriction (CR)-induced enhancement of skeletal muscle insulin sensitivity.

Materials and methods: Mice with knockout of p300 (mKO) in skeletal muscle were generated using Cre Recombinase methodology. Beginning at 10 weeks old, individually housed male, mKO and floxed/wildtype (WT) littermates continued on an ad libitum (AL) diet, or were switched to a CR (20 d at 60% of AL) diet. At 12 weeks old, an oral glucose tolerance test (OGTT; 2 g/kg) was performed, and at 13 weeks old, basal and insulin-stimulated 2-deoxyglucose uptake (2DOGU) was measured in isolated extensor digitorum longus (EDL) and soleus muscles using a physiological insulin concentration (60 μ U/mL). Before the 2DOGU experiments, body composition was assessed in all mice by magnetic resonance imaging.

Results: As expected, CR decreased fat, lean and total body mass compared to AL fed mice, with no genotype differences observed. Interestingly, while CR significantly reduced the glucose response to an OGTT by ~60% in WT mice, this improvement was ~25% lower in mKO vs. WT mice, suggesting that p300, in skeletal muscle, is required for the full effect of CR to improve glucose tolerance. Supporting this, insulin-stimulated 2DOGU (insulin 2DOGU / basal 2DOGU) in the EDL and soleus of WT-CR mice was ~3-5-fold higher as compared to WT-AL mice, but this CR-induced improvement was ~40-60% lower in mKO mice.

Conclusion: These results demonstrate while loss of p300 does not alter skeletal muscle insulin sensitivity in young AL-fed mice, p300 is essential for the full effect of CR to enhance skeletal muscle insulin sensitivity.

Dysregulated iron metabolism in human skeletal muscle cells are associated with free fatty acid-induced insulin resistance

K.-W. Lee¹, T. Kim², S.-E. Choi³, S.-A. Lee¹, J. Jeon¹, S. Ock⁴, S.-Y. An⁵, Y. Kang³, S. Han¹, H. Kim¹, D. Kim¹;

¹Endocrinology and Metabolism, Ajou University Hospital, Suwon, ²Division of Endocrine and Metabolism, Department of Internal Medicine, Seoul Medical Center, ³Physiology, Ajou University Hospital, Suwon, ⁴Endocrinology and Metabolism, Kosin University Gospel Hospital, Busan, ⁵Endocrinology and Metabolism, Hongik Hospital, Seoul, Republic of Korea.

Background and aims: Although iron is an important component of the respiratory system in mitochondria, the relationship between iron metabolism and insulin resistance (IR) in skeletal muscles has not been well studied.

Materials and methods: In this study, we investigated the relationship between iron metabolism and palmitate-induced insulin resistance in human skeletal muscle cells. We measured cellular iron levels in palmitate-induced insulin resistant skeletal muscle cells using calcein-AM. In addition, we tested the effects of a variety of chemical iron chelators such as deferoxamine (DFO), deferasirox (DS), FeCl₃, and FeSO₄ in palmitate-induced insulin resistant skeletal muscle cells using the glucose uptake method. Because iron is a critical factor for respiratory metabolism, the current study was initiated to determine whether abnormal iron metabolism is involved in palmitate-induced insulin resistance.

Results: Palmitate treatment reduced insulin-induced Akt phosphorylation and glucose uptake but increased the intracellular iron content in skeletal muscle cells compared with control cells. When palmitate-treated skeletal muscle cells were treated with iron chelators, insulin-stimulated phosphorylated Akt levels and glucose uptake were recovered. However, iron supplementation by treatment with FeCl₃ and FeSO₄ augmented palmitate-induced insulin resistance. Interestingly, iron supplementation in normal skeletal muscle cells reduced insulin-stimulated phosphorylated Akt and glucose uptake and evoked insulin resistance. Similarly, treating skeletal muscle cells with TNF- α elicited similar effects.

Conclusion: The current study revealed that iron overload in skeletal muscle cells induced insulin resistance, whereas reduced intracellular iron levels protected palmitate-induced insulin resistance. Therefore, these data provide a therapeutic strategy for the treatment of insulin resistance.

Muscle glucose uptake and insulin signalling do not correlate over the feeding/fasting cycle in high fat fed rats

L.B. Small, A. Brandon, E. Suryana, G.J. Cooney;
Diabetes and Metabolism, The Garvan Institute of Medical Research, Sydney, Australia.

Background and aims: Many studies investigating mechanisms of diet-induced insulin resistance impose controlled experimental conditions (constant insulin stimulation, constant glucose and/or fatty acid availability) designed to make interpretation of results simpler. These models may alter important parameters such as insulin or glucose to levels that are not ever experienced physiologically by the animal during normal feeding or fasting. We examined glucose uptake and markers of insulin action in muscle of high fat diet-fed (HFD) rats during the normal diurnal cycle.

Materials and methods: Male Wistar rats were fed a high fat diet (45% calories as fat) for 4 weeks. After 3 weeks of fat feeding rats were anaesthetised, implanted with a single chronic jugular cannula and allowed to recover. One week after surgery the cannula was used to sample blood and deliver 14C-glucose and 3H-2-deoxyglucose to monitor in vivo glucose uptake at several timepoints along the feedings/

fasting axis (4 pm, 9 pm, 12 am and 8 am). Tissues were collected for further analysis.

Results: Plasma insulin levels were the same in Chow and HFD rats in the basal state and after feeding. However glucose uptake into skeletal muscle was impaired in the tibialis anterior (TA) muscle of HFD rats at 12 am and 8 am (12 am Chow=19.3±2.8, HFD=7.7±0.9, 8 am Chow=10.4±1.2, HFD=5.6±0.6, $\mu\text{mol}/\text{min}/100\text{ g}$, $p<0.05$). There was no difference in the phosphorylation state of canonical signalling proteins AKT, GSK3 β and TBC1D4 in TA muscle from Chow and HFD rats at any of the time points studied. In contrast, pyruvate dehydrogenase (PDH) activity in the TA was dramatically lower in HFD rats at both 12 am and 8 am (12 am Chow=4.26±1.73 HFD=0.96±0.17, 8 am Chow=6.46±0.97 HFD=1.05±0.18, mU/g , $p<0.01$).

Conclusion: These data suggest that reduced glucose uptake in muscle of HFD rats assessed during the normal diurnal cycle of energy metabolism relates more to changes in glucose metabolism than altered canonical insulin signalling.

Effect of glucagon-like peptide-1 on glucagon secretion, endogenous glucose production and whole body lipolysis in patients with non-alcoholic liver disease

A.E. Junker¹, L. Gluud², G.V. Hall³, J.J. Holst⁴, F.K. Knop¹, T. Vilsbøll¹;

¹Center for Diabetes Research, Hellerup, ²Department of Gastroenterology, Hvidovre, ³Clinical Metabolomics Core Facility, ⁴NNF Centre for Basic Metabolic Research and Department of Biomedical Science, Copenhagen, Denmark.

Background and aims: We evaluated the glucagon-suppressive effect of glucagon-like peptide-1 (GLP-1) and its potential effects on endogenous glucose production and whole body lipolysis in non-diabetic patients with non-alcoholic fatty liver disease (NAFLD).

Materials and methods: Ten non-diabetic patients with biopsy-verified NAFLD (NAFLD activity score 2.5±1.0) and 10 matched controls underwent a 2-hour intravenous GLP-1 (0.8 $\text{pmol}\times\text{kg}^{-1}\times\text{min}^{-1}$) and placebo infusion on separate days. Since GLP-1-mediated glucagon suppression is glucose-dependent, plasma glucose was clamped at fasting level during the first hour, then raised and clamped at 'postprandial level' (fasting plasma glucose level plus 3 mmol/l) for the remaining hour. We evaluated plasma levels of glucagon, endogenous glucose production and whole body lipolysis rates with stable isotopes, and respiratory quotient using indirect calorimetry. Data are presented as median±interquartile range and groups are compared using non-parametric analysis of variance.

Results: Compared to controls, patients with NAFLD were more insulin resistant (HOMA-IR: 3.8±2.2 vs 1.6±1.5, $p=0.003$) and had higher fasting glucagon (7.5±5.3 vs 5.8±1.5 mmol/l , $p=0.045$). Similar relative glucagon suppression was seen in both groups during GLP-1 infusion at fasting (-97±75 vs -93±41 $\text{pmol}/\text{l}\times\text{min}^{-1}$, $p=0.566$) and 'postprandial' plasma glucose levels (-108±101 vs -97±53 $\text{pmol}/\text{l}\times\text{min}^{-1}$, $p=0.196$). Patients with NAFLD had impaired GLP-1-induced suppression of endogenous glucose production at fasting and 'postprandial' glucose levels and impaired elevation of respiratory quotient during 'postprandial' glucose levels.

Conclusion: Patients with NAFLD are insulin resistant and exhibit fasting hyperglucagonaemia, but intact GLP-1-mediated glucagon suppression independently of plasma glucose concentrations. Preserved glucagonostatic effect of GLP-1 in patients with NAFLD may be important to sustain normoglycaemia.

548

Glucagon suppression is, besides hyperinsulinaemia, an adaptation to reduced insulin sensitivity in individuals with normal and impaired glucose regulation

G. Pacini¹, B. Ahrén², D. Vistisen³, S.S. Torekov⁴, N.B. Johansen^{3,5}, D.R. Witte⁶, A.E. Jonsson⁴, O. Pedersen⁴, T. Hansen⁴, T. Lauritzen⁶, J.J. Holst⁴, M.E. Jørgensen³, K. Færch³;

¹Metabolic Unit, IN-CNR, Padova, Italy, ²Lund University, Lund, Sweden, ³Steno Diabetes Center, ⁴University of Copenhagen, ⁵Danish Diabetes Academy, Copenhagen, ⁶Aarhus University, Denmark.

Background and aims: Hyperinsulinaemia is an important adaptive mechanism to insulin resistance to maintain normoglycaemia. The aim of this study was to assess whether also glucagon is involved in the islet adaptation to insulin resistance.

Materials and methods: We evaluated 1,433 individuals (762 men/671 women) with normal or impaired glucose regulation from the Danish ADDITION-PRO study. All underwent 75 g oral glucose tolerance tests

with sampling of glucose, insulin and glucagon at 0, 30 and 120 min. Mean (SD) age was 66.1 (7.1) years, BMI 27.1 (4.5) kg/m² and HbA1c 5.7 (0.4) % or 38 (4) mmol/mol. Total areas under the curves (AUCs) for glucose, insulin and glucagon were calculated. Glucagon suppression (%) was calculated as $(1 - (\text{AUC}_{\text{glucagon}}/(\text{fasting concentration} \times 120 \text{ min}))) \times 100$. The insulin sensitivity index (ISI₀₋₁₂₀) was calculated using fasting and 120 min glucose and insulin concentrations as well as information on body weight. The study participants were divided into two groups depending on glucagon suppression: 1) No suppression ($\leq 0\%$; n=287); 2) Suppression ($>0\%$; n=1146).

Results: Median (IQR) of glucagon suppression was 22% (6–34%). While AUC for glucose did not differ between the groups, AUC for insulin was higher and insulin sensitivity was lower in individuals with glucagon suppression (Table 1). When quantifying the effect of insulin sensitivity on glucagon suppression, adjusting for age, sex, BMI, AUC insulin and AUC glucose, we found that a doubling in ISI₀₋₁₂₀ resulted in 13.0% less glucagon suppression (95%-CI: 8.1–18.2%, $P < 0.001$). Glucagon suppression was lower in individuals with screen-detected diabetes (median (IQR): 17% (3–30%)) than in individuals with pre-diabetes (13% (7–34%)) or normal glucose tolerance (13% (5–36%); $P < 0.001$). However, glucose tolerance status ($P = 0.745$) or obesity ($P = 0.505$) did not modify the association between glucagon suppression and ISI₀₋₁₂₀.

Conclusion: The results suggest that glucagon suppression, together with increased insulin secretion, is an adaptation to reduced insulin sensitivity in individuals with normal or impaired glucose regulation. Therefore, preservation of glucose tolerance in the presence of insulin resistance may depend not only on an individual's ability to secrete more insulin but also on their ability to suppress glucagon.

Table 1: AUCs of glucose and insulin as well as insulin sensitivity by glucagon suppression group

Glucagon suppression	Number	AUC glucose (mmol/l · 2hr)	AUC insulin (nmol/l · 2hr)	Insulin sensitivity (ISI ₀₋₁₂₀)
No	287	946 (195)	21.2 (15.0–31.2)	39.6 (28.8–54.0)
Yes	1146	947 (184)	23.5 (16.1–34.2)	36.1 (25.3–47.1)
<i>P</i> -value		0.938	0.007	<0.001

Means (SD) or medians (IQR). *P*-value is the unadjusted *t*-test of difference between groups according to glucagon suppression. AUC insulin and ISI₀₋₁₂₀ were log-transformed before performing the statistical test

Distinct roles of somatostatin in the control of glucagon secretion by glucose and K_{ATP} channel blockers from the perfused mouse pancreas

H. Chae¹, A. Gómez-Ruiz¹, B. Lai¹, N. Antoine¹, S. Seino², P. Gilon¹; ¹Pôle d'endocrinologie, diabète et nutrition, Institut de recherche expérimentale et clinique, Université catholique de Louvain, Brussels, Belgium, ²Kobe Biotechnology Research and Human Resource Development Center, Kobe University, Japan.

Background and aims: The mechanisms by which glucose controls glucagon release are hotly debated. In particular, it is unclear whether it acts directly on α -cells or indirectly through a paracrine factor released from non- α -cells within the islet. One of the reasons for the controversies might be linked to the different experimental models used in which paracrine and endocrine interactions might be altered (fresh or cultured tissue, single cells or isolated islets). To be as close as possible to the physiological situation, we used the *in situ* perfused mouse pancreas which preserves endocrine and paracrine interactions, and we investigated the role of somatostatin (SST) in the control of glucagon secretion by glucose and K_{ATP} channel modulators.

Materials and methods: The effects of glucose and K_{ATP} channel modulators were tested on glucagon secretion of the *in situ* perfused pancreas of *Sst*^{+/+} and *Sst*^{-/-} (to address the role of SST) and of C57BL/6 and *Sur1*^{-/-}

or *Kir6.2*^{-/-} mice (to address the role of K_{ATP} channels, the last two mouse models lacking a major functional subunit of the K_{ATP} channels). The effluent from the portal vein was collected every 4 min. The experiments were performed in the presence of a 6 mmol/l mixture of amino acids or a 2 mmol/l mixture of various amino acids present at physiological concentrations.

Results: Glucagon release of C57BL/6 or *Sst*^{+/+} mice was inhibited by a rise of the glucose concentration of the medium from 1 to 7 mmol/l, or by the addition of the K_{ATP} channel blocker tolbutamide (100 or 500 μ M) or the K_{ATP} channel opener diazoxide (100 μ M) to a medium containing 1 mmol/l glucose. Glucagon release of *Sur1*^{-/-} or *Kir6.2*^{-/-} mice was also inhibited by 7 mmol/l glucose but it was, as expected, unaffected by tolbutamide or diazoxide. This suggests that glucose can inhibit glucagon release independently of K_{ATP} channels. In *Sst*^{-/-} mice, glucagon secretion was inhibited by a rise of the glucose concentration of the medium from 1 to 7 mmol/l, but it was stimulated by tolbutamide. Because it has been suggested that tolbutamide might stimulate exocytosis by activating Epac2, we tested the effect of another sulfonylurea, gliclazide, which is ineffective on Epac2. Gliclazide (10 μ M) mimicked the glucagonostatic effect of tolbutamide in *Sst*^{+/+} mice and the glucagonotropic effect of tolbutamide in *Sst*^{-/-} mice.

Conclusion: Using the preparation of the *in situ* perfused mouse pancreas, we confirmed key observations previously obtained on perfused mouse islets. Glucose can inhibit glucagon release independently of K_{ATP} channels. SST is responsible for the glucagonostatic effect of sulfonylureas since ablation of SST transformed their glucagonostatic effect into a glucagonotropic effect. This suggests that sulfonylureas modulate glucagon secretion by two distinct mechanisms: a direct stimulatory effect of α -cells (independent of Epac2 activation and observed in the absence of SST influence) and an indirect inhibition via SST released from δ -cells which counteracts the direct stimulation.

Paradoxical Ca²⁺ kinetics in islet-located glucagon-releasing alpha cells

Q. Yu, J. Li, P. Ahooghalandari, A. Tengholm, E. Gylfe; Department of Medical Cell Biology, Uppsala University, Sweden.

Background and aims: Insulin and glucagon are the principle hormones that maintain blood glucose homeostasis. Previous studies have shown that insulin and glucagon are secreted in pulses with opposite phase from glucose-stimulated islets. Also secretion of somatostatin is pulsatile in opposite phase to glucagon. Since Ca²⁺ is regarded as the main trigger of both insulin and glucagon release, we compared glucose-induced cytoplasmic Ca²⁺ dynamics in α - and β -cells within pancreatic islets.

Materials and methods: Mouse islets were loaded with the fluorescent Ca²⁺ indicator Fluo-4 and the Ca²⁺ concentration in the sub-plasma membrane space ([Ca²⁺]_{pm}) was monitored with total internal reflection fluorescence microscopy. Discrimination between α - and β -cells was based on transgenic α -cell expression of red fluorescent protein and cell-characteristic Ca²⁺ responses. Glucagon and insulin secretion was measured from batch-incubated islets with immunoassays.

Results: At 3 mM glucose, RFP-positive α -cells showed non-synchronized irregular spikes of [Ca²⁺]_{pm}, whereas RFP-negative β -cells showed low and stable [Ca²⁺]_{pm}. Introduction of 20 mM glucose induced pronounced [Ca²⁺]_{pm} elevation with oscillations that were perfectly synchronized among β -cells whereas there was often temporary interruption of [Ca²⁺]_{pm} signaling in the α -cells. However, the recurring [Ca²⁺]_{pm} oscillations tended to synchronize among the islet α -cells, and cross-correlation analysis revealed unexpected synchronization between the [Ca²⁺]_{pm} oscillations in α - and β -cells. This synchronization was neither affected by addition of 400 nM somatostatin, nor by 100 nM insulin. The somatostatin receptor SSTR2 antagonist PRL 2903 (5 μ M) had only

subtle effects on $[Ca^{2+}]_{pm}$ signaling in α -cells despite potently stimulating glucagon secretion at both 3 and 20 mM glucose without preventing the inhibitory effect of glucose. Moreover, the $[Ca^{2+}]_{pm}$ synchronization between α -cells and β -cells exposed to 20 mM glucose remained after 18 h treatment of the islets with pertussis toxin, which prevents somatostatin receptor signaling via G α i. The insulin receptor antagonist S961 (20 nM) lacked significant effects on $[Ca^{2+}]_{pm}$ in α - and β -cells, as well as on insulin and glucagon release at 20 mM glucose.

Conclusion: Synchronization of $[Ca^{2+}]_{pm}$ oscillations between α -cells and β -cells at 20 mM glucose surprisingly indicates that pulsatile glucagon release is not generated by α -cell oscillations of $[Ca^{2+}]_{pm}$. Since somatostatin receptor antagonism potently stimulated glucagon release with little effects on $[Ca^{2+}]_{pm}$, pulsatile glucagon release is probably generated by inhibitory somatostatin pulses overriding the stimulatory effect of Ca^{2+} .

Calcium activated potassium channels modulate pancreatic alpha cell electrical excitability and glucagon secretion

D.A. Jacobson¹, K.R. Verlage², G. Amarnath¹, P.K. Dadi¹;

¹Molecular Physiology and Biophysics, Vanderbilt University, Nashville,

²School of Medicine, Texas Tech University Health Sciences Center, Lubbock, USA.

Background and aims: Ca^{2+} influx into pancreatic alpha-cells through voltage-dependent Ca^{2+} channels (VDCCs) is required for glucagon secretion and regulatory mechanisms of this process become defective during the pathogenesis of diabetes. Potassium channels are the primary regulators of membrane potential, and thus, regulate the activity of VDCCs. However, the roles of Ca^{2+} activated potassium channels ($K_{Ca^{2+}}$) during alpha-cell Ca^{2+} entry and glucagon secretion have not been determined. The aim of this study was to determine the influence of alpha-cell $K_{Ca^{2+}}$ channels on electrical excitability, Ca^{2+} entry and glucagon secretion.

Materials and methods: Whole cell current clamp and voltage clamp electrophysiological recordings were used to measure $K_{Ca^{2+}}$ currents and electrical excitability from human and mouse alpha-cells. Cells were confirmed as alpha-cells with either glucagon staining or via expression of a red fluorescent protein in glucagon positive islet cells. Ca^{2+} imaging was performed on mouse and human pancreatic islets and single cells with and without inhibitors of small conductance (SK) or intermediate conductance (IK) $K_{Ca^{2+}}$ channels (apamin and TRAM34 respectively); glucagon secretion was assayed under similar conditions. Immunofluorescent imaging was used to detect IK expression in mouse and human pancreatic sections.

Results: Mouse pancreatic alpha-cells have $K_{Ca^{2+}}$ currents (13.3 +/- 1.78 pA, n=19), which were elicited by Ca^{2+} entry following 26 voltage ramps that resembled action potentials. The alpha-cell $K_{Ca^{2+}}$ currents were partially inhibited by SK channel blockade with apamin (37.87 +/- 5.7%, n=8) or IK channel blockade with TRAM34 (25.75 +/- 4.4%, n=11). The membrane potential of alpha-cells was depolarized in response to SK or IK channel inhibition (1.61 +/- 0.49 mV with apamin, n=5; 1.94 +/- 0.32 mV with TRAM34, n=6) under elevated glucose (11 mM) conditions. Inhibition of SK channels also enhanced alpha-cell Ca^{2+} influx under both low and high glucose conditions, increasing Ca^{2+} levels by 36.18% (p<.01) and 17.15% (p<.0001) respectively. Moreover, SK channels limited glucose induced Ca^{2+} influx into alpha-cells within clusters of islet-cells and when inhibited increased Ca^{2+} influx by 23.72% (p<.05). IK channels are also expressed in pancreatic islets and we find that mouse and human pancreatic sections show IK channel expression in glucagon positive alpha-cells. Inhibition of IK channels caused a 41.76% (p<.001) increase of mouse alpha-cell Ca^{2+} influx in low glucose and a 28.76% (p<.05) increase of Ca^{2+} influx in high glucose. Human alpha-cells mirrored this behavior in response to IK channel inhibition,

showing a 31.66% (p<.05) increase in Ca^{2+} influx in low glucose and a 33.28% (p .05 vs. apamin treated islets); whereas IK channel blockade with TRAM34 caused an insignificant trend toward increased glucagon secretion.

Conclusion: In conclusion, this study suggests that SK channels play a role limiting glucagon secretion under high glucose conditions. SK and IK channels hyperpolarize the alpha-cell membrane potential, decreasing excitability and Ca^{2+} influx during glucose stimulation, which reduces glucagon secretion. Thus, $K_{Ca^{2+}}$ channel activity helps to modulate glucose-dependent inhibition of alpha-cell glucagon secretion.

Direct effects of anti-diabetic drugs on glucagon secretion in rat pancreatic islets

M. Yang, R. Chu, Y. Ge, A.K. Dhalla,;

Biology, Gilead Sciences, Fremont, USA.

Background and aims: Glucagon secreted by pancreatic α -cells plays an important role in maintaining glucose homeostasis via its ability to increase hepatic glucose production. Patients with type 2 diabetes exhibit fasting and paradoxical postprandial hyperglucagonemia, suggesting dysfunction of the pancreatic α -cell may contribute to hyperglycemia. Thus, suppression of inappropriate glucagon secretion is potentially an effective treatment strategy for patients with type 2 diabetes. We have previously shown that Na^{+} channel blockers directly inhibit glucagon secretion from pancreatic islets and have glucose lowering properties, without effecting hypoglycemia-stimulated glucagon release. Various glucose lowering therapeutics have been shown to modulate glucagon levels and action in both clinical and non-clinical studies, but it is unclear which of these therapies have a direct effect on glucagon secretion at the level of the pancreatic islet. The present study was carried-out to determine the direct effects of different classes of glucose lowering medications on glucagon secretion from rat pancreatic islets.

Materials and methods: Pancreatic islets were isolated from SD rats. Glucagon secretion was measured in equal sized isolated islets incubated with agents in Krebs-ringer buffer with 0.1% BSA, in 3 or 11 mM glucose for 1 h. Glucagon levels were measured by an ELISA kit.

Results: In the presence of 3 mM glucose, insulin at 10 or 100 nM significantly reduced glucagon secretion by 48±8 or 36±11% compared to vehicle control, respectively. Exendin-4 at 100 nM also significantly decreased glucagon secretion in the presence of 3 or 11 mM glucose, by 41±11 or 62±5% compared to control, respectively. In addition, exendin-4 significantly increased (154±24%) insulin secretion in the presence of 11 mM glucose compared to control. Tolbutamide (10-100 μ M), sitagliptin (0.003-3 μ M), canagliflozin (0.1-30 μ M) and metformin (1-100 μ M) had no significant effect on glucagon secretion. Veratridine, a Na^{+} channel activator, significantly increased glucagon secretion with 8-fold induction at 30 μ M, suggesting a direct role of Na^{+} channels in glucagon secretion. Accordingly, glucagon secretion was significantly and concentration-dependently reduced by Na^{+} channel blockers TTX or GS-458967, with a 47±6 or 53±8% reduction at 100 nM or 3 μ M, respectively.

Conclusion: Data show that insulin at high concentrations directly inhibits glucagon secretion in rat islets. GLP-1R agonist exendin-4 directly inhibits glucagon secretion from α -cells as well as through paracrine effect on β -cells by stimulating insulin secretion. The sulfonylurea tolbutamide, DPP-IV inhibitor sitagliptin, SGLT2 inhibitor canagliflozin and metformin do not directly regulate glucagon secretion in rat islets. Na^{+} channel blockers directly inhibit glucagon secretion in isolated pancreatic islets and present a potential new strategy for the treatment of diabetes.

Sodium-glucose transporter 1 and 2 are involved in the GLP-1 release from pancreatic alpha cells

V. Sancho Barnez, R. Lupi, S. Paparo, G. Penno, S. Del Prato; Dept of Clinical and Experimental Medicine, Section of Diabetes and Metabolic Diseases, University of Pisa, Italy.

Background and aims: It has been recently reported that human alpha cells express sodium-glucose co-transporters (SGLT) and that the diabetic condition is associated with reduced expression of SGLT2 and a concomitant increase in the expression of SGLT1 and glucagon genes. Moreover, SGLT2 silencing or functional inhibition with dapagliflozin was associated with increased expression of the glucagon gene. We have tested whether this system also is involved in the recently reported regulation of GLP-1 secretion by the alpha cell. Moreover, since glucagon/GLP-1 secretion by the alpha cell has been claimed to be under the control of the *TCF7L2* signaling pathway, we have also evaluated the interaction of the two systems in the alpha cell.

Materials and methods: We have studied a murine alpha cell line (TC1/6) in the presence of low (LG, 5.5 mM) or high (HG, 16.7 mM) glucose concentrations. Experiments were repeated with and without phloridzin (50 μM), a non-selective SGLT inhibitor. SGLT1, SGLT2 and *TCF7L2* mRNA and protein expression were determined by RT-PCR and Western blot. Glucagon and total GLP-1 secretion in culture medium was measured by ELISA. Cell viability was determined by MTT method, Reactive Oxygen Species (ROS) by H2DCFDA fluorescence and apoptosis by Annexin staining and Propidium Iodine (PI) fluorescence.

Results: At LG, mRNA and protein expressions of SGLT1 and 2, and *TCF7L2* were all detectable. HG incubation was associated with an increase of both mRNA and protein expression of *TCF7L2* (protein: +46±10%, $p<0.001$; mRNA 2.79±0.47 folds, $p<0.001$). Concomitantly, SGLT1 mRNA expression increased (2.31±0.49 folds, $p<0.001$) while SGLT2 decreased (0.48±0.09, $p<0.001$). Changes in mRNA expressions were associated with -34±11% ($p<0.01$) reduction in SGLT1 protein expression with no significant changes for SGLT2 protein. GLP-1 concentration in the medium increased by 25±3% ($p<0.001$) as compared to LG. SGLT1/2 inhibition by phloridzin did not affect GLP-1 release at LG (-10±6%, $p=NS$), while it was associated with a 30±3% reduction ($p<0.001$) as compared to LG, and also with an increment in glucagon secretion as compared to HG (HG: -16±5% vs. LG, $p<0.03$; HG+Phl: 1±5% vs. LG, $p<0.05$ vs. HG) and PC2 expression (HG+Phl: 1.40±0.12, $p<0.02$ vs. LG). The presence of phloridzin did not modify *TCF7L2* expression, at both low and high glucose concentrations. The presence of the SGLT inhibitor also modulates cellular state. When added to LG, phloridzin produced an increment in cell viability (+13±2%, $p<0.001$ vs. LG), a decrement in ROS production (-11±3%, $p<0.001$ vs. LG) with no modification of apoptosis rate. On the contrary, addition of phloridzin to cell incubated at HG was associated with reduced cell viability (-23±5%, $p<0.001$) and increased apoptosis (+19±2%, $p<0.001$ vs. LG).

Conclusion: These data suggest that GLP-1 and glucagon release from alpha cells in response to high glucose could be mediated by SGLT expression independently of *TCF7L2* activation.

Enteroendocrine secretion after meal challenge is preserved across glucose tolerance spectrum: lack of correlation with beta cell function

M. Gebauer¹, H. Ruetten¹, R.H. Raymond², R.P. Robertson³, P.J. Savage⁴, S.S. Shankar⁵, D. Stefanovski⁶, M.T. Vassileva⁷, A. Vella⁸, K.F. Wright⁹, D.A. Fryburg⁹, For the Foundation for the NIH Beta Cell Project Team;

¹Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, ²RSquared Solutions, Skillman, ³Pacific Northwest Diabetes Research Institute, Seattle, ⁴NIH-NIDDK, Bethesda, ⁵Eli Lilly and Co, Indianapolis, ⁶U. Pennsylvania, Philadelphia, ⁷Foundation for the NIH, Bethesda, ⁸Mayo Clinic, Rochester, ⁹ROI BioPharma Consulting, East Lyme, USA.

Background and aims: Although it is known that meal ingestion stimulates gut enteroendocrine secretion (ES) and beta cell function (BCF), the relationship between ES and BCF is not known across GT populations.

Materials and methods: In studies examining BCF in subjects with normal glucose tolerance (NGT), prediabetes (PDM), and type 2 DM (T2DM), total and active GLP-1, GIP, PYY, and glucagon (gln) were measured before and after a mixed meal (MTT). We hypothesized that these responses were associated with BCF. ES was assessed in overnight fasted subjects before and 30, 60 and 120 min after 470 kCal MTT.

Results: Table summarizes responses pre- and 30-min post MTT. Parameters of insulin secretion (Φ_{tot}) and sensitivity (SI) and disposition index (DI_{tot}) were estimated using minimal model. BCF: ES association was conducted using Spearman's Rank correlations. Before the MTT, ES was generally higher for T2DM versus NGT and PDM. MTT increased total and active GLP-1, GIP and PYY at 30 min. Changes were generally comparable across GT populations except gln which showed increases across the GT Populations NGT<PDM<T2DM (ANOVA $p<0.001$). Corr analysis revealed no strong relationships between ES at baseline or 30 min post-MTT, with SI, Φ_{tot} or DI_{tot} (to be shown in poster).

Conclusion: ES is not impaired after MTT in PDM and T2DM, yet there is no apparent correlation between ES and BCF, suggesting a defect in BCF rather than the ES in PDM and T2DM.

Renal extraction and acute effects of glucagon-like peptide-1 on central and renal haemodynamics in patients with type 2 diabetes

A. Asmar¹, L. Simonsen¹, M. Asmar¹, S. Madsbad², J.J. Holst^{3,4}, E. Frandsen⁵, C. Moro⁶, T. Jonassen⁴, J. Bilow^{1,4};

¹Clinical Physiology and Nuclear Medicine, Bispebjerg University Hospital, ²Department of Endocrinology, Hvidovre University Hospital, ³NNF Center for Basic Metabolic Research, University of Copenhagen, ⁴Department of Biomedical Sciences, University of Copenhagen, ⁵Department of Diagnostics, Clinical Physiology and Nuclear Medicine, Glostrup University Hospital, Copenhagen, Denmark, ⁶Institute of Metabolic and Cardiovascular Diseases, Paul Sabatier University, Toulouse, France.

Background and aims: During acute administration of native GLP-1, we previously demonstrated central hemodynamic effects in healthy males, whereas renal hemodynamics, despite renal extraction of GLP-1, were unaffected. In the present study, we elucidated hemodynamic effects of GLP-1 in type 2 diabetic subjects (n=8) under fixed sodium intake.

Materials and methods: During a 3-hour infusion of GLP-1 (1.5 pmol kg⁻¹ min⁻¹) or saline, cardiac output was continuously estimated by pulse contour analysis, concomitantly with intra-arterial blood pressure and heart rate. Renal plasma flow, glomerular filtration rate, and uptake/release of hormones and ions were measured using Fick's Principle after catheterization of a renal vein. Urine collection was conducted throughout the experiments at voluntary voiding, and subjects remained supine.

Results: During GLP-1 infusion, systolic and diastolic blood pressure remained unchanged. Heart rate increased significantly, whereas cardiac output remained unchanged. GLP-1 was extracted significantly in the kidneys, however, renal plasma flow and glomerular filtration rate as well as renal sodium and lithium excretion were not affected.

Conclusion: In conclusion, like in healthy subjects, acute administration of GLP-1 in type 2 diabetic subjects led to a positive chronotropic effect, but in contrast to healthy subjects, cardiac output did not increase in type 2 diabetic subjects. Renal hemodynamics and sodium excretion were not affected by GLP-1 infusion.

Preserving expression of GLP-1 receptor in beta cells of db/db mice increases insulin secretion

F. Kubo¹, T. Miyatsuka^{1,2}, S. Sasaki¹, M. Takahara¹, Y. Yamamoto¹, N. Shimo¹, H. Kaneto³, T.-A. Matsuoka¹, I. Shimomura¹;

¹Department of Metabolic Medicine, Osaka University Graduate School of Medicine, ²Department of Medicine, Metabolism and Endocrinology, Juntendo University Graduate School of Medicine, Tokyo, ³Department of Diabetes, Endocrinology and Metabolism, Kawasaki Medical School, Okayama, Japan.

Background and aims: GLP-1 signaling has been shown to play important roles in maintaining β -cell functions, such as insulin secretion and β -cell proliferation. While expression levels of GLP-1 receptor (Glp1r) and GIP receptor (Gipr) are compromised in the islets of diabetic rodent models, it remains unclear at which stage of glucose intolerance the incretin receptors are downregulated and whether preserving expression of Glp1r and/or Gipr affects the phenotypes of diabetic model mice.

Materials and methods: To address the first question, we investigated expression levels of Glp1r, Gipr, and other β -cell specific genes in the islets of db/db mice at 4, 8, and 12 weeks of age. Then, we generated a transgenic mouse model "CAG-CAT-Glp1r -IRES-eGFP" that

conditionally and specifically expressed Glp1r in β cells, and evaluated their glucose tolerance.

Results: The expression levels of Glp1r and Gipr in db/db islets were comparable to those in control (db/misty) mice at the age of 4 weeks, and significantly decreased at the age of 8 and 12 weeks. When CAG-CAT-Glp1r -IRES-eGFP mice were crossed with Pdx1-CreER mice, eGFP expression was detected exclusively in β cells of Pdx1-CreER; CAG-CAT-Glp1r -IRES-eGFP (β Glp1r). Oral glucose tolerance test (OGTT) after 4-week treatment of Exendin-4 (0.1 mg/kgBW/day) revealed that the glucose profiles were comparable between β Glp1r; db/db and control db/db mice, whereas serum insulin levels during OGTT were significantly higher in β Glp1r; db/db than control db/db mice.

Conclusion: The expression levels of Glp1r and Gipr in db/db mice were significantly downregulated with aging. Activation of Glp1r signaling in β cells of db/db mice increased insulin secretion.

557

Changes in postprandial glucagon-like peptide-1 secretion during the development of diet-induced obesity in rats

T. Hira, A. Kanehira, H. Hara;
Hokkaido University, Sapporo, Japan.

Background and aims: Diet-induced obesity is a major cause of metabolic syndrome such as diabetes. Incretins including glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) are secreted from enteroendocrine cells in response to meal ingestion, and contribute to preventing postprandial hyperglycemia by enhancing insulin secretion. It is unclear whether postprandial GLP-1 secretory response is affected (increased or decreased) during the development of diet-induced obesity. In the present study, meal tolerance test (MTT) was conducted in rats fed normal or high-fat/high-sucrose diet, and postprandial GLP-1, insulin and glycemic response were monitored.

Materials and methods: Male Sprague Dawley rats (5 weeks age) were fed control diet (AIN-93G, n=8) or high-fat/high-sucrose diet (HF/HS, n=8) containing 30% fat and 40% sucrose for 5 weeks. MTT was conducted every week for 4 weeks. In MTT, all rats were fed the control diet (5 or 10 g/kg) for 15 min after overnight fasting. Tail vein blood was collected before and after the meal feeding until 120 min, and plasma glucose, insulin and GLP-1 levels were measured. After 5 weeks feeding period, rats were killed and intestinal tissue samples (jejunum, ileum, cecum and colon) were collected for measurement of mRNA expressions by real-time PCR.

Results: Body weight was significantly higher in HF/HS rats than control rats (423.4 g vs 380.8 g, $P<0.05$) at the end of experiment (5 week). Fasting glucose levels were higher in HF/HS rats (94.7 mg/dL vs 75.0 mg/dL, $P<0.05$) after week 3 until the end of experiment. However, postprandial glycemia did not differ between control and HF/HS rats throughout the experimental period, suggesting some protective adaptations occurred in HF/HS rats. Postprandial GLP-1 secretion was significantly larger ($P<0.05$) in HF/HS rats than control rats at week 2 and 4, and this was reflected by increased insulin response in HF/HS rats. In the intestinal mucosa, among various nutrient sensing receptors and transporters evaluated, one of fatty acid receptors, FFAR1 had higher mRNA expression (150% increment against control rats, $P<0.05$) in the upper small intestine of HF/HS rats compared to that of control rats.

Conclusion: The present study demonstrates that postprandial GLP-1 secretion is increased in the early period of developing diet-induced obesity. These results suggest that increased postprandial GLP-1 response contributes to normalize postprandial glycemic response by enhancing insulin secretion. Increased expression of a fatty acid receptor may be involved in the protective adaptation against induction of glucose intolerance.

Farnesoid X receptor inhibits glucagon-like peptide-1 production by enteroendocrine L-cells

S. Lestavel^{1,2}, M.-S. Trabelsi^{1,2}, M. Daoudi¹, S. Ducastel^{1,2}, V. Touche^{1,2}, O. Briand^{1,2}, S.I. Sayin³, A. Perino⁴, C.A. Brighton⁵, J. Kluza^{6,2}, G. Baud^{7,2}, A. Tailleux^{1,2}, B. Staels^{1,2};

¹INSERM U1011, Lille, ²Université Lille, France, ³Wallenberg laboratory, Gothenburg, Sweden, ⁴Ecole Polytechnique Fédérale de Lausanne, Switzerland, ⁵Cambridge Institute for Medical Research, UK, ⁶INSERM U837, ⁷INSERM U859, Lille, France.

Background and aims: Bile acids (BA) are signalling molecules which activate the transmembrane receptor TGR5 and the nuclear receptor FXR. BA sequestrants (BAS) complex BA in the intestinal lumen and decrease intestinal FXR activity. The BAS-BA complex also induces Glucagon-Like Peptide-1 (GLP-1) production by L-cells which potentiates beta-cell glucose-induced insulin secretion. Whether FXR is expressed in L-cells and controls GLP-1 production is unknown.

Materials and methods: Glucose homeostasis and Proglucagon/GLP-1 production were studied in different *in vitro-ex vivo* models (GLUTag cell line and human jejunal biopsies) and in different mouse strains (Wild-type mice, mice invalidated for FXR or TGR5, conventional-raised and germ-free mice). FXR was activated by a synthetic ligand.

Results: We show that FXR activation in L-cells decreases proglucagon expression by interfering with the glucose-responsive factor Carbohydrate-Responsive Element Binding Protein (ChREBP) and GLP-1 secretion by inhibiting glycolysis. *In vivo*, FXR-deficiency increases GLP-1 gene expression and secretion in response to glucose hence improving glucose metabolism. Moreover, treatment of *ob/ob* mice with the BAS colesevelam increases intestinal proglucagon gene expression and improves glycemia in a FXR-dependent manner.

Conclusion: These findings identify the FXR/GLP-1 pathway as a new mechanism of BA control of glucose metabolism and a pharmacological target for type 2 diabetes.

The glucose lowering effect of small molecule GPR120 agonists is driven by glucagon-like peptide

M.S. Winzell, S. Myhre, L. Sundström, A. Ahnmark, A.-C. Nyström, M. Sundqvist, M. Nägård;

Cardiovascular and metabolic diseases, AstraZeneca R&D, Mölndal, Sweden.

Background and aims: GPR120 is a fatty acid receptor suggested to have anti-diabetic effects through multiple effects on different organs. It is also known that GPR120 is expressed in many tissues, including enteroendocrine cells in the gut, where it has been suggested to be involved in mediating the fatty acid effect on GLP-1 secretion. Whether GLP-1 plays a role in the glucose lowering effect observed after GPR120 activation by small molecule compounds *in vivo* is not completely understood. Here, we examine the acute mechanism of action of GPR120 agonism in lean mice.

Materials and methods: Insulin secretion was studied in lean female mice, following oral administration with a specific GPR120 agonist prior to an intravenous glucose tolerance test (IVGTT, 0.35 g/kg), with and without addition of a GLP-1 receptor antagonist, exendin 9-39 (30 nmol/kg). In a second experiment, the combination of a GPR120 agonist and a DPP-4 inhibitor, sitagliptin (15 mg/kg), to reduce the degradation of GLP-1, was examined. Insulin and glucose were measured after 0, 1, 5, 10, 20 and 40 min following the intravenous glucose administration. In a

separate experiment, total GLP-1 levels were measured in plasma following oral administration with the GPR120 agonist.

Results: The GPR120 agonist significantly increased insulin secretion in the IVGTT in lean mice, where the acute insulin response (AIR) was 0.9 ± 0.09 ng/ml versus 1.4 ± 0.21 ng/ml after GPR120 agonist administration ($p=0.001$). This increase in insulin secretion resulted in improved glucose elimination ($K_{G1-20min}$ $2.5 \pm 0.24\%/min$ versus $3.3 \pm 0.28\%/min$ after GPR120 agonist administration ($p=0.004$). Exendin 9-39, a GLP-1 receptor antagonist, completely blocked this effect, while the DPP-4 inhibitor sitagliptin, induced a significantly increased insulin response compared to GPR120 agonist (AIR 2.0 ± 0.22 ng/ml, $p<0.05$ compared to GPR120 agonist alone) or sitagliptin alone. Circulating total GLP-1 levels were measured and found to be increased after administration of the GPR120 agonist compared to vehicle (58 ± 6 pM versus 69 ± 6 pM, $p=0.02$).

Conclusion: This study clearly demonstrates that administration of a GPR120 agonist to lean mice resulted in increased insulin secretion, and it is suggested to be the main mechanism behind the acute glucose lowering effect of GPR120 agonists. The increased insulin secretion was mediated through increased circulating GLP-1 levels. The combination of GPR120 agonists and DPP-4 inhibition may be an attractive combination to improve glycemic control in diabetic individuals.

560

CART regulates GIP and GLP-1 expression and secretion in vitro and in vivo

L. Shcherbina, A.-H. Thoren Fischer, N. Wierup; Lund University Diabetes Centre, Malmö, Sweden.

Background and aims: Cocaine- and amphetamine-regulated transcript (CART) is a brain-gut peptide with several functions including regulation of islet hormone secretion and beta-cell survival. We have recently reported that CART is a constituent of human incretin-producing L- and K-cells in the duodenum and jejunum. The aim of the present study was to examine whether CART regulates secretion and expression of glucose-dependent insulinotropic peptide (GIP) and glucagon-like peptide 1 (GLP-1) *in vitro* and *in vivo*.

Materials and methods: To test the effect of CART on GIP and GLP-1 secretion *in vivo* in mice, CART was administered *i.v.* during an oral glucose-tolerance test (OGTT). Effects of siRNA-mediated CART silencing on incretin expression and secretion *in vitro* were studied in GLUTag and STC-1 cells, used as L- and K-cell models respectively. Gene expression was assessed with qPCR, protein content and secretion with ELISA

Results: In both GLUTag and STC-1 cells silencing of CART augmented incretin gene and protein expression. In GLUTag cells GLP-1 mRNA and protein (active) levels were increased by $133.7 \pm 12.5\%$ and $230 \pm 80\%$ respectively ($p<0.001$ and $p<0.05$). In STC-1 cells silencing of CART increased mRNA levels of both GLP-1 and GIP by $147 \pm 7.1\%$ and $125 \pm 8\%$ respectively ($p<0.001$). There were also trends towards increased GLP-1 and GIP protein content ($128 \pm 10\%$, $P=0.06$ and $117 \pm 8\%$, $P=0.06$). Moreover, silencing of CART provoked robustly increased GLP-1 (active) secretion in GLUTag cells stimulated with 2.8 mM glucose, 16.7 mM glucose and 10 μ M IBMX and 16.7 mM glucose (3.79 ± 0.15 , 3.78 ± 0.32 and 4.45 ± 0.32 -fold respectively, $p<0.001$). CART silencing in STC-1 provoked 1.5-fold increase in GLP-1 secretion in cells stimulated with 16.7 mM glucose and 10 μ M IBMX ($p<0.05$).

Intravenous administration of CART 54-102 during an OGTT in mice provoked elevated glucose-stimulated GIP secretion at 10 and 20 min ($P<0.01$ and $P<0.001$), greater AUC for GIP and GLP-1 at 0-60 min ($P<0.05$) and higher acute GIP release ($P<0.01$).

Conclusion: We conclude that CART in L- and K-cells acts as an endogenous inhibitor of GIP and GLP-1 expression and secretion. On the other hand, *in vivo* in mice CART stimulates GIP and GLP-1 secretion.

Whether this latter effect is direct or a consequence of altered insulin and glucagon secretion needs further investigation.

Intestinal GLUT2 inactivation leads to glucose malabsorption and reduces enteroendocrine cell density

C. Schmitt¹, T. Aranas¹, V. Carrière¹, A. Ribeiro¹, K. Garbin¹, M. Le Gall², E. Brot-Laroche¹, A. Leturque¹, A. Grosfeld¹, P. Serradas¹;

¹Inserm UMR_S 1138, Centre de Recherche des Cordeliers; Sorbonne universités, UPMC Univ Paris 06; Sorbonne Cités, UPD Univ Paris 05, ²Inserm UMR_S 1149, DHU Unity; Sorbonne Cités, UPD Univ Paris 05, France.

Background and aims: In western countries, diet has been considerably enriched in readily absorbable sugars. The absorption of sugars in the small intestine is mediated by several transporters. GLUT2, a very efficient glucose and fructose facilitative transporter, is located at the apical membrane of enterocytes, transiently during sugar-rich meals but constitutively in insulin resistant states. At the basal membrane of enterocytes, GLUT2 mediates glucose and fructose exit to the bloodstream. Our team have shown that GLUT2 is also present in another intestinal cell type: the enteroendocrine cells. Those cells produce Glucagon-Like Peptide-1 (GLP-1) and Glucose-dependent Insulinotropic Polypeptide (GIP), strong activators of glucose-induced insulin secretion. This study aims to elucidate the role of intestinal GLUT2 in enterocytes and enteroendocrine cells on glucose homeostasis in mice.

Materials and methods: To address this question, we generated an inducible GLUT2 deficient mouse model specifically in intestinal epithelial cells (GLUT2ΔIEC) by CreLox strategy. Body weight gain, oral glucose tolerance tests and plasma insulin measurements were performed at different time points after intestinal GLUT2 inactivation. GLP-1 and GIP positive cells were quantified in jejunum and colon by immunostaining.

Results: GLUT2ΔIEC mice have a lower body weight gain compared to control mice (7.5 g±0.2 vs. 5.2±0.3 g, P<0.01, 11 weeks post inactivation). This result could be explained by a slower glucose absorption in inactivated mice compared to their littermate controls from 4 weeks post inactivation (12.7±2.9 vs. 4.3±1.9 mg of glucose/dL/min, P<0.05) up to 12 weeks post inactivation (18.7±1.1 vs. 13.5±1.3 mg of glucose/dL/min, P<0.01). Nevertheless, glucose malabsorption is affecting neither oral glucose tolerance nor plasma insulin levels. Interestingly, there is a 6-fold decrease of GLP-1-producing cell density in jejunum of GLUT2ΔIEC compared to control mice (9.3±2.2 vs. 1.4±0.4 GLP1+ cells/mm², P<0.01). Intestinal GLUT2 inactivation reduces to a lesser extent (by 2-fold) GIP-producing cell abundance in this small intestine segment (19.2±6.3 vs. 8.9±1.2 GIP+ cells/mm², P=0.06), suggesting a preferential effect of GLUT2 on GLP-1-producing cells. Moreover, enteroendocrine cell density is not affected by intestinal GLUT2 inactivation in the colon (16.7±5.8 vs. 8.2±1.7 GLP1+ cells/mm², P=0.1135 and 12.2±5.3 vs. 12.8±1.8 GIP+ cells/mm², P=0.8747), probably because GLUT2 expression is low in the large intestine.

Conclusion: Our data highlight crucial roles of intestinal GLUT2 in glucose absorption and enteroendocrine cell density in the absorptive segment of the intestine. The impact of reduced enteroendocrine cell density on diabetes remains to be challenged by metabolic perturbations. The reduction of enteroendocrine cell number could be a consequence of the absence of GLUT2 either in enteroendocrine cells or in neighbouring enterocytes. To discriminate which GLUT2 expressing cell is involved in enteroendocrine cell plasticity, we are studying a new mouse model with specific GLUT2 inactivation in enteroendocrine cells.

Mechanisms regulating gastrointestinal somatostatin secretion

A.E. Adriaenssens¹, B. Lam¹, L. Billing¹, K. Skeffington¹, S. Sewing², F. Reimann¹, F. Gribble¹;

¹Clinical Biochemistry, University of Cambridge, UK, ²Roche Innovation Center, Basel, Switzerland.

Background and aims: Beginning with the control of acid secretion and gastric emptying, entero-endocrine cells (EECs) in the gastrointestinal tract shape post-prandial glucose excursions and nutrient delivery to peripheral tissues. Somatostatin (Sst)-producing D-cells are of particular interest because they exert profound inhibitory control over other EECs, particularly in the stomach where they regulate gastric acid secretion. The objective of this study was to identify molecular pathways underlying Sst release from D-cells.

Materials and methods: We generated transgenic mice expressing Cre driven by the Sst promoter. Upon crossing with Cre reporter strains, mice expressed red fluorescent protein (tdRFP), enhanced yellow fluorescent protein (EYFP), or a genetically encoded calcium indicator, GCaMP3, in Sst-expressing cells. RNA sequencing of gastric D-cells purified by fluorescence activated cell sorting identified the D-cell transcriptome. Molecular targets were verified by quantitative RT-PCR (qPCR). Primary gastric cultures were used in Sst secretion assays and to monitor calcium responses to test stimuli in D-cells by fluorescence imaging.

Results: By qPCR, sst message was enriched 690-fold (p<0.001) in the EYFP positive population, confirming D-cell specificity of transgene expression. RNA sequencing showed D-cells expressed mRNA encoding peptide YY (pyy), albeit at 14-fold lower levels than sst. RNAseq and qPCR found G-protein coupled receptors enriched in D-cells included glucose-dependent insulinotropic peptide (GIP) receptor (gipr), muscarinic receptor-4 (chrm4), calcitonin gene related polypeptide (CGRP) receptor (calcr/ramp1), trace amine associated receptor (taar1) and calcium sensing receptor (casr) (fold-enrichment vs neighbouring cells of 1300, 98, 110, 42, 13, and 78, respectively; p<0.01 each). D-cells also expressed receptors for glucagon-like peptide-1 (GLP-1: glp1r) and cholecystokinin (CCK: cckar but not cckbr). In gastric cultures Sst secretion was stimulated 1.9-fold by GLP-1, 1.5-fold by GIP and 1.8-fold by CCK (p<0.01 each). Acetylcholine decreased secretion 2-fold (p<0.001), whereas vasoactive intestinal polypeptide (VIP) and CGRP increased Sst release 2.3-fold and 4.6-fold, respectively (p<0.001 each). Oligopeptides and the TAAR1 agonist Ro5166017 stimulated Sst secretion 1.9-fold and 4.5-fold (p<0.001 each) suggesting that D-cells can sense ingested luminal factors. CCK and oligopeptides elicited increases in intracellular calcium in imaging experiments, consistent with the coupling of CCK-A receptors and CaSR to Gq signalling pathways.

Conclusion: Sst secretion from gastric D-cells is directly inhibited by the vagus nerve via muscarinic M4 receptors, and stimulated by the enteric neurotransmitters CGRP and VIP. Luminal factors like oligopeptides and trace amines stimulate Sst release via CaSR and TAAR1. Feedback stimulation of Sst by small intestinal hormones including CCK, GIP and GLP-1 likely provides a mechanism to tune the termination of acid secretion according to the nutrient content of a meal. Our data provide a first transcriptomic analysis and functional characterization of gastric D-cells, and identify regulatory pathways that underlie the direct detection of stimuli by this cell type which is intricately linked to rates of food intake and absorption, and the coordination of post-prandial digestion.

Impaired beta cell function and insulin secretion in non-diabetic patients with extrahepatic cholestasis

T. Mezza¹, V.A. Sun¹, S. Moffa¹, G. Sorice¹, C. Conte¹, C.M.A. Cefalo¹, A. Mari², A. Giaccari¹;

¹Università Cattolica del sacro cuore, Rome, ²National Research Council, Padua, Italy.

Background and aims: Several studies have shown the inverse correlation between serum bilirubin levels and the risk of diabetes, suggesting that bilirubin acting as antioxidant and cytoprotectant could antagonize oxidative stress-induced beta cell damage. Whereas, in both human and animal models, cholestasis is associated with altered glucose tolerance. However, the relationship between cholestasis and beta cell function has not been fully evaluated in the clinical setting. To investigate whether cholestasis, as evidenced by hyperbilirubinemia, affects β cell function and insulin secretory response, we performed oral glucose tolerance tests and hyperglycemic clamps (HC) followed by arginine stimulation in 44 patients (27 F/17 M, 51 \pm 15 yrs) scheduled for pancreatoduodenectomy for periampullary diseases, all without known history of diabetes.

Materials and methods: Based on bilirubin levels, subjects were divided into 2 groups: with resolved cholestasis and/or normal bilirubin levels (NChol, n=21, Bil: 0.29 \pm 0.03 mg/dl) and with active extrahepatic cholestasis (Chol, n=23, Bil: 4.30 \pm 0.69 mg/dl). Amylasemia was similar between the two groups (76.6 \pm 15.8 vs. 86.9 \pm 10.3 UI/L). To evaluate β cell function, β cell glucose sensitivity (GS) during hyperglycemic clamp was calculated as the ratio of insulin secretion (IS) and glucose increments.

Results: Cholestatic subjects displayed a significantly lower Insulinogenic index (II) (0.46 \pm 0.06 vs. 0.76 \pm 0.11, p=0.01), while no differences were detected in the Matsuda index (5.89 \pm 0.88 vs. 4.66 \pm 0.67, p=NS). The incremental first phase (p=0.01), second phase insulin secretion (p=0.02) and GS (57.5 \pm 10.5 vs. 92.3 \pm 11.3 pmol \cdot min⁻¹ \cdot m⁻² \cdot mM⁻¹, p=0.03) were significantly lower in Cholestatic subjects. Analysis of the entire group revealed an inverse correlation between bilirubin levels and Insulinogenic index (r=-0.40; p<0.05), and Arginine-stimulated Insulin Secretion (AIS) (r=-0.51; p<0.01).

Conclusion: Our data indicate that cholestasis associates with impaired β cell function and possibly reduced β cell mass (as estimated by AIS). We speculate that, in subjects with extrahepatic cholestasis, impaired β cell glucose sensitivity could represent a major determinant of the observed insulin secretory defect in response to both glucose and arginine stimulus. Further investigation of this mechanism might improve our understanding of the pathogenic events leading to altered insulin secretion in type 2 diabetes.

No effect of high-dose vitamin D treatment on beta cell function, insulin sensitivity or glucose homeostasis in subjects with abnormal glucose tolerance: a RCT

H. Wagner¹, M. Alvarsson¹, B. Mannheimer², M. Degerblad¹, C.-G. Östenson¹;

¹Endocrinology and Diabetes Unit, Molecular Medicine and Surgery, ²Department of Clinical Science and Education, Södersjukhuset, Karolinska Institutet, Stockholm, Sweden.

Background and aims: There has been conflicting evidence regarding the potential role of vitamin D in glucose homeostasis. This study was designed to investigate the effect of high-dose vitamin D treatment on beta cell function, insulin sensitivity and glucose tolerance in middle-aged subjects with pre-diabetes or diet treated type 2 diabetes.

Materials and methods: Subjects were randomised to 30 000 IU vitamin D3 once weekly or placebo for eight weeks. Hyperglycaemic clamp assessed first- (0-12 min) and second-phase (12-120 min) insulin response, insulin sensitivity and disposition index. Oral glucose tolerance test and HbA_{1c} assessed glycaemic control. Data are presented as medians (interquartile range) and non-parametric tests were used for the outcome assessments.

Results: 21 (vitamin D) and 22 (placebo) subjects completed the study, respectively. Baseline characteristics did not differ significantly between the two groups. Season-adjusted 25-OH-vitamin D level was doubled in the vitamin D group (+42 (32-50) nmol/l) and remained unchanged in the placebo group (0 (-7-11) nmol/l). No effect of vitamin D treatment, compared to placebo, was seen on first-phase insulin secretion, second-phase insulin secretion, insulin sensitivity or disposition index. There was a small reduction in median HbA_{1c} in the vitamin D group of 1 (-3-1) mmol/mol (P=0.06), but with no significant difference versus placebo (P=0.84). No other measurements of glycaemia showed any changes. Sub-group analyses of those with the lowest basal vitamin D values did not change these results. No hypercalcemia or other adverse effects of vitamin D treatment were seen compared to placebo.

Conclusion: This study gives no support for any substantial effect of high-dose vitamin D treatment for eight weeks in pre-diabetes or diet treated type 2 diabetes on beta cell function, insulin sensitivity or glycaemic control.

Early insulin secretion defect characterises males with type 2 diabetes of Yemenite origin

M. Blaychfeld–Magnazi^{1,2}, T. Zornitzki³, M. Ulman⁴, Z. Madar², H. Knobler¹;

¹Diabetes and Metabolic Disease Unit, Kaplan Medical Center, ²Hebrew University, Faculty of Agriculture Food and Environment, ³Endocrinology Unit, ⁴Endocrinology Laboratory, Kaplan Medical Center, Rehovot, Israel.

Background and aims: Yemenites who immigrated to Israel demonstrated within 6 decades a dramatic 20-fold increase in the prevalence of diabetes but the underlying mechanisms remain obscure. The aim of the current study was to compare parameters of β -cell function and insulin sensitivity in patients with new-onset Type 2 diabetes of Yemenite (Y-DM) and non-Yemenite origin (NY-DM) treated by diet with or without oral antihyperglycemic monotherapy.

Materials and methods: A 180-minutes meal tolerance test (MTT) was performed in 121 GAD negative patients: 59 Y-DM (57% males) and 62 NY-DM (48% males). Based on the MMT we calculated indexes of insulin resistance (Matsuda index, HOMA2IR) indexes of insulin secretion including the insulinogenic index [Δ insulin (30-0 min)/ Δ glucose (30-0)], and the disposition index that indicates the hyperbolic relationship between insulin sensitivity and insulin response.

Results: Age, sex, DM duration, BMI, HbA_{1c} and lipid profile were with no significant differences. A significant difference was found in family history: 63% of Y-DM had maternal inheritance compared with 35% in NY-DM (p<0.001), but no difference was found in paternal inheritance. Y-DM had increased hyperglycemia manifested by a significantly higher area under the curve (AUC) of glucose during MTT compared with NY-DM (p=0.005) but there was no difference in insulin and C-peptide AUC. There were no difference in insulin sensitivity but both the insulinogenic index and the disposition index were significantly lower in Y-DM compared with NY-DM (0.68 \pm 0.5 vs. 0.95 \pm 0.8, p=0.04; 2.25 vs. 3.3, p=0.03, respectively). When females and males were analyzed separately the difference in maternal inheritance remained significant in both (p<

0.005). The difference in β -cell function however remained significant only in males, with Y-DM having a lower insulinogenic index (0.56 ± 0.4 vs. 1.02 ± 1.12 $p=0.02$) and a shift to the left and downward of the curve describing the hyperbolic relationship between insulin sensitivity and insulin secretion (Figure).

Conclusion: Y-DM have a significantly higher maternal inheritance compared with NY-DM. Males of Yemenite origin have a significant reduction of β -cell function and reduced ability to compensate for insulin resistance compared with NY-DM. These data suggest different underlying mechanisms leading to early loss of β -cell function in Y-DM observed in males.

Exploring the role of secreted frizzled related protein 4 as a novel biomarker of beta cell dysfunction, insulin resistance and type 2 diabetes

K. Gokulakrishnan¹, V. Sudha², A. Kaviya¹, I. Lasrado², G.K. Pandey¹, A. Amutha¹, H. Ranjani¹, R.M. Anjana³, V. Mohan³;

¹Research Biochemistry, Madras Diabetes Research Foundation, Chennai, ²Kasturba Medical College, Manipal, ³Diabetology, Madras Diabetes Research Foundation, Chennai, India.

Background and aims: There is emerging data to indicate that secreted frizzled-related protein 4 (SFRP4) is highly expressed in islets. SFRP4 is associated with increased risk of type 2 diabetes mellitus [T2DM] but the physiological role of SFRP4 remains poorly understood. We report on the systemic levels of SFRP4 and its association with insulin resistance, beta cell dysfunction, prediabetes and type 2 diabetes in Asian Indians.

Materials and methods: Individuals with normal glucose tolerance [NGT; n=90], impaired glucose tolerance [IGT; n=50] and T2DM [n=90] were recruited from a large tertiary diabetes center and a medical college hospital in southern India. Insulin resistance was calculated using the homeostasis assessment model (HOMA-IR) and beta cell function by oral disposition index (DIo). SFRP4 levels were measured by the enzyme-linked immunosorbent assay.

Results: Circulatory age adjusted SFRP4 levels were highest in T2DM (246 ± 99 ng/ml) followed by IGT (167 ± 62 ng/ml) and NGT (101 ± 45 ng/ml; $p < 0.001$). Patients with older age onset T2DM had higher levels of SFRP4 compared to youth onset T2DM (286 vs 165 ng/ml, $p < 0.001$). However, no differences in SFRP4 levels were seen between males and females (158 ± 60 vs. 169 ± 64 ng/mL, respectively; $p > 0.05$). SFRP4 was positively correlated with HOMA-IR ($p < 0.01$), C-Peptide ($p < 0.01$) and inversely with DIo ($p < 0.01$). In linear regression analysis, SFRP4 was significantly associated with insulin resistance ($\beta = 1.592$; $p < 0.001$) and DIo ($\beta = -0.353$; $p < 0.05$) after adjusting for age, gender and waist circumference. In standardized polytomous regression models, higher levels of SFRP4 were independently associated with T2DM [odds ratio (OR) per standard deviation: 2.867, 95% CI 1.189 - 4.343; $p <$

0.001]. Adjustment for age, gender, waist circumference and insulin resistance, did not substantially change the association between SFRP4 and T2DM [OR per standard deviation: 2.185, 95% CI: 1.309 - 3.649, $p = 0.003$].

Conclusion: In Asian Indians, the circulatory levels of SFRP4 showed a significant association with glucose intolerance, insulin resistance, beta cell dysfunction and T2DM and could serve as a biomarker for early beta cell dysfunction and glucose intolerance.

The impact of family history of young-onset type 2 diabetes on metabolic profile and beta cell function in euglycaemic young-to-middle age Chinese individuals in Hong Kong

Y. Zhang;

Medicinen & Therapeutics, The Chinese University of Hong Kong, Shatin, China.

Background and aims: The prevalence of young-onset type 2 diabetes (YOD) is increasing globally. Family history of type 2 diabetes is associated with defect in insulin sensitivity and/or beta-cell function. We investigated the impact of family history of YOD (defined as age at diagnosis < 40 years) on the metabolic traits, insulin sensitivity and beta-cell function in young-to-middle aged Chinese individuals with euglycemia in Hong Kong.

Materials and methods: 415 participants with normal glucose tolerance (fasting plasma glucose [PG] < 5.6 mmol/L and 2-hour PG < 7.8 mmol/L during the 75-gram OGTT test) were studied. Among them, 220 individuals did not have family history of diabetes (FH-), 122 individuals had family history of late-onset type 2 diabetes (age at diagnosis ≥ 40 years, FH+LOD) and 73 had family history of YOD (FH+YOD). Insulin sensitivity was measured by Matsuda insulin sensitivity index (ISI) and early-phase insulin response was measured by insulinogenic index (IGI). Disposition index (DI) was used to measure beta-cell function. Metabolic data were compared between groups with adjustment for age, sex, body mass index and waist-to-hip ratio.

Results: The mean age was 35.5 ± 7.2 [SD] years in FH+YOD group, lower than those with FH+LOD (43.0 ± 7.2 years) and without family history of diabetes (42.2 ± 7.6 years, p trend < 0.001). Individuals with FH+YOD and FH+LOD had higher BMI, waist circumference (in men), LDL-cholesterol, and lower HDL-cholesterol compared to those without family history (all p trend < 0.05 , table). The FH+YOD group had highest 1-hour PG (p trend = 0.001, table), while fasting and 2-hour PG during OGTT were similar between the 3 groups. Subjects with positive family history had lower DI than the FH- group (p trend = 0.005), although DI did not differ between FH+LOD and FH+YOD groups. ISI was similar between all 3 groups. There was a tendency for IGI to be lower in the FH+YOD group with borderline significance between FH+YOD and FH- groups (post-hoc $p = 0.078$, table).

Conclusion: Normal glucose-tolerant first-degree relatives of patients with type 2 diabetes, especially those with family history of YOD, exhibit reduced beta-cell function and increased obesity. The disease burden of YOD calls for early detection and intervention program in subjects with family history of diabetes, especially YOD.

Table. Metabolic profile, insulin sensitivity and beta-cell function stratified by family history of diabetes.

	FH ^a (n=220)	FH ^a LOD (n=122)	FH ^a YOD (n=73)	p trend

568

Active GLP-1 but not insulin, glicentin or glucagon predicts the 2-hour OGTT glucose value in obese children

H. Ohlsson^{1,2}, J. Staaf^{1,2}, L. Manukyan¹, J. Cen^{1,2}, A. Forslund², P. Bergsten¹;

¹Department of Medical Cell Biology, ²Department of Women's and Children's Health, Uppsala University, Sweden.

Background and aims: Proglucagon is post-translationally processed to glucagon, glucagon-like peptide 1 (GLP-1) and glicentin, among other peptides. Despite the fact that glucagon and GLP-1 are well-known regulators of glucose metabolism, little is known of them in the context of childhood obesity and early stages of impaired glucose metabolism. Glicentin is less studied than other proglucagon peptides but functions described to date are inhibition of gastric acid secretion and gastrointestinal motility. The aim of this study was to investigate the levels of GLP-1, glicentin and glucagon in childhood obesity and their importance for the development of impaired glucose tolerance in this patient group.

Materials and methods: Obese (n=50) and lean (n=19) children, 10-18 years of age, were recruited from the Uppsala Longitudinal Study of Childhood Obesity cohort between June 2012 and October 2014. After an overnight fast, subjects underwent a standard OGTT. Classification of normal glucose tolerance (NGT), impaired glucose tolerance (IGT) and/or impaired fasting glucose (IFG) and type 2 diabetes (T2DM) was done according to WHO criteria. Fasting plasma active GLP-1 was quantified by electrochemi-luminescent immunoassay (Meso Scale Discovery, MD, USA). Fasting plasma insulin, glicentin and glucagon levels were quantified by ELISA (Mercodia AB, Uppsala, Sweden). Differences among groups were analysed by one-way ANOVA with Bonferroni post hoc test.

Results: Of the obese children, 25 had NGT, 21 had IGT (including 9 children with IFG) and 4 met the criteria for T2DM. All lean children had NGT. As the number of subjects with T2DM was limited, these were excluded from the data analysis. Lean controls had lower fasting GLP-1 levels than obese children with NGT (0.37±0.05 vs 0.58±0.07 pmol/l) and lower fasting glucagon levels than obese children with IGT (8.1±0.5 vs 14.1±1.4 pmol/l). Fasting GLP-1 levels were lower in obese children with IGT than in those with NGT (0.34±0.03 vs 0.58±0.07 pmol/l) and the same was true for glicentin levels (16.1±1.6 vs 26.5±2.4 pmol/l). Fasting glucagon levels were higher in obese children with IGT than in those with NGT (14.1±1.4 vs 10.8±0.7 pmol/l). In addition, multiple

regression analysis was performed with 2-hour glucose as the dependent parameter and age, sex, age-adjusted BMI, fasting insulin, GLP-1, glicentin and glucagon as independent parameters. Only fasting GLP-1 levels were significantly correlated to the two-hour blood glucose values (parameter estimate -1.91; SE 0.9; p<0.05).

Conclusion: Obese children with IGT are characterized by increased fasting glucagon and decreased fasting glicentin and GLP-1 levels. In obese children, fasting plasma active GLP-1 is correlated to the 2-hour OGTT glucose value independent of age, sex, BMI, and fasting levels of insulin, glicentin and glucagon.

Combined N-terminal and C-terminal truncations of Glucose dependent Insulinotropic Polypeptide (GIP) are potent and efficient GIP receptor antagonists

L.S. Hansen¹, A.H. Sparre-Ulrich², B. Svendsen³, M. Christensen¹, B. Hartmann³, F.K. Knop¹, J.J. Holst³, M.M. Rosenkilde²;

¹Center for Diabetes Research, Gentofte Hospital, Hellerup, ²Department of Neuroscience and Pharmacology, University of Copenhagen, ³Department of Biomedical Sciences, University of Copenhagen/Novo Nordisk Foundation, Denmark.

Background and aims: The intestinal hormone glucose-dependent insulinotropic polypeptide (GIP) exhibits several functions within lipid, bone, and glucose homeostasis. The GIP receptor (GIP R) is a family B 7-transmembrane receptor with the most established signaling pathway being Gα_s. It is expressed in the pancreas, brain, bone, cardiovascular system, and gastrointestinal tract. High affinity ligands are needed to explore the role of GIP in adiposity, osteogenesis, and glucose homeostasis in vivo. hGIP(1-30) is naturally occurring in humans. Here we report a pharmacological characterization of eight N-truncated GIP analogs of hGIP(1-30): hGIP(2- to 9-30).

Materials and methods: COS-7 cells were transiently transfected with the human GIP R for all assays. We used radiolabeled ¹²⁵I-hGIP(1-42), ¹²⁵I-hGIP(1-30), ¹²⁵I-hGIP(2-30) and ¹²⁵I-hGIP(3-30) for competitive binding analyses and an enzyme fragment-based cyclic AMP-accumulation assay. Pancreas perfusions in rats were performed with a single-pass system (10 mmol/l glucose) through arteries and collected effluent from the portal vein.

Results: hGIP(1-30) displaced ¹²⁵I-GIP(1-42) with similar affinity as native GIP(1-42) (Ki of 0.75 nmol/l). The eight truncated analogs displaced ¹²⁵I-GIP(1-42) with lower affinities (Ki from 2.3 to 347 nmol/l) following the truncation lengths with the highest affinities identified for GIP(3-30) and GIP(5-30) (Ki of 2.6 and 6.1 nmol/l, respectively). GIP(1-30) acted as a full agonist (EC₅₀ 9.8 pmol/l), whereas GIP(2-30), as the only one of the truncations, displayed potent partial agonistic properties (20% efficacy of hGIP(1-30) and an EC₅₀ of 1.8 nmol/l). GIP(2- to 9-30) displayed length-dependent antagonistic properties (IC₅₀ from 12 to 450 nmol/l) and resulted in right-shifts of the hGIP(1-42) dose-response curve in a dose-dependent manner. Schild plot analysis concluded that GIP(3-30) and GIP(5-30) were competitive antagonists with equal pA₂ values of 15 nmol/l and Hill-slopes of 0.93±0.02 and 1.1±0.04 respectively. Homologous binding studies revealed different binding confirmations that corresponded to the functional properties of the agonist GIP(1-30), the partial agonist GIP(2-30) and competitive antagonist GIP(3-30). In pancreas perfusion studies 100 nmol/l GIP(3-30) significantly reduced somatostatin secretion induced by 1 nmol/l GIP(1-42), and stimulated de novo and potentiated 1 nmol/l GIP(1-42)-induced insulin secretion. GIP(3-30) did not affect GIP(1-42) induced glucagon secretion nor stimulated de novo secretion.

Conclusion: Human GIP(3-30) and GIP(5-30) were highly potent competitive antagonists of the human GIP R. GIP(3-30), a presumed naturally

occurring degradation product, showed diverse effects on somatostatin and insulin release *in vivo* (rat). These antagonists could serve as tool compounds for further elucidation of the human GIP physiology and thereby in turn for future pharmacological interventions.

570

Translation of predictive *in vitro* GIP receptor assays to *in vivo* acute efficacy

D.C. Hornigold¹, J. Naylor¹, A.T. Suckow², A.T. Suckow², N. Bhagroo², H. Salari², D.J. Baker¹;

¹CVMD, MedImmune, Cambridge, UK, ²CVMD, MedImmune, Gaithersburg, USA.

Background and aims: Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), both Gs-coupled GPCRs, are incretin hormones whose primary role is to potentiate glucose-stimulated insulin secretion from pancreatic beta-cells. Dual agonism of the GIP and GLP-1 receptors has recently been speculated as being advantageous in treating type 2 diabetes. Drug discovery projects tasked with identifying agonists at these incretin receptors require high throughput *in vitro* functional assays to drive structure activity relationship hypothesis testing. It is imperative that these assays translate to biological effect assays in disease relevant cell lines and are predictive of the effects seen in preclinical *in vivo* models. In this study we show that potency and efficacy translates from transfected receptor cell line second messenger assays to endogenous receptor second messenger and insulin secretion assays, and also to acute efficacy *in vivo* in glucose tolerance tests.

Materials and methods: A panel of GIP peptides palmitoylated at different positions along the length of the peptide were tested *in vitro* for potency and intrinsic activity in transfected CHO-human GIPR, clonal rat beta cell (INS-1E) and mouse adipocyte (3T3L1) cell line cAMP accumulation assays. Cells were incubated with peptides for 30 min prior to lysis and detection of cAMP levels. A subset of potent peptides was then tested for glucose-stimulated insulin secretion in glucose-responsive INS 832/3 cells. Cells were cultured in the presence of low glucose (2.8 mM) for 1 hr at 37°C prior to incubation of peptides in the presence of high glucose (8.3 mM) for 1 h. Insulin secretion was quantified using Mesoscale Discovery ECL detection. Key peptides were then further profiled *in vivo* using glucose tolerance tests in C57Bl/6J mice. Fasted C57Bl/6J male mice were dosed SC with either Na²⁺ phosphate buffer or palmitoylated GIP ligands 2 h prior to intraperitoneal 2 g/kg glucose (ipGTT) challenge. Blood glucose was measured from tail vein samples at -120, 0, 15, 30, 45, 60 and 90 mins.

Results: The palmitoylated GIP molecules were all full agonists in CHO-human GIPR transfected receptor cAMP assays with potencies spread over a 1000-fold range. The peptide EC₅₀ from the transfected human GIPR correlated well with EC₅₀ determinations from both rat INS-1E and mouse 3T3L1 cAMP assays. Six peptides with potencies spanning 40 pM to 60 nM in the INS1E cAMP assay were shown to have robust activity in glucose stimulated insulin secretion (GSIS) assay in INS 832/3. There was also positive correlation for peptide potency in the INS 832/3 between cAMP and GSIS assays (slope =0.92, r²=0.94). Key molecules with a broad range of potencies in the INS GSIS assay were profiled in a lean mouse ipGTT study. There was consistent correlation between INS GSIS pEC₅₀ and AUC for ipGTT and peptide rank order was maintained with a good correlation (r²=0.91).

Conclusion: Here we show correlation of potency from transfected receptor *in vitro* assays to endogenous receptor assays at the level of cAMP accumulation. These potencies directly correlate with biological effect readouts of insulin secretion in rat beta cells. Furthermore we showed translation of these *in vitro* potencies and rank order to *in vivo* efficacy through glucose disposal in ipGTT studies. Based on these results we have the tools to successfully interrogate GIPR potency in a drug discovery screening cascade.

PS 040 New experimental models of insulin secretion

Enhancement of beta cell function by combination treatment with stromal derived factor 1 alpha (SDF-1) and the DPP-4 inhibitor vildagliptin in streptozotocin diabetic mice

B. Omar, B. Ahrén;

Clinical Sciences, Lund University, Lund, Sweden.

Background and aims: In both type 1 and type 2 diabetes, there is a decline in the mass and function of beta cells resulting in insulin insufficiency and hyperglycemia. In type 1 diabetes this is relatively rapid whereas in type 2 diabetes this occurs over a longer period of time. Recently it has been reported that the pancreatic islet alpha cells of type 2 diabetic humans and mouse models produce elevated amounts of the incretin hormone glucose dependent insulinotropic polypeptide 1 (GLP-1). In genetic mouse models of type 2 diabetes, alpha cell GLP-1 production appears to increase as diabetes develops. Additionally, it has been demonstrated that alpha cell production of GLP-1 is enhanced by the chemokine stromal derived factor 1 (SDF-1). We hypothesized that chemically induced beta cell loss would lead to a compensatory increase in alpha cell GLP-1 which could be enhanced by intervention with SDF-1 leading to preserved beta cell function. We therefore treated streptozotocin diabetic mice with a combination of recombinant stromal derived factor 1 and the DPP-4 inhibitor Vildagliptin to determine whether it could preserve and enhance beta cell function at an early stage of diabetes development.

Materials and methods: Four month old female C57BL6JBomTac mice were given interperitoneal injections of streptozotocin (50 mg/kg) or vehicle daily for 5 days. Three days after the final injection mice were subjected to a baseline oral glucose tolerance test (OGTT) and immediately placed on a regimen of daily injections with recombinant mouse SDF-1 alpha (1 µg/mouse) or vehicle for 5 days. Mice were concurrently treated with either a background of Vildagliptin (3 µmol/mouse per day) or water. Mice remained on a background of Vildagliptin or water for an additional 3 weeks and OGTTs were performed mid-study and at termination (4 weeks). Bodyweight was monitored weekly. Plasma glucose and insulin were measured at multiple time points during the OGTTs and beta cell function was calculated using the insulinogenic index. Beta cell mass was determined from histological sections of whole pancreas stained with insulin specific antibodies.

Results: After an initial decline the first week of the intervention, bodyweight was maintained throughout the final 3 weeks of the study. Diabetic mice that did not receive treatment saw a decline in beta cell function (insulinogenic index) by the end of the four week study period. Diabetic mice that were treated exclusively with a background of Vildagliptin saw a 2 fold improvement in insulinogenic index after four weeks compared to baseline (57±14 vs. 29±6 pmol/mmol, p=0.043). Diabetic mice that were treated with SDF-1 injections in week 1 combined with background Vildagliptin saw a 4-fold improvement in beta cell function after four weeks compared to baseline (53±6 vs. 14±4 pmol/mmol, p=0.0003). In addition, the SDF-1-vildagliptin treated group displayed significantly greater glucose elimination rates than untreated diabetic controls (1.02±0.07 vs. 0.79±0.07%/min, p=0.028). Immunohistochemical analysis of pancreata after the study revealed that all diabetic groups have significant reductions in beta cell mass with no significant differences in beta cell mass between treated and untreated diabetic mice.

Conclusion: The combination of SDF-1 alpha and vildagliptin represents a novel treatment concept which improves beta cell function and glucose elimination in an insulin deficient mouse model of diabetes.

Calcium independent functional compensation of beta cells predominates islet mass adaptation in diet induced insulin resistance

S. Speier, H. Chmelova, J.A. Chouinard, C.M. Cohrs, S. Jahn, C. Chen; Paul Langerhans Institute Dresden of Helmholtz Centre Munich at the University Clinic Carl Gustav Carus of the Technische Universität Dresden, Germany.

Background and aims: Pancreatic islets have been suggested to compensate in both mass and function to meet the increased insulin demand during obesity and insulin resistance (IR). However, the dynamics and relative contribution of these two forms of compensation are not well understood. In addition, the mechanisms underlying compensation *in vivo* remain to be elucidated. Here, we longitudinally *in vivo* assessed the adaptation of islet cell mass and function in correlation to glucose homeostasis during diet-induced obesity and IR in mice.

Materials and methods: Mice were transplanted with MIP-GFP or Pdx1CreER-GCaMP islets into the anterior chamber of the mouse eye. After engraftment period, the recipient mice were fed with HFD (60%) for 17 weeks before switching back to normal chow. Several parameters of glucose homeostasis were assessed and in parallel transplanted islets repetitively monitored noninvasively *in vivo*. Islet morphology and dynamics of cytosolic calcium were visualized by GFP and GCaMP expression.

Results: HFD feeding induced obesity, IR and impaired glucose tolerance. Total islet mass (1.92±0.50 fold increase, $p<0.001$; 16wk) and beta cell volume (1.91±0.39 fold increase, $p<0.001$; 16wk) continuously increased over the entire experimental time course. Intra-islet vessels adapted by dilation in response to HFD feeding. Glucose stimulated insulin secretion during an intraperitoneal glucose tolerance test (IPGTT) increased until 10 weeks HFD and reached a plateau thereafter. The functional efficacy of islets in relation to islet mass was initially increased (3.17±1.78 fold increase, $p<0.05$; 8wk) but slowly declined, indicating an initial functional compensation, followed by decompensation. To evaluate the mechanisms of functional beta cell compensation we measured beta cell calcium dynamics ($[Ca^{2+}]_i$) *in vivo*. Basal $[Ca^{2+}]_i$ increased shortly after HFD onset in association with elevated fasting plasma insulin. In contrast glucose-stimulated $[Ca^{2+}]_i$ decreased throughout the time course of HFD feeding (388±256 vs 853±230, $p<0.01$, 16wk), while insulin release remained increased. This indicates an early calcium independent compensatory mechanism, followed by a calcium dependent dysfunction of beta cells in response to long-term HFD. Interestingly, even after 17 weeks HFD feeding the detected changes were rapidly reversible after by 2 weeks normal diet feeding.

Conclusion: Our results demonstrate that the beta cell functional response outweighs mass adaptation in the compensation for insulin resistance. In addition, our data indicate that the observed functional compensation and dysfunction of beta cells are based on diverse mechanisms.

Regulation of GPR40 gene expression in pancreatic islets of non-obese and obese glucose-intolerant rat models, Goto-Kakizaki rat and Koletsky rat

Y. Kira¹, T. Tomita¹, S. Odori¹, J. Fujikura¹, K. Hosoda¹, K. Nakao², N. Inagaki¹;

¹Department of Diabetes, Endocrinology and Nutrition, ²Medical Innovation Center, Kyoto University Graduate School of Medicine, Japan.

Background and aims: G protein-coupled receptor 40 (GPR40; FFAR1) is a Gq-coupled receptor for middle- to long-chain fatty acids. GPR40 is highly expressed in pancreatic beta cells in rodents and we have reported that GPR40 is probably highly expressed in pancreatic beta cells also in humans. GPR40 is reportedly involved in the regulation insulin secretion

and is a potential therapeutic target in diabetes mellitus. However, little is known about the regulation of its gene expression. This study was designed to elucidate the regulation of GPR40 gene expression in glucose intolerance and to explore the pathophysiological implication of GPR40.

Materials and methods: As a non-obese glucose-intolerant model, we used Goto-Kakizaki (GK) rat, a Wistar substrain that develops Type 2 diabetes. As an obese glucose-intolerant model, we used Koletsky rat, a genetically obese model whose nonsense mutation in the Ob-R gene was reported by us. Six-week-old GK rat and 14-week-old Koletsky rat with established glucose intolerance were subjected to intraperitoneal glucose-tolerance tests (IPGTT, 2 g/kg), and compared with age-matched control rats (6-week-old Wistar rat and 14-week-old lean littermate, respectively). Blood glucose levels were determined by the glucose oxidase method. Plasma insulin levels were measured by EIA. Pancreatic islets were isolated from these rats and GPR40 mRNA expression was measured by quantitative PCR.

Results: In 6-week-old GK rats, blood glucose levels were markedly elevated at all time points during IPGTT. Serum insulin levels at 15 and 30 min after glucose load were significantly lower in GK rats compared to those in Wistar rats, though there was no significant difference at fasting, and at 60 and 120 min after glucose load. GPR40 mRNA levels in pancreatic islets of GK rats were markedly decreased compared to those of Wistar rats (43% vs Wistar rats, $p<0.05$). In 14-week-old Koletsky rats, blood glucose levels were significantly elevated after glucose load compared to lean littermates, while there was no significant difference at fasting between two groups. Serum insulin levels in Koletsky rats were approximately ~7 times higher than those in lean littermates at all time points during IPGTT, however, at 15 minutes after glucose load it was rather decreased vs before glucose load in Koletsky rats. GPR40 mRNA levels in pancreatic islets of Koletsky rats were markedly decreased compared to those of lean littermates (39% vs lean littermates, $p<0.05$).

Conclusion: We demonstrate that GPR40 mRNA levels in pancreatic islets are markedly decreased in both non-obese and obese model rats, suggesting decreased GPR40 gene expression in pancreatic beta cells in glucose intolerance. In both models, increment of insulin secretion after glucose load was attenuated, suggesting impaired early insulin response. GPR40 is implicated in the augmentation of glucose stimulated insulin secretion (GSIS), so the possible link between decreased GPR40 gene expression in pancreatic beta cells and impaired early insulin response *in vivo* seems plausible. Further investigations are now in progress.

574

Limited impact on glucose homeostasis of highly beta or alpha cell-selective disruption of leptin signalling

H. Soedling¹, D. Hodson¹, A. Adriaenssens², F. Reimann², F. Gribble², S. Trapp³, G. Rutter¹;

¹Medicine, Imperial College London, ²Clinical Biochemistry, Cambridge University, ³Neuroscience, University College London, UK.

Background and aims: The adipose tissue-derived hormone leptin plays an important role in maintenance of body weight and glucose homeostasis. Leptin mediates its effects by interaction with leptin receptors (LepR), which are highly expressed in the hypothalamus and reportedly at low levels in pancreas. Previous studies have used relatively promiscuous Cre deleter strains to explore the role of LepR in pancreatic beta and alpha cells, with conflicting results. Here, we investigate the role of LepR in these cells using more selective Cre deleter strains.

Materials and methods: Mice lacking leptin signalling specifically in beta and alpha cells respectively were generated by Ins1-Cre or iGlu[proglucagon promoter]-Cre-mediated recombination of LoxP sites within exon 17 of the leptin receptor gene. Highly purified beta and alpha cells were prepared by fluorescence-activated cell sorting (FACS) of islets from mice expressing YFP selectively in the latter. LepR expression was quantified by massive parallel sequencing (RNASeq) of purified islet

cells. *In vivo* glucose homeostasis, pancreatic histology and hormone secretion were monitored by standard techniques. Intracellular Ca²⁺ dynamics were assessed by confocal microscopy of the entrapped fluorescent probe, Fluo-2, in intact islets.

Results: Expression of LepR mRNA was undetectable or vanishingly low (0.2 reads per kilobase per million mapped reads, RPKM) in purified mouse pancreatic alpha and beta cells, respectively. Whereas male mice lacking the leptin receptor in beta cells mice exhibited no evident abnormalities in glucose tolerance up to 16 weeks of age, females displayed slightly improved glucose tolerance at 8 weeks (AUC=865.1±31.21 for WT, 937.7±32.38, *Ins1Cre::LepRF/F*; n=9-13 per genotype; mice, P=0.0292), but not at 12 weeks. No differences were seen between genotypes in body weight, fasting glucose or beta/alpha cell ratio. No differences were observed in glucose- (16.7. vs 3 mM) induced Ca²⁺ changes between WT and *Ins1Cre::LepRF/F* (AUC=1191±105.4 for WT, AUC=1024±148.3, *Ins1Cre::LepRF/F*, NS) mouse islets. Deletion of LepR from alpha-cells, a minority of beta cells, and a subset of proglucagon-expressing cells in the brain, exerted no effects on body weight, glucose or insulin tolerance, nor on pancreatic hormone secretion assessed *in vivo* and *in vitro*.

Conclusion: In contrast to earlier reports, the use here of a highly cell type-selective Cre recombinase indicates that leptin signalling plays a relatively minor, age- and sex-dependent role in the control of beta cell function in the mouse, consistent with low levels of LepR on these cells. No *in vivo* role for leptin receptors on alpha cells, nor in other proglucagon-expressing cells, was detected in this study. These studies suggest that the roles of leptin signalling in the endocrine pancreas may need to be re-evaluated.

Role of TGF-beta superfamily receptor ALK7 in the regulation of glucose-induced insulin secretion

K. Mezghenna, C.F. Ibáñez;

Neuroscience, Karolinska Institut, Stockholm, Sweden.

Background and aims: Activin ligands of the TGF-β superfamily are important regulators of adult pancreatic endocrine function. We have previously shown that mice lacking globally activin B or its receptor ALK7 (activin receptor-like kinase 7) display fasting hyperinsulinemia in early stages and increased glucose-stimulated insulin secretion (GSIS). The aim of our study is to determine whether ALK7 functions cell-autonomously in islets to negatively regulate insulin secretion.

Materials and methods: To address this issue, we generated the mouse line *Alk7fx/fx::Ptf1aCre/+* that displays a conditional inactivation of *Akl7* gene in pancreatic progenitors. The Cre recombinase activity was checked by immunohistochemistry using the Cre reporter strain, ROSA26-stop-YFP. ALK7 expression was analysed by q-PCR. Metabolic parameters were assessed in 8-10 week-old mice. Fasting intraperitoneal glucose tolerance test (IPGTT, 2 g/kg) and *in vivo* GSIS were assessed in mutant mice and their control littermates fed a standard chow diet or a 60% calorie high-fat diet for 2 weeks. *Ex vivo* GSIS was also assessed in isolated islets from conditional knock-out mice and their controls fed a standard chow diet.

Results: Using the Cre reporter strain ROSA26-stop-YFP, we first confirmed the Cre mediated-recombination occurred in different islet cell types such as alpha and beta cells in *Alk7fx/fx::Ptf1aCre/+* mice. In addition, ALK7 deletion in islets has been confirmed by q-PCR with a 70% decrease (P<0.001) in ALK7 mRNA levels. In *Alk7fx/fx::Ptf1aCre/+* mice, we showed a 60% significant increase (P<0.01) in fasting insulinemia compared to controls (*Alk7fx/fx*). Islets derived from *Alk7* mutants fed a standard chow diet significantly (P<0.05) increase *in vitro* GSIS by 36%. *In vivo* GSIS and IPGTT performed in mice fed a chow diet showed that *Alk7* mutant mice tended to secrete more insulin in

response to glucose (N.S) and displayed a slightly impaired glucose tolerance. However, when mice were fed a high-fat diet for 2 weeks, *in vivo* GSIS was highly enhanced (P<0.05) in *Alk7fx/fx::Ptf1aCre/+* mice although their glucose tolerance is not improved compared to controls. Interestingly, the conditional loss of ALK7 expression is associated to a significant (P<0.01) increase in mRNA level of the ATGL (adipose triglyceride lipase) lipase in islets of *Alk7fx/fx::Ptf1aCre/+* mice.

Conclusion: Our study suggests that ALK7 may regulate glucose-induced insulin secretion in a cell autonomous manner in islets. Moreover we have recently shown that ALK7 inhibition in adipocytes enhances lipolysis. Thus, ALK7 deletion could promote lipolysis in islets through lipases upregulation, thereby potentiating insulin secretion in response to glucose.

CART is a novel glucose-dependent peptide with antidiabetic actions in humans

M. Abels¹, M. Riva¹, W. Poon¹, H. Bennet¹, V. Nagaraj¹, O. Dyachok², B. Isomaa^{3,4}, T. Tuomi^{3,5}, B. Ahrén⁶, A. Tengholm², M. Fex¹, E. Renström¹, L. Groop¹, V. Lyssenko¹, N. Wierup¹;

¹Lund University Diabetes Centre, Malmö, ²Department of Medical Cell Biology, Uppsala, Sweden, ³Folkhälsan Research Center, Helsinki, ⁴Department of Social Services and Health Care, Jacobstad, ⁵Department of Medicine, Helsinki, Finland, ⁶Lund University Diabetes Centre, Lund, Sweden.

Background and aims: Cocaine- and amphetamine-regulated transcript (CART) is necessary for islet function in mice, but information from humans is lacking. We examined CART expression and function in human healthy and T2D islets, as well as the effect of genetic variations in the *CARTPT* gene. We also aimed to dissect the mechanisms by which CART affects islet hormone secretion using rodent models.

Materials and methods: Human islets from healthy and T2D cadaver donors and rodent islets were used to study CART expression by immunohistochemistry, qPCR and western blot. Islets from 64 human donors were subjected to Affymetrix GeneChip Human Gene 1.0ST array. Insulin and glucagon secretion was studied *in vivo* in mice and in human and mouse islets. Ca²⁺ oscillations and islet single cell exocytosis was studied in mouse islets. 22132 non-diabetic individuals were selected from 2 population-based cohorts (Malmö Preventive Project and the Prevalence, Prediction and Prevention of diabetes Botnia study) and genotyped for *CARTPT* gene variants.

Results: CART was expressed in human beta cells, alpha cells, and in cholinergic pancreatic neurons. CART mRNA was higher in hyperglycemic donors (p<0.015) and CART mRNA (p<0.009) and protein expression (p<0.008) were 3-times higher in islets of T2D patients compared to controls. Islet CART expression was several-fold increased in 4 diabetic rodent models and up regulated by glucose *in vivo* in rats (p<0.03). CART increased insulin secretion by 25% in human control- and T2D islets (p<0.02). Administration of CART *in vivo* and beta cell specific overexpression of CART provoked a 2-fold increased first phase insulin release (p<0.01), as well as improved glucose elimination *in vivo* in mice (p<0.02). The effect of CART on first phase insulin secretion was comparable to that of GLP-1 and notably, CART caused a 30% further increase in insulin secretion on top of that achieved by GLP-1 alone (p<0.02). Furthermore, CART augmented beta cell exocytosis 2-fold (p<0.05), triggered slow wave Ca²⁺ oscillations and synchronized oscillations within the islets. In addition, glucagon secretion was reduced by CART *in vivo* in mice (p<0.001) and CART diminished alpha cell exocytosis (p<0.05). Genetic variants in the *CARTPT* gene were associated with increased glucose levels (p<0.03), reduced insulin (p<0.04) and elevated glucagon secretion (p<0.008), and a BMI-dependent 1.5-1.7 fold increased T2D risk (p=0.001).

Conclusion: We conclude that CART is a novel glucose-dependent peptide with potential as a future anti-diabetic therapy. This is based upon its properties to stimulate insulin- and inhibit glucagon secretion, as well as the demonstration that genetic variants in the *CARTPT* gene increase risk of T2D in obese individuals.

Involvement of Rab3B in the regulation of beta cell insulin secretion

C. Johne, S. Baltrusch;

Institute of Medical Biochemistry and Molecular Biology, University Rostock, Germany.

Background and aims: Trafficking and exocytosis of insulin granules in pancreatic beta cells is a sophisticated process in which the coordinated interplay of many different proteins is essential. Rab proteins which belong to the Ras superfamily are crucial factors within this scene. Research in the past 2 decades mainly focused on Rab3A and Rab27A and revealed both as key regulators of late stages of exocytosis. Recent studies proposed that another member of the Rab family, Rab3B, has a pivotal function in coordination of beta cell insulin secretion. Therefore the aim of this study was to explore the role of Rab3B in beta cells.

Materials and methods: Mouse islets, murine tissues and MIN6 beta cells were analyzed for Rab3 expression by RT-PCR, Western Blot and immunofluorescence analyses. The influence of different culture conditions on Rab3 expression in MIN6 cells and isolated islets was followed by RT-PCR. For overexpression of Rab3A and Rab3B, cells were transiently transfected. Down regulation of Rab proteins was evoked by lentiviral shRNA transduction. Glucose-induced insulin secretion was measured by ELISA.

Results: Expression of both, Rab3A and Rab3B was detected in mouse islets, brain, liver and pancreas as well as in MIN6 beta cells. RT-PCR analysis showed that the two other isoforms Rab3C and Rab3D were only expressed at a low level in beta cells. But equal amounts of Rab3A and Rab3B were detectable in isolated islets, indicating the pivotal role of Rab3B in endocrine tissue. Immunofluorescence analyses of Rab3A and Rab3B in MIN6 cells and in primary beta cells revealed a vesicle-like distribution with, surprisingly, only little colocalization with each other. Rab3A displayed a higher degree of colocalization with insulin granules than Rab3B. Endogenous Rab3B protein expression was additionally detected in glucagon containing alpha cells. Investigating the effects of glucose and palmitic acid on Rab3 gene expression we observed a decrease in Rab3A and B expression in MIN6 cells but a significant increase in the expression levels of both isoforms in islets. To explore the functional impact of Rab3B on insulin exocytosis glucose-induced insulin secretion was studied. Neither Rab3A nor Rab3B overexpression in MIN6 beta cells modified insulin secretion. In contrast, knocking down Rab3A or Rab3B protein expression in MIN6 cells resulted in a significant reduction of glucose-induced insulin secretion. This result was also obtained after downregulation of Rab3A in mouse islets.

Conclusion: Besides the well known Rab3A we could determine Rab3B as an additional crucial factor of the insulin exocytosis machinery: 1) Rab3B is expressed in primary murine beta cells; 2) expression is altered upon exposure to high glucose and palmitic acid and 3) reduced protein expression impaired insulin secretion. Thus, both Rab3B and Rab3A are essential factors in beta cell function and a balanced expression might be a prerequisite to prevent the development of type 2 diabetes mellitus.

Knock-down of the alpha subunit (PDHA1) of pyruvate dehydrogenase E1 in insulin-secreting cells reduces glucose-induced respiration

J.K. Ofori, V.A. Salunkhe, A. Bagge, H. Mulder, L. Eliasson, J.L.S. Esguerra;

Department of Clinical Sciences, Lund University, Malmö, Sweden.

Background and aims: It has been reported that tight coupling between cytosolic and mitochondrial metabolism increases glucose-stimulated insulin secretion (GSIS). In β -cells, metabolism of pyruvate is critical for metabolic coupling, and hence the mitochondrial pyruvate dehydrogenase complex (PDC) may play an important role in β -cells in control of GSIS and regulation of blood glucose levels. We have previously reported that GSIS is regulated by miR-130a/b and miR-152 via PDHA1, which is a component of PDC enzyme complex. We showed that PDHA1 knock-down by siRNA reduced GSIS by 40%. Here, we aim to investigate the bioenergetics underlying the actions of PDHA1 in insulin-secreting cells.

Materials and methods: We silenced PDHA1 by siRNA in INS-1 832/13 cells. We measured the knock-down efficiency at both mRNA and protein levels by RT-qPCR and western blot, respectively. Basal respiration, glucose-induced respiration, non-mitochondrial respiration, maximal mitochondrial respiration capacity and maximal respiration were measured by the Seahorse Extracellular Flux Analyzer, XF24.

Results: We observed an approximately 70% knock-down of PDHA1 at both mRNA and protein levels ($n=3$; $p<0.01$). Glucose-induced respiration decreased by ~25% ($n=3$, $p<0.05$), non-mitochondrial respiration decreased by ~20% ($n=3$, $p<0.05$) and maximal respiration reduced by ~15% ($n=3$; $p<0.01$) in insulin-secreting cells upon PDHA1 knock-down. We found no significant difference in the proton leak, but there was a trend of decreased basal respiration and a decreased maximal mitochondrial respiration capacity.

Conclusion: PDHA1, a component of pyruvate dehydrogenase complex potentially involved in metabolic coupling in insulin-secreting beta cells, may contribute to beta cell dysfunction.

Larger glucagon response to OGTT compared to isoglycaemic i.v. glucose infusion translates into increased endogenous glucose production in patients with type 2 diabetes

J.I. Bagger^{1,2}, A. Lund^{1,2}, M. Christensen^{1,2}, G. Van Hall³, J.J. Holst², T. Vilsbøll¹, F.K. Knop^{1,2},

¹Gentofte University Hospital, Hellerup, ²NNF Center for Basic Metabolic Research, ³Clinical Metabolomics Core Facility, University of Copenhagen, Denmark.

Background and aims: OGTT induces less suppression of glucagon than isoglycaemic i.v. glucose infusion (IIGI) in healthy subjects and this difference is exaggerated in patients with type 2 diabetes (T2D). The impact of this difference on plasma glucose levels is not clear. We evaluated glucose clearance and endogenous glucose production (EGP) during OGTT and IIGIs with and without simulated lack of glucagon suppression in patients with T2D and healthy control subjects (CTRLs).

Materials and methods: Ten patients with T2D (age: 57±2 years [mean ±SEM]; BMI: 29.0±1.4 kg/m²; HbA1c: 53.8±3.5 mmol/mol) and 10 matched CTRLs (age: 56±3 years; BMI: 29.8±0.9 kg/m²; HbA1c: 33.8±1.7 mmol/mol) underwent three investigations, day A: 75 g-OGTT labelled with [U-13C]glucose, day B: [6,6D-2]-labelled IIGI corresponding to day A, and day C: IIGI as day B with glucagon infusion (0.8 ng/kg/min from 0–25 min).

Results: Isoglycaemia was obtained during all three study days in both groups. As expected, larger glucagon responses were observed in the initial phase of the OGTT (0–90 min) compared to the IIGI in both groups (Table 1). The IIGI with concomitant glucagon infusion resulted in similar glucagon AUCs (0–90 min) compared to the T2D OGTT response (Table 1). In both groups more glucose was infused during day B compared to day C (P=0.01 for healthy and P=0.14 for T2D; Table 1). In the T2D group, EGP was higher during day A compared to day B and C, whereas no difference in EGP between days were seen in the CTRL group. Peripheral glucose disappearance was higher during day A compared to day B and C among CTRLs, but similar on all days in the T2D group.

Conclusion: These findings suggest that glucagon release arising from glucose stimulation of the gastrointestinal tract may stimulate EGP and that exaggerated glucagon release during OGTT in patients with T2D may contribute to reduced glucose tolerance characterising these patients.

Table 1. Glucose and glucagon following OGTT and isoglycaemic i.v. glucose infusions (IIGIs) in patients with type 2 diabetes (T2D) and healthy control subjects (CTRL). Data are mean±SEM values. P values are from paired sample t test or repeated-measurement ANOVA. Significant differences (P≤0.05) between days (derived from post hoc analysis) are indicated by asterisks (*) followed by the letter of the day compared with.

Identification of secreted factors linking hepatic steatosis to insulin resistance

R.C.R. Meex¹, A.J. Hoy², A. Morris¹, R.D. Brown¹, M. Burke¹, R. Goode³, S.S. Rensen⁴, B.A. Kingwell⁵, G.I. Lancaster⁶, M. Kraakman⁶, M.A. Febbraio⁶, P.J. Meikle⁷, M.P. Molloy⁸, C.R. Bruce¹, M.J. Watt¹;

¹Physiology, Monash University, Clayton, ²Physiology, University of Sydney, ³Biochemistry and Molecular Biology, Monash University, Clayton, Australia, ⁴Internal Medicine, Maastricht University, Netherlands, ⁵Metabolic & Vascular Physiology, ⁶Cellular and Molecular Metabolism, Baker IDI, Melbourne, ⁷Chemistry & Biomolecular Sciences, Macquarie University, Sydney, Australia.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a common health problem that is associated with obesity. Liver steatosis is an early manifestation in the aetiology of NAFLD, which usually precedes the development type 2 diabetes. We tested the hypothesis that protein and lipid signals originating from the fatty hepatocyte induce 'cross-talk' with other tissues to modulate metabolic phenotypes.

Materials and methods: Male C57Bl/6J mice were fed a chow diet (Chow) or high-fat diet (HFD) for 6–8 weeks to induce simple steatosis. Hepatocytes were isolated and cultured, and the secreted products were collected in protein and lipid free media for analysis (=conditioned media, CM).

Results: HFD CM but not Chow CM induced insulin resistance and inflammation in cultured cells. Quantitative analysis of the CM detected 17 lipid classes and >200 lipid species, and showed increased secretion of 11 lipid classes in HFD CM compared with Chow CM (including cholesterol esters, ceramides, diacylglycerols, phosphatidylcholine and triacylglycerol). Isobaric tag for relative and absolute (iTRAQ) labelling and mass spectrometry quantification of the CM detected 538 proteins. Of these proteins, 115 were identified as 'classically secreted', 31 of which were upregulated, and three that were downregulated in HFD CM. Fetuin B was increased in the CM of HFD hepatocytes and subsequent studies showed that fetuin B was elevated in patients with liver steatosis compared with weight-matched patients without steatosis, and fetuin B correlated with insulin resistance. Further studies in lean mice showed that acute injection of fetuin B decreased glucose tolerance, whereas adeno-associated virus administration of fetuin B shRNA in obese mice reduced plasma fetuin B by 33% and improved glucose tolerance.

Conclusion: Hepatic steatosis invokes changes in the protein and lipid secretory profile that in turn causes inflammation and insulin resistance, and targeted profiling identified fetuin B as a steatosis responsive protein that was shown to cause glucose intolerance. Further interrogation of the secreted proteins may be a useful strategy for understanding the development of impaired glucose metabolism.

Metabolic assessment of cirrhotic patients before liver transplantation: relation between impaired glucose homeostasis, liver function and HCC

V. Grancini, M.E. Lunati, E. Palmieri, V. Resi, M. Smiraglia, E. Orsi; Endocrinology and Diabetology Unit, Fondazione IRCCS Ca' Granda - Ospedale Maggiore Policlinico di Milano, Italy.

Background and aims: Impaired glucose tolerance (IGT) and Diabetes Mellitus (DM) are common in patients with liver cirrhosis. DM development has been associated to advanced liver disease (LD) and HCV infection, but the relative roles played by these factors are still somewhat unclear. Moreover, it has been demonstrated that Insulin Resistance (IR), is related to increased risk of developing Hepatocellular Carcinoma (HCC), the first cause of death in patients with cirrhosis. Aim of the study is to assess, in cirrhotic patients candidate to organ transplantation with no

history of glucose abnormalities: a) prevalence of altered glucose homeostasis and its relation to liver function; b) IR and its relationship with HCC.

Materials and methods: 204 patients, aged 54.3 ± 8.4 , with liver cirrhosis and candidate to organ transplantation underwent an anthropometric and metabolic evaluation and an OGTT. IR was assessed with HOMA-IR (a cut off of 3 was utilized to identify insulin-resistant patients) and OGIS. **Results:** 35 patients had normal glucose tolerance (NGT), 68 had IGT, 101 had DM. Diabetic patients were older than patients showing IGT or NGT (age 56.2 ± 6.9 vs 53.3 ± 8.4 vs 50.9 ± 11.1 , respectively, $P < 0.01$). Glucose tolerance worsened with worsening of liver function: DM was diagnosed in 24.6% of patients in stage A and 65.4% of those in stage B or C, according to Child Pugh classification. Moreover, diabetes was related to lower levels of total cholesterol (128.3 ± 44.9 vs 132.2 ± 45.1 vs 160.0 ± 73.5 , $P < 0.01$), LDL-cholesterol (65.1 ± 35.1 vs 68.9 ± 35.5 vs 96.2 ± 65.4 , $P < 0.01$), albumin (3.4 ± 0.5 vs 3.5 ± 0.6 vs 3.7 ± 0.5 , $P = 0.01$), pseudocholinesterase (2683.2 ± 1673.2 vs 3720.3 ± 2472.9 vs 3534.5 ± 2169.8 , $P < 0.01$) and platelets count (73.1 ± 35.9 vs 102.8 ± 67.9 vs 124.8 ± 105.3 , $P < 0.01$) if compared to patients with IGT and NGT, showing worse hepatic synthetic capacity and liver function in patients with altered glucose homeostasis. HOMA-IR steadily increased with declining of glucose tolerance (2.85 ± 0.34 vs 4.66 ± 0.59 vs 5.9 ± 0.70 from NGT to DM, $P < 0.05$), and it was higher in presence of HCV: 68% of HCV+ patients showed IR vs 44.8% of HCV- patients ($P < 0.01$). OGIS level decreased from NGT to IGT to DM (425.5 ± 78.0 vs 372.5 ± 82.2 vs 352.9 ± 80.2 , $P < 0.01$). Finally, prevalence of HCC was significantly higher in patients with IR vs cirrhotic patients without IR (45.1% vs 27.9%, $P < 0.01$).

Conclusion: In cirrhotic patients, DM is related to the severity of LD. HCV infection might play a role in deteriorating glucose homeostasis via IR. Moreover HOMA, a reliable index to identify insulin-resistant patients, allows to characterize a class of patients at highest risk of developing HCC.

Clinical Trial Registration Number: NCT02038517

582

Selenoprotein-P as marker of insulin sensitivity in prediabetes and diabetes

M. Kumar¹, S. Mondal², D. Dutta³, S. Chowdhury¹, S. Mukhopadhyay¹; ¹Department of Endocrinology, ²Department of Biochemistry, IPGME&R SSKM Hospital, Kolkata, ³Department of Endocrinology, Post Graduate Institute of Medical Education & Research & Dr. Ram Manohar Lohia Hospital, Delhi, India.

Background and aims: Initial reports have suggested selenoprotein-P (SeP), a novel hepatokine, to modulate insulin resistance (IR) and energy metabolism in animals and humans. This study evaluated the relation between SeP, anthropometric parameters, IR, systemic inflammation and vitamin-D across the spectrum of glycemia, viz. normoglycemia (NGT), prediabetes (preDM) and newly diagnosed treatment naïve type-2 diabetes (T2DM) patients.

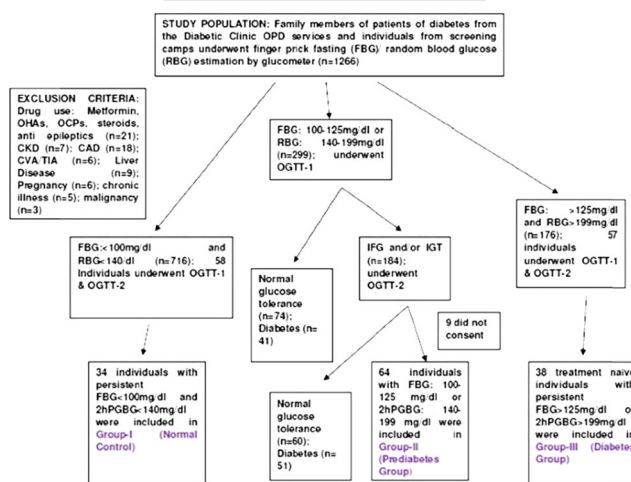

Materials and methods: Anthropometric parameters (waist circumference, hip circumference, neck circumference (NC)), Serum selenoprotein, fasting blood glucose (FBG), 2 h post 75gram glucose blood glucose (2hPGBG), HbA1c, fasting insulin, lipids, inflammatory cytokines [interleukin (IL)-6, IL1 β , soluble tumor necrosis factor receptor (sTNFR)-1, sTNFR2] and 25-hydroxy-vitamin-D (25OHD) were evaluated in 34 NGT, 64 preDM and 38 T2DM patients, selected from the eastern India vitamin-D in prediabetes study. Serum insulin was estimated using CLIA (Immunit-1000, Gwynedd, UK). Human SeP was estimated using sandwich ELISA, (Cat No. MBS2515309, MyBioSource, USA), detection range 0.156-10 ng/ml, sensitivity 0.094 ng/ml with intra and interassay coefficient of variation of $< 10\%$. 25OHD was measured using 125I radioimmunoassay kit (REF 68100E, Diasorin, USA). IL6, IL1 β , sTNFR1

and sTNFR2 were estimated using sELISA. Insulin sensitivity was estimated using QUICKI (Quantitative Insulin Sensitivity Check Index).

Results: NGT (age: 50.29 ± 13.2 years), prediabetes (age: 46.9 ± 12.3 years) and T2DM (age: 49.73 ± 13.4 years) had significantly different BMI (24.7 ± 2.75 , 24.6 ± 4.28 , 27.29 ± 5.08 kg/m², $P = 0.035$), waist-height ratio (0.55 ± 0.04 , 0.55 ± 0.06 , 0.59 ± 0.07 , $P = 0.009$), NC (34.72 ± 3.19 , 35.33 ± 2.9 , 37.3 ± 2.68 cm, $P = 0.003$), triglycerides (126.7 ± 60.1 , 115.9 ± 63 , 200.9 ± 62.6 mg/dl, $P = 0.031$), IL6 (4.93 ± 0.44 , 4.74 ± 2.65 , 5.7 ± 1.6 pg/ml, $P = 0.08$), sTNFR1 (2863.77 ± 1106.72 , 3371.89 ± 1102.4 , 3830.41 ± 1529.65 pg/ml, $P = 0.021$), 25OHD (30.50 ± 18.37 , 31.95 ± 23.25 , 42.07 ± 20.23 ng/ml, $P = 0.075$) and SeP (848.35 ± 220.21 , 1002.93 ± 279.50 , 826 ± 240.59 ng/ml, $P = 0.011$). SeP had very strong inverse correlation with insulin sensitivity (QUICKI) in NGT ($r = -0.94$, $P < 0.001$), prediabetes ($r = -0.92$, $P < 0.001$) and diabetes ($r = -0.96$, $P < 0.001$). SeP was persistently the strongest predictor of QUICKI in NGT, prediabetes and T2DM at baseline ($\beta = -1.124$, $P < 0.001$; $\beta = -1.003$, $P < 0.001$; $\beta = -0.957$, $P < 0.001$, respectively) and after adjusting for age, BMI and waist circumference (Model-1) ($\beta = -1.11$, $P < 0.001$; $\beta = -1.006$, $P < 0.001$; $\beta = -0.942$, $P < 0.001$, respectively).

Conclusion: SeP is elevated across the spectrum of dysglycemia with lowest in normoglycemia. SeP is a very good predictor of insulin sensitivity and may be considered as a biomarker of insulin sensitivity.

Phosphorylated serum IGFBP-1 as a non-invasive predictor of liver fat in NAFLD

E.M. Petäjä^{1,2}, Y. Zhou², M. Havana³, J. Ihalaenen³, A. Kotronen^{1,2}, H. Yki-Järvinen^{1,2};

¹Department of Medicine, University of Helsinki, ²Minerva Foundation for Medical Research, Helsinki, ³Medix Biochemica, Kauniainen, Finland.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is currently the most common chronic liver disease and it strongly associates with metabolic syndrome, insulin resistance, and type 2 diabetes. There is a need to develop non-invasive tools for diagnosis of NAFLD. Insulin is the major regulator of the hepatospecific insulin-like growth factor binding protein 1 (IGFBP-1). The majority of serum IGFBP-1 is phosphorylated. IGFBP-1 inversely correlates with liver fat content. Of all subjects 30-50% carry an I148M variant allele in PNPLA3, which increases the risk of NAFLD but not insulin resistance. The aim of the study is to determine whether measurement of fasting serum

phosphorylated IGFBP-1 (fS-pIGFBP-1) helps in prediction of liver fat compared to routinely available clinical parameters and PNPLA3 genotype at rs739409.

Materials and methods: A cross-sectional study comprised 378 subjects (62% women, age 43 (30–54) years, BMI 32.7 (28.1–39.7) kg/m², 46% with NAFLD) of whom liver fat content was determined by proton magnetic resonance spectroscopy (1H-MRS). fS-pIGFBP-1 was determined with an immunoenzymometric assay with an in-house monoclonal antibody as the detecting antibody. Subjects were randomly divided into discovery (2/3) and validation (1/3) groups that matched with respect to clinical and biochemical parameters and PNPLA3 genotype. Univariate analysis was used to evaluate correlations between liver fat content and measured parameters. To create a model for prediction of liver fat, variables identified by univariate analysis in the discovery group were selected for multiple linear regression analysis using backward stepwise regression based on Akaike Information Criteria. Random Forest modeling was used to evaluate relationships between liver fat predictors.

Results: fS-pIGFBP-1 inversely correlated with liver fat content ($r=-0.21$, $p=0.0009$). The final model, the ‘% Liver Fat Equation’, included age, fS-pIGFBP-1, an interaction term (age times fS-pIGFBP-1), S-ALT, waist-to-hip ratio, fP-Glucose and fS-Insulin, adjusted $R^2=0.44$, $p<0.0001$ (adjusted $R^2=0.49$ in the validation group and 0.47 in all subjects) (Table 1). The model was significantly better than S-ALT (adjusted $R^2=0.25$) or S-AST (adjusted $R^2=0.15$) ($p<0.0001$). Exclusion of fS-pIGFBP-1 significantly reduced the variation explained ($p=0.03$). Random Forest modeling identified the same predictors (adjusted $R^2=0.39$, $p<0.0001$). Correlation coefficient between measured liver fat% (1H-MRS) and estimated liver fat% with ‘%Liver fat equation’ was $r=0.62$, $p<0.0001$.

Conclusion: fS-pIGFBP-1 is significantly inversely correlates with liver fat content in NAFLD and independently contributes to prediction of liver fat even when its known associates are considered.

Table 1. Multiple linear regression analysis

Liver fat (log, %)	Beta	Standard error	P-value
$R^2 = 0.44^a$, $P < 0.0001$			
Age (years, log)	-2.707	1.376	0.05
fS-pIGFBP-1 ($\mu\text{g/l}$, log)	-2.635	1.177	0.026

Metabolomics profiling identifies potential pathways involved in the interaction of iron homeostasis with insulin resistance

L. Stechemesser¹, T. Felder², A. Stadlmayr³, S. Auer², S. Eder¹, M. Strasser¹, W. Patsch⁴, C. Datz³, E. Aigner¹;

¹Internal Medicine 1, ²Laboratory Medicine, Paracelsus Medical University Clinic, Salzburg, ³Internal Medicine, Hospital Oberndorf, ⁴Institute of Pharmacology and Toxicology, Paracelsus Medical University Clinic, Salzburg, Austria.

Background and aims: Elevated serum ferritin has been linked to type 2 diabetes and adverse outcomes in subjects with the Metabolic Syndrome (MetS). As the mechanisms underlying the negative impact of excess iron have so far remained elusive, we aimed to identify potential metabolic pathways using a metabolomics analysis.

Materials and methods: Metabolomics profiling was performed in patients with MetS with (n=56) and without iron overload (n=54) and a lean, healthy control group (n=53) in a targeted metabolomics approach utilizing the AbsoluteIDQ™ p180 kit (BIOCRATES Life Sciences AG).

Results: Clinically, subjects with MetS and high ferritin had higher indices of impaired glucose homeostasis as assessed by fasting glucose and HOMA-IR compared to subjects matched for components of the MetS without iron overload. Several differences between MetS and healthy controls confirmed previous studies, i.e. branched-chain amino acids, kynurenin, and alpha AA. However, significant differences between MetS with high and low ferritin were detected in the serum concentrations of sarcosine and methionine, citrulline and particularly long-chain phosphatidylcholines.

Conclusion: Our data confirm that high serum ferritin concentrations are linked to impaired glucose homeostasis. Additionally, our study identifies novel associations of iron excess in MetS subjects with distinct subsets of phosphatidylcholines as well as a pathway involving methionine, sarcosine and citrulline. These metabolic pathways may be involved in iron-induced augmentation of IR.

Gender specific association of serum leptin and insulinaemic indices with nonalcoholic fatty liver disease in prediabetic subjects

A. Rouf, I.A. Hossain, L. Ali;

Biochemistry and Cell Biology, Bangladesh University of Health Sciences (BUHS), Dhaka, Bangladesh.

Background and aims: Adipose tissue-derived hormone leptin play a functional role in glucose tolerance through its effects on insulin secretion and insulin sensitivity which also the risk factors for nonalcoholic fatty liver disease (NAFLD). The present study explored the gender specific association of serum leptin with insulinaemic indices in Bangladeshi prediabetic subjects having NAFLD.

Materials and methods: Under a cross-sectional analytical design a total of 110 prediabetic subjects diagnosed by WHO Group Study criteria, aged 35–68 years consisting of 57.3% male (55.6% non NAFLD and 44.4% NAFLD) and 42.7% female (57.4% non NAFLD and 42.6% NAFLD), were investigated. NAFLD was diagnosed by liver ultrasound to assess serum (S) glucose by glucose-oxidase method, S lipid profile by enzyme colorimetric method and glycated hemoglobin (HbA_{1c}) by high performance liquid chromatography (HPLC) method. S insulin and leptin were measured by enzyme-linked immunosorbent assay (ELISA). Insulin secretory function (HOMA%B) and insulin sensitivity (HOMA%S) were calculated from homeostasis model assessment (HOMA).

Results: On Pearson's correlation analysis, S leptin showed significant positive correlation with fasting insulin ($r=0.530$, $p=0.004$), postprandial insulin ($r=0.384$, $p=0.042$) and HOMA-IR ($r=0.541$, $p=0.003$) as well as significant negative correlation with HOMA%S ($r=-0.388$, $p=0.046$)

and HOMA%B ($r=-0.356$, $p=0.039$) in male prediabetic subjects having NAFLD. On multiple regression analysis, S leptin showed significant positive association with HOMA-IR ($\beta=0.706$, $p<0.001$) after adjusting the effects of major confounders of body mass index (BMI), triglyceride (TG) and HOMA%B in male subjects having NAFLD. On binary logistic regression analysis, only S leptin [odds ratio (OR)=1.296] in male subjects as well as HOMA%B (OR=0.942), HOMA-IR (OR=3.305) and leptin (OR=1.106) in female subjects were found to be independent determinants of NAFLD after adjusting the effects of potential confounders of BMI and TG.

Conclusion: Elevated levels of serum leptin seems to have an association with NAFLD both in male and female prediabetic subjects and this association in turn, is mediated by insulin secretory dysfunction and insulin resistance among these subjects.

Insulin pulse amplitude and frequency do not determine rates of endogenous glucose production in nondiabetic subjects

R.T. Varghese¹, J.C. Andrews², M. Shah¹, F. Piccinini³, C. Dalla Man³, R.A. Rizza¹, C. Cobelli², A. Vella¹;

¹Endocrinology, Diabetes, Metabolism and Nutrition, ²Vascular and Interventional Radiology, Mayo Clinic, Rochester, USA, ³Department of Information Engineering, University of Padova, Italy.

Background and aims: Diabetes, obesity and aging cause changes in insulin pulse amplitude and frequency, which affects the pulsatile secretion of insulin into the portal circulation. Insulin concentrations in the hepatic sinusoids in turn affect glucose production. In dogs, partial pancreatectomy decreases inter-digestive insulin pulsatility and results in decreased hepatic insulin action. Whether this mechanism is extant in humans remain unknown.

Materials and methods: 30 non diabetic subjects (Age 43 ± 2 years, BMI 29.0 ± 0.8 Kg/M²) were studied on 2 occasions. Endogenous glucose production (EGP) was measured on one occasion using an intravenous infusion of [3-H3] glucose after an overnight fast prior to a euglycemic clamp. On a separate study day a hepatic vein catheter was placed to allow sampling of hepatic venous insulin concentrations at 2 minute intervals. Samples were obtained during fasting conditions and after peripheral glucose concentrations were raised to 8.5 mmol/L. Indocyanine green was used to measure splanchnic blood flow.

Results: Under fasting conditions, Peak and Nadir insulin concentrations, (53 ± 9 and 21 ± 4 , respectively) and mean pulse amplitude and pulse frequency (30 ± 6 pmol/L and 11 ± 1 pulses/hr respectively) were measured. The relationship of insulin pulse frequency and amplitude to fasting EGP (14.3 ± 0.6 μ mol/kg/min) was also examined. Under fasting basal conditions EGP did not correlate with peak ($R^2<0.01$, $p=0.80$), and Nadir ($R^2=0.01$, $p=0.72$) insulin, pulse frequency ($R^2=0.08$, $p=0.30$) or pulse amplitude ($R^2=0.04$, $p=0.52$). The mean rates of insulin appearance calculated by multiplying mean insulin concentrations in the hepatic vein (35 ± 6 pmol/L) with splanchnic blood flow (1439 ± 95 ml/min) however correlated inversely with EGP ($R^2=0.36$, $p=0.03$).

Conclusion: The current experiment demonstrates that in nondiabetic individuals, it is mean insulin concentrations that determine EGP during fasting, rather than pulse frequency or pulse amplitude.

PS 042 Type 1 diabetes: new insights into therapy

587

Presence of remission after onset of type 1 diabetes predicts higher insulin sensitivity at 7 years

S. Pilacinski, P. Niedzwiecki, A. Uruska, D. Zozulinska-Ziolkiewicz; Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poland.

Background and aims: After onset of type 1 diabetes some patients experience remission of the disease. This phenomenon is associated with regeneration of beta cells and preserved insulin secretion, but also with increased insulin sensitivity. It was not evaluated whether presence of remission may be of value in predicting the degree of insulin sensitivity in the later course of disease. Aim of the study was to determine the association between presence or absence of remission after onset of type 1 diabetes and insulin resistance after 7 years from diagnosis of disease.

Materials and methods: We followed prospectively 240 consecutive adult patients (77 women and 143 men) hospitalized with new onset type 1 diabetes (NOT1DM) in the Department of Internal Medicine and Diabetology in the years 2004-2007. The presented analysis is a part of POZREM Study. Inclusion criteria were: new diagnosis of autoimmune type 1 diabetes (specific autoantibody-positive), age 18-35 years and informed consent to participate in the study. Adult patients with NOT1DM from the catchment area (the majority of Great Poland region) are referred to our department on a routine basis, independently from the severity of presentation. In the follow-up time of onset and duration of diabetes remission were registered. Presence of remission was determined in the third month after diagnosis of diabetes. Remission was defined as the time when the patients met all of the following criteria: HbA1c < 6.5%, daily dose of exogenous insulin < 0.3 U/kg body weight and serum C-peptide concentration > 0.5 ng/ml. Patients were divided into groups with and without remission. Insulin sensitivity was assessed using normoglycemic-hyperinsulinemic clamp with measurement of glucose disposal rate (GDR [mg/kg/min]). The test was performed after 7 years from diagnosis of diabetes. We excluded seven patients still fulfilling remission criteria.

Finally 74 patients [24 women and 50 men, median age at diagnosis 26 years (IQR 22-31)], in whom insulin sensitivity at 7 years was measured, were included into analysis. Patients were divided into groups with $GDR < 4$ (lower insulin sensitivity) and $GDR \geq 4$ (higher insulin sensitivity). In the statistical analysis Mann-Whitney U test, Spearman correlation and logistic regression were used. The calculations were performed using Statistica 10.

Results: In the study group GDR value < 4 mg/kg/min was observed in 23 (31%) patients. Comparison of GDR between groups with and without remission showed higher insulin sensitivity in the remission group [GDR 6.2 (IQR 4.2-7.0) vs 3.8 (IQR 3.0-4.8); $p=0.01$]. Furthermore, in the group with $GDR \geq 4$ duration of remission was longer than in the group with lower insulin sensitivity: [351 days (IQR 206-561) vs 70 days (0-289); $p=0.002$]. Duration of remission correlated positively with GDR value ($R_s 0.42$; $p=0.002$). In multivariate logistic regression analysis presence of remission was associated with higher odds of $GDR \geq 4$ at 7 years (OR 4.14; 95%CI: 1.08-15.88; $p=0.03$), independently from age, sex and BMI at 7 years.

Conclusion: Patients with type 1 diabetes who entered remission, despite its completion, have higher insulin sensitivity at seven years after diagnosis than nonremitters.

Inverse association of HbA_{1c} with faecal elastase 1 in people without diabetes

W. Rathmann¹, B. Haastert², J. Oscarsson³, N. Berglind³, N.J. Wareham⁴;

¹Institute for Biometrics and Epidemiology, German Diabetes Center, Düsseldorf, ²mediStatistica, Neuenrade, Germany, ³AstraZeneca, Mölndal, Sweden, ⁴MRC Epidemiology Unit, Cambridge, UK.

Background and aims: Faecal elastase 1 (FE1) concentrations, a marker of pancreatic exocrine function, are lower in type 2 diabetes than in non-diabetic controls. FE1 is also inversely correlated with glycated hemoglobin and diabetes duration in type 2 diabetes. The association of FE1 and HbA_{1c} has not been investigated in people without diabetes.

Materials and methods: Patients with type 2 diabetes (oral antidiabetic drugs or insulin: n=391; medically untreated: n=145) and matched (age, sex, practice) controls without diabetes (n=529) from general practices were included. FE1 measurements ($\mu\text{g/g}$ stool) were performed centrally. Linear mixed regression models were fitted using FE1 as dependent variable and HbA_{1c}, diabetes diagnosis (no, yes-untreated, yes-treated) and interactions as independent variables. Potential confounders were age, sex, body mass index, alcohol consumption, smoking, triglycerides, and amylase. Univariate regression models were stratified by diabetes groups, multivariate models were fitted on the whole study population.

Results: In univariate linear regression models, HbA_{1c} was significantly inversely related to FE1 in non-diabetic controls (β -coefficient: -108.74 , $p < 0.0001$), whereas no significant associations were found for the diabetes groups. The inverse relationship of HbA_{1c} with FE1 concentrations in patients without diabetes persisted after adjusting for potential confounders in multivariate regression (β -coefficient of HbA_{1c}: -109.18 , $p < 0.0001$). In people without diabetes, there were lower FE1 concentrations among those with increased diabetes risk (HbA_{1c} 5.7%–6.4% [$39\text{--}46$ mmol/mol]: 395 ± 204 $\mu\text{g/g}$ vs. HbA_{1c} $\leq 5.6\%$ [≤ 38 mmol/mol]: 476 ± 219 $\mu\text{g/g}$ ($p < 0.0001$). The prevalence of FE1 < 100 $\mu\text{g/g}$ was significantly increased among non-diabetic controls with an HbA_{1c} of 5.7%–6.4% ($39\text{--}46$ mmol/mol) compared with those with a normal HbA_{1c} $\leq 5.6\%$ (≤ 38 mmol/mol) (6.1% vs. 1.4%; $p = 0.004$).

Conclusion: The present study suggests that pancreatic exocrine dysfunction might be an early disturbance in prediabetes that develops in parallel with hyperglycaemia. Whether it is a consequence or a determinant of hyperglycaemia requires further investigation.

A parsimonious model of a mixed-meal test in patients with type 1 diabetes in insulin pump therapy

C. Brangani¹, M. Dauriz¹, L. Boselli¹, F. Reali², L. Marchetti², G. Ceradini¹, I. Rubbo¹, M. Trombetta¹, C. Priami², R.C. Bonadonna³;

¹Department of Medicine, Division of Endocrinology, Diabetes and Metabolism, University of Verona School of Medicine and AOUI Verona, ²The Microsoft Research - University of Trento Centre for Computational and Systems Biology (COSBI), Rovereto, ³Division of Endocrinology, Department of Clinical and Experimental Medicine, University and University Hospital of Parma, Verona, Italy.

Background and aims: Currently available closed-loop insulin delivery systems stem from sophisticated models of the glucose-insulin (G/I) system mostly based on complex studies employing glucose tracer technology. We asked the question whether simpler studies based on the minimal modeling approach (Bergman, 1981; Cobelli, 2007) could likewise reliably describe the G/I system during a mixed meal test (MMT) in patients with type 1 diabetes (T1D). If effective, this approach would expedite the creation of large bio-banks of virtual patients to develop robust models

“to close the loop”. To this end, we tested the performance of a minimal model of the G/I system to characterize the glucose (G) and insulin (I) dynamics during MMT in T1D patients on insulin pump therapy (CSII).

Materials and methods: In six T1D patients on CSII enrolled in the MMT-T1D Pilot Study we assessed on three separate days: (1) insulin sensitivity, by the hyperinsulinemic euglycemic clamp (HEC); (2) the G/I time-courses during a standardized 5 h-MMT (MMT1: 292 Kcal; 38.9 g complex CHO, 8.9 g lipids, 14 g proteins); (3) the G/I time-courses during a second identical (3 patients) or double-sized (3 patients) MMT (MMT2). The parameters estimated by modeling of the HEC were used to cast a comprehensive MMT model (GLUKINSLOOP.2), including the insulin delivery system and the metabolic G/I system of each patient. GLUKINSLOOP.2 was implemented and run in the SAAM 2.1 software.

Results: The GLUKINSLOOP.2 model identified the G/I system parameters (among others: insulin sensitivity, SI; glucose effectiveness, SG; glucose distribution volume, Vd; time of oral carbohydrate appearance in the peripheral circulation, expressed as ICMTT, Intestinal Carbohydrate Mean Transit Time) and provided a good fit of the G/I time-courses in all studies, as proved by the analysis of mean weighted residuals (WR, mean \pm SD; MMT1: WR(G) = -0.03 ± 0.71 ; WR(I) = 0.33 ± 1.04 ; MMT2: WR(G) = 0.09 ± 0.86 ; WR(I) = 0.01 ± 1.37). Both the identical and double-sized repeated MMTs showed good reproducibility of the G/I system parameters (mean \pm SEM; MMT1: SI = 0.57 ± 0.12 (mL \cdot min⁻¹)/(pmol L⁻¹); SG = 15.6 ± 10.1 mL \cdot min⁻¹; Vd = $11,482 \pm 1,131$ mL; ICMTT = 105 ± 14 min; MMT2: SI = 0.57 ± 0.13 ; SG = 38.2 ± 13.6 ; Vd = $11,609 \pm 1,031$; ICMTT = 101 ± 11).

Conclusion: The GLUKINSLOOP.2 model herein presented can provide a fairly good and reproducible description of the G/I system in T1D patients on CSII and it may be used to build a bank of “virtual patients”. Our results might be relevant to strategies directed to improve the architecture of upcoming closed-loop CSII systems.

Partial recovery of insulin secretion in type 1 diabetes?

A.S. Januszewski¹, Y. Cho², Y. Loh¹, D.N. O’Neal³, M. Craig², K. Donaghue², A.J. Jenkins¹;

¹NHMRC Clinical Trials Centre, University of Sydney, Camperdown, ²Childrens Hospital at Westmead, ³Department of Medicine, University of Melbourne, Fitzroy, Australia.

Background and aims: Even long-term Type 1 diabetes (T1D) can be associated with low level insulin production. Residual C-peptide may reduce risk of vascular complications and hypoglycaemia.

Materials and methods: Plasma C-peptide levels were measured in a cross-sectional study of 249 healthy controls (CON) and 365 T1D patients (F/M=198/167), aged 10–80 y, (mean \pm SD) 30 ± 16 y, with T1D duration of 16 ± 12 y. Of the T1D patients 129 had microvascular complications (CX+). HbA_{1c} was $8.4 \pm 1.6\%$ and $5.1 \pm 0.4\%$ in T1D and CON respectively ($p = 0.00001$). C-peptide levels were measured by ultra-sensitive ELISA (Merodia, Sweden), with a low detection limit of 1.25 pmol/L (0.0038 ng/mL). C-peptide levels below OD of the lowest calibrator were expressed as $\frac{1}{4}$ of the concentration of the assay’s lowest calibrator as per manufacturer’s instructions (Technical Note 34-0144).

Results: C-peptide in CON and T1D were 547.1 ± 1.2 pmol/L and 3.6 ± 1.2 pmol/L respectively; $p = 0.0001$. Undetectable C-peptide level frequency did not differ between CX+ and CX- groups. For T1D subjects with detectable levels C-peptide levels were lower in those with vs. without complications: 2.7 ± 0.9 pmol/L and 4.4 ± 0.6 pmol/L respectively, $p = 0.04$. Subjects were divided into cohorts by age of T1D diagnosis (≤ 10 , 10 to ≤ 20 and > 20 y) and T1D duration (≤ 10 , 10 to ≤ 20 and > 20 y). C-peptide levels are shown in the table. Young age diagnosis (≤ 10 y.o.) was associated with higher rates of undetectable C-peptide, $p = 0.0001$ vs.

combined age T1D diagnosis 10 to ≤ 20 y.o. and >20 y.o. For T1D diagnosed in early childhood C-peptide levels are higher in those with longer T1D duration, whilst for those diagnosed >20 y longer T1D duration is associated with lower C-peptide.

Conclusion: Although cross-sectional, our results are supportive of more complete beta cell loss in younger onset T1D, and potential beta cell regeneration. Residual C-peptide levels are higher in T1D subjects without vs with complications. Longitudinal studies are merited.

C-peptide levels (geometrical mean \pm SEM, age and gender adjusted)

Age T1D diagnosis (yrs)	n	T1D duration (yrs)	% with undetectable C-peptide	C-peptide (pmol/L)
≤ 10	62	≤ 10	82	2.2 \pm 1.2
≤ 10	61	10 to ≤ 20	67	3.5 \pm 1.2
≤ 10	34	>20	56	5.1 \pm 1.2 ‡
10 to ≤ 20	50	≤ 10	44	2.5 \pm 1.2
10 to ≤ 20	26	10 to ≤ 20	23	5.2 \pm 1.2 ‡

Endogenous C-peptide secretion in patients with long-duration type 1 diabetes

S.L. Prior¹, S.D. Luzio¹, G.J. Dunseath¹, G.V. Gill², S.C. Bain¹;

¹Diabetes Research Group, Swansea University, ²Department of Diabetes & Endocrinology, University of Liverpool, UK.

Background and aims: Classically, Type 1 diabetes is thought to proceed to absolute insulin deficiency; however, recent reports suggest that some Type 1 patients secrete low levels of endogenous insulin. It is thought that even small amounts of residual β -cell function may result in fewer complications including lower rates of hypoglycaemia and lower incidences of retinopathy and nephropathy. We aimed to assess amounts of detectable C-peptide in the Golden Years cohort who have had Type 1 diabetes for over 50 years, and to assess whether this had a bearing on the presence/absence of complications.

Materials and methods: Random serum C-peptide was measured in 334 samples from the Golden Years cohort, using a commercially available immunometric C-peptide assay. Subjects were divided into 'no secretor' and 'secretor' groups based on the detection limit of the C-peptide assay (5.0 pmol/L).

Results: A substantial proportion (15.9%) of the Golden Years patients continued to secrete detectable levels of C-peptide (5.1 - 245.2 pmol/L) despite having been diagnosed with Type 1 diabetes for ≥ 50 years. Both 'no secretor' and 'secretor' groups were well matched, with no significant difference in age, age at diagnosis, duration of diabetes, BMI, HbA1c or lipid levels (Table 1). There was however, a significant difference in insulin dose ('no secretor' vs 'secretor': 34.4 v 26.7 U/24 hr; p=0.002) between the groups, which appeared to be clinically significant. With respect to complications, there was no difference in UACR, or prevalence of diabetic retinopathy, IHD or hypertension.

Conclusion: In common with recent reports, our results confirm that some level of endogenous C-peptide production is evident in Type 1 diabetes and this persists for decades after disease onset, allowing a possible route for therapeutic intervention to preserve β -cell function, even in a population of patients with long-duration diabetes, such as the Golden Years cohort. However, the presence of detectable C-peptide did not appear to confer protection against diabetes related complications such as retinopathy, IHD or nephropathy.

Table 1: Clinical and biochemical measurements for Golden Years C-peptide samples

Measurement	'No secretor'	'Secretor'	P
n	281	53	
Age (yrs)	69.0 (9.0)	69.2 (9.5)	0.879

Glucose metabolism under differing exercise conditions in type 1 diabetes

L. Bally¹, T. Zueger¹, C. Speck¹, D. Paganini¹, N. Pasi¹, H. Loher¹, K. Feller¹, T. Buehler², A. Dokumaci², M. Fiedler³, L. Tappy⁴, M. Wilhelm⁵, C. Boesch², C. Stettler¹;

¹Div of Endocrinology, Diabetes and Clinical Nutrition, ²Dept of Clinical Research, MR-Spectroscopy & -Methodology, ³Center for Laboratory Medicine, University Hospital, Bern, ⁴Institute of Physiology, University, Lausanne, ⁵Div of Cardiovascular Prevention, Rehabilitation and Sports Cardiology, University Hospital, Bern, Switzerland.

Background and aims: The combination of aerobic exercise with interspersed high-intensity activity (intermittent high intensity exercise IHE) may be a strategy to attenuate exercise-related glucose fluctuations in diabetic patients not willing or unable to reduce insulin in the context of exercise. The present study comprehensively investigated glucose metabolism during IHE compared to isoenergetic continuous exercise (CONT) in individuals with T1DM.

Materials and methods: In a prospective, randomized cross-over study, 12 male, well controlled, complication-free patients with T1DM (mean \pm SD age 26 \pm 4 y, HbA1C 7.0 \pm 0.6%, diabetes duration 14 \pm 6 y) injected their usual morning insulin and had a standardized breakfast. In the postabsorptive phase they performed 90 min of cycling at 50% VO₂peak with (IHE) and without (CONT) 10 s maximal sprints every 10 min. Blood glucose, counter-regulatory hormones, lactate and acid-base parameters were measured at regular intervals. Euglycemia was maintained using a 10% oral glucose solution labelled with [U-13C] glucose following a pre-specified algorithm. Analysis of glucose kinetics was based on dual labelling stable isotope technique ([6,6-2H₂]glucose and [U-13C] glucose). Intramyocellular glycogen was measured using MR spectroscopy.

Results: Mean \pm SE glucose was 6.8 \pm 0.1 and 7.2 \pm 0.2 mM in IHE and CONT (n.s.). Insulin levels were 21.0 \pm 0.5 and 20.7 \pm 0.2 mU/l (n.s.). Exogenous glucose requirements in IHE were significantly lower compared with CONT (13.4 \pm 5.2 g vs 39.8 \pm 7.6 g, p<0.004). Catecholamine and growth hormone (GH) levels were significantly higher in IHE when compared to CONT (p<0.05) while cortisol and glucagon levels did not differ between groups. Lactate was significantly higher in IHE compared with CONT (7.3 \pm 0.4 vs 2.6 \pm 0.3 mM, p<0.01) and was paralleled by

significantly lower pH ($p < 0.001$) and bicarbonate ($p < 0.001$). Analysis of glucose fluxes revealed higher total Ra in CONT compared with IHE ($p < 0.01$) but similar hepatic glucose output (Ra from liver) and a trend towards lower Rd (glucose utilization) in IHE ($p = 0.054$). Relative changes in intramyocellular glycogen were -41.0 ± 3.7 and $-38.6 \pm 5.3\%$ for IHE and CONT (n.s.).

Conclusion: The present findings suggest that IHE is associated with lower requirements of exogenous glucose for maintenance of euglycemia in patients with T1DM compared with isoenergetic CONT over 90 min if insulin is not reduced. IHE elicits a strong metabolic response with higher levels of catecholamines, GH and lactate. Kinetic analyses suggest that hepatic glucose production is similar in IHE and CONT. Consumption of intramyocellular glycogen was also comparable between conditions. These findings implicate that the metabolic difference between IHE and CONT mainly relates to higher lactate levels in IHE, potentially providing an alternative carbohydrate source to the working muscle.

Regional cerebral haemodynamic response to incremental exercise is blunted in poorly controlled patients with uncomplicated type 1 diabetes

S. Tagougui¹, P. Fontaine², E. Leclair³, J. Aucouturier¹, R. Matran⁴, K. Oussaidene¹, A. Descatoire⁵, F. Prieur⁶, P. Mucci¹, A. Vambergue², G. Baquet¹, E. Heyman¹;

¹University of Lille, URePSSS, 'Physical Activity, Muscle, Health' Research Team, ²Department of Diabetology, Lille University Hospital, EA 4489, France, ³School of Kinesiology and Health Science, Faculty of Health, York University, Toronto, Canada, ⁴Department of Physiology, EA 2689 and IFR 22, Lille, ⁵Regional Hospital Centre of Roubaix, ⁶University Paris Sud-University of Orléans, EA 4532 'CIAMS', France.

Background and aims: Cerebral vasoreactivity to pharmacologically induced hypercapnia is impaired in poorly controlled patients with type 1 diabetes but otherwise free from microangiopathy. However, whether this response is also compromised during exercise, a daily-life physiological condition challenging regional cerebral hemodynamics, is unknown. We aimed to investigate prefrontal cortex hemodynamics incremental maximal exercise in patients with uncomplicated type 1 diabetes, taking into account long-term glycemic control as well as exercise- and diabetes-influenced vasoactive stimuli.

Materials and methods: Two groups of patients (type 1 diabetes with adequate glycemic control [T1D-A], $n = 8$, HbA1c $6.8 \pm 0.7\%$ [51 ± 7.7 mmol/mol]; type 1 diabetes with inadequate glycemic control [T1D-I], $n = 10$, HbA1c $9.0 \pm 0.7\%$ [75 ± 7.7 mmol/mol]) were compared with 18 healthy control subjects (CON-A and CON-I) matched for physical activity and body composition. Throughout exercise, near-infrared spectroscopy allowed investigation of changes in oxyhemoglobin (O2Hb), deoxyhemoglobin (HHb), and total hemoglobin (THb) in the prefrontal cortex. Venous and arterialized capillary blood was sampled during exercise to assess for factors that may alter prefrontal cortex hemodynamics and oxygenation.

Results: No differences were observed between T1D-A and CON-A, but VO₂max was impaired ($P < 0.05$) and cerebral blood volume (THb) increase blunted ($P < 0.05$) in T1D-I compared with CON-I. Nonetheless, O2Hb appeared unaltered in T1D-I probably partly due to blunting of simultaneous neuronal oxygen extraction (i.e., a lower HHb increase; $P < 0.05$). There were no intergroup differences in arterial oxygen content, PACO₂, pH, [K⁺], and free insulin levels.

Conclusion: Maximal exercise highlights subtle disorders of both hemodynamics and neuronal oxygenation in the prefrontal cortex of poorly controlled patients with type 1 diabetes. These findings may warn

clinicians of brain endothelial dysfunction occurring even before overt microangiopathy during exercise.

Imbalance of muscular carnosine and fatty acids assessed by 1H MRS in subjects with type 1 diabetes

L. Bruignara^{1,2}, A. García³, S. Murillo^{1,2}, M. Rodríguez^{4,2}, M. Vinaixa^{4,2}, T. Casserras⁵, S. Kalko⁵, J. Pomes³, X. Correig^{4,2}, A. Novials^{1,2};

¹Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Hospital Clínic de Barcelona, ²Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders (CIBERDEM), ³Department of Radiology – Hospital Clínic de Barcelona, ⁴Metabolomics Platform – Universitat Rovira i Virgili, Reus, ⁵Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Bioinformatics Core Facility, Barcelona, Spain.

Background and aims: Skeletal muscle represents one of the most active organs in glucose metabolism and is directly involved in insulin resistance and sensitivity. In subjects with type 1 diabetes (T1D), there is little information about muscle particularities and specific metabolism. Carnosine is a dipeptide with antioxidant activity that reflects the content of muscular type II fibers (glycolytic). Imbalances in muscular lipid metabolism may be estimated by intramyocellular lipids (IMCL), representing saturated fatty acids (FA), but also some unsaturated FA (UFA) components. The aim of this study was to analyze muscle alterations in T1D patients by estimating muscle carnosine, IMCL, UFA and unsaturation index (UI) by proton magnetic resonance spectroscopy (1H MRS), and to investigate the influence of physical activity and clinical variables on these parameters.

Materials and methods: 18 men with T1D (10 athletes and 8 sedentary) with 41.3 ± 7.2 years of age, 18.8 ± 9.4 years of T1D evolution, were matched with 14 control (CT) men (9 athletes and 5 sedentary). Clinical data were registered, body fat was obtained by iDXA, VO₂peak was estimated by ergospirometry test, basic biochemical parameters were analysed and 1H MRS were performed in the tibialis anterior, soleus and vastus intermedius in a 3 T unit. The spectra were processed in jMRUI for obtaining the concentrations of carnosine (C2-H peak at 8 ppm), IMCL (methylene protons at 1.2 ppm) and UFA (olefinic protons at 5.2 ppm) content, and UI was obtained from UFA/IMCL ratio. Differences between groups (Kruskal-Wallis and U-Mann Whitney), influence of exercise and diabetes (Anova with covariates) and the Pearson's correlation for clinical and muscle lipid variables were analysed ($p < 0.05$).

Results: T1D athletes presented a VO₂peak of 41.3 ± 10.4 mL/kg/min, and sedentary T1D subjects 20.2 ± 6.7 , confirming the differences between groups ($p = 0.01$). T1D patients presented an increase in carnosine ($p = 0.045$) in the soleus muscle after adjustments for age, physical activity and the presence of dyslipidemia, when compared to the CT group. Soleus carnosine was positively correlated with total body fat by iDXA ($R = 0.577$) and serum triglycerides ($R = 0.501$) and negatively correlated with VO₂peak ($R = -0.579$) and UI UFA/IMCL in soleus ($R = -0.473$). In the CT group, carnosine of soleus muscle presented a positive correlation with waist ($R = 0.848$), waist/hip ratio ($R = 0.836$), total body fat ($R = 0.699$), abdominal body fat ($R = 0.578$), BMI ($R = 0.674$) and soleus IMCL ($R = 0.795$). There was no difference in carnosine estimations between athletes and sedentary subjects, in both T1D and CT groups.

Conclusion: Carnosine (marker of glycolytic fibers) is increased in muscles with a predominance of oxidative fibers (soleus) in T1D patients. These findings could indicate a dysfunction in oxidative muscle fibers, thus requiring the increased function of glycolytic fibers, a circumstance also associated with poorer clinical parameters.

Effect of renal sympathetic denervation on hepatic glucose metabolism and blood pressure in a rat model of insulin resistance

M. Tian^{1,2}, L. Li^{1,2}, G. Yang³,

¹Key Laboratory of Diagnostic Medicine (Ministry of Education) & Department of Clinical Biochemistry, ²College of Laboratory Medicine, ³Department of Endocrinology, The Second Affiliated Hospital, Chongqing Medical University, China.

Background and aims: Hypertension and diabetes are associated with impaired glucose metabolism and insulin resistance. Chronic activation of the sympathetic nervous system may contribute to either condition. However, the effects of RD on glucose metabolism and insulin sensitivity have also not been systematically examined. The purpose of this study was to investigate the effect of renal sympathetic denervation (RD) on glucose kinetics and insulin signal pathways in high fat diet (HFD) fed rats.

Materials and methods: Mainly, we used 12-week-old male Sprague-Dawley rats as research object. We examined the effects of RD on glucose kinetics and insulin sensitivity in HFD-fed rats with the hyperinsulinemic-euglycemic clamp technique combined with [³-H]glucose and [U-¹⁴C]-lactate as a tracer. We also analyzed the in vivo flux through glucose-6-phosphatase (G6Pase) and the relative contribution of gluconeogenesis and glycogenolysis in RD rats. In addition, Western blotting was used to identify the activities of insulin signaling proteins.

Results: RD in HFD-fed rats markedly decreased blood pressure and hepatic glucose production (HGP). HGP reduction in RD-treated rats was due to an 18.2% decrease for left RD and a 31.9% decrease for bilateral RD in glycogenolysis and a 16.3% decrease for left RD and a 42.8% decrease for bilateral RD in gluconeogenesis. These changes were accompanied by decreased hepatic expression of glucose-6-phosphatase (G6Pase) and phosphoenolpyruvate carboxykinase (PEPCK). Importantly, RD increased phosphorylation of insulin receptors, insulin receptor substrate-1 (IRS-1) and Akt kinase in HFD-fed rats.

Conclusion: These data provide evidence for a mechanism of the RD role and corroborate the notion that RD potentiates hepatic insulin sensitivity.

Distinct contributions of hepatic insulin and IGF-1 signalling in metabolic alterations induced by liver-specific PTEN deletion in mice

D. Portius¹, C. Sobolewski¹, N. Calo¹, J.-L. Pitetti², A.-S. Ay¹, F. Berthou¹, M. Fournier¹, C. Maeder¹, S. Nef², M. Foti¹;

¹Cell Physiology and Metabolism, ²Genetic Medicine and Development, Faculty of Medicine, Geneva, Switzerland.

Background and aims: PTEN is a lipid/protein phosphatase that counteracts insulin and IGF1 signalling in hepatocytes by antagonizing the activity of PI3K. Hepatic Pten deletion in mice triggers the development of steatosis and liver to muscles and adipose tissue crosstalks resulting in increased muscle insulin sensitivity, a reduced fat mass and browning of white adipose tissue. Here, we investigated the specific contributions of hepatic insulin and IGF1 signalling in the deregulated liver metabolism and inter-organ communication triggered by liver-specific Pten deletion in mice.

Materials and methods: Mice with liver-specific deletions of the insulin receptor, the IGF1 receptor, or both, in addition to deletion of Pten were generated and metabolically phenotyped. Histological and molecular analyses were performed on explanted tissues.

Results: Suppression of both insulin receptor (IR) and IGF1 receptor (IGF1R) signalling was required in liver-specific PTEN knockout mice to completely prevent hepatomegaly and steatosis development. Surprisingly, the improved systemic glucose tolerance and impaired hepatic gluconeogenesis induced by PTEN deficiency in hepatocytes were reverted by suppressing hepatic IGF1R signalling. In contrast, the decreased adiposity observed in liver-specific PTEN KO mice was prevented in mice lacking hepatic expression of the IR.

Conclusion: Although they share important similarities, hepatic insulin and IGF-1 signaling exacerbated by PTEN deficiency in hepatocytes distinctly affect liver metabolism and communication with peripheral tissues including muscles and white adipose tissues.

Induction of hepatic de novo lipogenesis impairs hepatic but not muscle insulin sensitivity and associates with increased adiposity

T. Jelenik^{1,2}, K. Kaul^{1,2}, U. Flögel³, G. Séquaris¹, J. Kotzka⁴, G.I. Shulman^{5,6}, J. Szendroedi^{1,7}, M. Roden^{1,7};

¹Institute for Clinical Diabetology, German Diabetes Center, ²German Center for Diabetes Research, ³Department of Molecular Cardiology, Medical Faculty, HHU, ⁴Institute for Biochemistry and Pathobiochemistry, German Diabetes Center, Düsseldorf, Germany, ⁵Department of Internal Medicine, ⁶Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, USA, ⁷Department of Endocrinology and Diabetology, Medical Faculty, HHU, Düsseldorf, Germany.

Background and aims: Non-alcoholic fatty liver (NAFL) has been associated with insulin resistance, however, the causal relationships between NAFL, hepatic and muscle insulin sensitivity as well as underlying mechanisms are yet unclear. The aim of this study was to determine the effects of NAFL on the tissue-specific insulin sensitivity in mice with genetically induced hepatic *de novo* lipogenesis.

Materials and methods: We examined 36-week-old female mice with primary NAFL due to liver-specific overexpression of the sterol regulatory-element binding protein-1c (Alb-SREBP-1c: PRIM; n=7-8) and compared to wild-type C57BL/6 controls (CON; n=6-7). All mice were maintained on chow diet. Intracellular lipids and body fat distribution were assessed with proton magnetic resonance spectroscopy. Fatty acid composition of ceramides and diacylglycerols (DAG) was analyzed with HPLC-MS. Insulin sensitivity was measured with hyperinsulinemic-euglycemic clamp. Protein expression was assessed by western blot and gene expression by qRT-PCR. Redox potential in serum and hydrogen peroxide production in tissues were assessed to estimate oxidative stress. Data were statistically analysed by one-way ANOVA with Tukey post-hoc.

Results: Body weight (BW) was unchanged in PRIM vs. CON mice, while visceral and subcutaneous fat depots were enlarged by 225% (p<0.001) and 275% (p<0.001), respectively. Liver weight to BW ratio was unchanged, however, hepatic lipid content was increased by 87% (p<0.01) and expression of fatty acid synthase (fas) by 217% (p<0.001) in PRIM mice. While total ceramides and DAG were unchanged, the cytosolic DAG containing two oleic fatty acids (C 18:1) were increased by 61% (p<0.05) in the liver of PRIM mice. Insulin suppression of hepatic glucose production was decreased by 43% in PRIM mice (p<0.01). These results were in accordance with 63% lower tyrosine phosphorylation of IRS (pIRS2-Tyr; p<0.001) and lack of insulin stimulation of protein kinase B (Akt) in the liver of PRIM mice. No differences in serum redox potential and hydrogen peroxide production from the liver were observed in the PRIM mice. Intramyocellular lipid content of the soleus and tibialis muscles as well as ceramide and DAG levels were similar to CON mice. Furthermore, insulin-stimulated glucose disposal (Rd) as well as translocation of GLUT4 remained unimpaired in PRIM mice. No changes in muscle hydrogen peroxide production were observed.

Conclusion: Increased hepatic *de novo* lipogenesis *per se* leads to hepatic insulin resistance, even in the absence of obesity. This associates with increased accumulation of specific DAG species containing two oleic fatty acids. Furthermore, *de novo* lipogenesis does not necessarily result in impaired muscle insulin sensitivity, potentially due to increased storage of inert lipids in adipose tissue.

Up-regulation of selenoprotein P, a diabetes-associated hepatokine, and HIP/PAP, a mitogenic factor for the liver, in hepatocytes by intermittent hypoxia

H. Ota¹, A. Itaya-Hironaka², A. Yamauchi², S. Sakuramoto-Tsushima², T. Fujimura², H. Tsujinaka², K. Tomoda¹, M. Yoshikawa¹, H. Kimura¹, S. Takasawa²;

¹Second Department of Internal Medicine, ²Department of Biochemistry, Nara Medical University, Kashihara, Japan.

Background and aims: Sleep apnea syndrome (SAS) is characterized by recurrent episodes of oxygen desaturation during sleep, the development of daytime sleepiness, and deterioration in the quality of life. Accumulating evidence suggests that SAS is associated with glucose intolerance and insulin resistance independently age, gender, smoking status, body mass index, and waist circumference. The progression to type 2 diabetes is dependent on the development of glucose intolerance and insulin resistance. However the direct effects of intermittent hypoxia (IH), a hallmark of SAS, on insulin resistance have obscured. Recently, several proteins that are exclusively or predominantly secreted from the liver are known to directly affect glucose and lipid metabolism and are named as hepatokines. In the present study, using rat and human hepatocytes, we investigated the direct effect of IH on gene expression of hepatokines.

Materials and methods: Human JHH5, JHH7, and rat H4IIE hepatocytes were exposed either to 64 cycles/24 h of IH (5 min hypoxia (1% O₂)/10 min normoxia (21% O₂)), mimicking hepatocytes of SAS patients, or normoxia for 24 h. After the treatment, mRNA levels of *selenoprotein P*, *fibroblast growth factor (FGF) 21*, *alpha2-HS glycoprotein (AHSG)*, *angiopoietin-like protein (ANGPTL) 6*, *sex hormone-binding globulin (SHBG)*, *leukocyte cell-derived chemotaxin (LECT) 2*, *Lipasin*, which are diabetes-associated hepatokines, and *regenerating gene (Reg)* family genes, were measured by real-time RT-PCR. The concentrations of selenoprotein P in the culture medium were also measured by an ELISA kit.

Results: The mRNA levels of *selenoprotein P* were significantly increased in IH-treated H4IIE (1.31 fold vs normoxia, $P=0.0057$), JHH5 (2.25 fold, $P=0.0477$), and JHH7 (2.17 fold, $P=0.0027$) cells whereas mRNA levels of *FGF21*, *AHSG*, *ANGPTL6*, *SHBG*, *LECT2* and *Lipasin* were not increased by IH. The concentrations of selenoprotein P in the culture medium were significantly increased in all IH-treated hepatocytes (H4IIE (3.33±1.24 vs 6.15±0.545 ng/mL, $P=0.048$), JHH5 (1.57±0.464 vs 11.20±3.09 ng/mL, $P=0.037$), and JHH7 cells (2.24±1.65 vs 8.68±1.92 ng/mL, $P=0.043$)). In addition, mRNA levels of *hepatocarcinoma-intestine-pancreas (HIP)/pancreatitis-associated protein (PAP)* were significantly increased in IH-treated JHH5 ($P=0.0022$) and JHH7 cells ($P=0.0016$) whereas mRNA levels of the other *REG family* members (*REG I alpha*, *REG I beta*, *REG III* and *REG IV*) were not increased by IH.

Conclusion: These results indicate that IH stress up-regulates expression of *selenoprotein P* as well as *HIP/PAP* in hepatocytes. It is quite possible that the cyclic changes of hypoxia-reoxygenation, which occurs in SAS patients, up-regulate *HIP/PAP* to proliferate hepatocytes and selenoprotein P, accelerating insulin resistance in SAS patients.

The novel TRPV1 antagonist, AZV1, improves insulin sensitivity in ob/ob mice

M. Fritsch Fredin, A. Kjellstedt, D.M. Smith, N. Oakes; CVMD, Bioscience, AstraZeneca R&D Mölndal, Sweden.

Background and aims: Transient receptor potential cation channel subfamily V member 1 (TRPV1) is a ligand gated non-selective cation channel and the receptor for capsaicin on primary sensory nerves. Capsaicin treatment, which ablates these sensory nerves, has been shown to increase insulin secretion and improve insulin sensitivity in animal models. Functional TRPV1 antagonism might have an equivalent effect. AZV1 is a novel TRPV1 antagonist originally developed as an approach to suppress nociceptive pain (IC₅₀ of ~100 nM in cells overexpressing rodent TRPV1). The aim of this study was to test the ability of AZV1 to ameliorate aspects of the metabolic syndrome (diabetes, insulin resistance and dyslipidemia) in the ob/ob mouse.

Materials and methods: Nine week old male ob/ob mice on a C57BL/6 background (B6.V-Lepob/OlaHsd) were orally gavaged daily for 12 days with either vehicle or the TRPV1 antagonist at 30 mg/kg/day. Body weight and food intake were recorded. At termination, blood was collected under anaesthesia, 3 h following final dosing for the measurement of AZV1 content, plasma glucose, insulin, fructosamine and triglycerides (TG). In addition, liver TG content was determined.

Results: AZV1 was well tolerated with no apparent reductions of food intake or body weight gain over the dosing period. The AZV1 plasma concentration achieved 3 h following the final dosing was approximately 6-fold the in vitro potency consistent with robust TRPV1 antagonism. AZV1 treatment lowered plasma glucose and fructosamine levels compared to controls (20.7±2.1 to 13.0±0.6 and 95.0±2.5 to 76.0±6.8, $p<0.01$, t-test), consistent with a substantial treatment induced reduction in average diurnal blood glucose levels. This effect was achieved without any significant alteration in the 3 h fasted plasma insulin levels, indicating a treatment induced increase in glucose metabolic insulin sensitivity. AZV1 had no apparent effect on fasting plasma FFA, TG or liver TG content.

Conclusion: In conclusion, AZV1 was well tolerated and exerted a substantial antidiabetic action in the ob/ob mouse. Our data suggests that the improvement in glucose control was at least partially mediated by an enhancement in insulin sensitivity.

Insulin resistance impairs human liver progenitor cell function in vitro: Consequences for liver injury and tumorigenesis in metabolic disease and type 2 diabetes?

L.A. Noon¹, F. Manzano Núñez¹, C. Acosta Umanzor¹, A. Leal Tassias¹, A. Corlu², D.J. Burks¹;

¹Metabolic growth signals and regenerative medicine, Centro de Investigacion Principe Felipe (CIPF), Valencia, Spain, ²Foie, Métabolisme et Cancer, Inserm UMR 991, Rennes, France.

Background and aims: Insulin promotes liver growth and the proliferation of hepatocytes following injury, whereas insulin resistance is associated with chronic liver damage and the increased risk of hepatocellular carcinoma. However, the precise effects of aberrant insulin signalling on regenerative processes in the liver remain unclear. In this study, we set out to explore the role of insulin signalling in *de novo* human hepatogenesis by modelling insulin resistance during the differentiation of bipotent liver progenitor cells using: (1) hepatoma derived HepaRG progenitor cells and (2) hepatoblast-like cells derived from pluripotent human embryonic stem cells (hESCs).

Materials and methods: Insulin resistance was modelled by stable knockdown of the insulin receptor (IR-beta), IRS1 and IRS2 using shRNA-lentivirus. Enhanced insulin sensitivity was conferred by

overexpression of lentiviral mouse (m)IRS2, whereas the direct effects of insulin were assessed by inclusion/exclusion of supplemented insulin (0.88 μ M) in the differentiation medium. High-content “IN Cell” cytometry was used to quantify relevant aspects of hepatocyte differentiation.

Results: Insulin was required for the differentiation of bipotent human liver progenitor cells to hepatocytes as well as for the cell-specific proliferation of hepatocyte precursors expressing albumin and ApoA2 within the cultures, whereas insulin resistance, induced by knockdown of either IR-beta, IRS1 or IRS2, significantly blocked differentiation without diminishing the proliferation of undifferentiated cells. Conversely, overexpression of mIRS2, which mimicked hyperinsulinaemia by increasing insulin/IRS signalling, significantly enhanced the number and percentage of progenitors that differentiated to hepatocyte-like cells, whilst in long-term experiments excessive signalling blocked maturation and promoted steatosis in the differentiating fraction. Finally, we demonstrate that insulin sensitivity is dynamically regulated by IRS expression in a time dependent manner such that dampening of insulin/IRS signalling in immature hepatocytes leads to cell cycle exit, maturation and CYP3A4 expression. Insulin/IRS signalling therefore plays a dual role in promoting de novo hepatogenesis and transient amplification of immature hepatocytes whilst impairing normal maturation and promoting steatosis.

Conclusion: Our results demonstrate that insulin/IRS signalling has pro-hepatogenic actions in both tumour derived HepaRG, as well as non-transformed hESC derived hepatic progenitor cells, thus highlighting a potential role for IRS proteins in both regenerative and tumorigenic mechanisms in the liver. Chronic activation of this pathway, by sustained exogenous IRS expression in the presence of insulin had pathogenic effects in differentiating cells including steatosis, whereas, by limiting differentiation, insulin resistance maintained cells in a progenitor-like state - which if observed *in vivo* could have adverse consequences for regenerative pathways whilst simultaneously perpetuating a more aggressive undifferentiated state in liver cancer stem cells in insulin resistant patients.

Liver glutamate dehydrogenase knockout mice display impaired gluconeogenesis and altered feeding behaviour

M. Karaca, M. Grimaldi, J. Martin, P. Maechler;

Cellular Physiology and Metabolism, University of Geneva, Switzerland.

Background and aims: Glutamate dehydrogenase (GDH, encoded by *Glud1* gene) is mainly expressed in the liver, pancreas, kidney and the brain. In mammals, this enzyme is a homohexamer located in the mitochondrial matrix where it catalyzes the reversible oxidative deamination of glutamate to alpha-ketoglutarate and ammonia. GDH catalyzes the same reaction in every tissue, although direction of the predominant flux might be tissue specific. Moreover, physiological function of GDH varies greatly according to specific organs. GDH is of major importance for ammonia detoxification through nitrogen metabolism and urea synthesis in the liver and kidney. Hepatic GDH is also involved in the metabolism of most amino acids, in particular glutamine and alanine being transported from skeletal muscle during periods of active gluconeogenesis. The importance of GDH activity is witnessed by the severity of disorders where GDH function is inappropriate, such as hyperinsulinemia/hyperammonemia syndrome. Here, we have generated inducible liver-specific GDH knockout mice (Hep*Glud1*^{-/-}) to investigate consequences of the lack of hepatic GDH on metabolic homeostasis in basal and energy challenging conditions.

Materials and methods: The *in vivo* deletion of GDH in hepatocytes was induced at 8 weeks of age by subcutaneous implantation of tamoxifen pellets in *Glud1*^{lox/lox} mice (generated in our laboratory) carrying the Albumin-Cre-ER^{T2} construct (provided by P Chambon). Metabolic

parameters were investigated by *ip* challenges (glucose, pyruvate, glutamine, alanine), monitoring in metabolic cages, EchoMRI and commercially available kits.

Results: Three weeks after *in vivo* induction of recombination by tamoxifen, deletion was successful and specific for the liver in Hep*Glud1*^{-/-} mice (<5% remaining of immunoreactive GDH). We also observed abrogation of GDH enzymatic activity in liver homogenates (-67%, $p < 0.01$). In isolated primary hepatocytes, we measured the half-life of GDH lasting for about 2-3 days. In non-hepatic tissues of Hep*Glud1*^{-/-} mice, GDH expression was fully preserved as revealed by immunoblotting. Immunohistochemical analyses of Hep*Glud1*^{-/-} livers did not show morphological abnormalities. Intra-peritoneal glucose tolerance tests revealed normal glucose homeostasis in Hep*Glud1*^{-/-} mice upon standard conditions and both body weight and fat/lean mass ratio were similar between control and Hep*Glud1*^{-/-} mice. Remarkably, the food intake profile was changed by the absence of liver GDH, knockout animals exhibiting a shift in the circadian rhythm of feeding. Moreover, lipids were favored over carbohydrates as energy fuel in Hep*Glud1*^{-/-} mice. Finally, we tested the gluconeogenic capacity of Hep*Glud1*^{-/-} mice in response to substrates specific for situation of energy imbalance, such as fasting, i.e. glutamine and alanine. Control mice could increase glycemia in response to both glutamine and alanine challenge. However, the alanine response was abrogated in Hep*Glud1*^{-/-} mice, while its deaminated product pyruvate could induce gluconeogenesis.

Conclusion: Liver-specific GDH deletion induced substrate-specific impairment of liver gluconeogenesis, higher lipid consumption, and a shift in the circadian rhythm of feeding. These results highlight the central role of hepatic GDH in energy metabolism.

Phenotyping of the mitochondrial phosphoenolpyruvate carboxykinase (PEPCK) knockout mouse

R. Stark, M.W.Y. Cheung, Z.B. Andrews;

Physiology, Monash University, Melbourne, Australia.

Background and aims: The GTP-dependent enzyme phosphoenolpyruvate carboxykinase (PEPCK) is the key enzyme that provides phosphoenolpyruvate (PEP) for gluconeogenesis (de novo glucose production) and glyceroneogenesis (de novo glycerol production to store free fatty acids in form of triglycerides). Although, there are two isoforms, a cytosolic (PEPCK-C) and a mitochondrial (PEPCK-M) form, most research focused on the function and regulation of PEPCK-C, probably due to its hormonal regulation and the suggested absence of PEPCK-M in rodent metabolism. In contrast to PEPCK-C, in which transcription is strongly inhibited by insulin, PEPCK-M is constitutively expressed and therefore PEP is synthesized according to fuel supply and mitochondrial GTP (mtGTP). Although, previous reports suggest that rodents do not have significant PEPCK-M activity, we aimed to confirm the existence and importance of PEPCK-M in rodent metabolism.

Materials and methods: To assess the role of PEPCK-M in rodent metabolism we created PEPCK-M knockout mice on a C57Bl6 background (PCK2^{-/-}). At the age of 6 weeks we fed mice either a normal chow diet or a high fed diet up to 15 weeks long and performed metabolic tests to assess glucose homeostasis, including glucose tolerance test, insulin tolerance test and measurement of energy expenditure using a controlled animal monitoring system (CLAMS).

Results: There was no difference in body weight gain for PCK2^{-/-} on a normal chow diets and high fat diet compared to wild-type animals (wt). PCK2^{-/-} mice on a normal chow diet had higher fasting blood glucose levels (9.33±0.29 mmol/l versus 7.97±0.31 mmol/l; $P = 0.0031$) but showed normal glucose tolerance. After 4 weeks on a high fat diet PCK2^{-/-} mice showed glucose intolerance, measured by glucose and insulin tolerance test (GTT-area under the curve 1796±80.14 versus

1444.46±82.64; ITT-area under the curve 913.35±163.97 versus 607.91±61.8). The difference in glucose intolerance disappeared with increase of age. Thus, we targeted further experiments to investigate why knock-out mice are prone to become glucose intolerant. Interestingly, we noticed higher heat production and activity with PCK2^{-/-} mice on a normal chow diet using CLAMS. However, PCK2^{-/-} mice on high fat diet showed no difference in heat production or activity but had significant lower energy expenditure.

Conclusion: Despite previous reports that deletion of PCK2 would be insignificant, we confirm that PCK2 does have a role in rodent glucose metabolism and PCK2^{-/-} mice on a high fat diet are prone to develop glucose intolerance.

The role of TBC1D1 and TBC1D4 in contraction-induced glucose uptake in mouse skeletal muscle

C. de Wendt^{1,2}, A. Chadt^{1,2}, J. Löffing³, D. Löffing-Cueni³, H.-G. Joost⁴, H. Al-Hasani^{1,2},

¹Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center (DDZ), Duesseldorf, ²German Center for Diabetes Research (DZD e.V.), Neuherberg, Germany, ³Institute of Anatomy, University of Zurich, Switzerland, ⁴German Institute of Human Nutrition Potsdam Rehbruecke (DIfE), Nuthetal, Germany.

Background and aims: The RabGTPase-activating proteins TBC1D1 and TBC1D4 (AS160) are key players in AKT- and AMP-dependent protein kinase (AMPK) regulated glucose metabolism. The aim of this study is to analyze the contribution of these two homologous proteins to the contraction-mediated glucose uptake and metabolism in skeletal muscle.

Materials and methods: Tbc1d1-deficient mice (RCS.B6.SJL-Nob1.10) were crossbred with conventional Tbc1d4 knockout mice to yield double-deficient mice (D1/4KO) on a C57BL/6J background. *Ex vivo* muscle contraction of male 12-16 wk old knockout mice and wildtype controls (WT) was conducted using isolated *Extensor digitorum longus* (EDL) and *Soleus* muscles in a myograph chamber. Contraction force and time for half-capacity were measured. Subsequently, contraction- and insulin-induced ³H-2-deoxyglucose uptake and glycogen levels were determined.

Results: We could previously demonstrate that D1/4 knockout muscles show substantially reduced GLUT4 protein abundance in *EDL* and *Soleus* muscle (~50% of WT). Consistently, contraction-induced glucose uptake was similarly reduced in both, glycolytic *EDL* and oxidative *Soleus* muscle from D1/4KO mice (WT vs. D1/4KO; *EDL*: 4.45±0.25 vs. 2.00±0.14; p<0.001 and *Soleus*: 4.14±0.32 vs. 2.86±0.26 nmol/mg/20 min; p<0.05). Combined stimulation of the muscles with *ex vivo* contraction and insulin further increased glucose uptake in wildtype controls. In skeletal muscle from D1/4KO mice this effect was blunted (Contr vs. Ins+Contr; *EDL*, WT: 11.24±0.81 vs. 14.45±0.731, p<0.05; D1/4KO: 8.02±0.66 vs. 8.48±1.08 and *Soleus*, WT: 16.83±1.05 vs. 21.76±1.45, p<0.05; D1/4KO: 12.71±1.40 vs. 13.57±2.01 nmol/mg/20 min). Moreover, contraction force and time for half-capacity were unchanged between the genotypes. Glycogen levels were increased in skeletal muscle of D1/4KO mice (WT vs. D1/4KO: 1.53±0.30 vs. 2.74±0.31 µg/mg; p<0.05) whereas liver showed decreased glycogen content (WT vs. D1/4KO: 9.35±1.50 vs. 3.07±0.44 µg/mg; p<0.001).

Conclusion: Contraction-induced glucose uptake is severely reduced but not completely eliminated in *EDL* and *Soleus* muscle from D1/4KO mice, suggesting that a TBC1D-independent pathway also contributes to contraction-mediated GLUT4 translocation. Elevated glycogen levels may enable muscles of D1/4KO mice to develop the same contraction forces and times for half-capacity as wildtype controls.

604

Uncoupling protein 1 is required for fibroblast growth factor 21 mediated improvements in glucose tolerance but is dispensable for body weight loss in diet-induced obese mice

M.M. Kwon, S. O'Dwyer, R.K. Baker, T.J. Kieffer;

Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada.

Background and aims: Fibroblast growth factor 21 (FGF21) has emerged as a metabolic regulator with therapeutic potential for the treatment of diabetes. Administration of FGF21 to rodent models of type 2

diabetes reduces body weight and improves lipid and glucose homeostasis. FGF21 treatment also increases uncoupling protein 1 (*Ucp1*) mRNA and protein levels in brown and white adipose tissues. We sought to determine whether the anti-diabetic and anti-obesity effects of FGF21 therapy require UCPI.

Materials and methods: Mice with a genetic deletion of *Ucp1* (*Ucp1*^{-/-}) and wildtype controls (*Ucp1*^{+/+}) were fed either a low-fat diet or rendered obese with high-fat diet feeding. Next, we administered a vehicle (controls) or plasmid encoding the human *FGF21* gene by hydrodynamic delivery to high-fat fed mice and body weight and fasting blood glucose levels were tracked for 4 months. In addition, we performed glucose tolerance tests (days 6 and 22) and an insulin sensitivity test (day 14).

Results: High-fat diet resulted in excess body weight gain in both *Ucp1*^{+/+} and *Ucp1*^{-/-} mice. Hydrodynamic delivery of the human *FGF21* gene increased plasma human FGF21 to supraphysiological levels by day 3 compared to vehicle controls (42.6±7.8 ng/ml *Ucp1*^{+/+}, 51.2±12.7 ng/ml *Ucp1*^{-/-}, <0.05 ng/ml in both vehicle groups). On day 30, FGF21 treated *Ucp1*^{+/+} and *Ucp1*^{-/-} mice lost comparable body weight (-19.6±8.7% and -19.5±5.2%) whereas control *Ucp1*^{+/+} and *Ucp1*^{-/-} mice gained weight (9.4±1.4% and 4.8±1.1%). Despite maintenance of supraphysiological plasma human FGF21 levels, body weight reducing effects of FGF21 therapy waned in both *Ucp1*^{+/+} and *Ucp1*^{-/-} mice between days 22 and 30, and body weights returned to near pre-treatment values in most mice by day 95. FGF21 treated *Ucp1*^{+/+} mice had improved glucose tolerance at day 6 compared to vehicle (AUC 446±63 mM and 1253±31 mM, p<0.05), even beyond that of low-fat diet-fed *Ucp1*^{+/+} mice (AUC 713.4±61 mM, p<0.05). In contrast, FGF21 treatment did not improve glucose tolerance relative to vehicle in *Ucp1*^{-/-} mice (AUC 2174±37 mM vs 1892±174 mM). Similarly, glucose tolerance was also improved at day 22 with FGF21 treatment relative to vehicle in *Ucp1*^{+/+} mice (AUC 550±54 vs 1574±123, p<0.05) but not in *Ucp1*^{-/-} mice (AUC 1246±108 vs 1329±86). Glucose stimulated insulin secretion at 15 minutes post-glucose delivery in FGF21 treated *Ucp1*^{+/+} mice tended to be higher than vehicle on days 6 (2.8±0.8 fold vs 1.7±0.05 fold, p=0.1) and 22 (2.9±0.9 fold vs 1.9±0.3 fold, p=0.4). Similarly, FGF21 treated *Ucp1*^{-/-} mice had improved glucose stimulated insulin secretion at 15 minutes post-glucose delivery compared to vehicle on days 6 (5.2±1.9 fold vs 1.9±0.1 fold, p<0.05) and 22 (3.6±0.4 fold vs 1.9±0.2 fold, p<0.05). FGF21 treated *Ucp1*^{+/+} and *Ucp1*^{-/-} mice had improved insulin sensitivity compared to vehicle, and the degree of blood glucose lowering by insulin was similar between FGF21 treated *Ucp1*^{+/+} and *Ucp1*^{-/-} mice (AUC 3778±132 and 4006±581).

Conclusion: Genetic ablation of UCPI does not prevent FGF21 mediated lowering of body weight but prevents improvements in glucose tolerance despite improvements in glucose stimulated insulin secretion and insulin sensitivity by FGF21 therapy. These data suggest that UCPI dependent thermogenesis in brown or white adipose tissue is not required for body weight reduction but required for improvements in glucose tolerance by FGF21 therapy.

Validation of the intraperitoneal insulin tolerance test for the measurement of insulin sensitivity in mice

R. Codella¹, D. Gabellini², L. Luzi¹, A. Caumo¹;

¹Department of Biomedical Sciences for Health, University of Milan, ²Diabetes Research Institute, San Raffaele Scientific Institute, Milan, Italy.

Background and aims: Mouse models are helpful in clarifying the pathophysiological mechanisms by which insulin resistance contributes to the development of obesity and diabetes. Thus, the ability to accurately and easily quantify insulin resistance in mice is of interest. The reference standard for measuring insulin sensitivity is the glucose clamp, but

simpler methods previously developed in humans are frequently adopted in mouse studies. Here, we focused on the intraperitoneal insulin sensitivity test (IPIST). The domain of validity of the insulin sensitivity index derived from IPIST is unknown since no direct validation against the clamp is available in mice. Aim of this study was to compare the indices of insulin sensitivity derived from IPIST and the clamp in a group of wild-type mice.

Materials and methods: Six CB57BL/6 12-week old mice underwent the IPIST first, and the euglycemic clamp two weeks later. In the IPIST, after a 30-min stabilization period, a bolus of human insulin (0.5 U/kg) was administered by an intraperitoneal injection at t=0. Blood samples (~5 µl) for the determination of glucose concentration were collected at 0, 5, 10, 15, 30, 60, 90, 120 min. The IPIST-based index of insulin sensitivity, SI(IPIST), was calculated as the slope of the regression line between the logarithm of glucose concentration vs. time in the interval 0-15 min (i.e., when the linearity hypothesis was tenable). In the hyperinsulinemic-euglycemic clamp, after a 30-min stabilization period, a primed-continuous infusion of human insulin (2.5 mU/kg/min) was begun at t=0 and maintained constant for 120 min. Concurrently, 20% glucose was infused at a variable rate to maintain glucose at basal concentration. The clamp-based index of insulin sensitivity, ISI(clamp), was calculated as the ratio between the levels of the glucose infusion rate and insulin concentration measured at the end of the clamp. The relationship SI(IPIST) vs. ISI(clamp) was investigated by linear regression and the coefficient of determination, R², was evaluated to assess the goodness of the fit. Results were expressed as Mean ± SD and the level of statistical significance was 0.05.

Results: During IPIST, the glucose decay curve achieved a nadir (69.2±14.4 mg/dl) at 60 min (Figure, left panel). At the end of the clamp, insulin concentration was 50.3±2.0 µU/ml. SI(IPIST) was 3.36±0.95 10⁻² mg/dl per min. ISI(clamp) was 10.41±1.20 10⁻¹ mg/kg min per µU/ml. The association between the two indices was excellent and R² was 0.96, p=0.001 (Figure, right panel).

Conclusion: IPIST is simple and calculation of SI(IPIST) from glucose data collected during the initial 15 min of the test is straightforward. The findings of this preliminary report are encouraging since SI(IPIST) resulted extremely well correlated with ISI(clamp). If confirmed in a larger sample of mice, IPIST may constitute a cost-effective and validated approach to measure insulin sensitivity in mice.

Acyl-carnitines induce insulin resistance in high fat diet-fed db/db mice

M. Dambrova^{1,2}, M. Makrecka-Kuka^{1,2}, K. Volska¹, E. Sevostjanovs¹, I. Konrade², E. Liepinsh¹;

¹Latvian Institute of Organic Synthesis, ²Riga Stradins University, Riga, Latvia.

Background and aims: The important pathological consequences of diabetes arise from the detrimental effects induced by fatty acids and their

metabolites. The aim of this study was to test the role of long chain acylcarnitines in the development of insulin resistance. In addition, we tested whether pharmacological decreasing of the content of long chain acylcarnitines represents an effective strategy to improve insulin sensitivity in diabetes.

Materials and methods: In this study acylcarnitine content was measured in plasma and muscles of high fat diet-fed animals, as well as diabetic db/db and control db/L mice in fasted and fed states. Palmitoylcarnitine administration was used to study the detrimental effects of long chain acylcarnitines. To test whether the decreased content of acylcarnitines in skeletal muscle improves insulin sensitivity, we administered a novel compound, 4-[ethyl(dimethyl)ammonio]butanoate (methyl-GBB), which effectively decreases contents acylcarnitines in plasma and muscle.

Results: Pronounced accumulation of long chain acylcarnitines was detected in the fed state of high fat diet-fed and diabetic db/db mice (Fig.A). In addition, even single administration of palmitoylcarnitine induced decrease in 2-deoxy-glucose uptake in skeletal muscles by 47%. Long term administration of palmitoylcarnitine resulted in the insulin resistance equal to high fat diet-induced changes in insulin sensitivity. Methyl-GBB administration both improved glucose utilisation in tissues and insulin sensitivity, and thus significantly reduced blood glucose level in fed and fasted db/db mice (Fig.B).

Conclusion: The reduction of long chain acylcarnitine content represents an effective strategy to improve insulin sensitivity. Methyl-GBB decreases contents of carnitine and acylcarnitine, significantly reduces blood glucose concentration and improves insulin and glucose tolerance in db/db mice.

Figure. Methyl-GBB decreases content of acylcarnitines in muscles (A) and significantly reduces blood glucose concentration (B) in db/db mice. Each value represents the mean \pm SEM of 5-10 animals. *Significantly different from db/db control group (Tukey's test $P < 0.05$).

The roles of heat shock protein 72 in hepatic glucose metabolism in mice model of type 2 diabetes

T. Kondo¹, R. Matsuyama¹, S. Kitano¹, R. Goto¹, K. Ono¹, M. Igata¹, J. Kawashima¹, H. Motoshima¹, T. Matsumura¹, H. Kai², E. Araki¹;

¹Metabolic Medicine, ²Molecular Medicine, Kumamoto University, Japan.

Background and aims: Cell stress, such as endoplasmic reticulum stress or oxidative stress is one of the key mediators in pathophysiology of type 2 diabetes. Molecular chaperone, which modulate protein folding and/or assembly and protect cells from those stresses, may be a favorable target for diabetic treatment. Heat shock protein (HSP) 72 is a major inducible heat shock protein against heat, ultraviolet, heavy metals or infection, and works as a molecular chaperone to protect cells from inflammatory stresses or apoptotic signals. Induction of HSP72 by pharmacologic agent or mild electrical stimulation with heat shock improves glucose intolerance in diabetic model mice. In this study, we investigated glucose metabolism in whole body HSP72 deficient (KO) mice to explore the roles of HSP72 in diabetes.

Materials and methods: Male HSP72 KO mice or control (C) mice were subjected to a high-fat diet (HFD) regimen for 16 weeks. Several metabolic parameters and cellular stress markers were evaluated.

Results: KO mice showed significantly higher body weight after 10 weeks of HFD (KO: 36.9 g v.s. C: 33.4 g). Fasting blood glucose was significantly elevated after 11 weeks of HFD (KO: 143.3 mg/dL v.s. C: 115.5 mg/dL). Random fed blood glucose and food intake were comparable. Upon glucose challenge, blood glucose levels at any time points measured were higher in KO mice. On insulin tolerance test, KO mice exhibited insulin resistant phenotype. Epididymal, mesenteric and retroperitoneal fat masses were all increased in KO. Hepatic steatosis was obvious in KO liver. Upon insulin stimulation from inferior vena cava, phosphorylation of Akt was decreased by approximately 50% in KO liver extracts, with increased activation of c-jun N-terminal kinase. Hepatic gluconeogenesis was not suppressed in KO mice.

Conclusion: In summary, deficiency of HSP72 leads to increased visceral adiposity, hepatic insulin resistance, glucose intolerance and fatty liver. As induction of HSP72 is beneficial to treat diabetes, our observations strongly indicate the abundance of HSP72 is critical in diabetic pathophysiology.

Western diet intervention modulates regulation of IGFBP-1 protein in C57/Bl6 mice

I. Ansurudeen¹, T. Daraio¹, C. Kolonelou², C. Bark¹, K. Brismar¹, I. Valladolid-Acebes¹;

¹Department of Molecular Medicine and Surgery (MMK), ²Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden.

Background and aims: High calorie diet has a negative impact on glucose homeostasis, insulin responsiveness and liver function, especially during the development of adolescence. Growing evidence supports the concept that diet-induced metabolic disturbances lead to impairments both in the peripheral and brain insulin responsiveness, glucose utilization and energy metabolism. However, the mechanism by which diet interventions provokes tissue-specific insulin resistance is unclear. Insulin-like growth factor binding protein-1 (IGFBP-1), produced in the liver, modulates the distribution, bioactivity and bioavailability of the IGF-I and IGF-II proteins. Insulin is the predominant inhibitor of IGFBP-1 secretion under normal conditions. IGFBP-1 is regulated by acute changes in nutrition and cellular stress. Under stress and/or intensive exercise this negative feedback between insulin and IGFBP-1 is lost possibly due to hepatic insulin resistance or due to factors that directly stimulate IGFBP-1. In the current study we explored in mice the effect of short-term intervention with high-fat/high-sucrose diet (Western Diet, WD) during adolescence and its effect in the regulation on IGFBP-1.

Materials and methods: We subjected adolescent 5-week old male and female C57Bl/6CR mice to a 7-week diet intervention with high fat / high sucrose (WD) or regular chow diet (CD) and studied body weight during the diet intervention. After 7 weeks on diet we analyzed the glucagon, insulin, glucose and IGFBP-1 plasma levels during different metabolic conditions (starvation, after sleep phase 7 PM and wake phase 7 AM) and performed intraperitoneal insulin tolerance tests (ipITT) and morphological studies of the liver.

Results: After the diet intervention, we observed that the WD mice had developed overweight, dyslipidemia, hyperglycemia and presented significantly higher serum insulin and glucagon levels as compared to the CD mice. The insulin levels were increased at all the metabolic conditions. The IGFBP-1 fasting levels were decreased in the males but not in the females in the WD mice. Insulin and glucose homeostasis impairments detected in the WD mice were concomitant with a significant increase in IGFBP-1 levels in spite of increased insulin levels both in the sleep phase and wake phase. Furthermore, animals on WD

experienced insulin intolerance in the ipITT together with an evident deterioration of liver morphology.

Conclusion: Altogether these results suggest that high calorie diet can increase the levels of IGFBP-1 independently of circulating insulin. Hepatic insulin resistance as well as increased glucagon may explain the IGFBP-1 induction. These factors may also explain the increase in glucose levels. It is not excluded that the increase in IGFBP-1 secretion is secondary to WD activation of the central nervous system.

Nonteratis in insulin signalling in insulin-sensitive tissues contribute to insulin resistance induced by chronic intermittent hypoxia in rats
M.J. Ribeiro¹, J.F. Sacramento¹, T. Rodrigues², P. Matafome², L.N. Diogo¹, R.M. Seica², M.P. Guarino^{1,3}, S.V. Conde¹;

¹CEDOC, Centro de Estudos de Doenças Crónicas, NOVA Medical School, Faculdade de Ciências Médicas, Universidade Nova de Lisboa, ²Laboratório de Fisiologia, IBIL, Faculdade de Medicina, Universidade de Coimbra, ³UIS-Unidade de Investigação em Saúde- Escola Superior de Saúde de Leiria- Instituto Politécnico de Leiria, Portugal.

Background and aims: Chronic intermittent hypoxia (CIH) and sleep fragmentation are consequences of obstructive sleep apnea (OSA) that is characterized by recurrent obstruction of the upper airways. In last year's several clinical studies have demonstrated that OSA is associated with an increased prevalence of type 2 diabetes and it was recently shown to be a risk for incident in diabetes. In fact, evidence from animal models of CIH, that mimics OSA, shows its association with insulin resistance and dyslipidemia, however, the mechanisms underlying metabolic effects of CIH are still unknown. The aim of the present work was to investigate the effect of CIH on insulin sensitivity, exploring the time frame necessary to induce insulin resistance and the alterations in the insulin signaling pathways in skeletal muscle and adipose tissue.

Materials and methods: Experiments were performed in male Wistar rats (280–440 g). Control animals were maintained in room air atmosphere and CIH rats were submitted for 28 and 35 days during their sleeping period to a CIH paradigm: 5.6 hypoxic (5%O₂) cycles/h, 10.5 h/day. At the end of CIH paradigm the animals were anaesthetized (pentobarbitone 60 mg/Kg) and insulin sensitivity was evaluated by an insulin tolerance test. Mean arterial pressure (MAP), plasma catecholamines (norepinephrine plus epinephrine) levels and adrenal catecholamines content were evaluated. Skeletal muscle and adipose tissue expression were collected to quantify, by western blot, alterations in the expression of proteins involved in insulin signaling pathways.

Results: CIH during 28 and 35 significantly increased MAP. CIH Insulin sensitivity decreased by 20.84 and 35.92% ($p < 0.01$) with 28 and 35 days of CIH, respectively, but not modify fasting glycemia. Plasma catecholamines doubled at 28 days of CIH and more than triple after 35 days of CIH. 35 days of CIH, but not 28, decreased insulin receptor phosphorylation by 54.94% ($p < 0.01$) in skeletal muscle, without altering Glut4 expression. Also, in adipose tissue, 35 days of IH, but not 28, decreased: Akt expression by 36.25 ($p < 0.01$), AKt phosphorylation by 36.09% ($p < 0.05$) and insulin receptor expression by 32.49% ($p < 0.001$).

Conclusion: We have shown that insulin resistance induced by CIH is positively correlated with the period of time of CIH exposure. Also, our results demonstrated that insulin resistance induced by CIH is mediated by alterations in insulin signaling pathways in skeletal muscle and adipose tissue as well as in plasma catecholamines.

Changes in the adenosine / nitric oxide signalling pathways are associated skeletal muscle insulin resistance

C.R.S. Ferreira¹, I.B. Martins¹, B.F. Melo¹, J.F. Sacramento¹, M.P. Guarino², S.V. Conde¹;

Background and aims: Endothelial nitric oxide (NO) production is known to be positively co-related with insulin sensitivity. It is well established that adenosine induces NO release via A₁, A_{2A} and A_{2B} receptors and our group has recently described that adenosine increases insulin sensitivity in vivo through an NO-mediated effect. The aim of the present work was to investigate if adenosine modulates NO production in insulin-sensitive tissues, like the skeletal muscle, the liver and adipose tissue and if an altered interaction between adenosine and NO is present in insulin-resistant states. Additionally, adenosine receptors responsible for NO production in insulin-sensitive tissues were also characterized.

Materials and methods: Experiments were performed in 10–20 weeks Wistar rats (250–450 g). Two groups of rats were used: a high-sucrose diet-group (Hsu, 35% sucrose in drinking water for 28 days) and a control group. The liver, soleus muscle and visceral adipose tissue were dissected and incubated in Tyrode-Bicarbonate solution during 10, 30 and 60 minutes in the absence or in the presence of different concentrations of the following adenosine agonists: Bay-60-6583 (A_{2B} agonist), CPA (A₁ agonist) and CGS-21680 (A_{2A} agonist). Tissues were weighted and homogenized and NO in the homogenate was determined by chemiluminescence.

Results: NO in soleus muscle was 22.86 ± 2.54 nmol/g tissue, 20.06 ± 1.76 nmol/g tissue and 25.79 ± 4.41 nmol/g tissue after 10, 30 and 60 minutes of incubation in the absence of adenosine agonists, respectively. The Hsu diet did not change NO levels either in the liver or in adipose tissue, but in soleus muscle the NO levels were significantly increased by 35.89%, 50.42% and 41.37% when incubated during 10, 30 and 60 minutes, respectively. In control animals: CPA (3 nM) significantly increase NO production in liver by 54.2% and 58.75% after 30 and 60 min of incubation and in soleus muscle by 5.11%, 34.74% and 67.81% after 10, 30 and 60 minutes of incubation; CGS (30 nM) increased by 93.87%, 18.91% and 71.84% in soleus 100.64%, 68.17% and 6.81% and in adipose tissue after 10, 30 and 60 min of incubation respectively, without affecting the liver; and BAY (1 μ M) did not modify NO production in soleus muscle but decreased NO production in the liver by 53.2%, 32.0% and 55.9% after 10, 30 and 60 min of incubation. In Hsu insulin-resistant animals: CPA (30 nM) did not alter soleus muscle NO production; BAY (1 μ M) decreased NO production by 43.6%, 53.6% and 15.2% in the liver and by 47.0%, 37.9% and 46.8% in the soleus muscle after 10, 30 and 60 min of incubation.

Conclusion: In a physiological state adenosine modulates NO production in insulin sensitive tissues via an action on A₁ receptors in soleus muscle, A_{2B} in the liver and A_{2A} in adipose tissue. In Hsu insulin resistant animals, NO production increases only in the soleus muscle and there is a switch between A₁ and A_{2B} receptor in the control of NO production in this tissue. We conclude that an altered interaction between adenosine and NO in soleus muscle is associated with insulin resistant states.

Role of circular dorsal ruffles in the internalisation of the insulin receptorM. Araújo-Correia¹, A. Portelinha¹, D.C. Barral¹, M.P. Macedo^{1,2};¹Centro de Estudos de Doenças Crônicas (CEDOC), NOVA Medical School | Faculdade de Ciências Médicas, Universidade Nova de Lisboa, ²Associação Protectora dos Diabéticos de Portugal - Centro de Educação e Investigação (APDP - ERC), Lisboa, Portugal.

Background and aims: Upon insulin binding, the insulin receptor is rapidly internalized in clathrin-coated pits. After being endocytosed, the clathrin coat disassembles and the activated receptors are concentrated in endosomes to further stimulate pathways that regulate metabolism and mitogenesis. The uncoupling of the insulin-insulin receptor complex leads to signal termination. The receptors can then be degraded, recycled back to the surface or translocated to the nucleus. However, the number of receptors undergoing each pathway, how the cell decides the pathway that receptors take and how many rounds of recycling undergo each receptor before degradation, is currently unknown. The insulin receptor's fate influences peripheral insulin levels, as 50–70% of portal insulin is cleared during the first pass in the liver. Since insulin receptor trafficking is critical for normal development and maintenance of homeostasis, controlling the magnitude and specificity of the cell's response, it is crucial to determine the mechanisms involved in this process, both in physiology and pathophysiology. Our hypothesis is that alterations in the internalization and trafficking of the insulin receptor in hepatocytes impair insulin clearance.
