[1]Instituto de Investigaciones Biomédicas Alberto Sols (CSIC/UAM), Madrid, [2]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas (CIBERdem), ISCIII, Madrid, [3]Centro de Investigaciones Biológicas (CSIC), Madrid, [4]Instituto de Biología y Genética Molecular (CSIC), Universidad de Valladolid, Valladolid, Spain.

Background and aims: Obesity is an important global health problem that results from an imbalance between energy intake and expenditure. Whereas white adipocytes accumulate energy in the form of triglyceride depots, brown adipocytes are responsible for non-shivering thermogenesis, and control energy expenditure. Additionally, BAT is a secretory tissue producing *batokines*, one of which is fibroblast growth factor 21 (FGF21). Classical activation of thermogenesis occurs via noradrenaline (NA) released from the sympathetic nervous system being Tyrosine Hydroxylase (TH) the first enzyme catalyzing catecholamines synthesis. We have examined how *Th*-haploinsufficiency in mice affects the response to the stress induced by cold exposure in BAT, and whether FGF21 plays a role in this process.

Materials and methods: Wild-type and *Th* heterozygous ($Th^{+/-}$) mice were maintained at thermoneutrality (29°C) during one week after that one group from each genotype was exposure to cold (4°C) for 6 h. Catecholamines content in BAT was measured after cold exposure by ELISA. The expression of genes involved in BAT and iWAT activation was analyzed by RT-qPCR and different signaling mediators were studied by Western blot. Lipidomic analysis was performed to identify different lipid species in BAT.

Results: The reduced catecholaminergic response (dopamine and noradrenaline content) found in $Th^{+/-}$ mice did not impair cold adaptation since these mice maintained the induction of uncoupling protein-1 (UCP1) as the wild-type littermates. However, we found elevations in *Prdm16* ($^{**}p < 0.01$) and *Fgf21* ($^{*}p < 0.05$) expression, key genes in BAT activation, in $Th^{+/-}$ mice at thermoneutrality. Both were already increased in e18.5 embryos. Moreover, plasma FGF21 ($^{*}p < 0.05$) and liver expression of *Fgf21* ($^{*}p < 0.05$) were also elevated in $Th^{+/-}$ mice. Since endoplasmic reticulum (ER) stress triggers FGF21 production, we analyzed ER stress markers and found increased CHOP levels as well as IRE1 and JNK phosphorylation in BAT of $Th^{+/-}$ mice at thermoneutrality. Also, increased lipolysis in BAT of $Th^{+/-}$ mice during cold challenge was manifested by elevations in hormone-sensitive lipase (HSL) phosphorylation and diacylglycerol (DAG) and free fatty acids (FFA) content.

Conclusion: Our results suggest the existence of a *Th-Prm16-Fgf21-* axis in BAT under basal conditions that might operate under stress conditions to maintain BAT functionality/homeostasis. Thus, in a situation of *Th* haploinsuficiency, the elevation in *Fgf21*, probably as a result of the subsequent ER stress, together with the elevation in *Prdm16* already detectable before birth might ensure a normal response to cold exposure. This axis might also operate in iWAT. This compensation may be facilitated by the higher content of DAG and increased activity of HSL in BAT from $Th^{+/-}$ mice, yielding more availability of FFAs that ultimately are the fuels for UCP-1 activation and thermogenesis.

Unravelling the molecular mechanisms involved in adaptation of adipose tissue to cold

J. Rodó[1], M. Garcia[2], E. Casana[2], V. Sacristan[1], C. Jambrina[2], S. Muñoz[2], C. Mallol[2], X. Leon[2], S. Darriba[1], I. Grass[1], S. Franckhauser[2], V. Jimenez[2], F. Bosch[2];

[1]Center of Animal Biotechnology and Gene Therapy, Universitat Autònoma de Barcelona, Bellaterrra, [2]Center of Animal Biotechnology and Gene Therapy, Universitat Autònoma de Barcelona and Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Bellaterrra, Spain.

Background and aims: Type 2 diabetes (T2D) and obesity are strongly associated and consitute a major health problem. Novel and safe approaches are needed to prevent and combat the current T2D-obesity epidemic. New therapeutic strategies aiming at increasing metabolic rate thorough enhancement of non-shivering thermogenesis may hold great potential for the future treatment of obesity and T2D. To unravel the molecular mechanisms and factors capable of inducing browning of white adipose tissue (WAT), activation of brown adipose tissue (BAT) and/or improving glucose metabolism we performed an exhaustive, comparative transcriptomic analysis of mRNA and lncRNA isolated from brown and white adipose depots of adult mice exposed to cold.

Materials and methods: Mice were exposed either to cold (4°C) or room temperature for 4 days and RNAs from these tissues were extracted from interscapular BAT (iBAT), inguinal WAT (iWAT), epididymal WAT (eWAT) using specific kits. The expression of mRNAs and lncRNA was analyzed using the Affymetrix GeneChip Mouse Gene 2.1 ST microarray technology in 4 biological replicates. Microarray data was analysed by well-established statistic and bioinformatic tools.

Results: Principal component analysis (PCA) suggested that the gene expression profile of BAT exposed to RT or 4°C did not differ significantly. Similarly, no major differences were also observed in eWAT after cold exposure. However, the gene expression pattern of iWAT after cold exposure resembled that of BAT. Differentially expressed genes and lncRNA were then evaluated in each individual fat pad. Specifically, 243, 247 and 50 genes were upregulated in iBAT, iWAT and eWAT, respectively, whereas 87, 218 and 672 were downregulated in the same tissues. Similar tendency was observed for lncRNA within each tissue. The hierarchical clustering analysis of iBAT, iWAT and eWAT revealed that differentially expressed genes grouped in five different clusters. Functional analysis of this data further demonstrated that iWAT exposed to cold resembled BAT. iWAT also showed the highest number of enriched pathways and gene ontologies with significant statistically differences. Moreover, both pathway enrichment and gene ontology results indicated that major differences were due to metabolism- and mitochondrial-related genes. A second bioinformatic pipeline using several complementary approaches such as logical set relation, pattern matching, gene functional, co-expression and interaction networks analyses, was carried out to unravel novel cold-induced factors potentially capable of improving energy and glucose metabolism. The role of the most robust factors was then tested in mice fed a high fat diet (HFD) after gene transfer using adeno-associated viral (AAV) vectors. These factors were able to decrease body and, white adipose tissue and liver weight and to increase the expression levels of thermogenic genes in adipose tissue.

Conclusion: This study contributes to better understand the molecular mechanisms underlying adaptation of adipose tissue to cold and identifies novel factors able to enhance non-shivering thermogenesis.

Adenosine metabolism is deregulated in brown adipose tissue in diet-induced type 2 diabetes

I.B. Martins, B.F. Melo, C.S. Prego, J.F. Sacramento, S.V. Conde;
CEDOC, NOVA Medical School, Lisbon, Portugal.

Background and aims: Obesity is the major cause of type 2 diabetes (T2D). Brown adipose tissue (BAT) has been described as a potential target to control and treat these metabolic disorders, since is involved in body thermogenesis and energy expenditure. Moreover, BAT activity is inversed correlated with obesity and insulin resistance (IR). Adenosine (Ado) is a purine nucleoside that has been shown to be involved in glucose homeostasis. Ado has an insulin-sensitizer effect and the administration of Ado antagonists, as caffeine, increases IR. Ado is known to be involved in the regulation of lipolysis and inflammation, being expressed in adipose tissue and recently it was shown that Ado activates BAT via A_{2A} receptors. However, the role of Ado in BAT metabolism and dysfunction in metabolic disorders is unclear. Herein, we hypothesize that Ado metabolism is deregulated in BAT and that its amelioration will improve the metabolic profile. Therefore, in the present work we investigated if alterations in Ado metabolism and function in BAT contribute to metabolic dysfunction in T2D.
Materials and methods: Eight weeks male *Wistar* rats were divided in 2 groups: the control group that fed a standard chow, and the high-fat high-sucrose group (HFHSu), a model of T2D, that fed a combined diet (35% sucrose in drinking water and 60% fat chow) for 25 weeks. Animals were anesthetized with pentobarbital (60 mg/kg, i.p) and BAT was collected and weighted. Glucose uptake was evaluated by evaluating the uptake of 2-deoxyglucose (2-DG) into BAT in the presence and in the absence of Ado receptors agonists CPA 30nM (A_1 agonist), CGS-21680 30 nM (A_{2A} agonist) and Bay-606583 1 μM (A_{2B} agonist). For evaluation of Ado content and release, BAT was incubated in vitro, in the presence and/or absence of EHNA (Ado deaminase inhibitor, 25 μM) and NBTI (equilibrative nucleoside transport inhibitor, 5 μM) and Ado in the medium and within the tissue was quantified by HPLC. The expression of A_1, A_{2A} and A_{2B} receptors in BAT was investigated by western-blot as well as the expression of HIF-1α, ENT-1 and CD73. Statistical analysis was performed in GraphPad Prism 6.0 software and data compared using a t-test, One-Way or Two-Way ANOVA with Bonferroni post-tests.
Results: 2-DG uptake in BAT in control conditions (without Ado receptors agonists) was 4.55 ± 0.33 nmol/mg tissue. CPA increased glucose uptake by 33% (6.04 ± 0.30 nmol/mg, $p \leq 0{,}001$), while CGS and Bay decreased glucose uptake by 20% (3.64 ± 0.12 nmol/mg, $p \leq 0.05$) and 32% (3.09 ± 0.20 nmol/mg, $p \leq 0{,}001$), respectively. In HFHsu animals, BAT exhibited an increase by 30% (CTL = 1.79 ± 0.17 g/kg; HFHSu = 2.55 ± 0.14 g/kg). Ado content in BAT in control animals was 1.43 ± 0.21 nmol/g tissue, 1.42 ± 0.27 nmol/g and 1.09 ± 0.27 nmol/g after 10, 30 and 60 min of incubation. HFHSu diet significantly decreased Ado content by 61, 83 and 65% when tissues were incubated during 10, 30 and 60 min, respectively, without altering Ado release. HFHSu diet increased respectively CD73, ENT-1 and A_{2A} receptor expression by 135% ($p \leq 0.001$), 36% ($p \leq 0.05$), and 34% ($p \leq 0.01$), decreased A_{2B} expression by 54% ($p \leq 0.001$) and did not change A_1 expression. HFHsu diet increased BAT HIF-1α expression by 40%.
Conclusion: We conclude that glucose uptake in BAT in control conditions is modulated mainly via A1 receptors. Moreover, we demonstrate that BAT of T2D animals exhibit alterations in Ado metabolism and function suggesting that the reversion of these alterations will contribute to improve metabolic function in T2D.

Characterising the function of the Arl15 gene and its role in the development of metabolic traits

Y. Bai[1,2], Y. Wu[1], L. Bentley[1], R.D. Cox[1];
[1]MRC Harwell Institute, Oxford, [2]Department of Biochemistry, University of Oxford, Oxford, UK.

Background and aims: The *ARL15* human Genome Wide Association (GWA) locus is associated with increased risk of type 2 diabetes, lower plasma adiponectin, higher fasting plasma insulin, sexual dimorphic altered body composition and lower HDL cholesterol. Knocking down *ARL15* in a human β cell line and confluent 3T3-L1 cell line is reported to result in impaired insulin secretion and impaired differentiation, respectively. *ARL15* belongs to the small GTPase ARF family and is predicted to be involved in vesicle trafficking. The aim is to test the *Arl15* gene as a functional candidate underlying the GWAS associated metabolic traits.
Materials and methods: We have used the 3T3-L1 cell line to study the effect of knocking down *Arl15* in pre-adipocytes and during differentiation using siRNAs. Further, post-translational modification of ARL15 and its sub-cellular localisation were studied. Global, adipose tissue and islet specific *Arl15* knockout mouse models were generated to investigate the *in vivo* physiological function of ARL15.
Results: Knocking down *Arl15* in sub-confluent pre-adipocytes increased differentiation as measured by q-PCR of differentiation markers and increased triglyceride content ($P = 0.0098$). *Arl15* RNA levels were significantly reduced compared to control cells for 5 days after silencing (D0 $P < 0.001$, D3 $P < 0.001$, D5 $P < 0.001$). The master regulator of adipogenesis *Pparγ* was up-regulated from Day 5 ($P < 0.001$). *Fasn*, *Fabp4*, *Cebpα*, *Plin1*, *Glut4*, *Lipe* and *AdipoQ* were up-regulated from Day 3 ($P < 0.001$). By over-expressing C-Myc, N-Myc and N-EGFP tagged ARL15 constructs in 3T3-L1 and C2C12, ARL15 was co-localised with the Golgi marker RCAS1. Sub-cellular fractionation also confirmed the localisation of ARL15 in Golgi. Using a resin assisted capture assay, we found that ARL15 was palmitoylated in the Golgi. To study adiponectin secretion, cellular and secreted total adiponectin on Day 7 of differentiation was measured and found to be increased in silenced 3T3-L1 cells. However, Western blotting of non-denatured culture media showed an increase in the higher molecular weight form of adiponectin in silenced cells, indicating a potential role for ARL15 in adiponectin assembly and secretion pathways. *Arl15* homozygous global KO mice exhibit cleft palate and die postnatally. Heterozygous female mice on high fat diet showed lower fasting adiponectin levels at 20 weeks of age ($P = 0.0373$). Decreased body weight ($P = 0.0318$), gWAT ($P = 0.0459$) and BAT ($P = 0.0135$) weight was found post mortem at 32 weeks of age. Isolated islets from heterozygous male mice at 17 weeks of age in a static assay did not show a difference in glucose stimulated insulin secretion. Cohorts of adipose tissue specific KO and pancreatic β cell specific KO mice are being generated to investigate adiposity and insulin secretion in *Arl15* homozygotes.
Conclusion: Silencing *Arl15* in pre-adipocytes leads to increased adipogenesis *in vitro* and may alter adiponectin assembly and secretion. ARL15 is palmitoylated and localised to Golgi and we plan to investigate its role in protein trafficking. In the mouse, ARL15 is essential for normal palate development and for postnatal viability. Further, reduction of *Arl15* in heterozygous female mice altered plasma adiponectin levels and body weight and composition. Future experiments will focus on the physiological effects of tissue specific homozygous deletion of *Arl15.*

Suppression of hepatic VLDL production after weight loss is associated with the recovery of beta cell function in type 2 diabetes

A. Al-Mrabeh[1], S.V. Zhyzhneuskaya[1], C. Peters[1], A.C. Barnes[1], B.S. Aribisala[1], K.G. Hollingsworth[1], N. Sattar[2], M.E.J. Lean[2], R. Taylor[1];
[1]Newcastle University, Newcastle upon Tyne, [2]University of Glasgow, Glasgow, UK.

Background and aims: Overproduction of hepatic very low density lipoprotein (VLDL) is a characteristic of type 2 diabetes. This is driven mainly by the VLDL1 subclass with its higher triglyceride content. The Diabetes Remission Clinical Trial (DiRECT) has demonstrated reversal of diabetes in 46% of participants at 12 months. Previous work has indicated that this may be a consequence of decreased systemic delivery of triglyceride from the liver. DiRECT allows examination of the relationship between change in hepatic VLDL1-TG production and insulin secretion.
Materials and methods: The Tyneside sub-group of DiRECT underwent detailed metabolic tests. 64 participants (type 2 diabetes <6 years duration) were randomized to receive low calorie diet (825–853 kcal/d). We report here data from the Intervention group on 56 participants who have paired VLDL1-TG data between baseline and after weight loss. A non-isotopic competitive method was employed to measure VLDL1-TG production. Beta cell function was assessed using a Stepped Insulin Secretion Test with Arginine stimulation (SISTA). First phase insulin response was taken as the 6 minute increment in C-peptide concentration.
Results: Caloric restriction induced major weight loss (−15.2 ± 1.0 kg). Within those who achieved remission ($n = 38$), the group who had >10% decrease in VLDL-1 TG production ($n = 25$) achieved substantial increase in first phase insulin response compared with the group that had <10% change in VLDL-1 TG production (0.22 [−010–0.55] nmol/l, vs. 0.12 [−0.27–0.30] nmol/l, $p = 0.02$). In the whole intervention group there was a negative correlation between the change in VLDL-TG production and the first phase insulin response ($r = −0.33$, $p = 0.01$). Total plasma triglyceride and VLDL1-TG decreased only when VLDL1-TG decrease was >10% after weight loss (VLDL-TG: 0.63 ± 0.07 to 0.31 ± 0.05 mmol/l, $p < 0.0001$ vs. 0.82 ± 0.16 to 0.69 ± 0.10 mmol/l, $p = 0.38$; Total triglyceride: 1.8 ± 0.17 to 1.1 ± 0.10 mmol/l, $p < 0.0001$ vs. 2.0 ± 0.23 to 1.84 ± 0.30, $p = 0.52$). Similarly, VLDL1-TG pool decreased in the group with Δ VLDL1-TG >10% (2406.5 ± 301.2 to 944.6 ± 173.4 mg, $p < 0.0001$ vs. 2521.6 ± 541.8 to 1862.0 ± 304.8 mg, $p = 0.19$). The group who achieved >10% change in VLDL-TG production had significantly higher VLDL1-TG production at baseline (609.9 ± 37. vs. 466.2 ± 46.5 mg/kg/day, $p = 0.02$). This group was also characterized by higher fasting plasma glucose and insulin levels (8.9 ± 0.5 vs. 7.0 ± 0.4 mmol/l, $p = 0.007$; and 126.9 ± 13.1 vs. 69.8 ± 9.9 pmol/l, $p = 0.001$, respectively). This was accompanied with a lower baseline C-peptide level (0.01 [−0.30–0.67] nmol/l vs. 0.05 [−0.09–0.57] nmol/l, $p = 0.05$).
Conclusion: Overproduction of VLDL1-TG in early type 2 diabetes is associated with elevated levels of fasting plasma glucose and insulin and a weak acute insulin secretion response. The return of beta cell function after weight loss was associated with a greater suppression in VLDL1-TG production.

Correlates of pentraxin 3 serum concentration in men and women with type 2 diabetes

M. Walus-Miarka[1], M. Kapusta[2], A. Trojak[3], A. Hebda-Szydlo[1], P. Miarka[4], E. Kawalec[3], B. Idzior-Walus[1];
[1]Metabolic Diseases, Jagiellonian University, Krakow, [2]Biochemistry, Jagiellonian University, Krakow, [3]Jagiellonian University, Krakow, [4]Nephrology, Jagiellonian University, Krakow, Poland.

Background and aims: Pentraxin 3 (PTX3) is an essential component of innate immunity and a member of the long pentraxin superfamily, which are soluble proteins induced by various inflammatory stimuli. Several clinical investigations have demonstrated that elevated plasma PTX3 levels are associated with the risk of developing cardiovascular and chronic kidney diseases and retinopathy. PTX3, a marker of inflammation, is produced locally in relevant cells such as endothelial cells, macrophages and granulocytes. There are some data, that PTX3 also possess anti-microbial, anti-inflammatory and cardioprotective properties. **Aim**: In this study we aimed to determine factors associated with PTX3 serum concentrations in men and women with type 2 diabetes (DM2).
Materials and methods: Material included consecutive patients with DM2 from outpatient diabetic clinic. In each patient standardized questionnaire, anthropometric measurements, and laboratory tests, including fasting serum lipids, glucose, glycated hemoglobin HbA1c, PTX3 and apolipoproteins (apo) A1, B 100, B 48 and C3 were performed. Serum fasting lipids concentrations were determined by enzymatic methods using Roche reagents, HbA1c by HPLC, PTX3 by ELISA method using Cloud-Clone corp. reagents. Apolipoproteins A1 and B 100 were determined by immunoturbidimetry, apo C3 and apo B 48 by ELISA. Descriptive statistics and Spearman's/Pearson's correlation analyses were performed.
Results: We examined 116 patients with DM2, 67 men and 49 women. In the whole studied group of patients mean (sd) age was 59.1 (11.07) years, diabetes duration was 9,3 (7,5) years, HbA1c 8.6 (2.3)%, BMI 32.74 (5.79) kg/m^2. Men were characterized by significantly lower age and higher uric acid, creatinine and bilirubin concentrations, and as expected, higher WHR than women. In women LDL-C levels were higher than in men. In men median (IR) values of PTX3 were 4.02 (1.99) and in women 4.53 (3.31) ng/ml (ns).
In men PTX3 concentrations correlated significantly positively with total cholesterol ($r = 0.40$, $p < 0.0012$), triglycerides ($r = 0.51$, $p = 0.001$), apo C3 ($r = 0.48$, $p < 0.001$), apo B 48 ($r = 0.34$, $p = 0.0048$), glucose ($r = 0.35$, p 0.0128), and creatinine ($r = 0.32$, $p = 0.0092$) levels. In women PTX3 correlated significantly with total cholesterol and LDL-C ($r = 0.53$, $p = 0.0002$) and $r = 0.50$, $p = 0.0008$) respectively, and with apo B 100 ($r = 0.41$, $p = 0.0033$). We did not find any correlations between PTX3 and glycemic control, transaminases, GGTP or obesity parameters.
Conclusion: The results of our study indicate that in patients with type 2 diabetes in both sexes there is significant association between PTX3 and total cholesterol, while in men also with triglycerides, apoC3, apo B 48, glucose and creatinine. In women PTX3 correlated with LDL-C and apo B 100, strong cardiovascular risk factors. The results of our study suggest that there are different correlates between inflammation marker PTX3 and examined lipids and apolipoproteins in men and women, what potentially could be of importance in prevention of vascular complications in these patients.

Increased glycerophosphocholine concentration is associated with insulin resistance and hyperglycaemia in skeletal muscle

G.D. Clarke[1], J.A. Vasquez[1], C. Solis[2], M. Abdul-Ghani[2], D. Tripathy[2], R.A. DeFronzo[2];
[1]Radiology, University of Texas Health Science Center at San Antonio, San Antonio, [2]Medicine (Diabetes), University of Texas Health Science Center at San Antonio, San Antonio, USA.

Background and aims: We previously reported, using quantitative phosphorus-31 magnetic resonance spectroscopy (^{31}P-MRS), that phosphocreatine, [PCr], and [ATP] concentrations are lower in skeletal muscle of type 2 diabetic (T2D) versus normal glucose tolerant (NGT) subjects. Reduced PCr also was significantly and inversely correlated with measures of glycemia, i.e. HbA1c and fasting plasma glucose (FPG), but not with indexes of insulin resistance (IR). Increased phosphodiester (PDE)

signals relative to ATP (PDE/ATP) have been associated with reduced mitochondrial activity and insulin resistance (Szendroedi et al, 2011). The PDE signal mainly is due to glycerophosphocholine (GPC), a lipid intermediate involved in membrane homeostasis, skeletal muscle contraction and mitochondrial NAD+/NADH metabolism. In the present study we related *in vivo* [PDE] in NGT and T2D subjects to HbA1c, Matsuda index (MI) of insulin sensitivity, FPG, insulin-mediated rate of glucose disposal (Rd) (insulin clamp) and intramyocellular lipid concentration [IMCL].

Materials and methods: Fourteen NGT (age = 55 ± 11 y, A1c = 5.5 ± 0.3%, BMI = 28.6 ± 3.9 kg/m^2) and 11 T2D (age = 48 ± 12 y, A1c = 8.1 ± 1.3%, BMI = 30.8 ± 5 kg/m^2) subjects received an OGTT to quantitate glucose tolerance status and Matsuda index. On a separate day, subjects were scanned in a 3T MRI system (Siemens Trio) with a dual-tuned ^{1}H-^{31}P TX-RX coil to measure [PCr], [ATP], and [PDE] in resting vastus lateralis (VL) muscle. Roughly one week after the MRS study, subjects returned for a 4-hour euglycemic insulin clamp study. ^{31}P-MRS concentrations were calibrated to an external phosphate standard, as previously described. VL [IMCL] was measured with hydrogen-1 MRS. The AMARES fitting algorithm in jMRUI 5.0 was used for spectral analysis. Student's two-tailed t-test and Pearson's correlation were performed using R with significance set at $p < 0.05$.

Results: [PDE] was increased in T2D vs NGT subjects (3.11 ± 0.82 mM versus 4.04 ± 0.98 mM, $p = 0.02$). PDE/ATP also was significantly increased in T2D (5.35 ± 1.6 versus 3.11 ± 0.82 for NGT, $p = 0.005$) due to the combination of increased [PDE] and reduced [ATP] in skeletal muscle. [PDE] also was correlated negatively with the Matsuda Index of insulin sensitivity ($r = -0.43$, $p = 0.03$) and insulin-mediated Rd ($r = -0.44$, $p = 0.04$) and was positively correlated with HbA1c ($r = 0.57$, $p = 0.003$) and FPG ($r = 0.602$, $p = 0.001$) across all subjects. Increased [PDE] was positively correlated with [IMCL] ($r = 0.64$, $p < 0.005$) across all subjects. This novel observation has not reported previously.

Conclusion: Absolute [PDE] is significantly increased in skeletal muscle of T2D individuals and is closely associated with muscle insulin resistance and poor glycemic control. In mammalian cells, hydrolysis of GPC to glycerol-3-phosphate and choline is mediated by the glycerophosphocholine phosphodiesterase isoform, GDE5. We infer that the buildup of GPC in the skeletal muscle in insulin resistant T2D subjects is linked to a bottleneck in GPC catabolism due to reduced expression of GDE5, consistent with reduced mRNA expression in gastrocnemius muscles of diabetic KK-Ay mice (Okazaki et al, 2010). These results suggest that glycerophosphocholine is a key lipotoxic molecule that contributes to skeletal muscle insulin resistance in T2D individuals.

Acute hyperketonaemia does not reduce glucose or palmitate uptake in abdominal organs or skeletal muscle

E. Søndergaard[1], K.M. Lauritsen[1], N. Møller[1], L.C. Gormsen[2];
[1]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus C, [2]Department of Nuclear Medicine and PET Center, Aarhus University Hospital, Aarhus C, Denmark.

Background and aims: SGLT-2 inhibitors have been shown to prevent cardiovascular disease through mechanisms not fully understood. It has been hypothesized that the cardioprotective effects are mediated through an increase in circulating ketone bodies, which are energy-efficient oxidative fuels due to a lower oxygen consumption compared to glucose and fatty acid oxidation. We have previously shown that infusion of ketone bodies reduces myocardial glucose uptake by 50%, but it is still unknown whether an increase in ketone bodies affect substrate metabolism in other organs. In this study, we performed PET analysis of glucose and lipid metabolism in abdominal organs and skeletal muscle in healthy subjects during a ketone body infusion.

Materials and methods: The study was performed on eight healthy subjects [3 women; age: 60(50–68) years; BMI: 25.5 (21.5–34.6) kg/m^2] as a single-blinded, randomized cross-over study with a ketone study day (0.18 g/kg/hour Na-3-β-hydroxy-butyrate) and a placebo study day (0.9% saline). On both study days, subjects underwent a hyperinsulinemic-euglycaemic clamp (0.3 mIE/kg/min). PET/CT scans were performed dynamically (50 min each) with radiotracers ^{11}C-palmitate (≈280 MBq) and ^{18}F-FDG (≈200 MBq). Volumes of interest (VOI's) were drawn in erector spinae and biceps muscle, kidney, spleen, bone marrow, liver, visceral and subcutaneous fat. Relative substrate uptake rates were then calculated using linear fitting of input vs. tissue activity curves and Patlak or Logan plots as appropriate. Absolute uptake rates were calculated as k-values times substrate concentrations for the Patlak plots. Statistical comparison of organ metabolism during ketone body infusion vs. saline infusion was performed by a paired t-test.

Results: Ketone body infusion did not alter glucose uptake compared to saline infusion in erector spinae muscle (0.03 ± 0.01 vs. 0.03 ± 0.01 mmol/g/min, $p = 0.42$) or biceps muscle (0.05 ± 0.03 vs. 0.09 ± 0.15 mmol/g/min, $p = 0.49$), nor did it affect the volume of distribution (Vd (ml plasma/ml tissue)) in the kidneys (1.22 ± 0.17 vs. 1.40 ± 0.23, $p = 0.11$), spleen (0.80 ± 0.11 vs. 0.92 ± 0.40, $p = 0.30$), liver (1.19 ± 0.13 vs. 1.15 ± 0.14, $p = 0.60$), visceral fat (0.31 ± 0.23 vs. 0.27 ± 0.21, $p = 0.21$) or subcutaneous fat (0.20 ± 0.12 vs. 0.21 ± 0.15, $p = 0.92$). Ketone body infusion significantly increased glucose Vd in bone marrow (0.64 ± 0.08 vs. 0.51 ± 0.12, $p = 0.04$). Absolute palmitate uptake was low due to suppression of lipolysis by the hyperinsulinemic-euglycaemic clamp and was unaffected by ketone infusion in all organs. However, ketone body infusion led to an increased palmitate uptake capacity (Patlak k-values (ml plasma/ml tissue/min)) in erector spinae muscle (0.03 ± 0.01 vs. 0.02 ± 0.00, $p = 0.02$) and bone marrow (0.05 ± 0.01 vs. 0.03 ± 0.01, $p = 0.01$).

Conclusion: Even pronounced acute hyperketonaemia does not reduce glucose or palmitate uptake in abdominal organs or skeletal muscle. This underscores the priority of ketone body utilisation in the heart and brain in preference to other substrates during a state of energy deficiency. In addition, ketone bodies increase bone marrow glucose uptake. We speculate this is due to an increased haematopoiesis, which could contribute to the increased haematocrit values observed during SGLT-2 inhibition.

GlycA and lipoprotein by 1HNMR in subjects with type 2 diabetes, prediabetes and control and the association with clinical and inflammatory factors during a programme of exercise

L. Brugnara[1,2], S. Murillo[1,2], N. Amigò[3], R. Fuentes[3,4], X. Correig[4,2], A. Novials[1,2];
[1]IDIBAPS/Hospital Clínic, Barcelona, [2]CIBERDEM, Barcelona, [3]Biosfer Teslab SL, Reus, [4]Universitat Rovira i Virgili (URV-IISPV), Reus, Spain.

Background and aims: GlycA, a pro-inflammatory glycoprotein biomarker, is elevated in several chronic inflammatory diseases and recently associated with incident type 2 diabetes (T2D), cardiovascular (CV) events and mortality. The implementation of a program of exercise could improve the levels of GlycA, lipoprotein subfractions and clinical parameters in subjects with T2D.

Materials and methods: A total of 34 subjects (11 control [CT], 10 prediabetes [PD] and 13 T2D), between 40–65 years old, sedentary (physical activity <2 times/week), BMI <35, without CV or microvascular complications, were included in the study. The exercise program included 16 weeks of aerobic and strength exercise twice a week. Body fat composition (anthropometric and DXA measurements), physical fitness (1RM [repetition maximum] for strength capacity; VO_2max and Wmax for aerobic capacity) and biochemical analysis were evaluated before and

after the exercise program. Glycoprotein A (GlycA) and lipoprotein subfractions were analyzed by nuclear magnetic resonance (1HNMR) by Biosfer Teslab.

Results: Subjects were 52.2 ± 8.8, 58 ± 10.1 and 58.8 ± 5.8 years old in CT, PD and T2D, respectively. After the exercise program, there were no changes in body weight. However, there was a reduction in body fat composition by DXA in CT (1.6% in total body fat, $p = 0.004$; 5.1% in abdominal fat, $p = 0.007$; 10.4% in visceral fat, $p = 0.012$), and in T2D (2.1% in total body fat, $p = 0.026$; 2.1% in abdominal fat, $p = 0.033$), but not in PD. Also, fitness parameters improved in the three groups: in CT (23.1% in 1RM, $p = 0.005$; 18.8% in VO_2max, $p = 0.019$; 16.2% in Wmax, $p < 0.001$); in PD (13.9% in 1RM, $p = 0.005$; 12.2% in Wmax, $p = 0.007$); and in T2D (19% in 1RM, $p = 0.001$; 25.1% in Wmax, $p = 0.001$). There was a reduction in fasting glycemia in the CT group (from 85.1 ± 10.3 to 79.1 ± 8 mg/dl, $p = 0.043$). No changes in HbA1c, HOMA-IR, inflammatory parameters, lipoprotein subfractions or GlycA were identified in the three groups after exercise. In pre-exercise, the groups CT and T2D presented different results, respectively: GlycA (4.4 ± 0.6 vs 5.4 ± 1.2 A.U., $p = 0.024$), small-LDL-particle (376 ± 53 vs. 446 ± 46 nmol/L, $p = 0.004$), medium-HDL-particle (11.5 ± 2.7 vs. 8.7 ± 1.6 μmol/L, $p = 0.006$), VLDL-size (42.2 ± 0.2 vs. 42 ± 0.2 nm, $p = 0.04$), LDL-size (21.2 ± 0.2 vs. 20.8 nm, $p = 0.002$) and HDL-size (8.3 ± 0.05 vs. 8.2 ± 0.06 nm, $p = 0.011$). GlycA presented a direct correlation ($p < 0.05$, $R > 0.34$) with insulinemia, HOMA-IR, triglycerides, TNFalpha, VLDL-C, VLDL-TG, total-VLDL-particle, medium-VLDL-particle, small-VLDL-particle, small-LDL-particle, and inverse correlation with adiponectin, total-HDL-particle and medium-HDL-particle, but not with clinical variables.

Conclusion: GlycA was associated with several parameters of CV risk. GlycA and a more atherogenic lipoprotein profile were higher in subjects with T2D when compared to controls. The present program of exercise, despite improving fitness and body composition, was not able to improve GlyA, lipoprotein profile or metabolic parameters, indicating that the status of carbohydrate tolerance is more important than the effects of the program of exercise.

Energy metabolism and lipid turnover are altered in superficial subcutaneous adipose tissue of male type 2 diabetes patients

K. Bódis[1,2], J. Lundbom[1,3], T. Jelenik[1,3], D. Markgraf[1,3], A. Strom[1,3], O.-P. Zaharia[1,3], Y. Karusheva[1,3], V. Burkart[1,3], K. Müssig[1,2], M. Ouni[3,4], J.-H. Hwang[1,3], D. Ziegler[1,3], A. Schürmann[3,4], M. Roden[1,2], J. Szendroedi[1,2];

[1]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University, Duesseldorf, [2]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Duesseldorf, [3]German Center for Diabetes Research (DZD), München-Neuherberg, [4]German Institute of Human Nutrition, Potsdam-Rehbrücke, Germany.

Background and aims: Insulin resistant humans are characterized by lower mitochondrial gene expression and lipogenesis in subcutaneous adipose tissue (SAT). Furthermore, human carriers of a hormone sensitive lipase (*HSL)* gene mutation exhibited hepatic steatosis and increased risk for type 2 diabetes (T2D). SAT is composed of deep (DSAT) and superficial layers (SSAT). SSAT was assumed to have protective function in T2D, but sex specific differences have not been studied yet. This study aimed to characterize sex specificity and differences in SSAT between T2D patients and glucose-tolerant humans (CON) by assessment of mitochondrial efficiency, markers of lipogenesis and lipolysis in SSAT.

Materials and methods: We included 20 T2D and compared them to 20 CON of similar sex distribution, age and body mass index (BMI) (6/14 female/male per group; 52 ± 2 vs 54 ± 2 years, 32 ± 1 vs 31 ± 1 kg/m^2). All participants underwent euglycemic-hyperinsulinemic clamp tests to assess insulin sensitivity (M-value) as well as magnetic resonance spectroscopy to assess liver fat content (HCL) and visceral adipose tissue volume (VAT). Ultrasound guided biopsies were performed to obtain targeted samples of SSAT. In SSAT, mitochondrial efficiency from respiratory control ratio (RCR = state 3/state 4) was measured by respirometry. Two markers of lipogenesis were assessed in SSAT: stearic-to-palmitic acid ratio (18:0/16:0) by gas chromatography-mass spectrometry and stearoyl-CoA desaturase (*SCD*) mRNA by PCR. Additionally, lipolysis markers adipocyte triglyceride lipase (*ATGL*) and *HSL* mRNA were assessed by PCR.

Results: In insulin resistant T2D, HCL was 63% ($p < 0.01$) and VAT 22% higher ($p < 0.05$) compared to CON. T2D patients had lower RCR (−19%) and 18:0/16:0 ratios (−17%) as well as lower *SCD* (−50%), *ATGL* (−70%) and *HSL* (−49%) mRNA levels in SSAT (all $p < 0.05$). While also in males these differences were present, in female T2D, only *ATGL* was lower compared to female CON. In female T2D, VAT was 22% lower as well as RCR 37% and *HSL* mRNA 70% higher compared to male T2D patients (all $p < 0.01$).

Conclusion: Lower mitochondrial efficiency, lipogenesis and lipolysis gene expression in SSAT of male, but not female T2D patients suggest inadequate energy metabolism and lipid turnover in SSAT of male patients with T2D.

Dissociation of insulin sensitivity and bioactive lipid content in endurance-trained athletes

D. Pesta[1], E. Anadol-Schmitz[1], S. Gancheva[1], D. Markgraf[1], O.-P. Zaharia[1], H. Katsuyama[1], Y. Kupriyanova[1], J.-H. Hwang[1], D. Zhang[2], G. Shulman[2], M. Roden[1];

[1]German Diabetes Center, Düsseldorf, Germany, [2]Yale University School of Medicine, New Haven, USA.

Background and aims: Increased concentrations of bioactive lipids such as diacylglycerol (DAG) in the cell membrane of skeletal muscle have been associated with insulin resistance due to activation of protein kinase C (PKC) isoforms and subsequent disruption of insulin signaling. This study aimed at testing the hypothesis that cellular localization and molecular species of DAG differently affect insulin action in sedentary and endurance-trained individuals.

Materials and methods: Endurance-trained athletes (ATH; $n = 9$) and sedentary individuals (SED; $n = 12$) with comparable total IMCL, as measured by ^{1}H-magnetic resonance spectroscopy, who underwent spiroergometry and hyperinsulinemic-euglycemic clamps to assess maximal oxidative capacity and insulin sensitivity, respectively were included in this study. In skeletal muscle biopsies, translocation of protein kinase C (PKC) θ and ε were determined by Western blotting and concentrations of DAG were measured using targeted LC-tandem mass spectrometry upon separating fractions of cellular membranes, lipid droplets and cytosol by ultracentrifugation.

Results: Maximal oxidative capacity and insulin sensitivity were 46% and 47% higher in ATH than in SED (both $p < 0.01$), respectively. The membrane:cytosol ratio of PKCθ, which reflects PKCθ activity, was 62% lower in ATH consistent with their increased insulin sensitivity ($p < 0.01$), while PKCε was not different between both groups. In SED, PKCθ activation associated negatively with membrane and lipid-droplet DAG, while PKCε was negatively associated with total sn-1,2 DAG and membrane DAG. In ATH, PKCθ associated negatively with cytosolic and lipid droplet DAG, while PKCε associated negatively with lipid droplet and positively with cytosolic and membrane DAG. Concentrations of DAG in total and membrane (40% and 48%, both $p < 0.01$), but not in lipid droplet

and cytosolic fractions, were higher in ATH. In SED, insulin sensitivity correlated inversely with all stereoselective subspecies of lipid-droplet DAG. On the other hand, cytosolic sn-1,2 (C16:0–C18:2) and sn-1,3 (C18:1–C18:0) DAG correlated positively with insulin sensitivity in ATH.

Conclusion: Differences in the stereo-selectivity and/or sub-compartmentalization of cellular DAG between athletes and insulin resistant sedentary individuals may explain the lower muscle PKCθ activation and in turn higher insulin sensitivity in endurance trained athletes.

Both fructose and glucose contribute substantially to intestinal triglyceride synthesis in vitro

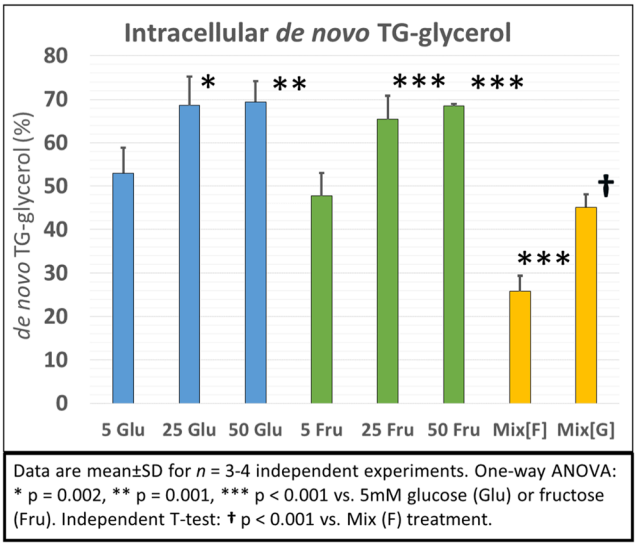
S. Steenson[1], K.G. Jackson[2], A.M. Umpleby[1], F. Shojaee-Moradie[1], N. Jackson[1], J.A. Lovegrove[2], B.A. Fielding[1];
[1]Department of Nutritional Sciences, University of Surrey, Guildford, [2]Department of Food & Nutritional Sciences, University of Reading, Reading, UK.

Background and aims: Fructose consumption has been associated with postprandial hypertriglyceridaemia. The cellular metabolism of fructose is an unregulated process, potentially providing excess three-carbon precursors for several metabolic pathways, including the formation of glycerol (glyceroneogenesis), which may be utilised for triglyceride (TG) synthesis. While the effects of fructose on hepatic TG metabolism have been widely reported, recent evidence suggests that the small intestine may in fact be the major site of fructose metabolism. The present study used Caco-2 cells, a well-characterised intestinal cell line, to determine the concentration dependent effects of fructose, and glucose, on TG-glycerol synthesis.

Materials and methods: Caco-2 cells (passage 49–53) were grown for 21 days on Corning Transwell® supports, ensuring maximal differentiation and TG synthesis capacity. Cells were treated for 96 h with carbohydrate-free media containing either 5, 25 or 50 mmol/l fructose or glucose (5, 25 or 50 Fru/Glu), or an equimolar mixture of 12.5 mmol/l fructose and 12.5 mmol/l glucose ("Mix"). In addition, a 0.5 mmol/l mixture of fatty acids was added, with a composition representing the UK diet. Stable isotope tracers were also added, accounting for 20% of the total glucose/fructose concentration in each treatment, to measure the proportion of TG-glycerol carbons derived from either fructose ($^{13}C_6$-fructose) or glucose ($^{13}C_6$-glucose). Following treatment, TG was extracted from the cells (intracellular) and media (secreted), hydrolysed to obtain the glycerol moiety, and the ^{13}C-enrichment measured via gas chromatography-mass spectrometry.

Results: A substantial proportion of TG-glycerol was derived from both fructose (range 25–69%) and glucose (33–70%) carbons, across all treatment types. Intracellular TG (see figure) contained significantly higher *de novo* TG-glycerol (%) after treatment with 25Fru, 50Fru, 25Glu and 50Glu versus either 5Fru or 5Glu, respectively (all $p \leq 0.002$). The same pattern was observed for secreted TG-glycerol (all $p \leq 0.003$). For the "Mix" treatments containing either fructose (Mix [F]) or glucose (Mix [G]) isotope tracer, Mix [G] yielded a higher percent intracellular ^{13}C-glycerol than for Mix [F] ($p < 0.001$).

Conclusion: The present study further highlights the potential importance of the small intestine in fructose metabolism. Glucose appears to be the preferred substrate for TG-glycerol synthesis within a sugar mixture. However, fructose is also highly utilised by intestinal enterocytes, both for TG directed toward lipoprotein formation and secretion, as well as for storage within intracellular lipid droplets. Whether a similar level of TG-glycerol may be derived from fructose *in vivo*, and its possible implications for post-prandial hypertriglyceridaemia, warrant further study in human subjects.



Data are mean±SD for n = 3-4 independent experiments. One-way ANOVA: * p = 0.002, ** p = 0.001, *** p < 0.001 vs. 5mM glucose (Glu) or fructose (Fru). Independent T-test: † p < 0.001 vs. Mix (F) treatment.

Background and aims: Adipose tissue (AT) expands to accommodate increased energy uptake by initiating proliferation and differentiation of preadipocytes, leading to its hyperplastic cytoarchitecture. Preadipocytes' shape changes dramatically during adipogenesis, in parallel with lipid accumulation and cytoskeletal reorganization. Failure to do so may impact the flexibility to shift between lipid storage and mobilization, leading to impaired metabolism and insulin resistance. Cytoskeletal Transgelin 2 (TAGLN2) was identified in obese AT, being closely associated with AT expandability and inflammation.
Materials and methods: We evaluated the impact of surgery stress *in vivo* and macrophages *in vitro*. Weight loss was chosen as an anti-inflammatory model, so TAGLN2 was analyzed in samples collected before and after bariatric surgery. Associations with inflammatory and metabolic parameters were analyzed in nonobese and obese subjects, in *ex vivo* isolated adipocytes/stromal-vascular cells (SVC), and *in vitro* cultured adipocytes. Causal characterization was assessed by silencing *Tagln2* in preadipocytes, over-expression in AT (aP2-Tagln2 mice), and the study of genetic variants modulating *TAGLN2* gene expression.
Results: *TAGLN2* was increased in obese AT in humans and mice, up-regulated with inflammation, and appropriately decreased after weight loss. *Tagln2* knockdown in preadipocytes prevented adipogenesis, mitochondrial biogenesis and mitosis, and was associated with down-regulation of genes related to growth, biosynthetic and oxidation-reduction processes in differentiated adipocytes. Female transgenic mice over-expressing *Tagln2* in fat exhibited enlarged AT and adipocyte hypertrophy not associated with insulin resistance. Conversely, male transgenic mice failed to expand their AT and showed impaired distribution of small/large adipocytes, in association with decreased glucose tolerance. The relevance of this phenotype was outlined by the existence of common variants within *TAGLN2* gene associated with increased expression and impaired AT expansion in men, as evidence by two independent cohorts and protection from ischemic heart disease in public datasets.
Conclusion: Current findings highlight the contribution of cytoskeletal *TAGLN2* regulation to AT expansion and protection from cardiometabolic disease in a sex-dependent manner.

Betatrophin predicts cardiovascular events independently from the presence of type 2 diabetes and coronary artery disease

A. Leiherer[1,2], A. Muendlein[1,2], K. Geiger[1], C.H. Saely[3,1], E.-M. Brandtner[1], J. Ebner[1], B. Larcher[3,1], A. Mader[3,1], P. Fraunberger[4,2], H. Drexel[1,5];
[1]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [2]Private University in the Principality of Liechtenstein, Triesen, Liechtenstein, [3]Medicine I, Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [4]Medical Central Laboratories Feldkirch, Feldkirch, Austria, [5]Division of Angiology, Swiss Cardiovascular Center, University Hospital Berne, Berne, Switzerland.

Background and aims: Betatrophin, also known as ANGPTL8 or lipasin is a nutritionally-regulated protein secreted by the liver and adipose tissue. It is associated with type 2 diabetes mellitus (T2DM) and lipid metabolism. Whether betatrophin is associated with the risk for cardiovascular events is unknown and is addressed in the present study.
Materials and methods: We measured betatrophin in 553 patients undergoing coronary angiography for the evaluation of established or suspected stable coronary artery disease (CAD) and prospectively recorded cardiovascular events in these patients during a follow-up period of up to 8 years.
Results: During follow-up, 301 cardiovascular events occurred. The incidence of cardiovascular events was significantly higher in patients with T2DM ($n = 161$) than in those who did not have diabetes (47.2% vs. 34.4%; $p = 0.005$). Betatrophin was significantly and inversely associated with cardiovascular events both univariately (HR 0.64 [95%CI 0.47–0.87], $p = 0.004$) and after full adjustment including T2DM and baseline CAD (HR 0.55 [95%CI 0.40–0.76], $p < 0.001$). The inclusion of betatrophin to a basic prediction model for the cardiovascular event risk significantly increased model performance (NRI = 0.188, $p < 0.01$).
Conclusion: In conclusion, this study for the first time shows that betatrophin predicts cardiovascular events independently from conventional risk factors including the presence of T2DM.

Dysregulated urocortin 3 expression and its modulation with physical exercise in adult humans with obesity and diabetes

S.A. Kavalakatt, A. Khadir, A. Tiss;
Research Division, Dasman Diabetes Institute, Dasman, Kuwait.

Background and aims: Obesity and Type 2 diabetes (T2D) are characterized by inflammation, disturbed insulin secretion and insulin resistance due to reduced insulin action in target tissues such as muscle, liver and adipose tissue. Urocortin3 (Ucn3) is a molecular marker for mature pancreatic β-cells that regulates glucose-stimulated insulin secretion. However, their release and expression by human adipose tissue and role in obesity and diabetes is still not well investigated. The aim of this study was to assess the effects of obesity and diabetes on circulating Ucn3 and its expression in adipose tissue. Also, to further assess if these levels are affected by physical exercise.
Materials and methods: Adult male and female human subjects consisting of 41 non-diabetic normal-weight ($20 \leq BMI < 25$ kg/m^2) and 205 overweight ($25 \leq BMI < 40$ kg/m^2, 107 non-diabetic and 98 diabetic) were enrolled in the study followed by a 3-month moderate exercise program. Subcutaneous adipose tissue (SAT) biopsies and venous peripheral blood were collected before and after exercise along with anthropometric measurements and blood biochemistry analysis. Plasma levels of inflammatory and metabolic markers were measured using Bioplex-200 system. The expression and circulating levels of Ucn3 were assessed using ELISA, RT-PCR, western blot and confocal microscopy.
Results: Ucn3 release was significantly decreased in non-diabetic overweight when compared to normal weight subjects and increased in

diabetic compared to non-diabetic overweight. On the contrary, in SAT, Ucn3 expression was increased in non-diabetic and decreased with diabetic overweight. Our 3-month supervised physical exercise protocol, increased the levels of circulating Ucn3 in non-diabetic overweight concomitantly with reduced insulin levels. Furthermore, significant decrease of Ucn3 levels was observed in the SAT of both diabetic and non-diabetic overweight subjects. In non-diabetic subjects Ucn3 levels negatively correlated with insulin, C-peptide and HOMA1. Interestingly, Ucn3 circulating levels strongly correlated with Visfatin in both diabetic and non-diabetic subjects.

Conclusion: Expression of Ucn3, representing the feedback loop linking insulin secretion and glucose, are disrupted not only in established diabetic subjects but also in overweight non-diabetic where glucose tolerance is only minimally impaired. Also, following physical exercise insulin levels were inversely related with circulating Ucn3 in both diabetic and non-diabetic subjects. These data suggest that Ucn3 might be a key player in the pathophysiology of diabetes and hence further studies are warranted to investigate its role in the onset and progression of diabetes.

Skin autofluorescence measurement and carotid intima media thickness in morbid obese patients

D. Gogas Yavuz[1], M. Uygur[2], D. Yazici[3];
[1]Endocrinology and Metabolism, Marmara University School of Medicine, Istanbul, Kadikoy, [2]Endocrinology and Metabolism, Marmara University School of Medicine, Istanbul, [3]Endocrinology and Metabolism, Koc University School of Medicine, Istanbul, Turkey.

Background and aims: Obesity associated with accelerated atherosclerosis independent of hyperglycemia. Advanced glycation end-products (AGEs) are known to play an important role in the pathogenesis of atherogenesis.The present study aimed to evaluate the skin autofluorescence (AF) as a marker of skin AGE accumulation and carotid intima media thickness(CIMT) as an early marker of atherosclerosis in diabetic and nondiabetic morbid obese patient

Materials and methods: 322 morbid obese patients (36 ± 10 year, F/M: 200/122) who were evaluated for bariatric surgery were included in the study. Skin AGE were measured using skin autofluorescence (SAF) in the forearm with an AGE Reader™ (DiagnOptics Technologies,Netherlands). Autofluorescence measurements were presented as arbitrary units (AU). CIMT was measured by ultrasonography. Fasting blood glucose (FPG) and HbA1c levels were measured, Body mass index(BMI) was calculated.Study parameters were compared between diabetic and nondiabetic obese patients. Students t test and spearman correlation tests were used.

Results: BMI were similar between diabetic and non diabetic patients (48.1 ± 7 kg/m^2 and 47.7 ± 7 p:0.1). FBG and HbA1c levesl were higher in the diabetic patients than nondiabetic obese patients ($p < 0.0001$). Skin AF was higher in diabetic obese patients (1.975 ± 0.44 AU)compared to non diabetic obese patients (1.773 ± 0.39 AU, $p < 0.0001$). CIMT measurements were 0.6019 ± 0.13 mm and 0.5691 ± 0.12 mm for diabetic and non diabetic obese patients respectively (p:0.003). CIMT and skin AF measurements have shown a positive correlation in the whole group. ($r = 0.19$, $p < 0.0006$).

Conclusion: Advanced glycation end product accumulation in skin measures as skin AF was higher in diabetic obese patients. Skin AF was found to be positively associated with CIMT in the whole group. Advanced glycation pathway may be accelerated independently in the presence of hyperglycemia in morbid obese patients. Further prospective studies are needed to clarify the association between AGE and atherosclerosis in nondiabetic obese patients.

Role of adipose tissue in development of insulin resistance in healthy non-obese male offspring of type 2 diabetes patient

M. Koc[1], E. Krauzová[1,2], M. Šiklová[1], L. Beranová[1], M. Štěpán[1,2], J. Gojda[2], V. Šrámková[1], L. Rossmeislová[1], V. Štich[1,2];
[1]Department for Study of Obesity and Diabetes, Charles University, Prague, [2]Second Department of Internal Medicine, University Hospital Kralovske Vinohrady, Prague, Czech Republic.

Background and aims: The risk of developing type 2 diabetes (T2DM) is higher in the offspring of diabetic patients. Although the development of T2DM is often associated with obesity, people with genetic predisposition to T2DM may exhibit signs of impaired insulin sensitivity already before the onset of excessive adipose tissue accumulation. Thus, the aim of our study was to investigate whether the early disturbances of glucose and lipid metabolism in non-obese first degree relatives of T2DM patients (FDR) could be partially based on the alteration of adipose tissue (AT) metabolism and expandability.

Materials and methods: 45 non-obese men (FDR $n = 24$; controls without family history of T2DM $n = 21$) were investigated. The groups were matched for age (35.7 ± 3.5 vs. 36.3 ± 4 years) and BMI (25.9 ± 1.1 kg/m^2 vs. 24.9 ± 0.5 kg/m^2). The subjects were healthy, non-smokers, without hypertension or any systemic disease. All subjects underwent oral glucose tolerance test (OGTT), blood examination, CT of abdominal L3 region to evaluate subcutaneous and visceral fat mass, and euglycemic hyperinsulinemic clamp (HEC). Abdominal subcutaneous AT was obtained by needle biopsy and used for the analysis of mRNA expression (qPCR on the microfluidic platform Fluidigm Biomark) and establishment of primary cultures of AT derived stem cells. These cells were in vitro differentiated into adipocytes. Insulin sensitivity of cells was assessed by the Western blot (detection of phosphoSer473-Akt levels) and by the ability of insulin to suppress Br-cAMP induced lipolysis.

Results: Compared to control subjects, FDR were characterized with higher fasting glycemia (5.6 mmol/l ± 0.1 vs. 5.3 mmol/l ± 0.1; $p < 0.05$) and insulinemia (8.1 mU/l ± 0.1 vs. 5.0 mU/l ± 0.1; $p < 0.05$). No significant difference was observed in glucose disposal evaluated by HEC (M value/FFM [mg/kg FFM/min] 5.8 ± 0.5 vs. 6.7 ± 0.4; $p = 0{,}29$). Despite similar BMI, FDR had higher visceral AT mass (312 ml ± 38 vs. 189 ± 24; $p < 0.05$). Insulin sensitivity in AT measured as suppression of lipolysis (FFA blood levels) at the 2 hour point of OGTT was lower in FDR compared to control group (89% ± 0.9 vs. 93% ± 1.0; $p < 0.01$). The extent of this suppression negatively correlated with visceral but not subcutaneous fat mass. In vitro, the levels of Akt phosphorylation in response to insulin and insulin dependent suppression of lipolysis were similar in differentiated subcutaneous adipocytes from both groups. Subcutaneous AT gene expression of pro- and anti-adipogenic regulators and markers of lipid metabolism, as well as in vitro proliferative and adipogenic capacity of subcutaneous AT derived stem cells, was not different between the groups.

Conclusion: The early disturbances of glucose and lipid metabolism detected in non-obese FDR were not associated with worsened characteristics of subcutaneous abdominal AT and adipocytes but appeared to be linked with the expansion of visceral AT depot. Thus, alteration of visceral rather than subcutaneous AT qualities could contribute to the onset of insulin resistance in non-obese men with genetic predisposition to T2DM.

Relationship of pigment epithelium derived factor to metabolic syndrome and vascular damage in patients with type 2 diabetes

D. Karasek[1], J. Spurna[1], O. Krystynik[1], V. Kubickova[2];
[1]Third Department of Internal Medicine – Nephrology, Rheumatology and Endocrinology, Faculty of Medicine and Dentistry, University

Hospital and Palacky University Olomouc, Olomouc, [2]Department of Clinical Biochemistry, University Hospital Olomouc, Olomouc, Czech Republic.

Background and aims: Pigment epithelium derived factor (PEDF) may participate in insulin resistance and vascular damage of patients with dysfunctional adipose tissue. Aim of the pilot study was to compare its circulating levels in type 2 diabetes patients with and without metabolic syndrome (MS) to healthy controls. Relationship to risk metabolic parameters and markers of vascular damage were also investigated.
Materials and methods: Fifty individuals with type 2 diabetes (23 men, 27 women) and forty healthy controls (15 men, 25 women) were included to the study. PEDF, lipids, anthropometric parameters, markers of insulin resistance and diabetes compensation were investigated in all subjects. Diabetics were divided into two groups: with ($n = 30$; 11 men, 19 women) and without ($n = 20$; 12 men, 8 women) MS. Von Willebrand factor (vWF) and plasminogen activator inhibitor-1 served as markers of endothelial dysfunction. Augmentation index (AI) and pulse wave velocity (PWV) were measured as markers of arterial stiffness.
Results: Compared to healthy controls only diabetics with MS had higher levels of PEDF [14160 (10240–16000) ng/ml versus 11120 (8560–14400) ng/ml; $p < 0.05$]. In all subjects PEDF significantly ($p < 0.05$) correlated: positively with BMI, waist, hs-CRP, triglycerides, non-HDL cholesterol, apolipoprotein B, fasting glucose, glycated hemoglobin, C-peptide and insulin; negatively with HDL-cholesterol and apolipoprotein A1. Additionally, in diabetics with MS a negative correlation of PEDF with vWF ($\rho = -0.46$ $p < 0.05$) were found. There were no significant correlations with AI, or with PWV.
Conclusion: Patients with type 2 diabetes and MS had significantly higher levels of PEDF. They were associated with obesity, dyslipidemia and insulin resistance. A negative correlation of PEDF with vWF may point out its vascular protective role, despite its association with adverse metabolic parameters.

Estrogen and glucocorticoid effects on lipocalin 2 expression in human adipose tissue: A role of ERβ pathway in insulin resistance?

P.G. Kamble, M.J. Pereira, G.J. Boersma, K.E. Almby, J.W. Eriksson; Medical Sciences, Uppsala University, Uppsala, Sweden.

Background and aims: Recently, we showed that the adipokine lipocalin 2 (LCN2) can produce insulin resistance in human adipose tissue (AT). Its expression was increased by a synthetic glucocorticoid, dexamethasone (Dex), in AT from pre-menopausal women but not in post-menopausal women or men, implying a role of sex steroids in regulating LCN2 expression in AT. Here, we aimed to study the direct effects of estrogen on LCN2 expression in AT. In this context, we also studied if any cross-talk occurs between estrogen and glucocorticoids in the regulation of AT LCN2 expression.
Materials and methods: Subcutaneous AT from non-diabetic post-menopausal women ($n = 42$, 68 ± 6 Y, BMI 28 ± 4 kg/m^2) was incubated with or without 17 β-hydroxy estradiol (E2, 0.01–100 nM), Dex (0.3 μM) or the combination for 24 h and LCN2 mRNA levels were measured. AT was co-treated with E2 (1 nM) or (E2+dex) and 100 nM of either estrogen receptor (ER) α or β antagonist, MPP or PHTPP, respectively. Moreover, AT was treated with ERβ specific agonist (DPN, 100 nM) for 24 h. In addition, LCN2 gene expression was measured in freshly snap frozen subcutaneous AT from pre- ($n = 23$, 32 ± 9 y, 31.5 ± 13.1) and post-menopausal ($n = 51$, 48 ± 18 Y, BMI 26.1 ± 3.2 kg/m^2) women and men ($n = 32$, 51.5 ± 17 Y, BMI 29.2 ± 9.5 kg/m^2).
Results: LCN2 gene expression in men was higher by 2 fold than pre-menopausal women ($p < 0.05$). Post-menopausal women showed a trend of a higher LCN2 expression than pre-menopausal women ($p = 0.079$). E2 (0.001 to 100 nM) dose-dependently increased LCN2 gene expression in AT up to 3.5 fold ($p < 0.01$, $n = 5$ to 18). Furthermore, E2 at 1 nM also increased LCN2 protein expression by 2.7 fold ($p < 0.05$, $n = 6$). E2 in the presence of ERα antagonist could significantly increase LCN2 gene expression by 4.8 fold ($p < 0.05$, $n = 11$). In contrast, the effect was blocked ($p < 0.05$, $n = 10$) by addition of ERβ antagonist. In addition, treatment with ERβ specific agonist alone increased LCN2 gene expression by 5.2 ($p < 0.01$, $n = 18$) fold compared to control. AT treated with E2 (1 nM) did not show any effect on ERα gene ($n = 10$) or protein ($n = 3$) expression compared to control. Interestingly, E2 incubation increased ERβ gene expression by 1.8 fold ($p < 0.05$, $n = 11$). Dex alone or E2 + Dex did not show any significant effect on LCN2 gene expression. However, E2 + Dex could significantly increase LCN2 gene expression by about 20 fold ($p < 0.5$, $n = 6$) in presence of ERα antagonist, but not in presence of ERβ antagonist ($n = 6$). Long-term Dex (0.3 μM) exposure significantly decreased ERα gene by 20% ($n = 24$, $p < 0.01$), and protein expression by 35% ($p < 0.01$, $n = 5$,), but increased ERβ gene expression by 120% ($p < 0.01$, $n = 24$). In bivariate analysis, Dex-induced reduction in expression of ERα was significantly correlated with BMI ($r = 0.569$, $p < 0.01$), waist circumference ($r = 0.565$, $p < 0.01$) fasting insulin ($r = 0.531$, $p < 0.05$) and C-peptide ($r = 0.560$, $p < 0.01$). In a stepwise multivariate analysis, BMI remained as an independent factor (standard β coefficient = 0.626, $p < 0.01$; model: $r^2 = 0.392$).
Conclusion: Our data suggest that E2 can increase LCN2 expression in subcutaneous AT from post-menopausal women and this action seems to be mediated via ERβ. The up-regulation of ERβ together with down-regulation of ERα seen following dexamethasone can be of importance for glucocorticoid-induced insulin resistance in human AT. Taken together, our data suggest that the ERβ and ERα pathways interact with glucocorticoid action and have reciprocal effects on LCN2 expression.

Differences in extracellular matrix expression in pancreatic fat cells of non-diabetic, pre-diabetic and diabetic individuals

D. Siegel-Axel[1,2], F. Gerst[1,2], S. Ullrich[1,2], N. Stefan[1,2], B. Sipos[3], S. Haen[4], F. Fend[4], A. Koenigsrainer[3], E. Schleicher[1,2], H.-U. Haering[1,2]; [1]Department of Internal Medicine, Medical Clinic IV, Division of Endocrinology, Diabetology, Angiology, Nephrology and Clinical Chemistry, Tuebingen, [2]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tuebingen and German Center for Diabetes Research (DZD), Muenchen-Neuherberg, [3]Department of General Visceral and Transplantation Surgery, University of Tuebingen, Tuebingen, [4]Institute of Pathology and Neuropathology, University of Tuebingen, Tuebingen, Germany.

Background and aims: Extracellular matrix (ECM) affects metabolic function in many tissues. Pancreatic β-cell's function maybe influenced by a specific microenvironment composed of ECM surrounding the islet. Laminin and collagen isoforms were found to enhance insulin gene transcription and secretion, β-cell survival rates and proliferation. Recently we found that pancreatic (pre)adipocytes (PA) and islets influence each other and that the crosstalk of the hepatokine fetuin-A/palmitate with PA and islets induces inflammatory responses in this specific pancreatic microenvironment. In the present study we determined the basal expression of a variety of ECM components in PA, as well as under the influence of fetuin-A/palmitate. In addition, ECM distribution and amount was examined histologically in human pancreatic resections.
Materials and methods: PA were isolated from each 6 non-diabetic, pre-diabetic and diabetic subjects. PA were treated with 600 μg/ml fetuin-A in combination with 60 μmol/L palmitate for 24 h. mRNA levels of collagen I, III, IV, fibronectin, decorin, laminin, elastin, tenascin and the growth factors transforming growth factor beta (TGF-β) and connective tissue

growth factor (CTGF) were quantified by real-time PCR analysis. ECM was analysed in pancreatic resections of the same individuals by (immuno)stainings against collagens, elastin and basement membrane (BM) proteins.
Results: Predominantly collagens but also fibronectin, decorin, laminin and elastin were expressed strongly while TGF-β and CTGF mRNA were less intensely expressed. Collagens, Elastin and CTGF were expressed significantly higher in PA of pre-diabetic patients compared to the other groups. Fetuin-A/palmitate decreased the mRNA expression of the ECM proteins collagen I, III and IV, fibronectin, elastin and CTGF significantly in PA of pre-diabetic subjects. In PA from diabetic patients the mRNA expression of the BM components collagen IV and laminin, as well as TGF-β was downregulated by fetuin-A/palmitate. In contrast no effect was observed in PA from healthy people. Individuals containing PA highly expressing ECM proteins showed also larger amounts of ECM (collagens, elastin) around fat cells and islets in their pancreatic resections.
Conclusion: Our study shows that the amount of ECM and BM components expressed by PA varies between non-, pre-, and diabetic individuals and that the crosstalk with the fatty liver by fetuin-A/palmitate influences the mRNA expression of structural and BM proteins in PA from pre-diabetic and diabetic subjects. Since we could show interactions between pancreatic fat cells and islets, the ECM and BM protein production by PA might influence islet function. This supports other studies showing that incompletely isolated islets that retain some ECM have reduced apoptosis rates and better function.

PS 043 Weight regulation and obesity in humans and rodent models

601

The association between BMI and mortality in type 1 diabetes is modified by gender, age at diabetes onset and diabetic kidney disease
E.H. Dahlström[1,2], N. Sandholm[1,2], C. Forsblom[1,2], L. Thorn[1,2], V. Harjutsalo[1,3], F.J. Jansson[1,2], P.-H. Groop[1,2], The FinnDiane Study group; [1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, [2]Abdominal Center, Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, [3]Chronic Disease Prevention Unit, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: The association between BMI and mortality is U-shaped, with an increased risk of premature mortality both for low and high BMI values. BMI is, however, influenced by many factors such as gender and age, but in patients with type 1 diabetes further by age at onset of diabetes, glycemic control, diabetes duration and the presence of diabetic complications. Thus, the aim of this study was to evaluate if the association between BMI and mortality in type 1 diabetes is modified by these factors.
Materials and methods: Totally, 5,836 adult individuals with type 1 diabetes from the Finnish Diabetic Nephropathy Study (FinnDiane) with data on BMI available, were followed until death or end of 2015. Mortality data were obtained from the Finnish National Death Register. Associations between mortality and BMI were evaluated by a Cox proportional hazard model with a restricted cubic spline transformation of the BMI variable using 4 knots. The reference value for HRs in the restricted cubic spline model was set to a BMI value of 23 kg/m^2. Effect modification was evaluated by introducing interaction terms one at a time, between the BMI spline variable and the variables that could possibly affect the relationship between BMI and mortality. Continuous variables were dichotomized by their median value into two similarly sized groups before included as interaction terms.
Results: During a median of 13.7 follow-up years (Inter-quartile range: 6.4–16.2), 876 individuals (15%) died. BMI was significantly associated with the risk of premature mortality; with both high and low BMI levels conferring increased risk. The nadir BMI (BMI value with lowest mortality risk) was in the normal weight region (24.3–24.8 kg/m^2) but when analyses were restricted to individuals with diabetic kidney disease, the nadir BMI located in the overweight region (25.9–26.1 kg/m^2). Diabetic kidney disease, age at diabetes onset and gender significantly modified the relationship between BMI and mortality ($P_{interaction} < 0.05$). In interaction analyses with gender (Figure1), the risk of mortality observed with higher BMI values appeared to be driven by individuals of male gender. Same was observed for age at diabetes onset, were mortality risk with higher BMI values was more marked among those with a later onset of diabetes.
Conclusion: BMI is nonlinearly associated with premature mortality and the association is modified by gender, age at diabetes onset and diabetic kidney disease. This study highlights the possibility that reducing obesity could potentially translate into reduced premature death in type 1 diabetes, particularly for individuals of male gender and later diabetes onset.

The role of weight in modulating metabolic parameters and vascular complications in patients with type 1 diabetes

R.J. Helliwell[1], H.L. Warnes[1], R.J. King[2], R.A. Ajjan[1];
[1]University of Leeds, Leeds, [2]Taunton and Somerset NHS Foundation Trust, Taunton, UK.

Background and aims: Type 1 diabetes (T1DM) is characterised by insulin deficiency, but some of these individuals can become overweight thus developing a type 2 diabetes phenotype, a group described as having double diabetes. Our aim was to analyse the prevalence of double diabetes in patients originally classified as having T1DM and investigate whether this population is at a higher risk of developing vascular complications of diabetes.
Materials and methods: Patients with T1DM from a single centre (n = 2365) were included in this cross-sectional analysis. They were classified per body mass index (BMI) to normal weight (BMI 18–25 kg/m^2), overweight (25–30 kg/m^2) and obese (>30 kg/m^2). The following metabolic and vascular parameters were investigated: HbA1c, alanine transaminase (ALT), total cholesterol, triglycerides, retinopathy, creatinine, urine albumin creatinine ratio (UACR) and composite cardiovascular outcomes (CV) of stroke and cardiac events.
Results: BMI data was available for 2313 patients (98%) distributed as follows: normal BMI 38.7%, overweight 38.0% and obese 23.3%. Lower HbA1c was observed in overweight patients compared to those with a normal BMI (67.6 mmol/mol vs. 69.8 mmol/mol, p = 0.032), while obese individuals had a similar HbA1c to normal BMI patients (70.2 mmol/mol, p = 0.201). When analysed by gender, normal weight and obese males had similar HbA1c (70.3 and 68.1 mmol/mol, respectively, p = 0.662), which was higher than overweight males (66.9 mmol/mol, p = 0.023). In contrast, female obese patients had higher HbA1c compared with normal weight patients (72.3 mmol/mol vs. 68.7 mmol/mol, p = 0.011). ALT was lower in normal weight patients at 20.7 iu/L than overweight and obese patients (22.6 iu/L and 26.1 iu/L; p = 0.026 and <0.001, respectively). Prevalence of retinopathy, defined as any abnormality other than background changes, was more prominent in obese patients compared with those who had normal weight [OR = 1.77 (1.33–2.34), p < 0.001] with only a trend detected in those who were overweight [OR = 1.29 (0.99–1.67), p = 0.056]. A gender difference was detected with overweight and obese females showing increased prevalence of retinopathy compared with normal weight patients, whereas males failed to show such a pattern. Creatinine and UACR were not different between the three BMI groups and were not affected by gender. Although triglycerides levels were raised in overweight and obese patients compared with normal BMI individuals and total cholesterol was raised in obese female patients, we failed to detect a difference in CV events in various BMI groups.
Conclusion: Almost two thirds of patients with T1DM have raised BMI, whilst higher BMI was not associated with worse glycaemic control, it appears to increase the risk of microvascular complications. Higher BMI was also associated with an abnormal lipid profile but no relationship was found with macrovascular disease, likely due to small sample size and limited number of events. Future longitudinal studies in overweight and obese T1DM patients are warranted to establish whether weight reduction modulates microvascular risk and improves the dyslipidaemic profile.

Effects of irisin on leptin and ghrelin secretion and expression of the major appetite regulators in mouse brain

N. Marrano, A. Natalicchio, R. Spagnuolo, L. Dipaola, G. Biondi, A. Cignarelli, S. Perrini, L. Laviola, F. Giorgino;
Department of Emergency and Organ Transplantation, University of Bari Aldo Moro, Bari, Italy.

Background and aims: Irisin is a newly discovered muscle-derived hormone, produced by cleavage of the membrane protein fibronectin type III domain-containing protein 5 (FNDC5) and proposed to bridge exercise with metabolic homeostasis. In mammals, irisin acts in different organs and tissues, improving energy homeostasis. However, the role of irisin on body weight and food intake is still unclear. The aim of this study was to assess the effects of intraperitoneal injections of irisin on leptin and ghrelin secretion, mRNA expression of the major appetite regulators (anorexigenic genes: cocaine- and amphetamine-regulated transcript [CART] and pro-opiomelanocortin [POMC]; orexigenic genes: agouti related neuropeptide [AgRP], neuropeptide Y [NPY], orexin [HCRT] and pro-melanin-concentrating hormone [PMCH]; UCP2 and brain-derived neurotrophic factor [BDNF]), and feeding behaviour in healthy mice.
Materials and methods: Twelve male 6-weeks old C57BL/6 mice were randomized into two groups, and intraperitoneally injected daily with irisin (0.5 microg/g body weight) or vehicle (PBS) for 14 days. On the last day, animals were sacrificed and brains and sera were collected. Leptin and ghrelin levels were measured by ELISA assays. mRNA expression levels were analyzed by quantitative RT-PCR.
Results: Irisin administration did not change leptin and ghrelin serum concentration. Furthermore, irisin injection increased CART, POMC, NPY and BDNF mRNA levels, without affecting the mRNA expression of AgRP, orexin, PMCH and UCP2. Finally, over the short time frame of this observation, body weight and feeding behaviour were unaltered.
Conclusion: In conclusion, intraperitoneal injection of irisin is able to increase the expression of anorexigenic genes in mice. However, this does not translate into significant differences in feeding behaviour and body weight over a 14-day treatment period with this muscle-derived hormone.
Disclosure: **N. Marrano:** None.

Effect of ARHGAP21 reduction upon energy homeostasis of diet-induced obese mice

G.M. Soares[1], L. Zangerolamo[1], S.T.O. Saad[2], A.C. Boschero[1], H.C.L. Barbosa-Sampaio[1];
[1]Department of Structural and Functional Biology, Biology Institute, University of Campinas, Campinas, [2]Haematology Centre, School of Medicine, University of Campinas, Campinas, Brazil.

Background and aims: GTPase activating proteins (GAP's) seems to impact glycemic homeostasis. The reduction of ARHGAP21, a GAP, alters glucose-induced insulin secretion as well as body composition of diet-induced obese mice, suggesting changes in the energetic metabolism. However, the possible role of ARHGAP21 in energy homeostasis

remains unknown. Here we used ARHGAP21 haplodeficient mice, aiming to explore the involvement of ARHGAP21 in energy homeostasis.

Materials and methods: 30 days old C57BL/6 mice, ARHGAP21 haplodeficient or not, were fed on chow (Ctl and Het) or a high-fat diet (Ctl-HFD and Het-HFD) for 10 weeks. Body composition was analyzed by body weight gain during all experimental period and also by perigonadal fat content. We also evaluated the food intake and energy homeostasis through voluntary physical activity and energy expenditure, by indirect calorimetry. Data were analyzed by Student's t-test. Data are mean ± SEM, and the difference between the groups were considered statistically significant if $P \leq 0.05$.

Results: Het mice displayed reduced body weight compared with Ctl mice (28.44 g ± 0.33 Ctl x 26.26 g ± 0.30 Het). Besides that, Het animals present a reduction in food intake (13.35 Kcal ±0.34 Ctl x 10.80 Kcal ±0.15 Het) and increase of O_2 consumption (light period: 2048 ml/Kg/hr ± 46.76 x Ctl x 3016 ml/Kg/hr ± 22.67 Het; dark period: 3695 ml/Kg/hr ± 71.02 x Ctl x 4002 ml/Kg/hr ± 80.32 Het), in heat rate (light period: 0.42 Kcal/h ± 0.003 x Ctl x 0.45 Kcal/h ± 0.02 Het; dark period: 0.56 Kcal/h ± 0.01 x Ctl x 0.60 Kcal/h ± 0.003 Het) and in the ambulatory activity (3739 Row means ±47.52 Ctl x 5436 Row means ±182.1 Het). As expected, Ctl-HFD mice developed the deleterious effects inherent in the consumption of the high fat diet. Interestingly, Het-HFD animals did not become obese (35.51 g ± 0.66 Ctl-HFD x 27.66 g ± 0.68 Het-HFD) and had less accumulation of fat deposits (3.22% body weight ± 0.24 Ctl-HFD x 1.72% body weight ± 0.06 Het-HFD), which may be due to a decreased food consumption (15.40 Kcal ±0.21 Ctl-HFD x 13.05 Kcal ± 0.06 Het-HFD) and an increased energy expenditure. Het-HFD mice displayed increased energy expenditure, through the increase of O_2 consumption (light period: 3450 ml/Kg/hr ± 55.90 x Ctl-HFD x 3819 ml/Kg/hr ± 113.0 Het-HFD; dark period: 4155 ml/Kg/hr ± 74.25 x Ctl-HFD x 4407 ml/Kg/hr ± 48.79 Het-HFD), respiratory exchange ratio (RER) (dark period: 0.76 RER ± 0.01 x Ctl-HFD x 0.95 ml/Kg/hr ± 0.01 Het-HFD) and heat rate (light period: 0.53 Kcal/h ± 0.01 x Ctl-HFD x 0.64 Kcal/h ± 0.02 Het-HFD; dark period: 0.64 Kcal/h ± 0.01 x Ctl-HFD x 0.74 Kcal/h ± 0.02 Het-HFD). Moreover, during some points of the dark period, the ambulatory activity was significantly higher in the Het-HFD group when compared to Ctl-HFD group (2279 Row means ±180.3 Ctl-HFD x 3934 Row means ±142.5 Het-HFD).

Conclusion: Taken together, our study indicates a possible role of ARHGAP21 in whole body metabolism, impacting on body weight gain, by reducing food consumption and increasing energy expenditure, regardless of diet composition. The data suggest that GAP protein member as a potential candidate to prevent and treat obesity and related diseases.

Medi0382, a GLP-1/glucagon receptor dual agonist, reduces weight and improves metabolism via central and peripheral actions

D. Baker[1], S. Oldham[2], S. Will[2], C. Church[1], G. Davies[1], L. Burke[1], L. Brown[1], M. Sulikowski[1], J.-M. Lapointe[1], A. Lewis[1], H. Jouihan[2], P. Barkholt[3], R. Veggerby Grønlund[3], C. Rhodes[2], J. Trevaskis[2];
[1]MedImmune, Cambridge, UK, [2]MedImmune, Gaithersburg, USA, [3]Gubra, Hørsholm, Denmark.

Background and aims: MEDI0382, a balanced GLP-1/glucagon dual receptor agonist, is under development for the treatment of Type 2 Diabetes and nonalcoholic steatohepatitis. Here we characterize the effect of MEDI0382 on metabolic endpoints in leptin-deficient *ob/ob* mice. We further characterize the central actions of MEDI0382 via identification of key neuronal regions activated by subcutaneous delivery and explore the sub-chronic effect of MEDI0382 on improving leptin sensitivity in diet induced obese (DIO) mice.

Materials and methods: MEDI0382 (10, 20 or 30 nmol/kg; s.c., q.d.), liraglutide (Lira; 30 nmol/kg; a GLP-1 analog), or G1437 (30 nmol/kg; a lipidated glucagon receptor agonist) was administered to *ob/ob* mice for 21 days. Body weight, GTT, liver fat and gene expression in adipose tissue was examined. To determine the central sites activated by MEDI0382, 4 h fasted lean C57BL6J mice ($n = 4$/group) were injected s.c with MEDI0382, Lira or G1437 (3 nmol/kg) or vehicle. After 2 h, mice were sacrificed and brains removed and immersion-fixed in formalin (24–48 h). The brains were cut into 3 mm serial slices and processed to paraffin blocks and immunohistochemically stained for c-fos using a rabbit anti-fos polyclonal, with haematoxylin counterstain. To determine effects on leptin sensitivity, DIO mice were administered vehicle, MEDI0382 (10 nmol/kg; s.c., q.d.) or vehicle and pair-fed to MEDI0382-treated mice ($n = 15$–16/group). On day 10, half of the mice from each group were administered vehicle or murine leptin (10 mg/kg) and the mice sacrificed 45 min later for assessment of phosphorylated STAT3 (pSTAT3) in various brain regions.

Results: In *ob/ob* mice, body weight was reduced by MEDI0382 compared to vehicle, with 15% weight loss observed at the highest 30 nmol/kg dose, whereas Lira reduced body weight by 8% and G1437 by 29% (both $p < 0.0001$ vs. vehicle and MEDI0382). GTT was improved by MEDI0382, similar to Lira, but worsened by G1437. Liver fat was reduced in a dose-dependent manner (11%, 14% and 22%, respectively) by MEDI0382 compared to vehicle. Both Lira (12%) and G1437 (10%) also reduced liver fat content (both $p < 0.05$ vs. vehicle and MEDI0382 30 nmol/kg). Expression of *Ucp1*, *Ppargc1a* and *Adrb3* tended to be increased in BAT and WAT by MEDI0382 administration. In lean mice, MEDI0382 increased c-fos in the area postrema and nucleus tract of the solitaries vs. vehicle, whereas Lira and G1437 showed no difference from vehicle in these regions. There was no c-fos activation in the arcuate nucleus in any treatment group. DIO mice treated with MEDI0382 exhibited 11% weight loss ($p < 0.01$ vs. vehicle), whereas pair-fed mice lost a similar weight as MEDI0382 group during the first 5 days, but rebounded such that final weight loss was 3% from baseline by day 10 ($p < 0.05$ vs. vehicle and MEDI0382). Acute administration of exogenous leptin resulted in increased levels of pSTAT3 in the arcuate nucleus of the hypothalamus in MEDI0382-treated but not vehicle or pair-fed mice.

Conclusion: MEDI0382 induced significant metabolic improvement in *ob/ob* mice, superior to Lira without the glycemic liabilities of glucagon. These effects may be mediated via improved peripheral energy utilization in peripheral tissues as well as activation of key central sites that regulate metabolism, including enhanced leptin action.

ICA6150349, a highly selective glucagon agonist, in combination with exenatide significantly reduces weight and glucose in obese and diabetic rats

M. Paulik[1], T. Tlusty[1], M. Grizzle[1], M. Copeland[1], S. Weng[1], W. Blackwell[1], V. Srivastava[1], J. Way[1], S. Roller[1], D. Zane[2], R. Hodge[1], A. Young[1], P. Feldman[1];
[1]Intarcia Therapeutics Inc, Research Triangle Park, [2]Intarcia Therapeutics Inc, Hayward, USA.

Background and aims: ICA6150349, a 38-amino acid analog of glucagon, is peptidase resistant and highly selective for the human glucagon receptor. Our objectives were to determine the magnitude and timing of effects of 27 days continuous subcutaneous (s.c.) infusion of ICA6150349 alone and in combination with exenatide (GLP-1 agonist) on body weight, body composition, food intake, HbA1c, glucose and serum chemistries in rodent models of obesity and T2D.

Materials and methods: Male Long Evans (LE) Diet Induced Obese (DIO) rats at 18 weeks of age (14 weeks on high fat diet) were s.c. implanted with two Alzet osmotic mini-pumps delivering 7.5, 24 or 50 mcg/kg/d of ICA6150349 with or without exenatide (10 mcg/kg/d;

n = 8/group). Male Zucker Diabetic Fatty (ZDF) rats at 8 weeks of age were similarly implanted with mini-pumps delivering ICA6150349 (15 or 50 mcg/kg/d) with or without exenatide (10 mcg/kg/day; n = 10/group).
Results: ICA6150349 continuously s.c. infused at 50 mcg/kg/d in DIO LE rats reduced weight (21%), fat mass (37%), and food intake (17%) and normalized triglycerides and cholesterol to lean control levels. ICA6150349 (50 mcg/kg/d) in combination with exenatide (10 mcg/kg/d) further significantly reduced weight (38%), fat mass (70%), and food intake (52%) and also normalized glucose and lipids to lean control levels. ICA6150349 continuously infused at 50 mcg/kg/d in ZDF rats significantly increased HbA1c (1.3%), reduced weight (29%), fat mass (42%), and food intake (13%) and normalized triglycerides (66%) and cholesterol (38%) to lean control levels. ICA6150349 (50 mcg/kg/d) in combination with exenatide (10 mcg/kg/d) significantly decreased HbA1c (1.5%), off-setting the increase seen with ICA6150349 monotherapy. The ICA6150349 and exenatide combination significantly reduced weight (19%), fat mass (25%), food intake (29%) cholesterol (27%) and triglycerides (41%).
Conclusion: In rodent models of obesity and T2D, the selective glucagon agonist ICA6150349, in combination with exenatide can significantly reduce weight, fat mass, glucose and lipids, sometimes normalizing these parameters to lean control levels.

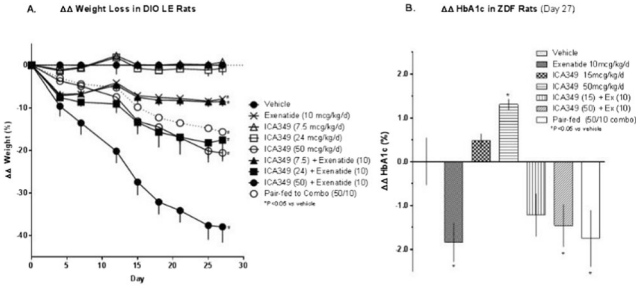

Figure 1. Chronic Effects of ICA6150349 (ICA349) and Exenatide Alone and in Combination on (A) ΔΔ Weight loss in DIO LE Rats and (B) ΔΔ HbA1c % in ZDF Rats

ATG7-expression and chemerin secretion are co-regulated in adipocytes

S. Heinitz[1], C. Gebhardt[2], P. Piaggi[3], J. Krüger[2], H. Heyne[4], J. Weiner[5], J. Heiker[5], M. Stumvoll[1], M. Blüher[1], L. Baier[6], A. Rudich[7], P. Kovacs[1], A. Tönjes[1];
[1]Department of Medicine, Division of Endocrinology and Nephrology, University of Leipzig, Leipzig, Germany, [2]IFB Adiposity Diseases, Leipzig University Medical Center, Leipzig, Germany, [3]Obesity and Diabetes Clinical Research Section, Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, USA, [4]Broad Institute, Cambridge, USA, [5]Institute of Biochemistry, University of Leipzig, Leipzig, Germany, [6]Diabetes Molecular Genetics Section, Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, USA, [7]The National Institute for Biotechnology in the Negev Ltd., Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Background and aims: In obese individuals, adipocyte endocrine function is affected by altered autophagy. In a recent genome-wide association study (GWAS) genetic variants in autophagy-related gene 7 (*ATG7*) correlated with serum chemerin (*RARRES2*) concentrations. To investigate a possible interplay between chemerin and ATG7, how it may relate to autophagy-mediated adipocyte dysfunction in obesity, and the functional relevance of genetic variants in *ATG7*.
Materials and methods: Adipose *ATG7*-mRNA expression and adiposity measures were available in 100 Caucasians and 83 Native Americans. The effect of a 12-week high-calorie diet on adipose *RARRES2* and *ATG7*-expression was investigated in mice. In 3T3L1-adipocytes, the effect of *ATG7*-knockdown on chemerin expression and secretion was studied. The influence of single nucleotide polymorphisms (SNPs) in linkage disequilibrium with the tag-SNP from recent GWAS on *ATG7*-transcription and chemerin physiology were investigated using a luciferase assay.
Results: *ATG7*-mRNA expression in human subcutaneous adipose tissue positively correlated with BMI, fat mass, body weight ($r > 0.27$, $P < 0.01$), and measures of adipocyte cell size ($r > 0.42$, $P < 0.02$). In mice fed a high-calorie diet, adipose *ATG7*-expression did not parallel an increase in*RARRES2*-expression. *ATG7*-knockdown in 3T3L1-adipocytes decreased chemerin secretion by 25% ($P < 0.01$; CI 0.6, 0.9). Rs2606729 in *ATG7* was predicted to alter *ATG7*-transcription and induced higher luciferase activity *in vitro* ($P < 0.0001$; CI 2.6, 24.8).
Conclusion: *ATG7*-mRNA expression in human adipose tissue relates to measures of adiposity. *ATG7* regulates chemerin secretion from adipocytes *in vitro* supportive of a functional interplay between *ATG7* and chemerin in autophagy-mediated adipocyte dysfunction.

Plasma lipidomics are associated with cardiometabolic risk factors in overweight or obese non-diabetic adults

B. de Courten[1], A. Mousa[1], N. Naderpoor[1], J. Johnson[1], N. Mellett[2], P. Meikle[2];
[1]Monash University, Melbourne, [2]Baker Heart & Diabetes Institute, Melbourne, Australia.

Background and aims: Dyslipidaemia is a key risk factor for type 2 diabetes and cardiovascular disease. Novel lipidomics methods are providing new insights into the pathophysiology of these diseases. However, human studies are limited and no previous human studies have examined relationships between the plasma lipidome and insulin secretion using gold-standard methods. The aim of this study was to examine whether dysregulation of certain lipid species or classes was associated with reduced insulin sensitivity and/or impaired insulin secretion measured by gold-standard methods, as well as other cardiometabolic risk factors in overweight or obese, non-diabetic adults.
Materials and methods: In 65 adults, we performed lipid profiling of 459 lipid species across 26 lipid classes (liquid chromatography mass spectrometry). Gold-standard methods were used to assess body composition (% body fat, dual X-ray absorptiometry), insulin sensitivity (hyperinsulinaemic-euglycaemic clamps) and insulin secretion (intravenous glucose tolerance tests). Additional measures included anthropometry (BMI, waist-to-hip ratio [WHR]), oral glucose tolerance tests (OGTT) for fasting and 2-hour post-OGTT glucose concentrations, and measurement of serum inflammatory markers including high-sensitivity C-reactive protein (hsCRP by immunoturbidimetry), tumor necrosis factor (TNF), and several interleukins (ILs) and adipokines (multiplex assay; flow cytometry). Multivariable regression was performed with adjustment for age, sex, and % body fat, and all analyses were adjusted for multiple testing using Benjamini-Hochberg correction.
Results: The sample comprised 35 males and 19 females, with a mean age of 31.3 ± 8.5 years and BMI of 31.5 ± 5.2 kg/m^2 (mean ± SD). On univariable analyses, BMI, WHR, fasting glucose, 2-hour post-OGTT glucose, fasting insulin, and insulin sensitivity were not associated with lipid species or classes (all $p > 0.05$). Total % body fat was associated with nine lipid classes; however, after adjustment for age and sex, only an inverse relationship between % body fat and the alkylphosphatidylethanolamine

(PE-plasmalogen) lipid class was observed ($p = 0.01$). Total and second-phase insulin secretion were positively associated with the lysophosphatidylinositol (LPI) lipid class ($\beta = 781.9$ mU/L, $p = 0.01$ and $\beta = 521.3$ mU/L, $p = 0.01$, respectively). After adjustment for age, sex, and % body fat, LPI remained associated with total ($p = 0.02$) and second-phase insulin secretion ($p = 0.01$), and insulin sensitivity became negatively associated with the dihydroceramide (dhCer) lipid class ($p = 0.01$) and several diacylglycerol and triacylglycerol lipid species (all $p < 0.05$). IL-1β was positively associated with the cholesterol ester (CE) lipid class ($\beta = 11.9$ pg/ml, $p = 0.04$) and adiponectin was inversely associated with several diacylglycerol (DG) and triacylglycerol (TG) lipid species (all $p < 0.05$); however these associations were attenuated after adjustment for age, sex, and body fat.

Conclusion: Using gold-standard methods in a well-characterised cohort of overweight or obese non-diabetic adults, we found that decreased PE-plasmalogens and increased dhCer and LPI were associated with greater adiposity, reduced insulin sensitivity, and impaired insulin secretion, respectively. Our findings suggest that these lipid classes may be involved in the pathophysiology of type 2 diabetes.

The inTandem1 study: 52-week efficacy and safety of sotagliflozin, a dual SGLT1 and SGLT2 inhibitor, as adjunct therapy to insulin in adults with type 1 diabetes

S.K. Garg[1], J. Buse[2], J. Rosenstock[3], T. Bailey[4], P. Banks[5], B.W. Bode[6], T. Danne[7], J.A. Kushner[8], W.S. Lane[9], P. Lapuerta[5], D.K. McGuire[10], A. Peters[11], J. Reed[12], S. Sawhney[5], P. Strumph[5];
[1]Department of Medicine and Pediatrics, University of Colorado Denver, Aurora, USA, [2]Department of Medicine, University of North Carolina School of Medicine, Chapel Hill, USA, [3]Dallas Diabetes Research Center at Medical City, Dallas, USA, [4]AMCR Institute, Escondido, USA, [5]Lexicon Pharmaceuticals, Inc., The Woodlands, USA, [6]Emory University School of Medicine, Atlanta, USA, [7]Department of Diabetes, Endocrinology, and Clinical Research, Hannover Medical School, Hannover, Germany, [8]Baylor College of Medicine and Texas Children's Hospital, Houston, USA, [9]Mountain Diabetes and Endocrine Center, Asheville, USA, [10]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, USA, [11]Keck School of Medicine of the University of Southern California, Los Angeles, USA, [12]Endocine Research Solutions, Inc., Roswell, USA.

Background and aims: Sotagliflozin (SOTA), a dual SGLT1 and SGLT2 inhibitor, is currently in development as an oral adjunct to insulin in type 1 diabetes (T1D).

Materials and methods: In this double-blind, 52-week North American trial, 793 adults with T1D treated with multiple daily insulin injections (40%) or pump (60%) were randomized 1:1:1 to placebo ($n = 268$), SOTA 200 mg ($n = 263$) or SOTA 400 mg ($n = 262$) once daily after 6 weeks of insulin optimization. Primary endpoint was change from baseline in A1C at Week 24. Other endpoints included A1C, body weight, bolus insulin dose and FPG changes at Week 52, patient (pt) reported outcomes and net clinical benefit (NCB), assessing the proportion of pts with A1C <7.0% without severe hypoglycemia (SH) or diabetic ketoacidosis (DKA).

Results: Baseline characteristics were similar between groups. Compared with placebo, SOTA 200 and 400 mg improved A1C and pt satisfaction at Week 24 and reduced A1C, weight, bolus insulin, FPG and pt distress at Week 52. More pts achieved NCB with SOTA vs placebo (each $P < 0.05$; Table). The highest incidence of SH was in the placebo arm; more genital mycotic infections, diarrhea and DKA events (> patients using a pump than MDI) were in the SOTA arms (Table).

Conclusion: SOTA 200 and 400 mg provided statistically significant A1C reductions that were sustained ($P < 0.05$) at Week 52. SOTA was associated with an increased (but low) rate of DKA, and a lower incidence of SH, when compared with placebo.

inTandem1 and inTandem2: increased time in range with sotagliflozin as adjunct therapy to insulin in adults with type 1 diabetes by 24-week continuous glucose monitoring

T. Danne[1], B. Cariou[2], J.B. Buse[3], S.K. Garg[4], J. Rosenstock[5], P. Banks[6], J.A. Kushner[7], D.K. McGuire[8], A.L. Peters[9], S. Sawhney[6], P. Strumph[6];
[1]Department of Diabetes, Endocrinology, and Clinical Research, Hannover Medical School, Hannover, Germany, [2]Department of Endocrinology, CHU Nantes, Nantes, France, [3]Department of Medicine, University of North Carolina School of Medicine, Chapel Hill, USA, [4]Department of Medicine and Pediatrics, University of Colorado Denver, Aurora, USA, [5]Dallas Diabetes Research Center at Medical City, Dallas, USA, [6]Lexicon Pharmaceuticals, Inc., The Woodlands, USA, [7]Department of Pediatrics, Baylor College of Medicine and Texas Children's Hospital, Houston, USA, [8]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, USA, [9]Keck School of Medicine of the University of Southern California, Los Angeles, USA.

Background and aims: Sotagliflozin (SOTA), a dual SGLT1 and SGLT2 inhibitor, is currently in development as an oral adjunct to insulin in type 1 diabetes (T1D).
Materials and methods: This was a pooled analysis of the inTandem1 and inTandem2 trials in adults with T1D treated with multiple daily insulin injections or pump therapy who were randomized 1:1:1 to placebo, SOTA 200 mg or SOTA 400 mg once daily after 6 weeks of insulin optimization. Of these, 278 patients participated in a blinded continuous glucose monitoring (CGM) sub-study. The primary endpoint of this sub-study was the percentage of time in the target glucose range (70 mg/dL–180 mg/dL). Mean daily glucose and amplitude of all glycemic excursions (MAGE) of <70 and >180 mg/dL were also assessed.
Results: Baseline characteristics were similar among groups. Compared with placebo, treatment with SOTA 200 and 400 mg significantly increased the time in range (+1.3 and +2.8 hours/day, respectively) and reduced MAGE at Week 24, while SOTA 400 mg also significantly reduced mean daily glucose (Table).
Conclusion: SOTA used as adjunct therapy in T1D, provided glycemic control beyond decreasing A1C as seen by improvements in the time in target glucose range compared with placebo.

Sotagliflozin in combination with optimised insulin therapy reduced HbA_{1c} levels with a decreased daily insulin requirement after 52 weeks in adults with type 1 diabetes

J. Pettus[1], S. Weinzimer[2], R. McCrimmon[3], F. Ampudia-Blasco[4], J. Stewart[5], P. Strumph[6], J. Oliveira[7], P. Lapuerta[8], R. Castro[7];
[1]University of California, San Diego, San Diego, USA, [2]Yale School of Medicine, New Haven, USA, [3]University of Dundee, Dundee, UK, [4]Hospital Clínico Universitario de Valencia, Valencia, Spain, [5]Sanofi, Westmount, Canada, [6]Lexicon Pharmaceuticals, Woodlands, USA, [7]Sanofi, Bridgewater, USA, [8]Lexicon Pharmaceuticals, Princeton, USA.

Background and aims: In most patients with T1D, adequate glycemic control is not achieved with insulin therapy alone, and intensifying insulin therapy can increase the risk of hypoglycemia. Sotagliflozin (SOTA) is a dual SGLT1 & SGLT2 inhibitor, which blunts and delays postprandial hyperglycemia and reduces renal glucose reabsorption. The goal of this analysis was to determine the effect of SOTA on HbA1c levels and insulin requirements in patients with T1D.
Materials and methods: In two 52 weeks phase 3 studies adults with T1D were randomized 1:1:1 to placebo + insulin (PBO), SOTA 200 mg + insulin or SOTA 400 mg + insulin, once daily, after 6 weeks of insulin therapy optimization. HbA1c change over 52 weeks, along with change of daily insulin dose and safety, were assessed using a pooled analysis. Statistical comparisons of each SOTA arm to placebo were preplanned and performed using a generalized linear model with repeated measures statistics. Proportion of insulin reduction attributable to bolus or basal insulin was calculated by LS Mean of absolute bolus or basal insulin dose change (IU) from baseline over bolus + basal absolute dose change from baseline (IU). Number of patients on which the raw means and LS means are not the same for each type of insulin.
Results: Significant HbA1c reductions were observed with SOTA 200 or 400 vs. PBO at week 24 and sustained to 52 weeks, with a concomitant decrease in total daily insulin dose, mainly due to reduction in bolus insulin (BI), as 70–80% of the total insulin reduction was from BI for both SOTA doses. At 52 weeks, patients in SOTA groups had a lower incidence of severe hypo (SH) but more genital mycotic infections, DKA and diarrhea than PBO.
Conclusion: SOTA demonstrated additional and sustained reduction of HbA1c on top of optimized insulin while reducing total daily insulin dose (mainly BI doses), with less incidence of SH. This may be an additional therapy for patients with T1D without good glycemic control despite optimized insulin therapy.

Pooled data analysis of composite endpoints from the DEPICT-1 and DEPICT-2 studies using dapagliflozin compared to placebo added to adjustable insulin in type 1 diabetes

P. Dandona[1], F. Thorén[2], A.M. Langkilde[2], L. Hansen[3], J. Xu[4], C. Mathieu[5];
[1]State University of New York at Buffalo, Buffalo, USA, [2]AstraZeneca, Mölndal, Sweden, [3]MedImmune, Gaithersburg, USA, [4]AstraZeneca, Gaithersburg, USA, [5]University of Leuven, Leuven, Belgium.

Background and aims: Treatment with insulin (INS) is the mainstay of therapy for patients with type 1 diabetes (T1D). Besides INS, adjunct therapy with INS-independent antihyperglycaemic agents has been proposed for adequate glycaemic control in T1D patients. In this sub-analysis of pooled data from the DEPICT 1 and DEPICT 2 studies, we evaluated the effect of dapagliflozin (DAPA), a selective sodium glucose cotransporter-2 inhibitor, in T1D patients on adjustable INS treatment on two composite endpoints: (a) proportion of patients with a reduction in HbA1c of ≥0.5% from baseline to week 24 with no weight gain and; (b) proportion of patients with a reduction in HbA1c of ≥0.5% from baseline to week 24 with no severe hypoglycaemia and no diabetic ketoacidosis (DKA).
Materials and methods: T1D patients (n = 1591) with inadequate glycaemic control (HbA1c ≥7.7% and ≤11.0%) on INS for ≥12 months with a total INS dose of ≥0.3 U/kg/day for ≥3 months prior to screening, a BMI of ≥18.5 kg/m^2 and C-peptide <0.7 ng/mL, were randomised in a 1:1:1 ratio to receive either DAPA 5 mg/day plus INS (n = 530) or DAPA 10 mg/day plus INS (n = 529) or placebo (PBO) plus INS (n = 532). Logistic regression, with adjustment for study, baseline HbA1c and randomisation stratification factor, was performed to evaluate the two composite endpoints for patients on 5 mg DAPA/INS, 10 mg DAPA/INS, and PBO/INS.
Results: At baseline, patients included in this sub-analysis (n = 1591) had a mean (SD) age of 42.6 (13.6) years, BMI of 28.0 (5.4) kg/m^2, duration of T1D of 19.8 (11.8) years and HbA1c of 8.5% (0.7%). Overall, demographics and baseline characteristics of patients were comparable across study groups. More patients in the 5 mg DAPA/INS (38.5%) and 10 mg DAPA/INS (42.4%) groups achieved a reduction in HbA1c of ≥0.5%, without weight gain, than in the PBO/INS group (10.8%). A larger proportion of patients on 5 mg DAPA/INS and10 mg DAPA/INS versus those on PBO/INS showed a reduction in HbA1c of ≥0.5%, without hypoglycaemia or DKA (43.9% and 45.3% vs. 22.1%, respectively). The ORs of patients achieving both composite endpoints were greater in the DAPA/INS groups versus the PBO/INS group (Table).
Conclusion: DAPA as an adjunct therapy to INS may facilitate improvement in glycaemic control with less risk of weight gain and with more patients achieving improved glycaemic control without severe hypoglycaemia or DKA, in patients with inadequately controlled T1D treated with adjustable INS.

Table: Composite endpoint analysis

	5 mg DAPA/INS (n=530)	10 mg DAPA/INS (n=529)	PBO/INS (n=532)
HbA1c reduction ≥0.5% + no body weight gain (baseline to week 24)			
Number of patients	522	521	526
Patients achieving composite endpoint, n (%)	201 (38.5)	221 (42.4)	57 (10.8)
Odds ratio vs. PBO/INS (95% CI)	5.4 (3.9, 7.6)	6.5 (4.7, 9.1)	-
HbA1c reduction ≥0.5% + no severe hypoglycaemia or DKA (baseline to week 24)			
Number of patients	522	521	526
Patients achieving composite endpoint, n (%)	229 (43.9)	236 (45.3)	116 (22.1)
Odds ratio vs. PBO/INS (95% CI)	2.9 (2.2, 3.9)	3.2 (2.4, 4.2)	-

n (%) is the number of patients in the full analysis dataset with non-missing baseline and week 24 (LOCF) values.
Weight (kg) gain is defined as that weight at week 24 (LOCF), which is larger than baseline weight.
DAPA/INS, dapagliflozin plus insulin; DKA, diabetic ketoacidosis; PBO/INS, placebo plus insulin.

Clinical Trial Registration Number: NCT02460978 and NCT02268214

Pooled analysis of the duration of type 1 diabetes in dapagliflozin vs placebo on adjustable insulin therapy from DEPICT 1 and 2: effects on glycaemia, weight and insulin dosage

J. Lüdemann[1], T. Schaum[2], C. Mathieu[3], J. Xu[4], F. Thorén[5];
[1]Diabetes-Falkensee, Diabetes Centre and Centre for Clinical Studies, Falkensee, Germany, [2]Sana Kliniken Ostholstein GmbH, Oldenburg In Holstein, Germany, [3]University of Leuven, Leuven, Belgium, [4]AstraZeneca, Gaithersburg, USA, [5]AstraZeneca, Mölndal, Sweden.

Background and aims: In Type 1 diabetes (T1D), add-on therapy with insulin (INS)-independent agents is likely to enhance glycaemic control compared to INS monotherapy. In DEPICT 1 and 2 (double-blind, Phase 3) studies, improvement in glycaemic control, weight loss and reduction in INS dose were reported for dapagliflozin (DAPA) vs. placebo (PBO), without increases in hypoglycaemia. In this subgroup analysis, pooled data from DEPICT 1 and 2, were analysed on T1D duration on the effect of DAPA.
Materials and methods: T1D pts (n = 1591; aged 18–75y; HbA_{1c} ≥7.7% and ≤11.0%; BMI ≥18.5 kg/m^2; C-peptide <0.7 ng/mL; prescribed INS for ≥12 months [m] before enrolment with a total INS dose of ≥0.3 IU/kg/day for ≥3 m prior to screening) were randomised (1:1:1) to add DAPA 5 mg (n = 530) or DAPA 10 mg (n = 529) or PBO (n = 532) to INS. Endpoints were adjusted mean change in HbA_{1c}, percent changes in total daily INS dose and total body weight; 24-hour mean glucose readings and amplitude of glycaemic excursion (MAGE), the proportions of pts maintaining glucose within 70–180 mg/dL using continuous glucose monitoring, and HbA_{1c} reduction ≥0.5% without severe hypoglycaemia from baseline to Week 24. Endpoints were analysed by T1D duration tertiles (<12.9, ≥12.9–≤23.5 and ≥23.5y) for each treatment arm. No formal statistical testing was done.
Results: Pts with the longest T1D duration tended to have slightly lower HbA_{1c} reductions and greater weight loss (**Table**). No noticeable changes in HbA_{1c} reduction or weight loss were observed in pts on PBO in any of the three age groups (**Table**). When plotted as continuous variables, the correlation coefficients between change in HbA_{1c} vs. T1D duration for DAPA 5 mg, DAPA 10 mg and PBO were 0.05635, 0.11214 and −0.09277, respectively. No trends were evident for INS dose, or the other analysed parameters with respect to duration of T1D.
Conclusion: Pts with T1D on DAPA added on to INS with longest T1D duration demonstrated relatively lower reductions in HbA_{1c}; however, were able to achieve greatest weight loss.

Table: Changes in major endpoints from baseline to week 24

	<12.9 years Baseline mean age 37.6 years (SD 13.99)			≥12.9-≤23.5 years Baseline mean age 40.1 years (SD 12.88)			>23.5 years Baseline mean age 50.0 years (SD 10.40)

Sotagliflozin further improves percentage of patients achieving HbA_{1c} goal without weight gain in adults with type 1 diabetes after insulin therapy optimisation

R. Henry[1], H. Rodbard[2], A. Giaccari[3], R. Lajara[4], J. Stewart[5], P. Strumph[6], J. Oliveira[7], P. Lapuerta[8], R. Castro[7];
[1]UC San Diego, San Diego, USA, [2]Endocrine & Metabolic Consultants, Rockville, USA, [3]Fondazione Policlinico A. Gemelli, Rome, Italy, [4]DCoA - DFW, Plano, USA, [5]Sanofi, Westmount, USA, [6]Lexicon, Woodlands, USA, [7]Sanofi, Bridgewater, USA, [8]Lexicon, Princeton, USA.

Background and aims: Data indicate that more than 50% of adults with T1D are overweight or obese. Although intensive insulin therapy improves glycemic control and reduces the incidence and progression of diabetes-related complications, it is also associated with potential undesirable effects, including increased risk of hypoglycemia and notably weight gain. Sotagliflozin (SOTA) is a dual SGLT1 and SGLT2 inhibitor, which blunts and delays postprandial hyperglycemia while also reducing renal glucose reabsorption. The goal of this analysis was to determine if SOTA, combined with insulin, could significantly increase the percentage of adults with T1D who achieve HbA1c goals without weight gain.
Materials and methods: In two 52-week phase 3 studies, adults with T1D were randomized 1:1:1 to placebo + insulin (PBO), SOTA 200 mg + insulin, or SOTA 400 mg + insulin, once daily after 6 weeks of insulin therapy optimization. Statistical comparisons of each SOTA arm to PBO were preplanned and performed using a generalized linear model with repeated measures statistics. A pooled data analysis was conducted using an integrated dataset of 1,575 patients (mean BMI: 28.72 kg/m^2 [s.d. 5.28]) to evaluate the percentage of patients achieving HbA1c target of <7% and that had reductions of HbA1c from baseline of ≥0.5%, change of body weight, and safety.
Results: Significant HbA1c reductions were observed with SOTA 200 mg or 400 mg vs. PBO at week 24 and still statistically significant at 52 weeks. Analyses of change from baseline showed significant reduction in weight (kg) at 24 weeks with SOTA vs. PBO (200 mg: −2.17 kg; 400 mg: −3.02 kg) and sustained at 52 weeks (200 mg: −2.67 kg; 400 mg: −3.64 kg), $p < 0.001$, in patients receiving SOTA + insulin vs. PBO. A significantly greater percentage of patients achieved HbA1c reduction of <7% with no weight gain ($p < 0.001$) at both SOTA doses vs. PBO at weeks 24 and 52. Similar results were obtained for patients who achieved HbA1c reductions of ≥0.5% at 24 and 52 weeks ($p < 0.001$). At 52 weeks, patients in both SOTA groups had a lower incidence of severe hypoglycemia (SH) but higher incidence of genital mycotic infections, DKA and diarrhea vs. PBO.
Conclusion: SOTA added to optimized insulin demonstrated significant and sustained reduction of HbA1c and body weight, with a greater percentage of patients reaching their HbA1c goals, without weight gain and with fewer events of SH. More patients on SOTA experienced DKA, genital mycotic infections and diarrhea vs. PBO. In conclusion, for T1D with suboptimal control, adding SOTA to optimized insulin therapy offers a treatment option that improves glycemic control with no increase in body weight and less severe hypoglycemia.

Patients with type 1 diabetes value increased glucose stability and associate it with improved well-being: exit interviews from Sotagliflozin Phase 3 study

P. Lapuerta[1], V.N. Joish[1], C. Ervin[2], E. Evans[2], M. Reaney[3], R. Preblick[3], B. De Fanti[3], R. Castro[3], D. DiBenedetti[2];
[1]Lexicon Pharmaceuticals, Inc., The Woodlands, [2]RTI Health Solutions, Research Triangle Park, [3]Sanofi, Bridgewater, USA.

Background and aims: Sotagliflozin (SOTA) is a dual SGLT1 and SGLT2 inhibitor in Phase 3 development for type 2 and as adjunct to insulin in type 1 diabetes (T1D). In a Phase 3 study (inTandem 1) after 24 weeks, SOTA 200 and 400 mg adjunctive to insulin resulted in higher glycemic control versus insulin alone (plus placebo). A qualitative study was conducted with inTandem 1 participants to better understand experiences with T1D before and during the study.
Materials and methods: All participants who completed or discontinued early from US and Canadian clinical sites, within the past 12 months, were invited to participate in an individual phone interview. Trial sites referred participants sequentially, starting with those who exited the study most recently. All parties were blinded to treatment assignment. Open-ended questions were posed to ascertain a full understanding of the participants' experiences both before and during the trial, including their experience related to trial-related ketone monitoring. Follow-up probes addressed treatment satisfaction and the importance and impact of reported treatment benefits. Importance of symptom improvement was rated on a 5-point scale ranging from "Not at all important" to "Extremely important". Thematic methods were used to analyze the interview transcripts and descriptive statistics were computed for quantitative data. All study procedures were approved by central Institutional Review Boards.
Results: Results were pooled across treatment arms. Thirty-two participants with characteristics representative of the overall study population, completed a phone interview. All participants reported challenges in achieving glycemic control prior to the trial, characterized by frequent "high" ($n = 31$) and "low" ($n = 24$) blood sugar events, included high HbA_{1c} levels ($n = 29$), lack of glucose stability ($n = 27$), and increased insulin use ($n = 18$). Participants reported feelings of stress/worry about T1D ($n = 21$), low energy levels that reduced productivity/physical activity ($n = 20$), and negative impacts on mood including feeling depressed and/or irritable ($n = 21$). Participants who reported greater glucose instability generally reported greater negative impacts across various areas of their lives. Twenty-six participants (81%) reported at least 1 improvement

during the trial, including reduction in the frequency of hyperglycemic ($n = 26$) and hypoglycemic ($n = 14$) events, greater glucose stability and reduced insulin use (both $n = 23$), and lower HbA_{1c} levels ($n = 21$). Improvements most frequently reported as "very important" or "extremely important" included reductions inHbA_{1c} levels (95%) and greater glucose stability (91%). Improvements in T1D symptoms were associated with feeling happier, less stressed/worried, and more in control of T1D. Participants also noted increased energy and improved quality of life related to improved glucose stability. The ketone monitoring requirement was accepted by participants and was not noted as burdensome. No new safety signals were identified.

Conclusion: In this Phase 3 study, interview participants consistently reported that improvement in glycemic stability/control was meaningful and that this improvement had a significant positive impact both clinical and emotional on their lives.

Clinical Trial Registration Number: NCT02384941

Off-label use of SGLT-2 inhibitors in type 1 diabetes: a German/Austrian DPV multicentre analysis of 119,819 patients

B. Bohn[1,2], J. Seufert[3], T. Danne[4], H. Kalscheuer[5], F. Kopp[6], S. Kress[7], P. Fasching[8], R.W. Holl[1,2], on behalf of the DPV-initiative;
[1]Institute of Epidemiology and Medical Biometry, University of Ulm, Ulm, Germany, [2]German Center for Diabetes Research (DZD), Munich-Neuherberg, Germany, [3]Division of Endocrinology & Diabetology, Dep of Medicine II, Medical Faculty, University of Freiburg, University Hospital of Freiburg, Freiburg, Germany, [4]Diabetes Center for Children and Adolescents, Kinder- und Jugendkrankenhaus AUF DER BULT, Hannover, Germany, [5]First Department of Medicine, University of Lübeck, Lübeck, Germany, [6]Diabetes Center, Augsburg Clinical Center, Augsburg, Germany, [7]Medical Clinic I, General Internal Medicine, Gastroenterology, Hepatology, Endocrinology, Diabetes, Vinzentius Hospital Landau, Landau, Germany, [8]5th Medical Department, Wilhelminenspital, Vienna, Austria.

Background and aims: Sodium-glucose cotransporter type-2 inhibitors (SGLT-2i) are not approved for the treatment of type 1 diabetes (T1D). Randomized controlled trials (RCTs) revealed that adding SGLT-2i to insulin therapy in T1D could be advantageous for metabolic control and bodyweight (BW). But an increase in the risk of diabetic ketoacidosis (DKA) was reported as well. Extent and effects of off-label use of SGLT-2i therapy in T1D in real-life diabetes care are currently not known. The aim of this analysis was, therefore, to identify and characterize patients with T1D and SGLT-2i from the German/Austrian diabetes patients follow-up (DPV) registry.

Materials and methods: 119,819 patients with T1D were selected from the DPV registry. Off-label use of SGLT-2i was detected in 184 patients. For each patient, the last year of treatment (before adding SGLT-2i) was analyzed. Sociodemographic and clinical differences were compared between patients initiating add-on therapy with SGLT-2i and those without SGLT-2i. Linear regression models were implemented for hemoglobin A1c (HbA1c), body mass index (BMI) and daily insulin dose/kgBW. Logistic regression was conducted for the proportion of patients with at least one severe hypoglycemia, hypoglycemic coma, or DKA. Models were adjusted for age, sex, and diabetes duration. *P*-level was set at <0.05.

Results: Off-label use of SGLT-2i in T1D ($n = 184$) was predominantly observed in adult patients (≥18 years of age: 90.1%). Patients initiating therapy with SGLT-2i were older (median age: 52.0 years (Q1: 37.4; Q3: 62.9) compared to those without SGLT-2i (17.9 years (14.8; 37.6); $p < 0.0001$) and had a longer diabetes duration (14.8 years (4.1; 25.6) vs. 7.1 years (2.9; 13.7); $p < 0.0001$). Subjects starting with SGLT-2i displayed a higher HbA1c (8.6% vs. 8.3%; $p = 0.0315$) and a higher BMI (28.2 kg/m^2 vs. 23.3 kg/m^2; $p < 0.0001$) compared to those without SGLT-2i. Daily insulin dose/kgBW was comparable (0.81 IU vs. 0.79 IU; $p = 0.4907$). The proportion of patients with at least one severe hypoglycemia, hypoglycemic coma, or DKA did not differ between patient groups (severe: 7.1% vs. 8.2%; $p = 0.5116$/coma: 3.6% vs. 3.1%; $p = 0.6266$/DKA: 0.8% vs. 1.4%; $p = 0.5829$).

Conclusion: SGLT-2i off-label use in T1D was observed in patients with generally worse metabolic control and a higher bodyweight. Potential benefits of SGLT-2i in T1D reported by RCTs could have contributed to the prescription behavior. Further research is needed to investigate efficacy and safety (especially DKA) of adding SGLT-2i therapy in selected patients with T1D in real-life diabetes care.

Dapaglifozin preserves renal function in patients with type 2 diabetes: a longitudinal meta-analysis of eGFR across clinical trials

S. Johansson[1], B. Hamrén[1], M. Åstrand[1], R. Penland[2], D. Boulton[3];
[1]Quantitative Clinical Pharmacology, Early Clinical Development, IMED Biotech Unit, AstraZeneca R&D, Gothenburg, Sweden, [2]Quantitative Clinical Pharmacology, Early Clinical Development, IMED Biotech Unit, AstraZeneca R&D, Boston, USA, [3]Quantitative Clinical Pharmacology, Early Clinical Development, IMED Biotech Unit, AstraZeneca R&D, Gaithersburg, USA.

Background and aims: Results from the recently-completed cardiovascular outcomes trials (CVOTs) testing the sodium-glucose transport protein 2 (SGLT2) inhibitors empaglifozin and canaglifozin (EMPA-REG and CANVAS/R, respectively) indicated renal benefit and lower rates of clinically relevant renal events for SGLT2 inhibitor-treated subjects' vs placebo. Dapaglifozin, an SGLT2-inhibitor approved for the treatment of T2DM is being studied in the ongoing CVOT, DECLARE and in renal outcome. We have done a first, cross-trial model-based analysis with the aim to assess whether dapaglifozin could have renal benefit properties.
Materials and methods: Integrating data cross clinical trials can allow better quantitative insights than assessment of individual trials. We did a model-based meta-analysis, that includes individual serial estimated glomerular filtration rate (eGFR) measurements in T2DM subjects from 8 randomized, placebo-controlled double-blind Phase 2 and 3 dapaglifozin trials. A linear mixed-effect model was used to estimate the effect of placebo and dapaglifozin over time. A baseline model was developed, accounting for the differences in baseline eGFR. Next, a placebo model was added using serial data from placebo subjects, accounting for differences in placebo response observed across trials. Lastly and including all data, dapaglifozin dose-response model was developed characterizing the dapaglifozin effect on eGFR. The effect of population characteristics on the rate of eGFR change, eg duration of T2DM, body mass index, age, gender and concomitant/prior treatment was explored and included if significant ($p < 0.05$) using a chi-square test.
Results: 4.894 subjects with T2DM having a total of 58626 eGFR measurements from 8 dapaglifozin clinical studies were included in this analysis. Subjects were treated with placebo, 1, 2.5, 5 or 10 mg dapaglifozin once daily for up to 2 years. The pooled mean baseline characteristics were an age of 60 years, an HbA1c of 8.2% and an eGFR of 78.5 ml/min/1.73 m^2. On average, the eGFR in placebo treated subjects declined steadily over time (0.3 ml/min/1.73 m^2/year). Subjects treated with dapaglifozin showed a small and immediate decline (~2 ml/min/1.73 m^2, placebo-corrected) as seen with other SGLT2-inhibitors. After the initial, small eGFR drop, dapaglifozin then slowed any further loss of eGFR leading to a dose-dependent net preservation and increase of eGFR over the two-year treatment period. In the average patient, the placebo-corrected treatment effect, post the initial drop was an increase in the rate of eGFR change of +1.2 and +1.4 ml/min/1.73 m^2/year for 5 and 10 mg dapaglifozin respectively. Females had a somewhat larger treatment effect compared to males, whereas no other covariates were identified which indicates similar benefit across the subgroups studied.
Conclusion: This is the first integrated and model-based analysis which shows that dapaglifozin prevents the progressive loss of renal function in T2DM over the two years treatment studied. These results build confidence in the ongoing dapaglifozin renal outcome study.

SGLT2 inhibitor dapagliflozin is renoprotective via mitigation of protein O-GlcNAcylation in streptozotocin-induced diabetes

D.B. Balogh[1,2], J. Hodrea[1], L. Lenart[1], A. Hosszu[1,3], C.K. Mezei[1,2], A. Vannay[4], L.J. Wagner[3], A.J. Szabo[2,4], A. Fekete[1,2];
[1]MTA-SE „Lendület" Diabetes Research Group, Hungarian Academy of Sciences, Budapest, [2]1st Department of Pediatrics, Semmelweis University, Budapest, [3]Department of Transplantation and Surgery, Semmelweis University, Budapest, [4]MTA-SE Pediatrics and Nephrology Research Group, Hungarian Academy of Sciences, Budapest, Hungary.

Background and aims: Normalizing hyperglycaemia is vital in slowing the progression of diabetes and preventing devastating secondary consequences such as diabetic kidney disease (DKD). Sodium-glucose cotransporter 2 inhibitors (SGLT2i) have recently been approved as new anti-hyperglycaemic drugs. To-date SGLT2i have only been approved in type 2 diabetes mellitus, while only a few studies are currently underway in type 1 diabetes mellitus (T1DM) using SGLT2i as an add-on to insulin therapy. Growing body of clinical data support that SGLT2i have renoprotective effects; but the mechanism of action is still not fully clarified. We previously showed that enhanced *O*-GlcNAcylation (increased addition of single *O*-GlcNAc moieties by *O*-GlcNAc tranferase (OGT) or decreased removal by *O*-GlcNAcase (OGA)) in DKD induces cellular processes leading to kidney fibrosis. Since there is still an unmet need for oral therapies in T1DM here we investigated the antidiabetic effect and the underlying mechanisms of renoprotection of the highly selective SGLT2 inhibitor dapagliflozin (DAPA) in a streptozotocin-induced model of T1DM.
Materials and methods: Diabetes (D) was induced by streptozotocin (65 mg/bwkg, *ip.*) in adult, male Wistar rats. Following the onset of D, animals were treated for six weeks with dapagliflozin (D+DAPA, 1 mg/bwkg/day, *po.*). Metabolic, renal parameters and kidney fibrosis were evaluated. *O*-GlcNAc, OGT and OGA protein levels were measured. Specific markers of tubular damage (NGAL, KIM-1), profibrotic factors (TGF-β, CTGF, PDGF, PAI-1) and proinflammatory cytokines (IL-6, IL-1β, TNF-α) were determined.
Results: Development of DKD was confirmed by functional impairment, massive proteinuria and structural damage of kidneys. DAPA reduced weight loss (D: 256 ± 10.9 *vs.* D+DAPA: 333 ± 13.9 g; $p < 0.01$), decreased blood glucose levels (D: 37 ± 2.7 *vs.* D+DAPA: 18 ± 5.6 mmol/L; $p < 0.05$) and improved renal function (creatinine clearance: D: 3.8 ± 0.4 *vs.* D+DAPA: 8.91.0 mL/min; $p < 0.01$). DAPA treatment minimized hyperglycaemia-induced protein *O*-GlcNAcylation and OGT levels. Subsequently profibrotic growth factor (CTGF, PDGF, TGF-β, PAI-1) expressions and renal fibrotic tissue accumulation were reduced. Renal proinflammatory cytokine (TNF-α, IL-1β, IL-6) expressions were also decreased by DAPA.
Conclusion: Our results support that DAPA is an effective and safe treatment in experimental DKD. Here we identified a novel mechanism: inhibition of OGT by DAPA results in decreased *O*-GlcNAcylation which leads to alleviated kidney fibrosis and improved renal function.

Effect of dapagliflozin on renal and cardiac function in patients with type 2 diabetes and albuminuria: a randomised study

M.K. Eickhoff[1], F.J. Olsen[2], M. Frimodt-Møller[1], L.J. Diaz[1], M.T. Jensen[2], P. Rossing[1,3], F. Persson[1];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]Herlev & Gentofte Hospital, Gentofte, [3]University of Copenhagen, Copenhagen, Denmark.

Background and aims: To evaluate the effect of dapagliflozin treatment on renal and myocardial funtion assessed with advanced echocardiography,

and cardiac biomarkers when added to standard care in patients with type 2 diabetes (T2D).

Materials and methods: This is a sub-study of a double-masked randomized placebo-controlled crossover trial of 12 weeks treatment with dapagliflozin 10 mg once daily or matching placebo. All patients were on RAS blocking treatment. Included patients ($n = 40$) had T2D and albuminuria at baseline. At the end of the treatment period echocardiography (TTE) was performed, ^{51}Cr-EDTA, albuminuria and 24h blood pressure were measured, as well as cardiac markers in plasma; troponin I, MRproANP, MRproADM and copeptin.Global longitudinal strain (GLS) was the primary systolic echocardiographic endpoint. To assess diastolic function a combined diastolic endpoint was used including mean early diastolic myocardial velocity (e'), ratio between early transmitral inflow velocity (E) and e' (E/e'), atrial volume, and pulmonary pressure (TRmaxPG). Values at the end of treatment periods (placebo vs. dapagliflozin) were compared using mixed model analysis. Change in the four variables estimating change in diastolic function were weighted with an individual z-score and combined with a computed weighted average with weights equal to the inverse estimated variance.

Results: Baseline geometric mean urinary albumin creatinine ratio (UACR) was 147 (IQR 75–289) mg/g, mean eGFR 85 (SD ±19.7) ml/min/1.72 m^2. Baseline HbA_{1c} was 73 (SD ±15) mmol/mol, 24 h blood pressure 148/82 (SD ±12.5/7.7) mmHg, diabetes duration 16.5 (SD ±4.8) years, age 65 (SD ±8) years and 90% were male. After 12 weeks treatment with dapagliflozin vs. placebo, GFR decreased by 10.9 (5–16) ml/min ($p < 0.01$), UACR was reduced by 36% (95% CI 16–56%), HbA_{1c} was reduced by 7.4 (5–10) mmol/mol ($p < 0.01$) and 24 h blood pressure decreased 4.8/2.7 mmHg ($p = 0.023/0.031$). Left ventricular ejection fraction after placebo was 55.5 (SD ±6.7) % and 53.7 (SD ±6.7) % after active treatment - a non-significant change. GLS did not change whereas diastolic function improved significantly with 19.8% (3.3–36.3%, $p = 0.021$). Plasma concentration of NTproBNP , troponin, MRproANP, and MRproADM did not change. Plasma concentration of copeptin increased with 32.3% ($p < 0.0001$).

Conclusion: Treatment of dapagliflozin 10 mg vs. placebo in patients with albuminuria was associated with a clinically significant reduction in albuminuria, 24 h blood pressure, and GFR, paralleled by improvement in diastolic function but not GLS, demonstrating simultaneous beneficial renal and cardiac effects of SGLT2 inhibition.

Composite retinopathy outcome in patients treated with empagliflozin versus placebo in the EMPA-REG OUTCOME trial

S.E. Inzucchi[1], C. Wanner[2], U. Hehnke[3], J. Lee[3], S. Kaspers[3], D. Clark[3], J.T. George[3], B. Zinman[4];
[1]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [2]Department of Medicine, Würzburg University Clinic, Würzburg, Germany, [3]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [4]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Canada.

Background and aims: Recently, questions have been raised about the effect of glucose-lowering drugs on retinopathy. In the EMPA-REG OUTCOME trial in patients with type 2 diabetes and established cardiovascular (CV) disease, empagliflozin (EMPA) given in addition to standard of care reduced the relative risk of 3-point major adverse CV events by 14%, driven by a 38% reduction in CV death. In addition, the relative risk of a pre-specified composite microvascular outcome of time to first initiation of retinal photocoagulation, vitreous haemorrhage, diabetes-related blindness, or incident or worsening nephropathy was reduced by 38% vs placebo (PBO), driven by the renal component. We analysed the effect of EMPA on retinopathy in the EMPA-REG OUTCOME trial.

Materials and methods: Patients were randomised to receive EMPA 10 mg, EMPA 25 mg, or PBO. Background glucose-lowering therapy was to remain unchanged for 12 weeks then be adjusted to achieve glycaemic control according to local guidelines. In post hoc analyses, we assessed the risk of a composite outcome of time to first initiation of retinal photocoagulation, vitreous haemorrhage, diabetes-related blindness, or administration of intravitreal agents. Differences in risk between the pooled EMPA and PBO groups were assessed using a Cox proportional hazards model in patients treated with ≥1 dose of study drug. To assess the potential impact of glucose lowering on retinopathy, we assessed the risk of the composite outcome after week 12 in subgroups by reduction in HbA1c at week 12 (<1% and ≥1%).

Results: There was no difference between EMPA and PBO in the risk of the composite retinopathy outcome (HR 0.78 [95% CI 0.54, 1.12]; $p = 0.1732$), nor any of its components (Figure). In subgroup analyses, the risk of the composite retinopathy outcome with EMPA vs PBO after week 12 was similar irrespective of whether patients had a reduction in HbA1c at week 12 of <1% (HR 0.87 [95% CI 0.58, 1.31]) or ≥1% (HR 0.40 [95% CI 0.14, 1.14]) ($p = 0.1755$ for treatment by subgroup interaction).

Conclusion: In the EMPA-REG OUTCOME trial in patients with T2DM and established CV disease, there was no difference in risk of retinopathy between patients treated with EMPA and PBO.

Assessment of adverse renal effects in patients with type 2 diabetes receiving ertugliflozin

S.G. Terra[1], S. Patel[2], A. Hickman[3], R. Frederich[4], B. Lauring[2], S. Johnson[4], S. Huyck[2], J.P. Mancuso[3];
[1]Pfizer Inc., Andover, [2]Merck & Co., Inc., Kenilworth, [3]Pfizer Inc., Groton, [4]Pfizer Inc., Collegeville, USA.

Background and aims: Ertugliflozin (ERTU) is a selective inhibitor of sodium-glucose cotransporter 2 (SGLT2) for the treatment of adults with type 2 diabetes mellitus (T2DM). Based on the mechanism of action of SGLT2 inhibitors, the risk of adverse renal effects was assessed in patients with T2DM receiving ERTU.

Materials and methods: Adverse renal effects were assessed in adults with T2DM receiving ERTU relative to placebo (PBO) or active comparators in pooled analyses of 7 randomised, double-blind, Phase 3 trials. Patients ($N = 4859$) received ERTU 5 mg ($n = 1716$), ERTU 15 mg ($n = 1693$) or non-ERTU (PBO, glimepiride or sitagliptin; $n = 1450$) for up to 2 years.

Results: Mean age was 57.8 y and 25.8% were ≥65 y; 51.8% were males. Mean eGFR was 85.3 ml min^{-1} 1.73 m^{-2} and ~12% had moderate renal impairment (RI). The mean duration of T2DM was 7.9 y and mean baseline HbA_{1C} was 66 mmol/mol (8.2%). The incidence of renal-

related adverse effects (AEs) was low across all groups (ERTU 5 mg, 0.6%; ERTU 15 mg, 0.8%; non-ERTU, 0.4%); few were serious (0.1% in all groups) or led to treatment discontinuation (0.1%, 0.2% and 0.1%, respectively). Subgroup analyses demonstrated that in patients with moderate RI, renal-related AEs were more frequent in the ERTU groups relative to the non-ERTU group (ERTU 5 mg, 3.6%; ERTU 15 mg, 2.1%; non-ERTU, 1.1%). Incidence of renal-related AEs was similar across groups for patients ≥65 y old (excluding those with moderate RI at baseline) (ERTU 5 mg, 0.3%; ERTU 15 mg, 1.0%; non-ERTU, 0.8%) or those using diuretics (ERTU 5 mg, 1.2%; ERTU 15 mg, 0.8%; non-ERTU, 0.8%) or ACE inhibitors/angiotensin-receptor blockers (ERTU 5 mg, 0.9%; ERTU 15 mg, 0.9%; non-ERTU, 0.5%). Independent blinded adjudication for causality was performed for prespecified renal-related AEs and renal laboratory changes from baseline. Four patients had renal events that were adjudicated as causally related to study medication ("possible" or "very likely"; 1 in the ERTU 5 mg group, 2 in the ERTU 15 mg group and 1 in the non-ERTU group).

Conclusion: There was no evidence of increased risk of adverse renal effects in patients with T2DM receiving ERTU relative to PBO or active comparators, except in those with baseline moderate RI.

Effect of dapagliflozin (DAPA) on cardiovascular and renal risk factors in patients with type 2 diabetes treated with or without renin-angiotensin system inhibitors (RASi)

D.H. van Raalte[1], R. Correa-Rotter[2], R. Toto[3], H.J.L. Heerspink[4], V. Cain[5], B.V. Stefansson[6], C.D. Sjöström[6], P. Sartipy[6];
[1]Department of Internal Medicine, VU University Medical Center, Amsterdam, Netherlands, [2]Nephrology and Mineral Metabolism, National Medical Science and Nutrition Institute Salvador Zubirán, Mexico City, Mexico, [3]University of Texas Southwestern Medical Center, Dallas, USA, [4]Clinical Pharmacy and Pharmacology, University of Groningen, Groningen, Netherlands, [5]Bogier Clinical and IT Solutions Inc, Raleigh, USA, [6]Cardiovascular, Renal and Metabolic Disease, AstraZeneca, Gothenburg, Sweden.

Background and aims: Reduction of urinary protein excretion and optimal blood pressure (BP) control are the main focus of current therapeutic strategies to prevent and slow progression of diabetic proteinuric kidney disease in type 2 diabetes (T2D). RASi are the most effective treatment options but significant residual proteinuria remains. Novel therapeutic strategies, such as sodium-glucose cotransporter 2 inhibitors (SGLT2i) may complement RASi by offering additional proteinuria reduction and renal protection. This study investigated the effects of the SGLT2i DAPA in patients with T2D with micro- and macro-albuminuria treated with or without RASi at baseline.

Materials and methods: In this post hoc analysis, we evaluated the effect of DAPA 10 mg/day over 24 weeks (w) across 13 placebo-controlled studies in patients with T2D with urinary albumin: creatinine ratio (UACR) ≥30 mg/g at baseline. The patient population was divided into 2 subgroups based on treatment (Yes/No) with RASi at baseline.

Results: A total of 957 and 302 patients were included in the groups with or without RASi treatment at baseline, respectively. Demographic and baseline characteristics were similar between groups, but patients without RASi treatment had shorter duration of diabetes (7 vs 12 years), higher estimated glomerular filtration rate (eGFR) (90 vs 79 mL/min/1.73 m^2), and slightly lower UACR, serum uric acid (sUA), body weight, and systolic blood pressure (SBP) at baseline. Placebo-adjusted treatment effects of DAPA 10 mg on UACR, eGFR, HbA_{1c}, and hematocrit over 24 w were similar across groups (Table). Mean reductions in body weight and sUA were more distinct in patients treated without RASi at baseline. The placebo-adjusted treatment effect of DAPA 10 mg on UACR in the overall population was independent of other covariates (age, race, body weight, SBP, eGFR, and RASi use). Adverse event (AE) profiles were similar between placebo and DAPA 10 mg in each group, consistent with known DAPA safety profile. There were more serious AEs and hypoglycaemia in patients with RASi.

Conclusion: Treatment with DAPA over 24 w provides similar clinically relevant improvements in metabolic and haemodynamic parameters and similar reductions in UACR in patients with T2D with albuminuria treated with or without RASi at baseline. Further investigation of cardiovascular and renal outcomes in patients with T2D treated with DAPA on top of RASi is warranted.

Table I. Adjusted change from baseline at week 24

	Adjusted change from baseline at week 24, difference vs PBO*		
	With RASi at baseline	Without RASi at baseline	*P* value for overall treatment by subgroup interaction
UACR (%)**	-19.0 (-28.5, -8.2)	-17.3 (-35.7, 6.4)	0.7499
SBP (mm Hg)	-3.4 (-5.0, -1.7)	-6.3 (-9.1, -3.6)	0.1449
DBP (mm Hg)	-1.9 (-2.9, -0.9)	-2.8 (-4.6, -0.9)	0.7249
eGFR (mL/min/1.73 m^2)	-1.4 (-3.1, 0.2)	-2.0 (-5.1, 1.1)	0.3808
HbA_{1c} (%)	-0.4 (-0.5, -0.3)	-0.5 (-0.7, -0.2)	0.4116
Body weight (kg)	-1.7 (-2.1, -1.3)	-2.5 (-3.3, -1.7)	0.0198
sUA (mg/dL)	-0.4 (-0.5, -0.2)	-0.6 (-0.8, -0.4)	0.0433
Haematocrit (%)	2.9 (2.5, 3.2)	2.5 (1.8, 3.1)	0.5944

Acute renal outcomes with sodium glucose co-transporter 2 inhibitors: real world data analysis

C. Melzer Cohen[1], A. Cahn[2,3], R. Pollack[2,3], V. Shalev[1,4], G. Chodick[1,4];
[1]Medical division, Maccabi Healthcare Services, Tel Aviv, [2]Diabetes Unit and Endocrinology and Metabolism Unit, Hadassah Hebrew University Hospital, Jerusalem, [3]Diabetes Clinic, Maccabi Healthcare Services, Jerusalem, [4]School of Public Health, Tel Aviv University, Tel Aviv, Israel.

Background and aims: Sodium glucose co-transporter 2 inhibitors (SGLT2-i) ameliorate hyperglycemia by blocking renal glucose reabsorption and are indicated for the treatment of adults with type 2 diabetes mellitus (T2DM). We aimed to evaluate short-term renal outcomes in a real-world cohort of new users of SGLT2-i compared to new users of Dipeptidyl Peptidase-4 inhibitors (DPP-4i).

Materials and methods: Included in this retrospective cohort study were patients with T2DM who initiated SGLT2-i or DPP-4i during 1/4/2015–30/6/2017, had a baseline serum creatinine (SCr) measurement within 180 days prior to treatment initiation and had a second SCr measurement, hospitalization with acute kidney injury (AKI) or death within 24 weeks of index date. Primary endpoints were (1) ≥30% reduction in estimated glomerular filtration rate (eGFR) from baseline; and (2) hospitalization with AKI, initiation of dialysis, or sustained eGFR of <15 mL/min/1.73 m^2. Additional endpoints included deterioration in chronic kidney disease (CKD) category, doubling of SCr, hospitalization for AKI, all-cause mortality and hospitalization for any cause.

Results: Overall, 6418 and 5604 patients initiated SGLT2-i and DPP-4i, respectively. Baseline mean (SD) eGFR was higher among SGLT2-i users (88.3 [17.4] mL/min/1.73 m^2) vs. DPP-4i users (82.8 [23.7] mL/

min/1.73 m^2), yet eGFR levels were similar between groups when stratified by CKD stages. Fewer patients with eGFR ≤60 mL/min/1.73 m^2 were in the SGLT2-i (n = 503, 7.8%) vs. DPP4-i group (n = 1059, 18.9%). The adjusted OR (95% CI) for ≥30% reduction in eGFR with SGLT2-i vs. DPP4-i was 0.70 (0.49–1.00) and adjusted ORs ranged from 1.97 (0.62–6.26) to 0.45 (0.21–0.99) in patients with baseline eGFR 30–45 and ≥90 mL/min/1.73 m², respectively. The adjusted OR for CKD stage deterioration was 1.01 (0.90–1.14). Although not statistically significant, a similar trend was observed with adjusted ORs ranging from 1.95 (0.96–3.97) to 0.85 (0.68–1.08) among patients with baseline eGFR 30–45 and 60–90 mL/min/1.73 m², respectively. There was a lower risk of hospitalization for AKI with SGLT2-i vs. DPP-4i (adjusted OR (95% CI) 0.47 (0.27–0.80)) with grossly similar ORs across eGFR categories. Two patients initiated dialysis, both in the DPP-4i group. All-cause mortality, and hospitalizations were reduced with SGLT2-i vs. DPP-4i as well (adjusted OR (95% CI) 0.43 (0.20–0.95) and 0.66 (0.56–0.78) respectively).

Conclusion: This real-world data analysis supports evidence from previous randomized clinical trials demonstrating a reduction in hospitalizations for AKI, any hospitalizations and mortality among SGLT2-i users across all CKD categories. Nevertheless, due to the more prominent decrease in eGFR in patients with moderate CKD, cautious use of these agents in patients with low eGFR is advisable.

Disclosure: **C. Melzer Cohen:** None.

Effect of sotagliflozin on renal threshold for glucose reabsorption and on gastrointestinal glucose absorption in subjects with type 2 diabetes: a model based quantification

H.-C. Schneider, A. Strougo, B. Göbel, T. Klabunde, R. Dahmen, M. Riz;
Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: The dual SGLT1 and 2 inhibitor sotagliflozin reduces plasma glucose by blocking renal SGLT2 and by inhibiting intestinal SGLT1, thus increasing urinary glucose excretion and protracting gastrointestinal glucose absorption. The reduced rate of oral glucose appearance has previously been shown in healthy volunteers using glucose tracer techniques. Here, we investigated the effect of sotagliflozin on renal threshold for glucose excretion (RTg) and gastrointestinal glucose absorption in type-2-diabetic (T2D) subjects using the oral glucose minimal model and clinical data of a Phase IIa study with sotagliflozin in T2D subjects.

Materials and methods: In the Phase IIa study, after a 14-day metformin washout period, subjects were randomized to receive placebo or 150 mg or 300 mg QD sotagliflozin in an oral liquid formulation for 4 weeks. Oral glucose tolerance tests (OGTT) were performed in each arm before the treatment period (Day -2) and at the end of treatment (Day 27). First, the effect on RTg was quantified using total amount of glucose excreted via the urine and 8-point self-measured blood glucose. This first step allowed including urinary glucose excretion induced by SGLT2 inhibition into the oral glucose minimal model. The validity of the resulting model to estimate the protraction in gastrointestinal glucose absorption was shown using data of a glucose tracer study in healthy volunteers. This validated, modified version of the oral glucose minimal model was then applied to the OGTT data to evaluate the rate of oral glucose appearance in T2D subjects.

Results: The first step of the analysis showed that both sotagliflozin doses significantly lowered RTg from 212.4 ± 44.4 to 108.8 ± 26.3 mg/dL (mean ± SD) under 150 mg QD and from 226.5 ± 27.6 to 96.2 ± 24.0 mg/dL under 300 mg QD. Moreover, both sotagliflozin doses reduced the amount of glucose absorbed during the first hour after glucose intake. The area under the curve (AUC) for the rate of oral glucose appearance in the first hour was reduced from Day -2 to Day 27 by 33.3% (from 347.6 ± 68.3 to 232.0 ± 38.0 mg/kg) under 150 mg QD sotagliflozin and by 42.3% (from 385.4 ± 70.1 to 222.5 ± 53.4 mg/kg) under 300 mg QD sotagliflozin, while there was no significant effect in the placebo group. No difference was found in AUC between 0 and 3 hours from Day -2 to Day 27 indicating that sotagliflozin mediated inhibition of intestinal SGLT1 protracts but does not generally block glucose absorption.

Conclusion: The oral glucose minimal model could be extended to analyze the rate of oral glucose appearance under sotagliflozin treatment from OGTT data in T2D subjects without the need for complex and expensive glucose tracer studies. The analysis showed that after 4 weeks of treatment sotagliflozin significantly reduced the renal threshold for glucose excretion. In addition, the model based analysis demonstrated that sotagliflozin in T2D subjects protracts the time course of oral glucose absorption, but the total amount of glucose absorbed during an OGTT is not reduced. This additional effect is attributed to the inhibition of gastrointestinal SGLT1 and is expected to add beneficial effects of this dual SGLT1 and 2 inhibitor in the post-prandial phase.

PS 046 Efficacy and safety of the SGLT2 inhibitor ertugliflozin

625

A pooled analysis of the efficacy and safety of ertugliflozin as add-on therapy to metformin

R.A. Calle[1], J. Liu[2], S. Huyck[2], L. Wu[2], A. Pong[2], J.P. Mancuso[3], S.G. Terra[4], B. Lauring[2];
[1]Pfizer Inc., Cambridge, [2]Merck & Co., Inc., Kenilworth, [3]Pfizer Inc., Groton, [4]Pfizer Inc., Andover, USA.

Background and aims: Ertugliflozin, an oral sodium-glucose cotransporter 2 inhibitor, improves glycaemic control in adult patients with type 2 diabetes mellitus (T2DM). This pooled analysis characterised the efficacy and safety of ertugliflozin when used as add-on therapy to metformin.
Materials and methods: Pooled data from two randomised, double-blind, placebo-controlled Phase 3 studies with similar design and patient population (VERTIS MET and VERTIS SITA2) were analysed. Adult patients with T2DM inadequately controlled on metformin (± sitagliptin) with HbA1c 53–91 mmol/mol (7.0–10.5%) were randomised to placebo, ertugliflozin 5 mg or 15 mg for 26 weeks.
Results: Mean baseline characteristics of included patients ($N = 1083$) were similar across pooled treatment groups (age 57.7 years; T2DM duration 8.6 years; HbA1c 65 mmol/mol (8.1%); body weight 85.7 kg; systolic blood pressure [SBP] 130.6 mmHg; estimated GFR 89.4 mL min^{-1} 1.73 m^{-2}). Changes in HbA1c, body weight and SBP after 26 weeks are shown in the Table. Relative to placebo, more patients receiving ertugliflozin had HbA1c <53 mmol/mol (7.0%), body weight reduction of ≥5%, or SBP <130 mmHg (among patients with baseline SBP ≥130 mmHg) at Week 26. Ertugliflozin had an overall similar safety profile to placebo, except for a higher incidence of adverse events (AEs) of genital mycotic infections and of AEs related to osmotic diuresis.
Conclusion: Addition of ertugliflozin to metformin (± sitagliptin) provides reductions in HbA1c, body weight and SBP, resulting in more patients achieving metabolic treatment goals.

Long-term efficacy and safety of ertugliflozin in patients with type 2 diabetes inadequately controlled with metformin monotherapy: 104-week VERTIS MET Trial

S. Gallo[1], B. Charbonnel[2], A. Goldman[3], H. Shi[4], S. Huyck[5], A. Darekar[6], B. Lauring[5], S.G. Terra[7];
[1]Pfizer Deutschland GmbH, Berlin, Germany, [2]University of Nantes, Nantes, France, [3]Pfizer Inc., Collegeville, USA, [4]Pfizer Inc., New York, USA, [5]Merck & Co., Inc., Kenilworth, USA, [6]Pfizer Ltd., Tadworth, UK, [7]Pfizer Inc., Andover, USA.

Background and aims: Ertugliflozin (ERTU) is a selective inhibitor of sodium-glucose cotransporter 2 for treatment of adults with type 2 diabetes mellitus (T2DM). The present study evaluated the long-term safety and efficacy of ERTU in patients with T2DM inadequately controlled with metformin (MET) monotherapy.
Materials and methods: This Phase 3 randomised, double-blind study in adults with T2DM (HbA_{1C} 53–91 mmol/mol [7.0–10.5%]) on MET (≥1500 mg/d ≥8 wk) included a 26-wk placebo (PBO)-controlled period followed by a 78-wk extension where non-rescued PBO patients with fasting finger-stick glucose ≥6.1 mmol/l received blinded glimepiride

(GLIM). Efficacy, safety and effect on bone mineral density (BMD) of ERTU 5 mg and 15 mg once daily at Wk 104 are reported.

Results: Patients ($N = 621$) had baseline mean ± SD: age 56.6 ± 8.8 y; T2DM duration 8.0 ± 6.0 y; BMI 31.1 ± 4.7 kg/m^2; HbA_{1C} 65.2 ± 9.9 mmol/mol (8.1 ± 0.9%); 41% were post-menopausal women. At Wk 104, ERTU 5 mg and 15 mg reduced HbA_{1C}, fasting plasma glucose, body weight (BW) and BP compared with baseline, and increased the proportion of patients with HbA_{1C} <53 mmol/mol (7%) (Table). Incidence of female genital mycotic infections was higher with ERTU 5 mg (7.3%; $P = 0.017$) and 15 mg (9.8%; $P = 0.003$) vs PBO/GLIM (0.9%). The incidence of symptomatic hypoglycaemia was lower with ERTU 5 mg (5.8%; $P = 0.009$) and 15 mg (5.9%; $P = 0.009$) vs PBO/GLIM (13.4%). ERTU had no impact on BMD vs PBO/GLIM, except total hip where BMD reduction was greater for ERTU 15 mg (Table). Fractures occurred in 3 (1.4%), 2 (1.0%) and 7 (3.3%) patients in the ERTU 5 mg, 15 mg and PBO/GLIM groups, respectively.

Conclusion: ERTU added to MET improved glycaemic control, BW and BP over 104 wk in patients with inadequately controlled T2DM. ERTU was well tolerated, with no clinically meaningful impact on BMD.

Table: Change in efficacy (vs baseline) and bone mineral density (vs PBO/GLIM) endpoints

		ERTU 5 mg	ERTU 15 mg

Safety and efficacy of ertugliflozin compared with glimepiride after 104 weeks in patients with type 2 diabetes inadequately controlled on metformin: VERTIS SU extension

P. Hollander[1], J. Liu[2], J. Hill[2], J. Johnson[2], Z.W. Jiang[3], D. Wang[3], G. Golm[2], S. Huyck[2], S. Terra[4], J.P. Mancuso[5], S.S. Engel[2], B. Lauring[2]; [1]Baylor Endocrine Center, Dallas, USA, [2]Merck & Co., Inc., Kenilworth, USA, [3]MSD R&D (China) Co., Ltd, Beijing, China, [4]Pfizer Inc., Andover, USA, [5]Pfizer Inc., Groton, USA.

Background and aims: Ertugliflozin, an oral sodium-glucose cotransporter 2 (SGLT2) inhibitor, improves glycaemic control in adults with type 2 diabetes mellitus (T2DM). This 52-week extension to the 52-week base study compared the long-term safety and efficacy of ertugliflozin with that of glimepiride over 104 weeks.

Materials and methods: In this double-blind, Phase 3 study (VERTIS SU), adults with HbA1c 53–75 mmol/mol (7.0–9.0%) on metformin ≥1500 mg/day were randomised 1:1:1 to ertugliflozin 5 mg, 15 mg, or glimepiride (initiated at 1 mg/day, up-titrated to 6 or 8 mg/day dependent on local labelling or maximum tolerated). The primary time point for efficacy was Week 52; treatment was continued until Week 104 in a blinded extension.

Results: Baseline characteristics of randomised, treated patients eligible for analysis ($n = 1315$) were similar across groups (mean age 58.2 years, HbA1c 62 mmol/mol [7.8%], duration of T2DM 7.5 years, estimated GFR [eGFR] 87.2 mL min^{-1} 1.73 m^{-2}). Approximately 60% of patients in each group completed Week 104 on study medication. Mean dose of glimepiride at Weeks 52 and 104 was 3.0 mg/day and 3.5 mg/day, respectively. As previously reported, ertugliflozin 15 mg was non-inferior to glimepiride in reducing HbA1c at Week 52. After 104 weeks, reductions in HbA1c from baseline were observed in all treatment groups; greater reductions in body weight and systolic BP were seen with ertugliflozin relative to glimepiride (Table). A similar incidence of adverse events (AEs) (Table) and serious AEs was reported across groups at Week 104. A total of 7 (1.6%), 2 (0.5%), and 1 (0.2%) patients receiving ertugliflozin 5 mg, 15 mg, or glimepiride, respectively, died; none of the AEs leading to death were considered drug-related. The incidence of symptomatic hypoglycaemia was significantly lower with ertugliflozin 5 mg and 15 mg compared with glimepiride ($p < 0.001$ for each comparison). Incidence of severe hypoglycaemia was lower with ertugliflozin (1 [0.2%] in each group) compared with glimepiride (15 [3.4%]). Incidence of genital mycotic infection (GMI) was significantly higher with ertugliflozin 5 mg and 15 mg than glimepiride ($p < 0.05$ for each comparison). Incidences of urinary tract infection and hypovolaemia were similar across groups. Mean change from baseline in eGFR at Week 104 was 0.7, 0.7 and −1.9 mL min^{-1} 1.73 m^{-2} in the ertugliflozin 5 mg, 15 mg, and glimepiride groups, respectively.

Conclusion: In patients with T2DM inadequately controlled on metformin, ertugliflozin led to clinically meaningful reductions in HbA1c over 104 weeks, similar to those observed with glimepiride. Relative to glimepiride, the incidence of symptomatic and severe hypoglycaemia was lower, and incidence of GMI was higher, for both ertugliflozin 5 mg and 15 mg doses.

Effects of ertugliflozin monotherapy or combination therapy on glycaemic control, body weight, and blood pressure in patients with type 2 diabetes: a pooled analysis

B. Lauring[1], J. Liu[1], L. Tarasenko[2], S.G. Terra[3], S. Huyck[1], L. Wu[1], A. Pong[1], R.A. Calle[4], S. Gallo[5], A. Darekar[6], J.P. Mancuso[7];
[1]Merck & Co., Inc., Kenilworth, USA, [2]Pfizer Inc., New York, USA, [3]Pfizer Inc., Andover, USA, [4]Pfizer Inc., Cambridge, USA, [5]Pfizer Pharma GmbH, Berlin, Germany, [6]Pfizer Ltd, Walton Oaks, UK, [7]Pfizer Inc., Groton, USA.

Background and aims: Ertugliflozin, an oral sodium-glucose cotransporter 2 inhibitor, improves glycaemic control in adult patients with type 2 diabetes mellitus (T2DM). This pooled analysis assessed changes from baseline in HbA1c, body weight (BW) and systolic blood pressure (SBP), with ertugliflozin 5 mg and 15 mg relative to placebo across three placebo-controlled Phase 3 studies.
Materials and methods: The analyses were conducted on pooled data from three randomised, double-blind, placebo-controlled Phase 3 studies with similar design and patient population (VERTIS MONO, VERTIS MET and VERTIS SITA2). Adult patients with T2DM inadequately controlled on diet and exercise only, or on metformin alone, or on metformin and sitagliptin, were randomised to receive placebo, ertugliflozin 5 mg, or ertugliflozin 15 mg for 26 weeks. Change from baseline to Week 26 in HbA1c and BW (predefined analyses), and in SBP (post-hoc analysis), for each ertugliflozin group was compared with placebo. Analyses were also conducted by baseline subgroup categories (including age, sex, race, ethnicity, region, body mass index, HbA1c, estimated GFR [eGFR], and duration of T2DM).
Results: Mean baseline characteristics of included patients ($n = 1544$) were similar across treatment groups (overall mean age 57.3 years; T2DM duration 7.5 years; eGFR 88.9 mL min^{-1} 1.73 m^{-2}). Overall, 89% of patients were overweight or obese, and 68% had a diagnosis of hypertension at baseline. Mean baseline HbA1c, BW and SBP were similar across groups (HbA1c: 65.1, 64.9 and 65.7 mmol/mol [8.1, 8.1 and 8.2%]; BW: 88.0, 88.5 and 87.3 kg; SBP: 129.7, 131.0 and 130.5 mmHg; in the placebo, ertugliflozin 5 mg, and ertugliflozin 15 mg groups, respectively). At Week 26, greater reductions from baseline in HbA1c, BW and SBP were observed with ertugliflozin compared with placebo (Table). More patients receiving ertugliflozin had HbA1c <53 mmol/mol (7.0%), a BW reduction of ≥5%, or SBP <130 mmHg (among patients with baseline SBP ≥130 mmHg) at Week 26 relative to placebo (Table). Clinically meaningful reductions in HbA1c, BW and SBP with ertugliflozin compared with placebo were generally consistent across subgroup categories analysed. The safety profile of ertugliflozin was similar to that of placebo, except for a higher incidence of drug-related adverse events that was primarily driven by genital mycotic infections and adverse events related to osmotic diuresis.
Conclusion: After 26 weeks of treatment in patients with T2DM, ertugliflozin led to greater reductions from baseline in HbA1c, BW and SBP compared with placebo, resulting in more patients achieving metabolic treatment goals.

Design and baseline characteristics of the eValuation of ERTugliflozin effIcacy and Safety CardioVascular outcomes trial (VERTIS-CV)

D.K. McGuire[1], C.P. Cannon[2], R. Pratley[3], S. Dagogo-Jack[4], J. Mancuso[5], S. Huyck[6], B. Charbonnel[7], W.J. Shih[8], S. Gallo[9], U. Masiukiewicz[5], G. Golm[6], F. Cosentino[10], B. Lauring[6], S.G. Terra[11];
[1]University of Texas Southwestern Medical Center, Dallas, USA, [2]Harvard Medical School, Baim Institute for Clinical Research, Boston, USA, [3]Florida Hospital Translational Research Institute for Metabolism and Diabetes, Orlando, USA, [4]University of Tennessee Health Science Center, Memphis, USA, [5]Pfizer Inc., Groton, USA, [6]Merck & Co., Inc., Kenilworth, USA, [7]University of Nantes, Nantes, France, [8]Rutgers Cancer Institute of New Jersey, New Brunswick, USA, [9]Pfizer Inc., Berlin, Germany, [10]Unit of Cardiology, Karolinska University Hospital Solna, Stockholm, Sweden, [11]Pfizer Inc., Andover, USA.

Background and aims: Ertugliflozin (ERTU) is a selective inhibitor of sodium-glucose cotransporter 2 (SGLT2). The VERTIS cardiovascular (CV) outcomes trial has a primary objective to demonstrate noninferiority of ERTU vs placebo (PBO) on time to the first major cardiac event outcome (CV death, nonfatal myocardial infarction or nonfatal stroke). Secondary objectives are to demonstrate superiority of ERTU vs PBO on time to first event of CV death or hospitalisation for heart failure; CV death; and first event of renal death, dialysis/transplant or doubling of serum creatinine from baseline.
Materials and methods: Patients ≥40 years old with type 2 diabetes mellitus (T2DM) (HbA_{1C} 53–91 mmol/mol [7.0–10.5%]) and established atherosclerotic vascular disease of the coronary, cerebral and/or peripheral arterial systems were randomised 1:1:1 in a double-blind fashion to PBO or ERTU 5 mg or 15 mg added to existing therapy.
Results: 8246 patients were randomised and 8238 patients received ≥1 dose of study drug. Coronary artery disease, cerebrovascular disease and peripheral arterial disease were present in 76.3%, 23.1% and 18.8% of patients, respectively. In all, 21.6% of patients had Stage III kidney disease (eGFR 30 to <60 ml min^{-1} 1.73 m^{-2}); 30.2% had micro- and 9.2% had macroalbuminuria; 11.0% were ≥75 years old. Baseline characteristics are in the table compared with other SGLT2 inhibitor CV outcome trials. VERTIS-CV is ongoing and data are preliminary.
Conclusion: VERTIS-CV enrolled patients with T2DM with a history of established atherosclerotic vascular disease, and enrolment of a substantial proportion of patients with renal impairment, heart failure and older patients. Notably, the proportion of participants with established CV disease has varied across the SGLT2 inhibitor CV outcome trials.

Incidence of urinary tract infections in patients with type 2 diabetes receiving ertugliflozin, placebo or active comparator

M.A. Hickman[1], S. Patel[2], B. Lauring[2], S.G. Terra[3], S. Johnson[4], S. Huyck[2], J.P. Mancuso[1];
[1]Pfizer Inc., Groton, [2]Merck & Co., Inc., Kenilworth, [3]Pfizer Inc., Andover, [4]Pfizer Inc., Collegeville, USA.

Background and aims: Ertugliflozin, an oral sodium-glucose cotransporter 2 inhibitor (SGLT2), improves glycaemic control in adult patients with type 2 diabetes mellitus (T2DM). Although an increased risk of genital mycotic infections has been consistently observed with SGLT2 inhibitors, data on urinary tract infections (UTIs) are not consistent among this class of agents. This study aimed to assess the risk of UTIs, including complicated UTIs, in adult patients with T2DM receiving ertugliflozin relative to placebo or active comparators.
Materials and methods: Pooled analyses were performed on seven randomised, double-blind, Phase 3 studies (VERTIS studies MONO, MET, SITA2, FACTORIAL, SU, SITA, RENAL). Adult patients with T2DM received ertugliflozin 5 mg, 15 mg, placebo or active comparators (glimepiride or sitagliptin) for ≥26 weeks. Analyses were conducted on a broad pool (all studies) and a placebo pool (subset of studies). UTIs were identified using a pre-specified custom MedDRA query (CMQ). Complicated UTIs were defined as serious adverse events (SAEs) that were UTIs or UTIs considered to be potentially medically significant; complicated UTIs were analysed in the broad pool. Subgroup analyses by baseline demographics, including sex, age and renal function were also conducted in the broad pool.
Results: The broad pool comprised 4859 patients (n = 1450 non-ertugliflozin [placebo/active comparator]; n = 1716 ertugliflozin 5 mg; n = 1693 ertugliflozin 15 mg) with a mean treatment duration of ~355 days. The placebo pool comprised 1544 patients (n = 515 placebo; n = 519 ertugliflozin 5 mg; n = 510 ertugliflozin 15 mg) with a mean treatment duration of ~172 days. At baseline in the broad pool, mean age was 57.8 years, 25.8% were ≥65 years and 51.8% were males. Mean estimated GFR was 85.3 mL min^{-1} 1.73 m^{-2}. The mean duration of T2DM was 7.9 years and mean HbA1c was 66 mmol/mol (8.2%). Similar baseline characteristics were observed in the placebo pool. The incidence of UTIs in the broad pool was similar across groups (7.9%, 6.9% and 7.0% for non-ertugliflozin, ertugliflozin 5 mg and 15 mg, respectively), as was the incidence in the placebo pool (3.9%, 4.0% and 4.1% for placebo, ertugliflozin 5 mg and 15 mg, respectively). In the broad pool, ≥90% of UTIs in all groups were assessed by the investigator as mild or moderate in intensity. Few UTIs (<0.5%) in all groups were SAEs or led to drug discontinuation. The incidence of complicated UTIs, including pyelonephritis and urosepsis, was low across groups (0.3%, 0.2% and 0.6% for non-ertugliflozin, ertugliflozin 5 mg and 15 mg, respectively). In subgroup analyses by age, sex, and renal function, the incidence of UTIs was similar across treatment groups.
Conclusion: The risk of UTIs, including complicated UTIs, was not increased in patients with T2DM receiving ertugliflozin relative to placebo or active comparators.

Evaluation of fractures, bone mineral density and bone biomarkers in patients with type 2 diabetes receiving ertugliflozin

U. Masiukiewicz[1], A. Hickman[1], R. Frederich[2], S. Patel[3], S. Gallo[4], B. Lauring[3], S.G. Terra[5], S. Johnson[2], S. Huyck[3], J.P. Mancuso[1];
[1]Pfizer Inc., Groton, USA, [2]Pfizer Inc., Collegeville, USA, [3]Merck & Co., Inc., Kenilworth, USA, [4]Pfizer Deutschland GmbH, Berlin, Germany, [5]Pfizer Inc., Andover, USA.

Background and aims: Ertugliflozin (ERTU) is a sodium-glucose cotransporter 2 (SGLT2) inhibitor for the treatment of type 2 diabetes mellitus (T2DM) in adults. As other members of the SGLT2 inhibitor class have been associated with an increased risk of bone fracture, the risk of adverse bone effects was assessed in patients with T2DM receiving ERTU.
Materials and methods: The risk of fracture was assessed in adults with T2DM receiving ERTU relative to placebo (PBO) or active comparator in pooled analyses of 7 randomised, double-blind, Phase 3 trials. Patients (N = 4859) received ERTU 5 mg (n = 1716), ERTU 15 mg (n = 1693) or non-ERTU (PBO, glimepiride or sitagliptin; n = 1450) for up to 2 y. In an add-on to metformin study (VERTIS MET; N = 621 [41.1%

postmenopausal (PM) women]; ERTU 5 mg, $n = 207$; ERTU 15 mg, $n = 205$; PBO, $n = 209$), bone mineral density (BMD) was measured at the lumbar spine, femoral neck, total hip and distal forearm through 2 y. Biomarkers of bone metabolism were also measured.

Results: In pooled analyses, mean age was 57.8 y and 25.8% were ≥65 y; 51.8% were male. Mean eGFR was 85.3 ml min^{-1} 1.73 m^{-2}. Mean duration of T2DM was 7.9 y and mean baseline HbA_{1C} was 66 mmol/mol (8.2%). The incidence of adjudication-confirmed fractures was similar across groups (ERTU 5 mg, 0.5%; ERTU 15 mg, 0.5%; non-ERTU, 0.6%). At Wk 26, serum calcium did not change from baseline when compared across groups, but there were small mean increases in serum magnesium (0.06 mmol/l vs −0.01 mmol/l) and phosphate (0.08 mmol/l vs 0.01 mmol/l) for all ERTU vs PBO. In VERTIS MET at Wk 104, overall and in the PM subgroup ($n = 255$), ERTU had no impact on BMD, except at the total hip where small reductions in BMD were observed (−0.84% overall; −1.17% PM) for ERTU 15 mg vs PBO. At Wk 104, there were no meaningful differences from baseline in procollagen type 1 N-terminal propeptide (P1NP; ERTU 5 mg, 10.1%; ERTU 15 mg, 24.2%; PBO, 19.4%) or parathyroid hormone (ERTU 5 mg, 8.2%; ERTU 15 mg, 5.5%; PBO, 10.1%) across groups. A small non-sustained increase in serum C-terminal telopeptide of type 1 collagen (CTX) was noted at Wk 26 and Wk 52 with ERTU vs PBO, which attenuated at Wk 104 (ERTU 5 mg, 26.9%; ERTU 15 mg, 32.5%; PBO, 19.3%).

Conclusion: There was no increased risk of fracture and no clinically meaningful change in BMD or bone biomarkers in patients with T2DM receiving ERTU.

Safety and tolerability of empagliflozin in East Asian patients with type 2 diabetes: pooled analysis of phase I-III clinical trials

D. Yabe[1,2], A. Yasui[3], L. Ji[4], M.-K. Lee[5], R. Ma[6], T.-J. Chang[7], T. Okamura[3], C. Zeller[8], S. Kaspers[9], J. Lee[9], S. Kohler[9], Y. Seino[1,10];
[1]Kansai Electric Power Medical Research Institute, Kobe, Japan, [2]Kyoto University, Kyoto, Japan, [3]Nippon Boehringer Ingelheim Co., Ltd., Tokyo, Japan, [4]Peking University People's Hospital, Beijing, China, [5]Sungkyunkwan University School of Medicine, Seoul, Republic of Korea, [6]The Chinese University of Hong Kong, Hong Kong SAR, China, [7]National Taiwan University Hospital, Taipei City, Taiwan, [8]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany, [9]Boehringer Ingelheim International GmbH & Co. KG, Ingelheim, Germany, [10]Kansai Electric Power Hospital, Osaka, Japan.

Background and aims: We investigated the safety and tolerability of empagliflozin in East Asian patients with type 2 diabetes (T2DM).

Materials and methods: Data were pooled from patients with T2DM randomized 1:1:1 to placebo, empagliflozin 10 mg, or empagliflozin 25 mg in 15 Phase I-III trials. Adverse events (AEs) were analyzed in the subgroup of patients from East Asian countries.

Results: In total, 709, 724 and 708 East Asian patients received placebo, empagliflozin 10 mg and empagliflozin 25 mg, respectively; total exposure was 953, 1072, and 1033 patient-years in these groups, respectively. The incidence of any AEs, severe AEs, serious AEs, and AEs leading to discontinuation was not higher in patients treated with empagliflozin than placebo. The incidence of hypoglycemia differed according to glucose-lowering medication used at baseline. The incidence of events consistent with urinary tract infection was numerically lower with empagliflozin (5.3–5.8/100 patient-years) than placebo (7.2/100 patient-years). Events consistent with genital infection occurred more frequently with empagliflozin (1.5–1.7/100 patient-years) than placebo (0.2/100 patient-years). The incidence of AEs consistent with volume depletion was similar across treatment groups (0.8–1.4/100 patient-years) but higher with empagliflozin 25 mg vs placebo in patients aged ≥65 years (3.5 vs 2.0/100 patient-years). Rates of bone fractures, renal AEs, venous thromboembolic events, hepatic injury, lower limb amputation and diabetic ketoacidosis were similar or not higher with empagliflozin than placebo.

Conclusion: In this pooled analysis, empagliflozin was well tolerated in East Asian patients with T2DM based on >3,000 patient-years' exposure, consistent with results from the overall analysis population.

Safety and efficacy of ertugliflozin in Asian patients with type 2 diabetes inadequately controlled with metformin monotherapy: VERTIS-Asia

M. Yang[1], L. Ji[2], Y. Liu[3], H. Miao[4], Y. Xie[5], W. Wang[1], Y. Mu[1], P. Yan[1], S. Pan[6], B. Lauring[7], S. Liu[8], S. Huyck[7], D. Wang[8], S.G. Terra[9];
[1]Pfizer (China) R&D Co., Shanghai, China, [2]Peking University People's Hospital, Beijing, China, [3]Yancheng First People's Hospital, Yancheng, China, [4]The Second Affiliated Hospital of Nanjing Medical University, Nanjing, China, [5]Pingxiang People's Hospital, Pingxiang, China, [6]Pfizer Inc., New York, USA, [7]Merck & Co., Inc., Kenilworth, USA, [8]Merck & Co., Beijing, China, [9]Pfizer Inc., Andover, USA.

Background and aims: Ertugliflozin (ERTU), a selective inhibitor of sodium-glucose cotransporter 2 (SGLT2), was recently approved in the United States for treatment of adult patients with type 2 diabetes mellitus (T2DM). This Phase 3, randomised, double-blind, 26-week (wk) multicentre study evaluated the efficacy and safety of ERTU vs placebo

(PBO) in Asian adults with T2DM inadequately controlled on metformin (MET) monotherapy.

Materials and methods: 506 Adult Asian patients from mainland China, Hong Kong, Republic of Korea, Philippines and Taiwan with T2DM and inadequate glycaemic control (HbA_{1C} 53–91 mmol/mol [7.0–10.5%]) on MET monotherapy (≥1500 mg/d for ≥8 wk) were randomised 1:1:1 to receive PBO ($n = 167$) or ERTU 5 mg ($n = 170$) or 15 mg ($n = 169$) once daily.

Results: Overall, 480 (94.9%) patients completed the study and 465 (91.9%) completed study medication. Baseline characteristics (mean ± SD) were similar among treatment groups: age 56.5 ± 9.1 y; T2DM duration 6.95 ± 5.08 y; body weight 70.3 ± 11.5 kg; BMI 26.0 ± 3.2 kg/m^2; HbA_{1C} 8.1 ± 0.9%; eGFR 99.3 ± 19.7 mL min^{-1} 1.73 m^{-2}. At Wk 26, patients randomised to ERTU 5 mg or 15 mg had significantly greater reductions (all $P < 0.001$) in HbA_{1C}, fasting plasma glucose, body weight and systolic BP and were significantly more likely to have an HbA_{1C} <53 mmol/mol (7.0%) vs PBO (Table). At Wk 26, 16.2%, 38.2% and 40.8% had an HbA_{1C} <53 mmol/mol (7.0%) with PBO, ERTU 5 mg and ERTU 15 mg, respectively. Mean reduction in diastolic BP with ERTU 5 mg and 15 mg was numerically greater vs PBO. Incidence of adverse events (AEs) was 59.3%, 56.5% and 53.3% with PBO, ERTU 5 mg and ERTU 15 mg, respectively. Serious AEs were more frequent with ERTU 5 mg (5.3%) and 15 mg (5.9%) vs PBO (1.2%). Overall, 1.8%, 1.2% and 0.6% of patients receiving PBO, ERTU 5 mg and 15 mg, respectively, discontinued study medication due to an AE. The incidence of genital mycotic infection, urinary tract infection and hypovolemia was similar with PBO, ERTU 5 mg and ERTU 15 mg. The incidence of symptomatic hypoglycaemia was higher with ERTU 15 mg (4.7%) compared with PBO (0.6%; $P = 0.019$), and the incidence was 2.4% with ERTU 5 mg.

Conclusion: ERTU significantly improved glycaemic control and reduced body weight and systolic BP in Asian patients with T2DM inadequately controlled on MET monotherapy. Significantly more patients treated with ERTU had an HbA_{1C} <53 mmol/mol (7.0%) at Wk 26 compared with PBO. Ertugliflozin was well tolerated.

Stroke safety with Sodium-Glucose Cotransporter-2 (SGLT-2) inhibitor use: a systematic review and meta-analysis

A.J. Roddick[1], S.L. Zheng[2];
[1]King's College London, London, [2]Imperial College Healthcare NHS Foundation Trust, London, UK.

Background and aims: Sodium-Glucose Cotransporter-2 (SGLT-2) inhibitors are among the most recent treatments to be approved for the treatment of type 2 diabetes. SGLT-2 inhibitors have been shown to be efficacious not only for glycaemic control but also in reducing all-cause and cardiovascular mortality. However, previous meta-analysis has indicated an increased risk of harm from non-fatal stroke with SGLT-2 inhibitor use. The aim of the present study is to investigate stroke safety in this treatment class.

Materials and methods: MEDLINE, Embase and CENTRAL databases and published meta-analyses were searched from inception through October 11th, 2017 for phase 2–4 randomised controlled trials of greater than 12 weeks' duration, enrolling patients with type 2 diabetes, and comparing SGLT-2 inhibitors with placebo. Study outcomes were any and non-fatal stroke events. Random-effects pairwise meta-analysis was undertaken using the Mantel-Haenzel method.

Results: For any stroke outcome, 25 trials of four different SGLT-2 inhibitor types were included for meta-analysis, comprising 358 events in 20,732 patients. Stroke safety was not negatively impacted by SGLT-2 inhibitors compared to placebo (RR 0.99; 95% CI 0.79 to 1.23; $P = 0.92$). For non-fatal stroke safety, 12 trials from three different SGLT-2 inhibitor types were included, accounting for 501 events in 21,490 patients. Non-fatal stroke was not associated with SGLT-2 inhibitor use compared to placebo (RR 1.03; 95% CI 0.86 to 1.23; $P = 0.78$). For both outcomes, no individual type of SGLT-2 inhibitor was associated with increased risk of any or non-fatal stroke events, and between-study heterogeneity was low ($I^2 = 0\%$ for both outcomes).

Conclusion: In this comprehensive meta-analysis of stroke safety in SGLT-2 inhibitors, we find no evidence of increased risk of any or non-fatal stroke with SGLT-2 inhibitors compared to placebo treatment. The inclusion of data from the CANVAS program contributes considerable strength to this study and permits expansion upon previous meta-analyses. Our data suggest that SGLT-2 inhibition does not negatively impact on stroke safety in patients with type 2 diabetes.

Lower cardiovascular risk with SGLT-2 inhibitors vs other glucose-lowering drugs: real world data from Asia Pacific, North America, Europe and Middle East: the CVD-REAL study

M. Kosiborod[1], C.S.P. Lam[2], S. Kohsaka[3], D. Kim[4], A. Karasik[5], S.-Y. Goh[6], J. Shaw[7], N. Tangri[8], A. Norhammar[9], J. Franch-Nadal[10], M. Thuresson[11], F. Surmont[12], N. Hammar[13,14], P. Fenici[15], CVD-REAL Investigators and Study Group;
[1]Saint-Luke's Mid. America Health Institute, Kansas City, USA, [2]Singapore and SingHealth Duke-NUS, National Heart Centre, Singapore, Singapore, [3]Keio University School of Medicine, Tokyo, Japan, [4]Ajou University School of Medicine, Suwon, Republic of Korea, [5]Tel Aviv University, Tel Aviv, Israel, [6]Singapore General Hospital, Singapore, Singapore, [7]Baker IDI Heart and Diabetes Institute, Melbourne, Australia, [8]Department of medicine, University of Manitoba, Winnipeg, MB, Canada, [9]S:t Göran Hospital, Stockholm, Sweden, [10]Institut Universitari d'investigació en Atenció Primaria (IDIAP Jordi Gol), Barcelona, Spain, [11]Statisticon AB, Uppsala, Sweden, [12]AstraZeneca, Luton, UK, [13]Institute of Environmental Medicine, Stockholm, Sweden, [14]AstraZeneca, Gothenburg, Sweden, [15]AstraZeneca, Cambridge, UK.

Background and aims: Results from CVD-REAL have been previously reported, showing consistently lower risk of cardiovascular events, death and heart failure hospitalization (HHF) with sodium glucose cotransporter-2 inhibitors (SGLT-2i) vs other glucose-lowering drugs (oGLD) in patients with type 2 diabetes (T2D). The aim of this analysis was to extend the CVD-REAL analyses across larger number of countries and patients, and longer duration of follow up.

Materials and methods: New users of SGLT2i or oGLD were included from established data sources in South Korea, Japan, Singapore, Israel, Spain, Sweden, Canada, the US and Australia. Propensity scores for SGLT-2i initiation were developed in each country by a standardized protocol, with 1:1 matching. Hazard ratios for death, hospitalization for heart failure (HHF), death or HHF, MI and stroke were derived using proportional hazards regression (intent-to-treat approach), and pooled in a weighted meta-analysis.

Results: After propensity-match, there were 360,356 episodes of treatment initiation in each group; ~29% had established CVD. Baseline characteristics were well balanced between treatment groups. As a proportion of total exposure in the SGLT-2i group, 53.8% of treatment episodes were with dapagliflozin, 20.1% canagliflozin, 18.3% empagliflozin and 7.8% other SGLT-2i. Mean follow up was 410 and 421 days for SGLT-2i and oGLD, respectively. Initiation of SGLT-2i vs oGLD was associated with lower risk of HHF and death; and modestly lower risks of myocardial infarction and stroke (Figure).The results were directionally consistent across countries in various geographic regions.

Conclusion: In a large cohort of patients with T2D from clinical practice in Asia-Pacific, Europe, the Middle East and North America, initiation of SGLT-2i was associated with lower risks of HHF, death and major cardiovascular events.

Figure: Hazard ratios for death and CV events after initiation of SGLT-2i vs oGLD

CANadian CAnagliflozin REgistry (CanCARE): a prospective, observational, assessment of canagliflozin (CANA) treatment in type 2 diabetes; 12 month results

V. Woo[1], A. Bell[2], M. Clement[3], F. Camacho[4], N. Georgijev[5], J.B. Rose[5], W. Rapattoni[5], H.S. Bajaj[6];
[1]University of Manitoba, Winnipeg, MB, [2]University of Toronto, Toronto, [3]University of British Columbia, Vancouver, [4]University of Waterloo, Waterloo, [5]Janssen Inc., Toronto, [6]LMC Diabetes & Endocrinology and Mt. Sinai Hospital, Brampton and Toronto, Canada.

Background and aims: CanCARE is a Canadian multicenter, prospective cohort study that enrolled SGLT2 inhibitor-naïve adult patients with T2DM, with HbA1c ≥7% on a stable anti-hyperglycemic agent (AHA) regimen at baseline and eGFR ≥60 mL/min/1.73 m^2, who were initiated on CANA as part of their usual treatment.

Materials and methods: This real-world (RW) study assessed the effectiveness and safety outcomes of the enrolled cohort of 527 subjects (mean age 60.7 yrs, mean baseline A1c 8.3%) over 12 months.

Results: Mean A1c reduction was −1.06 (1.12), with an observed dose response: −0.96 for CANA 100 mg, −1.20 for CANA 300 mg. 84.9%, 57.9% and 33% of subjects experienced >0%, ≥3%, ≥5% weight loss, respectively. Overall, 38.8% of subjects achieved A1c <7.0%, while 41% achieved the composite endpoint of A1c reduction ≥0.5%, body weight loss ≥3%. 17.9% subjects discontinued CANA. Safety data showed 37.4% subjects had ≥1 Adverse Event (AE), 3.5% had serious AEs, 14.5% had AEs special Interest: GMI (9.5%), polyuria (3.7%), UTI (1.5%), severe hypoglycemia (0.9%) and volume-related AE (0.7%). No reports to date of diabetic ketoacidosis or amputations.

Conclusion: CANA shows sustained, clinical meaningful improvement in cardiometabolic (CM) parameters in the RW, confirming findings from Phase 3 trials.

Table 1: Baseline characteristics and response of CM parameters at 6 and 12 months after initiation with CANA

Vital of Lab Value	Baseline	6 Months	12 Months	Change 6 Months from Baseline mean (std)	Change 12 Months from Baseline mean (std)
Hemoglobin A1C (%)	8.4	7.4	7.3	-0.90 (1.16)	-1.06 (1.12)
Hemoglobin A1C (mmol/mol)	68.8	57.7	56.2	-33.34 (12.68)	-35.06 (12.23)
Weight (kg)	90.1	88.5	89.4	-2.87 (4.62)	-3.24 (4.81)
Body Mass Index (kg/m2)	32.1	31.6	31.8	-1.02 (1.61)	-1.15 (1.68)
Waist Circumference (cm)	107.4	104.7	105.9	-3.11 (9.39)	-2.91 (11.12)
Diastolic Blood Pressure (mmHg)	78.3	75.3	75.3	-2.90 (8.78)	-3.50 (8.68)
Systolic Blood Pressure (mmHg)	130.8	126.1	126.3	-4.52 (13.64)	-4.65 (13.04)
Glomerular Filtration Rate Corrected (mL/min/1.73m^2)	85.8	81.3	81.4	-3.96 (10.72)	-5.55 (11.50)

2 year metabolic outcomes in the ABCD nationwide canagliflozin audit

A. Puttanna[1], M. Yadagiri[1], P. Sen Gupta[1], I. Gallen[2], A. Bickerton[3], S. Phillips[4], A. Evans[4], D. Sennik[5], R. Ryder[1];
[1]Diabetes and Endocrinology, Sandwell and West Birmingham NHS Trust, Birmingham, [2]Diabetes and Endocrinology, Royal Berkshire Hospitals NHS Trust, Berkshire, [3]Diabetes and Endocrinology, Yeovil District Hospital NHS Trust, Yeovil, [4]Diabetes and Endocrinology, Cheltenham General Hospital, Cheltenham, [5]Diabetes and Endocrinology, Princess Alexandra Hospital, Harlow, UK.

Background and aims: The ABCD nationwide canagliflozin audit was launched in January 2016 to evaluate the efficacy of canagliflozin in a real world setting of clinical use in the United Kingdom (UK).
Materials and methods: Two year follow up data from 21 centres across the UK on 690 patients treated with canagliflozin. Male 60.2%, mean age (±SD) 58.9 ± 10.9 years, weight 101.3 ± 22.2 kg, BMI 34.0 ± 6.9, Hba1c 76.3 ± 16.3 mmol/mol. Patients with baseline, first return and second return follow up data were included in the analysis.
Results: Mean Hba1c fell by 9.0 ± 13.4 mmol/mol at first return and 11.1 ± 14.7 mmol/mol at second return ($n = 297$, $p < 0.001$) with 2.1 mmol/mol fall between first and second return ($p = 0.001$). Mean weight fell by 2.8 ± 4 kg at first return and 4.0 ± 5.4 kg at second return ($n = 242$, $p < 0.001$) with 1.3 kg fall between first and second return ($p < 0.001$).Mean alanine aminotransferase (ALT) fell by 3.8 ± 23.2 U/L at first return ($p < 0.031$) and 5.6 ± 18 U/L at second return ($n = 177$, $p < 0.001$) with 1.8 U/L fall between first and second return ($p = 0.25$). Mean systolic blood pressure (SBP) fell by 1.9 ± 15.4 mmHg at first return ($p = 0.035$) and 3.7 ± 16.2 mmHg at second return ($n = 285$, $p < 0.001$) with 1.8 mmHg fall between first and second return ($p = 0.05$). Mean diastolic blood pressure (DBP) fell by 1.0 ± 10.1 mmHg at first return ($p = 0.086$) and 2.6 ± 11.1 mmHg at second return ($n = 284$, $p < 0.001$) with 1.5 mmHg fall between first and second return ($p = 0.006$). Median range of weeks for follow up for first and second returns (IQR) were 21 (15–30) and 44.9 (34.3–58.9) for Hba1c, 26.8 (15.5–41.6) and 54.6 (38.6–75) for weight, 30 (19–48.3) and 57.6 (42.7–77.5) for ALT, 27.3 (17.4–42.7) and 53.1 (40.4–70.3) for SBP, 27.2 (17.3–42.8) and 50 (40.3–71) for DBP.
Conclusion: Canagliflozin showed statistically significant and sustained reduction in Hba1c, weight, ALT, systolic and diastolic blood pressure across a wide range of real-world UK patients with type 2 diabetes. Further benefit was seen between first and second returns with statistically significant reductions in Hba1c, weight, systolic and diastolic blood pressures.

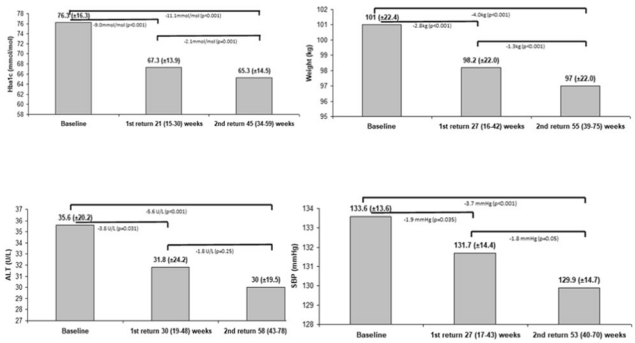

Figure: Mean (±SD) HbA1c (n=297) , weight (n=242), ALT (n=177) and systolic blood pressure (n=285), baseline vs first and second return (after median (interquartile range) weeks) to clinic following commencement of canagliflozin.

Temporal trends in the use of sodium-glucose cotransporter-2 inhibitors: the global DISCOVER study

L. Ji[1], H. Chen[2], J. Cid-Ruzafa[3], P. Fenici[4], M.B. Gomes[5], N. Hammar[6], K. Khunti[7], S. Pocock[8], M.V. Shestakova[9], I. Shimomura[10], F. Surmont[11], F. Tang[12], M. Kosiborod[12];
[1]Peking University People's Hospital, Beijing, China, [2]AstraZeneca, Gaithersburg, USA, [3]Evidera, Barcelona, Spain, [4]AstraZeneca, Cambridge, UK, [5]Rio de Janeiro State University, Rio de Janeiro, Brazil, [6]AstraZeneca Gothenburg, Mölndal, Sweden, [7]University of Leicester, Leicester, UK, [8]London School of Hygiene and Tropical Medicine, London, UK, [9]Endocrinology Research Center, Diabetes Institute, Moscow, Russian Federation, [10]Osaka University, Osaka, Japan, [11]AstraZeneca, Luton, UK, [12]Saint Luke's Mid America Heart Institute, Kansas City, USA.

Background and aims: Sodium-glucose cotransporter-2 inhibitors (SGLT-2is) reduce the risk of cardiovascular (CV) events in patients with type 2 diabetes (T2D), first demonstrated in the EMPA-REG OUTCOME trial (EMPA-REG). We examined trends in the use of SGLT-2is during the first year of DISCOVER, a 3-year observational study of patients with T2D initiating second-line glucose-lowering therapy in 37 countries.
Materials and methods: Patients who weren't receiving an SGLT2i at first-line and who had data on glucose-lowering medications at baseline, 6 and 12 months were included ($N = 11\,706$). We assessed the numbers and characteristics of patients who were initiated on an SGLT-2i (initiation of second-line therapy at baseline, or later-line therapy during the first year of follow-up) overall and according to whether the date of initiation was before or after EMPA-REG.
Results: Overall, 1138 patients were prescribed an SGLT-2i at baseline or during follow-up (9.7%; across-country range: 0.0–68.9%). There were no substantial differences in patient characteristics among those who were prescribed an SGLT-2i before or after EMPA-REG: 10.4% (before) and 14.4% (after) of patients had a history of macrovascular complications, compared with 12.9% of patients prescribed a different class of medication ($p = 0.24$). At baseline (initiation of second-line therapy), the proportion of patients who received an SGLT-2i was higher when the initiation occurred after vs before EMPA-REG (8.4% vs 5.9%, $p < 0.001$).
Conclusion: The overall proportion of patients prescribed an SGLT-2i was low, but varied greatly across countries. SGLT-2i use increased modestly after EMPA-REG. Although the CV benefits of SGLT-2i use have been best demonstrated in people with established macrovascular disease,

the clinical decision to prescribe these agents does not appear to be primarily driven by the presence of macrovascular complications.

Economic evaluation of dapagliflozin as add-on to metformin in type 2 diabetes in the Israeli healthcare setting

S. Moshel, M. Hirsch Vexberg, O. Shavit, Y. Toledano;
Meuhedet health fund, Tel Aviv, Israel.

Background and aims: Dapagliflozin is a potential for combination therapy with metformin in T2DM. However, its cost-effectiveness relative to other alternatives in the Israeli healthcare setup remains unknown.The purpose of this work was to evaluate the cost-effectiveness of dapagliflozin 10 mg as add-on to metformin, compared to common alternatives (sitagliptin 100 mg, glimepiride 2 mg, liraglutide 1.2 mg) based on Meuhedet health services database.
Materials and methods: A cost-effectiveness evaluation was performed using the Cardiff diabetes model. A cohort of 1000 T2DM patients (ages 21 and older) who had received additional medication to metformin was randomly chosen from Meuhedet's database. Baseline values for demographic and clinical variables prior to the add-on therapy, along with data from clinical trials served as inputs to the model. Simulation was performed for each drug, calculating its total costs and benefits (QALYs). The model's time horizon was set to 40 years, annual discount rate for both costs and benefits was 3.5% and incremental cost effectiveness ratio (iCER) threshold was £20,000/QALY. Finally, single-variable and multivariable sensitivity analyses were performed.
Results: In the base-case scenario, dapagliflozin was found cost-effective compared to sitagliptin, liraglutide and glimepiride (iCER values of £1,232, £-16,517 and £13,476, respectively). For all comparisons, iCER was driven by differences in costs, while differences in QALYs were minimal. Dapagliflozin remained cost-effective even after performing sensitivity analyses. However, when performing the simulation under comparators' generic competition scenario, dapagliflozin was no longer cost-effective compared to liraglutide (iCER = £24,900/QALY).
Conclusion: Dapagliflozin as add-on treatment to metformin was cost-effective compared to several alternatives in T2DM patients in Israel's healthcare system. Additional research is needed in order to evaluate the effects of evolving new clinical data.

DAPADream: improvement of time in range after SGLT2-add-on-medication in youth and young adults with type 1 diabetes during unannounced meals under full closed loop CSII

T. Biester[1], A.K. Nieswandt[1], S. Biester[1], K. Remus[1], I. Muller[2], E. Atlas[2], M. Philip[3], R. Nimri[3], T. Battelino[4], N. Bratina[4], K. Dovc[4], M.F. Scheerer[5], O. Kordonouri[1], T. Danne[1];
[1]Diabetes-Centre for Children and Adolescents, AUF DER BULT, Hannover, Germany, [2]DreaMed Diabetes Ltd., Petah Tikvah, Israel, [3]Schneider Children's Medical Center, Petah Tikvah, Israel, [4]University Children's Hospital, University Medical Centre Ljubljana, Ljubljana, Slovenia, [5]Astra Zeneca GmbH, Wedel, Germany.

Background and aims: Therapeutic aims such as HbA_{1c} are often hard to reach - particularly in youth and young adults with Type 1 Diabetes (T1D). The SGLT2-inhibitor dapagliflozin (DAPA) has been submitted for regulatory approval in the EU as adjunct to insulin therapy in adult T1D patients to improve glycemic control. The CE-marked DreaMed Substance Administration System© with a fuzzy logic closed loop algorithm was proven to be safe and effective in hybrid closed loop settings. In full closed loop (FCL) setting, postprandial time has so far been associated with a prolonged phase of hyperglycemic excursions. The aim of this trial is to investigate the effect of DAPA on glucose levels overnight and after two unannounced meals under FCL conditions.
Materials and methods: For this monocentric, double-blind, randomized, placebo-controlled cross-over trial, eligible patients (T1D, CSII, non-severe obese) were admitted to the research center on two occasions for 24 hours. 10 mg DAPA or placebo were administered twice: First in the evening and second on the following morning. After the latter application, two consecutive mixed meal tests (MTT) were performed 6 hours apart. Glucose control was achieved automatically by DreaMed FCL. Primary outcome was "Time in Range 70–180 mg/dl" (TIR). For safety, ß-Hydroxybutyrate (BHB), Glucagon, Insulin, Proinsulin and GIP were measured during the first MTT.
Results: 15 adolescents [age 15.3 ± 1.5 years, diabetes duration (DD) 9.8 ± 3.5 years, HbA1c 8.3 ± 0.9%] and 15 young adults [19.0 ± 0.8; DD 11.9 ± 4.3; 8.4 ± 1.0%] completed the trial. In both age groups, TIR increased significantly in the DAPA-arm compared to placebo (adolescents 68.7 ± 6.6 vs. 50.7 ± 11.9% $p < 0.001$; adults 66.5 ± 6.9 vs. 49.8 ± 14.0%, $p = 0.001$). In the combined analysis, nocturnal glucose was significantly lower with DAPA versus placebo (112 ± 15 vs. 132 ± 30 mg/dl; $p = 0.003$) without an increase in hypoglycemic episodes (3.3 ± 6.0 vs 3.1 ± 5.2% <70 mg/dl, $p = 0.75$).Urinary glucose excretion was increased threefold using DAPA (135.4 ± 42.3 vs. 44.4 ± 18.8 g/24 h). However, no abnormal elevated BHB-values were observed using the FCL Setting.
Conclusion: The SGLT2 inhibitor was able to improve glycemic control by increasing TIR on average by 259 minutes per day and reducing glycemic variability significantly without any signals for hypoglycemia or ketoacidosis. For achieving in-range post prandial glucose control after MTT challenges during FCL condition, pre-meal boluses should be considered even if using DAPA.

Effect of combination therapy with liraglutide plus canagliflozin on HGP, plasma hormones and HbA_{1c} versus each therapy alone in type 2 diabetes

M. Abdul-Ghani, A. Ali, R. Martinez, J. Adams, E. Cersosimo, C. Triplitt, R.A. DeFronzo;
UTHSCSA, San Antonio, USA.

Background and aims: We previously have shown that SGLT2 inhibitors cause an increase in HGP accompanied with an increase in plasma glucagon concentration. We hypothesized that the increase in plasma glucagon concentration is, at least in part, responsible for the increase in HGP. The aim of the present study was to examine whether inhibition of glucagon secretion by liraglutide can prevent the increase in HGP.
Materials and methods: 51 T2DM patients (age = 51 ± 1 yr; 40% female; BMI = 34.6 ± 0.7; diabetes duration = 6.8 ± 0.8 yr; FPG = 175 ± 7; HbA1c = 8.3 ± 0.1%) were randomized to receive for 16 weeks: (i) canagliflozin 300 mg; (ii) liraglutide 1.8 mg; or (iii) canagliflozin 300 mg plus liraglutide 1.8 mg. HGP (measured with 3-^{3}H-glucose infusion) and plasma glucagon concentration were measured before and after 16 weeks of treatment.
Results: Canagliflozin monotherapy caused a significant reduction in HbA1c (−1.1 ± 0.2%, $p < 0.01$) accompanied with an increase in plasma glucagon concentration (by 28%, $p < 0.05$) and HGP (by 15%, $p < 0.05$) which lasted for 16 weeks. Conversely, liraglutide monotherapy caused a 1.6 ± 0.5% ($p < 0.01$) reduction in HbA1c accompanied by a small (6%) reduction in HGP (P=NS) without significant change in fasting plasma glucagon concentration. The combination of canagliflozin plus liraglutide caused a greater reduction in HbA1c (1.9 ± 0.5%, $p < 0.05$ vs canagliflozin and p = NS vs liraglutide) and attenuated the increase in fasting plasma glucagon and basal HGP at 16 weeks.
Conclusion: These results: (1) support a possible role for increased plasma glucagon levels in the long term maintenance of increase in HGP caused by SGLT2i, and (2) suggest that factors other than/in addition to glucagon contribute to the initiation of the increase in HGP.
Clinical Trial Registration Number: NCT02324842

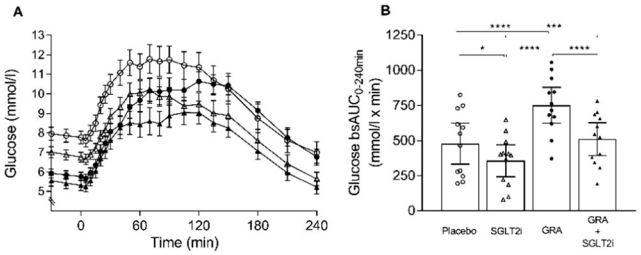
Individual and combined glucose-lowering effects of glucagon receptor antagonism and sodium-glucose cotransporter 2 inhibition

S. Haedersdal[1], A. Lund[1], H. Maagensen[1], E. Nielsen-Hannerup[1], J. Holst[2], F. Knop[1,3], T. Vilsbøll[4,3];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Hellerup, [2]Novo Nordisk Foundation Center for Basic Metabolic Research, Copenhagen, [3]Department of Clinical Medicine, Health and Medical Sciences, Copenhagen University, Copenhagen, [4]Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Studies suggest that sodium-glucose cotransporter 2 inhibitors (SGLT-2i) induce hyperglucagonaemia, which might counteract its glucose-lowering ability in type 2 diabetes.
Materials and methods: In a randomised, placebo-controlled, double-dummy, double-blinded, cross-over study, 12 patients with type 2 diabetes (Age [mean (SD)]: 59.5 (5.8) years, BMI 30.3 (5.6) kg/m^2; HbA1c: 47.3 (6.2) mmol/mol) underwent four 4-hour liquid mixed meal tests preceded by single-dose administration: 1) Placebo, 2) SGLT-2i (25 mg empagliflozin) 2 hours before the meal, 3) glucagon receptor antagonist (GRA) (300 mg LY2409021) 10 hours before the meal, and 4) GRA + SGLT-2i. Indirect calorimetry, plasma glucose, C-peptide, glucagon and paracetamol (paracetamol absorption test) was measured. Stable isotopes were infused for glucose and glycerol turnover and endogenous glucose production.
Results: The SGLT-2i and GRA individually lowered fasting plasma glucose (FPG) compared to placebo and the combination further decreased FPG. SGLT-2i reduced postprandial glucose excursions as assessed by baseline-subtracted area under curve (bsAUC) whereas GRA increased bsAUC compared to placebo (Figure). The paradoxical GRA-induced increment in bsAUC was annulled by a potent SGLT-2i-induced reduction of bsAUC during the combination of SGLT-2i and GRA (Figure).
Conclusion: The SGLT-2i and GRA combined reduce FPG beyond their individual capacity in patients with type 2 diabetes, and in the context of GRA, SGLT-2i's beneficial effect on postprandial glucose excursions seems to be potentiated.



Plasma glucose excursions (A) following a mixed meal tolerance test preceded by single doses of 1) placebo (open circles), 2) SGLT2i (open triangles), 3) Glucagon receptor antagonist (GRA) (filled circles) and 4) GRA+SGLT2i (filled triangles). Baseline-subtracted AUCs (bsAUC) (B) of the postprandial glucose excursion. * $p < 0.05$, *** $p < 0.001$, **** $p < 0.0001$.

Continuous glucose monitoring glycaemic profiles are more favourable for dapagliflozin plus saxagliptin compared to glimepiride when added to metformin in type 2 diabetes

D.C. Simonson[1], M.A. Testa[2], J. Maaske[3], R. Garcia-Sanchez[3], E. Johnsson[4], M. Su[2], J.P. Frias[5];
[1]Endocrinology, Brigham and Women's Hospital, Boston, [2]Biostatistics, Harvard T. H. Chan School of Public Health, Boston, [3]AstraZeneca, Gaithersburg, [4]AstraZeneca, Mölndal, Sweden, [5]National Research Institute, Los Angeles, USA.

Background and aims: Within-day glycaemic excursions and variability characterized by short-term oscillations in glucose are gaining increasing clinical interest independent of A1C and hypoglycaemia in treatment of patients with type 2 diabetes (T2D). This study compares glycaemic profiles of dapagliflozin (DAPA) plus saxagliptin (SAXA) versus glimepiride (GLIM) when added to metformin (MET).
Materials and methods: Masked continuous glucose monitoring (CGM) data were analyzed from patients with T2D inadequately controlled on MET in a substudy of n = 118 of 443 patients participating in an international randomized, 52-week, double-blind trial of DAPA co-administered with SAXA (n = 61) compared to GLIM (n = 57) when added to MET. Six-day CGM (288 glucoses/day) and A1C were measured at baseline and Week 52.
Results: At baseline, patients had mean ± SD age 55.1 ± 10.7 years, A1C 8.7 ± 0.8%, diabetes duration 10.3 ± 6.7 years, and were 45.8% male. Using linear mixed models, the primary CGM substudy endpoint, Week 52 change from baseline in the mean amplitude of glycaemic excursion (MAGE) for Week 52 per protocol (PP) completers not requiring rescue medication (addition of insulin or other glucose-lowering agent), favored

DAPA+SAXA+MET (mean ± SE −0.89 ± 0.22 mmol/L) vs GLIM+MET (0.40 ± 0.26 mmol/L), nominal $p = 0.0003$. Secondary CGM measures also favored DAPA+SAXA+MET by demonstrating lower mean glucose and variability (see Table). One subject (1.6%) in DAPA+SAXA+MET and 8 (14.0%) in the GLIM+MET required rescue therapy prior to 52 weeks, $p = 0.033$. For the intent to treat (ITT) sample including all subjects with evaluable Week 52 data, the differences were more pronounced (see Table). The percent time spent in hypoglycaemia was low in both groups and did not show a difference. In the substudy, 52-week A1C changes were −1.43 ± 0.22% for DAPA+SAXA+MET and −1.10 ± 0.21% for GLIM+MET. In the full study population corresponding changes were −1.35 ± 0.07% for DAPA+SAXA+MET ($n = 193$) vs −0.98 ± 0.07% for GLIM+MET ($n = 171$), $p < 0.001$.

Conclusion: In this substudy, CGM glycaemic profiles and variability measures demonstrated relatively strong differences between the two therapeutic regimens that were not apparent using A1C alone. Subjects on DAPA+SAXA+MET had lower average 24-hour glucose levels, less glycaemic variability, and spent more time in the normal glucose range and less time with hyperglycaemia as compared to subjects on GLIM+MET. The CGM summary measures and indices that are derived from diagnostic CGM can provide important clinical insight for optimizing diabetes treatment regimens and should be used to supplement the standard measures of A1C, fasting plasma glucose and patient reports of hypoglycaemic episodes.

Change from Baseline in CGM Measures at Week 52 for Per Protocol (PP) Sample [LS Mean (SE)]

CGM Endpoint	DAPA+SAXA+MET (N = 46)	GLIM+MET (N = 32)	p-value (PP)	p-value (ITT)[3]

Head to head comparison of efficacy between dapagliflozin and canagliflozin in long standing type 2 diabetes

C. Mahesh Babu;
Diabetology, Meenakshi mission hospital and research centre, Madurai, India.

Background and aims: the study is done in patients with long standing diabetes for more than 10 years. we compared the efficacy of dapagliflozin and canagliflozin in reducing the fasting plasma glucose (FPG), postprandial plasma glucose (PPG), glycosylated hemoglobin (HbA1c), body weight (BW) and systolic BP (SBP).

Materials and methods: 200 type 2 diabetes patients were randomized into two groups each group having 100 patients. One gropu was given dapagliflozin 10 mg and other was given canagliflozin 100 mg per day in addition to the existing oral drugs. All patients were already on sulphonylurea and metformin combination without good control. All patients had HbA1c more than 10%. Both the groups were matched on gender and age distribution. Both groups were followed for one year and results were analysed.

Results: FPG dropped from a baseline of (180 ± 58 mg/dL) to (97 ± 9 mg/dL) in dapagliflozin group and (158 ± 45 mg/dL) to (94 ± 9 mg/dL) in canagliflozin group. PPG dropped from a baseline of (289 ± 86 mg/dL) to (163 ± 22 mg/dL) in dapagliflozin group and (267 ± 76 mg/dL) to (159 ± 22 mg/dL) in canagliflozin group. HbA1c dropped from a baseline of (9.9 ± 1.9%) to (7.4 ± 0.6%) in dapagliflozin group and (9.5 ± 1.7%) to (7.4 ± 0.7%) in canagliflozin group. 4 mmHg systolic BP reduction was seen in both the groups.Body weight dropped from a baseline of (72 ± 12 kg) to (69 ± 11 kg) in dapagliflozin group and (74 ± 12 kg) to (70 ± 10 kg) in canagliflozin group. Incidence of genital mycotic infection(GMI) was 2% in dapagliflozin group and 3% in canagliflozin group. Incidence of urinary tract infection (UTI) was 3% in both the groups. The UTI and GMI were occuring only during the first 3 months of therapy

Conclusion: Both dapagliflozin and canagliflozin are equally effective in long standing diabetes with uncontrolled hyperglycemia when added to existing oral drugs. They produced a meaningful reduction in FPG, PPG, HbA1c, BW and SBP. The incidence of UTI and GMI are negligible after first 3 months of therapy.

Dose-ranging effects of SGLT2 inhibitors in patients with type 2 diabetes: a systematic review and meta-analysis

L.C. Pinto, D.R. Rados, L.R. Remonti, M.V. Viana, C.B. Leitão, J.L. Gross;
Endocrine Division, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil.

Background and aims: The lowest dosage of empagliflozin (10 mg) produced similar benefits on glycated hemoglobin (HbA1c), body weight, blood pressure, total and cardiovascular mortality in comparison with the highest available dose (25 mg) in EMPAREG trial. It is uncertain if canagliflozin and dapagliflozin behave similarly. Aims: To compare the effect of different doses of SGLT2 inhibitors in HbA1c and body weight of patients with type 2 diabetes.

Materials and methods: MEDLINE, Cochrane and Embase databases were searched for randomized controlled trials of SGLT2 inhibitors in type 2 diabetes patients, lasting at least 12 weeks. HbA_{1c} and body weight variations were described as standard mean difference. We performed direct, indirect meta-analysis, as well as a metarregression with medications' doses as covariates.

Results: Eighteen studies were included (16,095 patients). In direct meta-analysis, canagliflozin, dapagliflozin and empagliflozin lead to similar effects on HbA_{1c} (−0.62%; 95% CI −0.66 to −0.59) and body weight (−0.60 kg; 95% CI −0.64 to −0.55). Indirect meta-analysis showed that canagliflozin 300 mg had the greatest effect in both HbA1c and body weight reduction (−0.79%; 95% CI −0.84 to −0.75; −2.35 kg; 95% CI −2.73 to −1.97), however the differences from the other medications or dosages was small and probably not clinically relevant (−0.15 to −0.44% in HbA1c and −0.28 to −1.04 kg in body weight). All SGLT2 inhibitors in different doses were associated with similar increased risk for genital infections.

Conclusion: Different doses of SGLT2 inhibitors results in similar reductions of HbA1c and body weight. Whether these glycemic and weight effects reflect on mortality and cardiovascular events is still uncertain and may be a topic of further studies.

Comparison of ipragliflozin and metformin for visceral fat reduction in elderly patients with type 2 diabetes: a prospective, blinded-endpoint, randomised controlled study

M. Koshizaka, K. Ishikawa, R. Ishibashi, H. Yoko, K. Sakamoto, T. Ishikawa, Y. Maezawa, M. Takemoto, K. Yokote, PRIME-V Study Group;
Chiba University Hospital, Chiba, Japan.

Background and aims: Dipeptidyl peptidase-4 (DPP-4) inhibitors have low risk of side effects, such as hypoglycemia, and are often used as the first drug of choice in elderly patients with type 2 diabetes (T2DM) in Japan. However, T2DM in some patients is not controlled sufficiently with DPP-4 inhibitor and requires multiple drug treatment. To determine the effects of either sodium glucose transporter 2 (SGLT2) inhibitor or metformin on reducing visceral fat and other effects in Asian elderly patients with T2DM inadequately controlled with DPP-4 inhibitor, we performed a sub-analysis of a prospective, multicenter, blinded-endpoint, randomized controlled study on elderly patients aged 65 and older.
Materials and methods: The study was conducted to evaluate the efficacy of treatment with SGLT2 inhibitor (ipragliflozin) or metformin added to sitagliptin for reducing visceral fat and glucose control in 103 patients with T2DM. Patients with T2DM, taking sitagliptin for more than 12 weeks and having BMI of ≥22 kg/m^2 and HbA1c of ≥7% and <10% were included. They were randomized (1:1) to receive ipragliflozin (50 mg/day) or metformin (1000–1500 mg/day). The primary outcome was the rate of change in visceral fat area, measured using computed tomography (CT) after 24 weeks of therapy. Two radiologists, blinded to the information, analyzed the images. The secondary outcome included total and subcutaneous fat area, muscle volume, bone mineral density measured by CT, fasting blood glucose, insulin level, HbA1c, and grip strength. Among the patients, we selected those aged ≥65 years for sub-analysis.
Results: The reduction rate in visceral fat area was significantly greater in the ipragliflozin group than that of the metformin group (−12.1% vs. −3.7%, $P < 0.05$). Sub-analysis was performed with a full analysis set of 14 patients in the ipragliflozin group and 14 patients in the metformin group, and no difference was found between the two groups. Patients mean age of 69.2 were included. The mean HbA1c was 8.0 ± 0.8 percent. The rate of reduction in visceral fat area was significantly greater in the ipragliflozin group than the metformin group (−16.5% vs. 0.6%, $P = 0.02$). There was no significant difference in changes on muscle volume and bone mineral density between the groups. However, grip strength in metformin group improved more compared to the ipragliflozin group (−1.8% vs. 11.4%, $P = 0.01$).
Conclusion: As the second agent to be used in combination with DPP-4 inhibitors, ipragliflozin significantly reduced the visceral fat area compared with metformin. For elderly patients with the risk of sarcopenia, metformin might increase grip strength; and ipragliflozin could reduce visceral fat for elderly patients with abdominal obesity. Our results can help with drug selection for the Asian elderly patients with T2DM inadequately controlled on DPP-4 inhibitor.

Dapagliflozin plus saxagliptin add-on to metformin reduces liver fat and adipose tissue volume in patients with type 2 diabetes

L. Johansson[1], P. Hockings[1], E.K. Johnsson[2], J. Maaske[3], R. Garcia-Sanchez[3], J.P. Wilding[4];
[1]Antaros Medical AB, Bioventure Hub, Mölndal, Sweden, [2]Global Medicines Development, AstraZeneca, Gothenburg, Sweden, [3]Global Medicines Development, AstraZeneca, Gaithersburg, USA, [4]Obesity & Endocrinology Research Group, Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK.

Background and aims: Oral administration of a fixed-dose combination of the sodium glucose co-transporter (SGLT)-2 inhibitor dapagliflozin (DAPA) and the dipeptidyl peptidase 4 (DPP-4) inhibitor saxagliptin (SAXA) is approved for improving glycaemic control in adult patients with type 2 diabetes (T2D).
Materials and methods: A 52-week, multicentre, randomised, double-blind, parallel-group trial evaluated the efficacy and safety of DAPA 10 mg/day + SAXA 5 mg/day vs titrated glimepiride (GLIM) 1–6 mg/day in 443 patients with T2D (A1C, 7.5%–10.5%) on metformin (MET) ≥1500 mg/day background. In a sub-study, we used magnetic resonance imaging (MRI) to assess effects on liver fat (proton density fat fraction [PDFF]) and visceral and subcutaneous adipose tissue volumes over 52 weeks of treatment. An MRI was performed on 59 patients; liver fat and adipose tissue volumes were analysed for 59 and 57 patients, respectively.
Results: There was a significant >30% reduction from baseline in liver fat ($P = 0.007$) and a >10% reduction in visceral and subcutaneous adipose tissue volumes ($P < 0.01$) with DAPA + SAXA + MET at week 52 vs GLIM + MET (Table). In the full study population, DAPA + SAXA + MET decreased body weight and serum levels of alanine aminotransferase and aspartate aminotransferase over 52 weeks.
Conclusion: DAPA + SAXA significantly decreased liver fat and adipose tissue volume vs GLIM, and reduced serum liver enzyme levels, indicating a favourable metabolic profile of DAPA + SAXA in patients with T2D on MET therapy.

An inhibitor of sodium-glucose cotransporter 2 shows a rational effect for reducing body weight but not for lowering plasma glucose in type 2 diabetes with mild renal failure

S. Taneda, K. Tsuchida, H. Bando, S. Hagiwara, Y. IIjima, K. Misawa, M. Kikuchi, K. Ohta, H. Nakayama, N. Manda;
Internal Medicine, Manda Memorial Hospital, Sapporo, Japan.

Background and aims: Sodium-glucose cotransporter 2 (SGLT2) inhibitor reduces rates of hyperglycemia and body weight in patient with type 2 diabetes (T2DM) by decreasing renal glucose reabsorption, thereby increasing urinary glucose excretion. However, the effects supposed to be impaired in the state of renal failure , because It does not reach the target, i.e. SGLT2 existed on the membrane of proximal tubular epithelium. So, treatment with SGLT2 inhibitor for the T2DM patient with renal failure is not recommended in Japan. In addition, the effects of reducing plasma glucose and body weight may not be paralleled each other. In this presentation, we try to clarify the difference between the two effects of SGLT2 inhibitor In T2DM with mild renal failure.
Materials and methods: 80 T2DM patients (male 54, female 26) were newly administrated standard dose of SGLT2 inhibitors (Dapagliflozin 32, Empagliflozin 23, Tofogliflozin 22,Ipragliflozin 3). Their estimated glomerular filtration rate (eGFR) was distributed from 21.9 to 110.5 ml/min/1.73 m², and we devided into 2 groups i.e. 64 cases of normal renal function group (eGFR >60) and 16 cases of mild renal failure group (eGFR <60). The changes of plasma glucose and body weight were tested every month by 6 months in both groups, and the relationship between the changes of these parameters and their renal function before intake of SGLT2 inhibitors was analyzed.
Results: HbA1c lowering effects is more markedly in normal renal function group than in mild renal failure group (−1.03% ± 1.48 vs −0.43% ± 0.72), contrary body weight was reduced equally in both groups (−3.3 kg ± 2.7 vs −3.2 kg ± 3.6). Renal function was unchanged during these 6 months except one month after administration in both groups. By Analyzing in all cases, we found that body weight was reduced regardless of eGFR, however, the decrease of HbA1c was correlated with eGFR (Fig).
Conclusion: SGLT2 inhibitor is effective even in T2DM patients with mild renal failure, especially body weight lowering effects is shown regardless of renal function. Body weight lowering effects of SGLT2 inhibitor seems to be due to an accumulation of energy loss, contrary plasma glucose lowering effect reflects the balance of the amount of urinary glucose extraction and plasma glucose. SGLT2 inhibitor has various clinical effects and each effect does not appear in a parallel. It is very important to consider which effects will be expected for the T2DM patients mostly when we use SGLT2 inhibitors, especially for the patients with an impairment of renal function.

Effects of sodium glucose cotransporter-2 inhibitors on circulating stem and progenitor cells in patients with type 2 diabetes

B. Bonora, R. Cappellari, A. Avogaro, G. Fadini;
University of Padova, Padova, Italy.

Background and aims: Reduction in the levels of circulating stem cells (CSCs) and endothelial progenitor cells (EPCs) predicts development or progression of micro- and macroangiopathy in patients with type 2 diabetes (T2D). Since sodium glucose cotransporter-2 (SGLT2) inhibitors improve cardiovascular and renal outcomes, we tested whether treatment with SGLT2 inhibitors affects the levels of CSCs and EPCs in patients with T2D.
Materials and methods: Thirty-one patients with T2D were randomized to receive dapagliflozin 10 mg ($n = 16$) or placebo ($n = 15$) for 3 months. CSCs ($CD34^+$) and EPCs ($CD34^+KDR^+$) were measured by flow cytometry at baseline, at 3 months and after an open-label extension period. CSCs and EPCs were also quantified at baseline and after 3 months of open-label treatment with empagliflozin 10 mg ($n = 15$).
Results: After 3 months, CSCs non-significantly declined in the dapagliflozin group (from 321 ± 25 to 270 ± 29/10^6; $p = 0.13$) and remained stable in the placebo group (from 328 ± 29 to 332 ± 28/10^6; $p = 0.88$), but the change from baseline was not significantly different between the two groups ($p = 0.21$). EPCs non-significantly declined in the dapagliflozin group (from 12.9 ± 2.1 to 8.7 ± 1.9/10^6; $p = 0.11$) and non-significantly increased in the placebo group (from 10.5 ± 1.9 to 15.9 ± 3.1/10^6; $p = 0.19$), and the change from baseline was significantly different between the two groups ($p = 0.042$). After an open-label extension period of 12 months, CSCs remained stable over time (reaching 294 ± 35/10^6 in the dapagliflozin and 357 ± 29/10^6 in the placebo group), while EPCs significantly increased in patients who received dapagliflozin during the randomized and/or open-label periods (26.6 ± 6.6/10^6; $p = 0.047$ versus baseline; $p = 0.033$ versus 3 months). In all patients, irrespectively of treatment, EPCs increased significantly from baseline to end of observation, concomitantly with improvement in HbA1c, which declined from 8.2 ± 0.1 to 7.7 ± 0.3% ($p < 0.001$). In a cohort of 15 patients who received open-label empagliflozin for 3 months, CSCs non-significantly declined (from 281 ± 35 to 222 ± 31/10^6; $p = 0.22$), whereas EPCs remained stable (from 11.0 ± 1.8 to 11.5 ± 1.6/10^6; $p = 0.82$).
Conclusion: During 3 months of treatment, SGLT2 inhibitors do not significantly increase CSCs or EPCs. Improvement in glucose control over >1 year, is associated with a significant increase in EPC levels

Dapagliflozin preserves renal vasodilating capacity in hypertensive patients with type 2 diabetes

R. Bruno, L. Giannini, A. Dardano, E. Biancalana, M. Seghieri, S. Taddei, L. Ghiadoni, A. Solini;
University of Pisa, Pisa, Italy.

Background and aims: Mechanisms through which SGLT-2 inhibitors achieve cardiovascular and renal protection are still unknown. We investigated whether dapagliflozin (Dapa) modulates Na and water balance and systemic and renal vascular parameters like endothelial function, arterial stiffness and renal vasodilating capacity, exploring the epigenetic regulation behind it.
Materials and methods: Two groups of hypertensive patients with type 2 diabetes were studied at baseline (V0) and after four weeks (V1) of Dapa 10 mg ($N = 20$) or hydroclorothiazide 12.5 mg (HCT, $N = 20$), collecting blood and urinary samples for routine analyses, determination of plasma renin activity, aldosterone, norepinephrine, adrenaline and 24

hour-urinary electrolytes. Flow-mediated dilation of the brachial artery (FMD), baseline (RI) and dynamic renal resistive index (DRIN), carotid-femoral pulse-wave velocity (PWV) and Augmentation Index (AIx) were also measured. Circulating miRNA related to chronic heart failure (miR27a-3p, miR30e-5p, miR199a-3p) and renal function (miR130b-3p, miR21-5p) were assessed.

Results: The two groups were comparable for age, sex, BMI and HbA1c. Both Dapa and HCT marginally lowered systolic and diastolic BP values, with no effect on heart rate. Fasting glucose did not significantly vary. Estimated GFR (by CKD-EPI equation) was unmodified in both groups after treatment. Serum magnesium concentration significantly rose in Dapa group (from 1.88 ± 0.27 to 2.01 ± 0.22 mg/dl, $p = 0.02$ for time*treatment interaction), while urinary magnesium was unchanged. 24h diuresis and glycosuria and osmolar clearance increased in Dapa ($p < 0.001$ for time*treatment interaction), with no changes in sodium excretion and creatinine clearance. Dapa induced also a rise in aldosterone ($p = 0.02$ for time*treatment interaction), with no influence on cathecolamines. Nor DAPA neither HCT modified FMD and PWV. Interestingly, in Dapa group DRIN remained unmodified, while tended to increase in HCT group ($p = 0.05$ for time*treatment interaction). Preliminary data show differences in circulating miRNAs between the two groups.

Conclusion: 4-week treatment with Dapa did not significantly influence BP, glucose values, eGFR and systemic indices of vascular function. However, in comparison to HCT, renal vasodilating capacity was preserved in Dapa group, indicating a selective effect on renal vascular function, which may act as a mechanism of nephroprotection. Furthermore, the increase in serum magnesium might contribute to cardiovascular protection.

Small increases in serum magnesium levels by dapagliflozin and normalisation of hypomagnesaemia in patients with type 2 diabetes

R. Toto[1], R. Goldenberg[2], G.M. Chertow[3], V. Cain[4], B.V. Stefansson[5], C.D. Sjöström[5], P. Sartipy[5];
[1]University of Texas Southwestern Medical Center, Dallas, USA, [2]LMC Diabetes & Endocrinology, Thornhill, Canada, [3]Stanford School of Medicine, Stanford, USA, [4]Bogier Clinical and IT Solutions, Raleigh, USA, [5]Cardiovascular, Renal and Metabolic Disease, AstraZeneca, Gothenburg, Sweden.

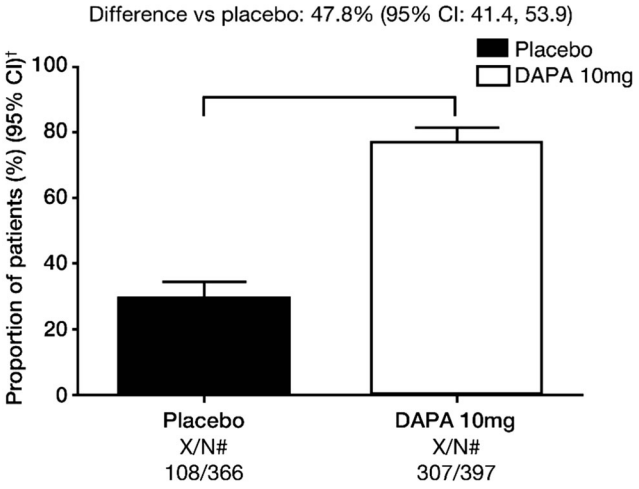
Background and aims: Hypomagnesaemia (serum magnesium [Mg] concentration <0.74 mmol/L) is common in patients with type 2 diabetes mellitus (T2DM). It is associated with increased risk of cardiometabolic complications, insulin resistance, ventricular arrhythmia, and chronic kidney disease. Small increases in serum Mg have been reported in patients treated with sodium-glucose co-transporter 2 inhibitors (SGLT2i). This study investigated the effect of the SGLT2i dapagliflozin (DAPA) on serum Mg in patients with T2DM.

Materials and methods: This post hoc analysis evaluated the effect of DAPA 10 mg on serum Mg level over 24 weeks (w) across 10 placebo-controlled studies in patients with T2DM. The patient population was subdivided based on serum Mg levels at baseline (<0.74 [$n = 773$] or ≥0.74 mmol/L [$n = 3625$]).

Results: Demographic and baseline characteristics were similar between subgroups. Patients with hypomagnesaemia (<0.74 mmol/L) had slightly longer average mean duration of T2DM (11 vs 9 years) and numerically higher frequency of reported cardiovascular-related disease history (67% vs 47%). Treatment with daily DAPA 10 mg increased placebo-adjusted serum Mg concentrations in patients with hypomagnesaemia and serum Mg concentrations ≥0.74 mmol/L (0.08 and 0.05 mmol/L, respectively). Similar changes occurred in patients with different estimated GFRs at baseline. The proportion of patients with baseline serum Mg <0.74 mmol/L achieving serum Mg ≥0.74 mmol/L at 24 w was >48% with DAPA 10 mg vs placebo (Figure). The proportions of patients with hypermagnesaemia (defined as >1.05 mmol/L) at baseline in the DAPA 10 mg and placebo groups were 2.2% (39/1811) and 1.3% (24/1781), respectively. These proportions remained similar post 24 w treatment with DAPA 10 mg and placebo (1.7% [31/1811] and 0.7% [13/1781], respectively). While treatment with DAPA 10 mg over 24 w reduced systolic blood pressure (SBP) vs placebo (~3 mm Hg), no clinically meaningful differences were observed in placebo-adjusted changes over 24 w in SBP and heart rate between patients in both subgroups at baseline. The frequency of reported adverse events under the MedDRA system organ class 'Cardiac Disorders' was numerically lower post 24 w treatment with DAPA 10 mg vs placebo in patients with serum Mg <0.74 mmol/L at baseline (3.5% vs 5.7%, respectively) and similar post 24 w treatment in the DAPA 10 mg and placebo groups (3.5% in both) in patients with serum Mg ≥0.74 mmol/L at baseline.

Conclusion: In patients with T2DM, 24 w treatment with DAPA 10 mg normalised serum Mg levels more than placebo in hypomagnesaemic patients. There was no increase from baseline to 24 w in the proportion of patients displaying hypermagnesaemia post treatment with DAPA 10 mg.

Figure: Proportion of patients with baseline serum Mg<0.74 mmol/L achieving serum Mg ≥0.74 mmol/L at 24 w



†Proportion of patients with low baseline serum Mg (<0.74 mmol/L) whose serum Mg level increased into normal range (≥0.74 mmol/L) at 24 weeks after treatment with either placebo or DAPA 10 mg.

SGLT-2 inhibitors efficacy in type 2 diabetic patients with bariatric surgery

J.P. Valderas[1], Y. Preiss[2], M. Sepulveda[3], F. Crovari[4], C. Boza[5];
[1]Medical Sciences, Universidad de Antofagasta, Antofagasta, [2]Center of obesity treatment, Hospital Dipreca, Santiago, [3]Surgery, Universidad Diego Portales, Santiago, [4]Surgery, Pontificia Universidad Catolica de Chile, Santiago, [5]Surgery, Clinica Las Condes, Santiago, Chile.

Background and aims: The Bariatric Surgery (BS) is part of the treatment of Type 2 Diabetes (T2D) in patients with obesity at worldwide, but

a great percentage of these patients undergo hyperglycemia after the procedure and require antidiabetic drugs. The same algorithm employed with non-operated diabetic subjects is used with these patients. However, the anatomical and physiological changes produced by BS could affect the efficacy of the drugs as well increase the adverse effects. The SGLT-2 inhibitors (iSGLT-2) are a new antidiabetic drugs with positive effects in body weight, blood pressure, cardiovascular events and nephropathy. Aim: To evaluate the efficacy of iSGLT-2 in T2D patients with a BS

Materials and methods: A retrospective study on 17 consecutive T2D patients with BS from 3 chilean centers. We report the changes in Hba1c and weight 6 months after the use of iSGLT-2, as well the main adverse effects.

Results: The patients had 54 ± 7.6 years old, a BMI of 27.6 ± 4.4 kg/m^2, and a Hba1c of 7.9 ± 0.9%. 11 subjects had a gastric bypass and 6 had a sleeve gastrectomy. The procedure was performed between 6 to 72 months ago (median of 26). At baseline 14 patients were on metformin, eight used insulin and two were off drugs. All patients had an Hba1c greater then 7% and 14 had overweigth. 13 patients started empagliflozin and four started dapagliflozin on the recommended doses. After 6 months, Hba1c was reduced in 0.9% [95% CI 0.6 to 1.1] $p < 0.0001$. Body weight decreased 0.7 kg [95% CI 0.7 to 2.9] $p = 0.003$. Two patient suspended insulin and nobody augmeted the hypoglycemic therapy. One patient had a mycotic balanitis that responded to topical treatment without withdraw the treatment. One additional patient developted a vulvovaginitis that did not relieve with topical and oral treatment and stopped the iSGLT-2 at 2 weeks, therefore she was not included in this report. No other adverse effects were observed.

Conclusion: In our cohort of T2D patients with bariatric surgery the SGLT-2 inhibitors preserved the hypoglycemic efficacy and this was similar than published in non-operated subjects. A small but significant weight loss was also observed. The genital infection was the only adverse effect observed but it can induce the withdrawal of the treatment. iSGLT-2 could be a good alternative in the management of hyperglycemia in bariatric patients.More studies are needed to develop an special pharmacological algorithm for the bariatric patients

Background and aims: SGSGLT2 inhibitors alter the pattern of substrate utilisation in patients with type 2 diabetes. Metabolomics has been used to predict, diagnose and monitor metabolic disorders, including diabetes. Proton nuclear magnetic resonance (^{1}H NMR) spectroscopy is a rapid and reproducible technique, requires minimum sample pretreatment and quantitates multiple metabolites. We employed a targeted NMR-based metabolomics approach to evaluate the effects of dapagliflozin on serum and urine metabolic profile

Materials and methods: Twenty-five patients with type 2 diabetes [14 males, age 60.3 ± 9.3 years, BMI 32.8 ± 5.4, HbA1c 8.3 ± 1.5%], inadequately controlled with metformin monotherapy, were included. All patients received 10 mg dapagliflozin daily for 3 months. Blood and urine samples were collected after a 12-hour fast at baseline and at the end of the active treatment period. For targeted metabolomics, the ^{1}H NMR spectra of the deproteinized serum samples and urine were recorded on a 700 MHz Bruker Avance DRX spectrometer

Results: Dapagliflozin administration resulted in several significant alterations of the metabolic profile in both serum and urine. As expected, serum levels of ketone bodies (acetone, 3-hydroxybutyrate and acetoacetate) showed a significant increase ($p < 0.01$), which was accompanied by a significant increase in their urine excretion ($p < 0.05$). Also, a significant decrease in serum lactate ($p < 0.05$) was observed while the urine levels of this metabolite were slightly but non-significantly increased. Dapagliflozin significantly increased the serum concentrations of branched-chain amino acids (leucine, isoleucine and valine: $p < 0.001$, $p < 0.05$ and $p < 0.001$, respectively). Of note, a smaller increase in the renal excretion of these amino acids was observed, suggesting that their reabsorption in proximal tubular cells was preserved and not affected by dapagliflozin. Depletion of urinary citrate has been attributed to either an impairment of the tricarboxylic acid cycle or to renal tubular acidosis, which typically appears as part of a generalized proximal tubule dysfunction. We found an increase in urine levels of citrate ($p < 0.05$) after dapagliflozin administration, which may indicate an improvement in the function of proximal tubular cells. Finally, an increase in the urine concentrations of various endogenous osmolytes (such as betaine, myoinositol and trimethylamine-N-oxide, $p < 0.001$ for all) was observed after dapagliflozin administration, which may result from an enhanced medullary production of these molecules. These changes may represent an adaptive response to the large amount of glucose that reaches the renal medulla and the resulting extracellular hypertonicity.

Conclusion: Dapagliflozin increases the availability of ketones and branched-chain amino acids as fuel to tissues; effects on the kidney include increased excretion of citrate and osmolytes

Effects of SGLT2 inhibitors in cells (human myeloid angiogenic cells and platelets) pivotally involved in atherosclerotic plaque (in)stability/thrombosis

V. Spigoni, F. Fantuzzi, C. Carubbi, G. Pozzi, E. Masselli, D. Galli, G. Gobbi, P. Mirandola, M. Vitale, R.C. Bonadonna, A. Dei Cas;
University of Parma, Parma, Italy.

Background and aims: The rapid emergence of cardiovascular (CV) benefits in SGLT2 inhibitor (SGLT2i) trials might suggest a direct effect on atherosclerotic plaque vulnerability and/or thrombosis. Circulating myeloid angiogenic cells (MAC; CD14$^+$ CD31$^+$ KDR$^+$ cells) and platelets (PLT) are pivotally implicated in these processes. We hypothesized that SGLT2i may influence MAC and/or PLT function. The aim of this study was to assess the effects of SGLT2i in reducing a) inflammation, oxidant stress and apoptosis in a published model of stearic acid (SA)-induced lipotoxicity in MAC; b) PLT activation. The possible involvement of the Na^+/H^+ exchanger (NHE) was also explored.

Materials and methods: MAC and PLT were isolated from peripheral blood of healthy subjects and incubated with/without SGLT2i [empagliflozin (EMPA) and dapagliflozin (DAPA) 1–100 μM] to assess the effects on: a) SA (100 μM)-induced cytokine expression, oxidant stress (qPCR) and apoptosis (caspase activation) in MAC and b) flow cytometric expression of PLT activation markers (CD62p and PAC-1) after ADP-stimulation. Digital/qPCR and western blot were used to test the expression of NHE isoforms and SGLT2 in MAC and purified PLT; NHE involvement was assessed with amiloride (aspecific NHE inhibitor) or cariporide (NHE1 specific inhibitor).

Results: NHE isoforms (1.6–9), but not SGLT2 expression, were detected in MAC and PLT. EMPA and DAPA (100 μM) reduced SA-induced inflammation (IL1β, IL8, TNFα, MCP1; $p < 0.005$), oxidant stress (SOD2, TXN, HO1; $p < 0.05$), but not apoptosis in MAC. EMPA and DAPA (both 1 μM) reduced PLT activation (CD62p and PAC1

expression; $p < 0.05$). SGLT2i effects were mimicked by amiloride, but not cariporide, in MAC, and by both inhibitors in PLT.
Conclusion: The effects of EMPA and DAPA - reduced lipotoxicity in MAC and PLT activation, possibly via NHE-inhibition - point to plaque stabilization and/or thrombosis inhibition as potential mechanism(s) involved in SGLT2i-mediated CV protection.

Determinants of the improved arterial stiffness observed after empagliflozin treatment

R.E. Schmieder, A. Bosch, S. Jung, K. Striepe, M.V. Karg, D. Kannenkeril, T. Dienemann, C. Ott;
Universitätsklinikum, Erlangen, Germany.

Background and aims: The selective sodium-glucose cotransporter 2 inhibitor empagliflozin has been shown to reduce cardiovascular morbidity and mortality, but the underlying pathogenetic mechanisms are poorly understood. Most recently, a reduction in central systolic blood pressure (BP) and pulse pressure, both parameters reflecting arterial stiffness, has been observed. Factors triggering the improvement of arterial stiffness are now in detail analyzed.
Materials and methods: Fifty eight male and female patients with diagnosed type 2 diabetes mellitus participated in an investigator-initiated prospective, double-blind, randomized, placebo-controlled, interventional clinical trial. Patients received either 6-weeks treatment with 25 mg empagliflozin orally once daily or placebo, followed by the second 6-week treatment with the other compound (crossover). Radial artery waveforms were recorded by the SphygmoCor System (AtCor Medical) and corresponding central (aortic) waveforms were then automatically generated through a validated transfer function. Now, we investigated the influence of parameters of glucose metabolism, volume status, sympathetic activation and inflammation on vascular parameters of arterial stiffness using multivariate regression analysis.
Results: Therapy with empagliflozin improved arterial stiffness as indicated by reduced central systolic BP (113.6 ± 12.1 vs 118.6 ± 12.9 mmHg, $p < 0.001$), central pulse pressure (39.1 ± 10.2 vs 41.9 ± 10.7 mmHg, $p = 0.027$) forward (27.1 ± 5.69 vs 28.7 ± 6.23 mmHg, $p = 0.031$) as well as reflected wave amplitude (18.9 ± 5.98 vs 20.3 ± 5.97 mmHg, $p = 0.045$) compared to placebo. The results of the multivariate regression analysis revealed that besides 24-hour ambulatory systolic BP ($p = 0.016$), age ($p = 0.022$) and sex ($p = 0.092$), change in high sensitive CRP (hsCRP) ($p = 0.029$) emerged as a significant determinant of empagliflozin induced reduction in central pulse pressure, whereas copeptin, hematocrit, heart rate, HbA1c and LDL-cholesterol did not emerge as significant determinants. When replacing HbA1c with fasting plasma glucose, again the change in hsCRP ($p = 0.020$) was an independent determinant of central pulse pressure. Repeating the analysis with "improvement of reflected wave amplitude", change in hsCRP ($p = 0.037$) predicted significantly the change in the reflected wave amplitude ($p = 0.037$).
Conclusion: Besides age, sex and change in systolic 24 hour ambulatory BP, change in high sensitive CRP was an independent determinant of empagliflozin induced improvement of arterial stiffness, whereas parameters of change in glucose metabolism and volume status had no significant influence. Our analysis revealed a signal that empagliflozin exerts, at least to some extent, beneficial vascular effects via anti-inflammatory mechanisms.

SGLT2 inhibitors effect on fatty liver disease in patients with Berardinelli-Seip lipodystrophy

E.B. Parente[1], V.R.F. Simoes[1], M.A. Medeiros[1], I.E. Bacha[2], E.R. Parisi[2], J.E.N. Salles[1];
[1]Internal Medicine- Endocrinology, Faculty of Medical Science of Santa Casa of Sao Paulo, São Paulo, [2]Medicine- Endocrinology, Federal University of Sao Paulo, São Paulo, Brazil.

Background and aims: Berardinelli-Seip congenital lipodystrophy (BSCL) is a rare autosomal recessive disease with almost complete absence of adipose tissue and severe insulin resistance. Its prevalence worldwide is 1 in 12 million people. BSCL patients usually develop severe diabetes mellitus (DM), hypertriglyceridemia and fatty liver disease. The glucose control in BSCL is very difficult due the severity of insulin resistance, so they need high doses of insulin. Because of few options of treatment available for these patients, we tried to associate iSGLT2 to insulin, aiming to improve glucose control, liver disease and reduce insulin doses. There is no data in the literature regarding the use of iSGLT2 in patients with BSCL.
Materials and methods: This is a retrospective, descriptive study of four patients with BSCL using more than 1 ui/kg of insulin and fatty liver disease that received iSGLT2 for 12 months. Liver disease was evaluated by elastography (FibroScan 502) considering a value of CAP >200 dB/m as steatosis and a kPa >6.0 for liver fibrosis. Patients were submitted to elastography before, 6 and 12 months after iSGLT2. A1c, fasting triglycerides (TG), liver enzymes, fasting glucose, body weight were measured at the same time.
Results: Patient 1: 28 year-old woman, 50.4 kg, DM since 14 years old. At diagnosis: TG 896 mg/ml and A1c 14.2%. Leptin 0.6 ng/mL. Before empagliflozin 10 mg: A1c 9.4%, using 1.2 ui/kg of insulin, CAP 341, kPa 4.8. After 6 months: A1c 10%, insulin 1.3 uikg, CAP 351, kPa 6.6. After one year: A1c 10%, insulin 1.2 uikg, CAP 311, kPa 5.9 Patient 2: 33 year old woman, 64.4 kg, DM since puberty. At diagnosis: TG 678 mg/ml A1c 12.6%. Leptin 0.8 ng/mL. Before empagliflozin 10 mg: A1c 6.0% using 2.4 ui/kg of insulin, CAP 161, kPa 3.7. After 6 months: A1c 5.9%, insulin 2.4 uikg, CAP 234, kPa 4.9. After one year: A1c 6.1%, insulin 2.5 uikg, CAP 245, kPa 5.2.Patient 3: 59-year-old woman, 58.1 kg, DM since 40 years old. At diagnosis: TG 792 mg/ml and A1c 8.6%. Leptin 1.9 ng/mL. Before dapagliflozin 10 mg: A1c 8.5% using 2.0 ui/kg of insulin, CAP 304, kPa 8.1. After 6 months: A1c 7.5%, insulin 1.8 uikg, CAP 390, kPa 7.3. After one year: A1c 8.5%, insulin 1.8 uikg, CAP 320, kPa 7.1.Patient 4: 61-year-old woman, 54.4kg, DM since 47 years old. At diagnosis: TG 937 mg/ml and A1c 8.1%. Leptin 0.5 ng/mL. Before empagliflozin 10 mg: A1c 9.1% using 1.1 ui/kg of insulin, CAP 364, kPa 6.1. After 6 months: A1c 8.0%, insulin 1.1 uikg, CAP 287, kPa 5.8. After one year: A1c 8.5%, insulin 1.2 uikg, CAP 309, kPa 5.3.The use of iSGLT2 with insulin in patients with BSCL did not reduce A1c, insulin doses, weight nor triglycerides, but improved liver fibrosis in the two patients that presented this condition. The period of exposure to metabolic disturbances seems to be an important factor for liver fibrosis, since it was present in the two oldest patients. After one year of iSGLT2, without glycemic, body weight or steatosis improvements, the two patients with liver fibrosis reduced it in 12.3% and 13.1%. Maybe it was a direct effect of iSGLT2 in liver fibrosis, but as this is a rare disease we will a greater sample size to conclude this effect.
Conclusion: The association of iSGLT2 to insulin for one year in four patients with BSCL did not improve steatosis, glycemic control neither insulin doses, but reduced liver fibrosis when it was present.

Dapagliflozin improves liver dysfunction in parallel with a decrease in serum soluble DPP-4/CD26 level in type 2 diabetic patients with non-alcoholic fatty liver

H. Kishi, K. Suzuki, K. Kato, M. Shimizu, T. Jojima, T. Iijima, I. Usui, Y. Aso;
Dokkyo Medical University, Mibu, Japan.

Background and aims: Serum levels of soluble DPP-4/CD26 are elevated in patients with type 2 diabetes and non-alcoholic fatty disease (NAFLD). Hepatocyte-secreted sDPP-4 induce directly inflammation and insulin resistance in the liver. Similar to a carbohydrate-restricted diet, SGLT2 inhibitors reduce hepatic steatosis by inhibiting hepatic de novo lipogenesis. We investigated effects of dapagliflozin, an SGLT2 inhibitor, on liver dysfunction, hepatic steatosis, and serum levels of sDPP-4 in patients with type 2 diabetes and NAFLD.
Materials and methods: Fifty-seven patients with type 2 diabetes and NAFLD were randomized into a dapagliflozin (5 mg/day) treatment group ($n = 33$) or an active placebo group ($n = 24$) for 24 weeks. Visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) volumes were measured using a dual bioelectrical impedance analysis (Dual Scan). Hepatic steatosis was evaluated by controlled attenuated parameter (CAP) using a transient ultrasound elastography. Serum levels of sDPP-4 were measured with a commercially available ELISA kit.
Results: At baseline, serum sDPP-4 showed positive correlations with aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyl transferase (GGT), and HOMA-IR, an index of hepatic insulin resistance, in a total of 57 patients. Both VAT and SAT significantly decreased in the dapagliflozin group, but not in the placebo group. Serum level of AST, ALT, and GGT showed a significant decrease at 24 weeks in the dapagliflozin group, while they were unchanged in the placebo group. CAP also significantly decreased in the dapagliflozin group. Although both groups showed a significant reduction in serum sDPP-4 at 24 weeks after treatment, the magnitude of sDPP-4 reduction was greater in the dapagliflozin group. Changes in liver enzymes (AST, ALT, and GGT) after treatment with dapagliflozin correlated positively with those in serum sDPP-4 levels, but not those in VAT (Fat volume) or HbA1c.
Conclusion: A improvement of liver dysfunction was associated with a decrease in serum sDPP-4, but not that in VAT or HbA1c, after treatment with dapagliflozin in patients with type 2 diabetes and NAFLD, suggesting that reducing serum sDPP-4 by SGLT2 inhibitors may be a therapeutic strategy for treatment of NAFLD/non-alcoholic steatohepatitis in people with type 2 diabetes.

Canagliflozin prevents development of hepatocellular carcinoma (HCC) from non-alcoholic steatohepatitis (NASH) in a novel mouse model of NASH-HCC under diabetic state

T. Jojima, H. Kishi, T. Iijima, I. Usui, Y. Aso;
Dokkyo Medical Unversity, Mibu, Japan.

Background and aims: Non-alcoholic steatohepatitis (NASH), which is characterized by hepatocellular lipid accumulation (steatosis) along with lobular inflammation, hepatocellular ballooning, and fibrosis, can result in liver cirrhosis and hepatocellular carcinoma (HCC). Several studies have shown that some SGLT2 inhibitors alleviate hepatic steatosis or steatohepatitis in type 2 diabetic mice or rats.We investigated the effects of canagliflozin (CANA), an SGLT2 inhibitor, on steatohepatitis and fibrosis in a novel diabetes-non-alcoholic steatohepatitis (NASH) -HCC progression model mice. Moreover, we investigated inhibitory effects of CANA on development of HCC in this model mice
Materials and methods: Mice aged 5 weeks were divided into two groups (vehicle and CANA 30 mg/kg) and fed for 3 more weeks. Next, mice aged 5 weeks were divided into three groups of 9 animals: vehicle, CANA initial administration 30 mg/kg (5 to 9 W), CANA continuous administration 30 mg/kg (5 to 16W).
Results: The histological non-alcoholic fatty liver disease activity score (NAS) was lower in the CANA group than in the vehicle group at age of 8 weeks. The expression of type 1 and 3 collagen mRNA was reduced in the CANA group.CANA continuous administration 30 mg/kg (5 to 16W). CANA continuous treated mice had greater survival at 16 weeks of age compared with vehicle mice (89% vs 56%, $P < 0.01$). At the age of 16 weeks, the NAS was significantly lower in the CANA continuous administration group than in the vehicle or the CANA initial administration groups. The number of hepatic tumors was significantly smaller in the CANA continuous administration group than in the vehicle group. Immunohistochemistry showed that expression of glutamine synthetase, a marker of HCC, was reduced in the CANA continuous administration group compared with the vehicle group. The CANA continuous administration significantly decreased expression of mRNAs for α-fetoprotein, a tumor maker of HCC, compared with the vehicle administration
Conclusion: Canagliflozin attenuates development of NASH showing anti-steatotic and anti-inflammatory effects, and prevents progression of HCC from NASH, leading to prolongation of survival in STAM mice.

Improvements in blood pressure and markers of arterial stiffness with canagliflozin in the CANVAS Program

S. Genovese[1], R.R. Townsend[2], M. Dharmalingham[3], A. Steele[4], J. Arenas León[5], A. Slee[6], E. Fabbrini[7], K.W. Mahaffey[8];
[1]Diabetes Endocrine and Metabolic Disease Unit, IRCCS Centro Cardiologico Monzino, Milan, Italy, [2]Hospital of the University of Pennsylvania, Philadelphia, USA, [3]Ramaiah Medical College, Bengaluru, Karnataka, India, [4]Lakeridge Health, Oshawa, Canada, [5]Hospital Angeles Centro Médico del Potosí, San Luis, Mexico, [6]Axio Research, Seattle, USA, [7]Janssen Research & Development, LLC, Raritan, USA, [8]Stanford Center for Clinical Research, Department of Medicine, Stanford University School of Medicine, Stanford, USA.

Background and aims: The CANagliflozin cardioVascular Assessment Study (CANVAS) Program demonstrated a reduced risk of cardiovascular (CV) and renal outcomes with the SGLT2 inhibitor canagliflozin (CANA) versus placebo (PBO) in adults with type 2 diabetes mellitus (T2DM) and established CV disease or ≥2 CV risk factors ($N = 10,142$; mean age, 63.3 y; systolic blood pressure [SBP], 136.6 mmHg; diastolic blood pressure [DBP], 77.7 mmHg). This analysis assessed the effects of CANA on blood pressure (BP), pulse, and markers of arterial stiffness, including pulse pressure (PP) and double product (DP), in the CANVAS Program.
Materials and methods: SBP, DBP, and pulse were measured in the CANVAS Program and were used for post hoc analyses of least squares (LS) mean change in PP (PP = SBP − DBP) and DP (DP = pulse × SBP) over time.
Results: CANA lowered SBP and DBP compared with PBO over the CANVAS Program (mean differences of −3.93 mmHg [95% confidence interval [CI]: −4.30, −3.56]) and −1.39 mmHg [95% CI: −1.61, −1.17]; both $P < 0.001$). There were no meaningful differences in pulse over 104 weeks; a ~0.5 bpm reduction in pulse was seen with CANA at Week 26, which remained stable over time, while pulse with PBO was similar to baseline over 104 weeks. CANA provided reductions in PP and DP compared with PBO (**Figure**). There was an initial reduction in PP that increased over time with CANA, but remained lower compared with PBO. CANA also provided an initial reduction in DP that was sustained over time.
Conclusion: Favourable effects of CANA on BP, pulse, and markers of arterial stiffness were observed in patients with T2DM with CV risk factors or established CV disease, which may contribute to the beneficial effects of CANA on CV outcomes.

Figure. Change in (A) PP and (B) DP with CANA versus PBO over time.

Effects of canagliflozin on HbA_{1c} and changes in antihyperglycaemic agents in the CANVAS Programme

G. Fulcher[1], M. Davies[2], M. Tsoukas[3], M. Desai[4], C. Wysham[5];
[1]The Royal North Shore Hospital and University of Sydney, Sydney, Australia, [2]University of Leicester, Leicester Diabetes Centre, Leicester, UK, [3]McGill University Health Centre, Montreal, Canada, [4]Janssen Research & Development, LLC, Raritan, USA, [5]University of Washington, Spokane, USA.

Background and aims: Canagliflozin (CANA) improved glycaemic control by reducing HbA1c in a broad range of patients with type 2 diabetes (T2D) across its clinical trial program. This analysis examines the effects of CANA on HbA1c and changes in use of antihyperglycaemic agents (AHAs) in patients with high cardiovascular (CV) risk in the CANagliflozin cardioVascular Assessment Study (CANVAS) Program.
Materials and methods: The CANVAS Program randomly assigned 10,142 participants with T2D and established CV disease or ≥2 CV risk factors to treatment with CANA or placebo (PBO). Least squares (LS) mean changes from baseline HbA1c and initiation of new AHAs were analysed in the on-treatment population (patients receiving CANA/PBO or within 30 days after discontinuation; $n = 10,134$).
Results: From a baseline mean HbA1c of 8.2%, the maximum difference between CANA and PBO (PBO-subtracted difference [95% CI]: −0.64% [−0.68, −0.61]; mean 8.1% vs 7.5%) was observed at Week 26. After Week 26, the curves began to converge, reaching a minimum difference between CANA and PBO of −0.23% (95% CI: −0.33, −0.14; 8.2% vs

8.0%) at Week 286. At the end of the study (Week 338), the mean difference HbA1c with CANA versus PBO was −0.24% (95% CI: −0.37, −0.10; 8.1% vs 7.9%), with a mean reduction of −0.58% (95% CI: −0.61, −0.56) with CANA versus PBO over the entire follow-up period. Discontinuation from study drug was about the same in both treatment groups during the first year of the study; after Week 52, more patients discontinued PBO versus CANA. At baseline, the treatment groups were well-balanced with respect to AHA use. Almost all patients (98.6%) were being treated with ≥1 AHA at baseline (18.7% on 1 AHA, 43.6% on 2 AHAs, and 36.3% on ≥3 AHAs). The most common AHAs at baseline were biguanides (77.2%), insulin (50.3%), and sulfonylureas (43.0%). Over the course of the study, approximately 22% of patients initiated new AHAs during treatment with study drug, with DPP-4 inhibitors and insulin being the most common newly initiated AHAs (**Table**). A higher proportion of PBO-treated patients initiated AHA therapy across all classes, including insulin. Through the first and second years of the study, patients in the PBO group initiated new AHAs approximately twice as often as CANA-treated patients (first year: 6.3% and 14.7% with CANA and PBO; first 2 years: 11.3% and 22.9% with CANA and PBO).
Conclusion: In the CANVAS Program, patients treated with CANA had greater reductions in HbA1c compared with patients treated with PBO. After 52 weeks of treatment, the difference in HbA1c between the CANA and PBO groups began to decrease likely due to the joint effects of discontinuation of randomized therapy and a higher rate of initiating new AHA therapies in the PBO group.

Table. Newly Initiated Concomitant AHA Medications

Concomitant medication	PBO (n = 4344)	CANA (n = 5790)	Total (n = 10,134)
Patients with concomitant therapy, n (%)	1173 (27.0)	1029 (17.8)	2202 (21.7)
Alpha glucosidase inhibitors	59 (1.4)	59 (1.0)	118 (1.2)
Biguanides	209 (4.8)	188 (3.2)	397 (3.9)
DPP-4 inhibitors	385 (8.9)	340 (5.9)	725 (7.2)
GLP-1 receptor agonists	148 (3.4)	138 (2.4)	286 (2.8)
Insulin	380 (8.7)	271 (4.7)	651 (6.4)
SGLT2 inhibitors	21 (0.5)	29 (0.5)	50 (0.5)
Sulfonylureas	251 (5.8)	218 (3.8)	469 (4.6)
Thiazolidinediones	81 (1.9)	53 (0.9)	134 (1.3)

DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; SGLT2, sodium glucose co-transporter 2.

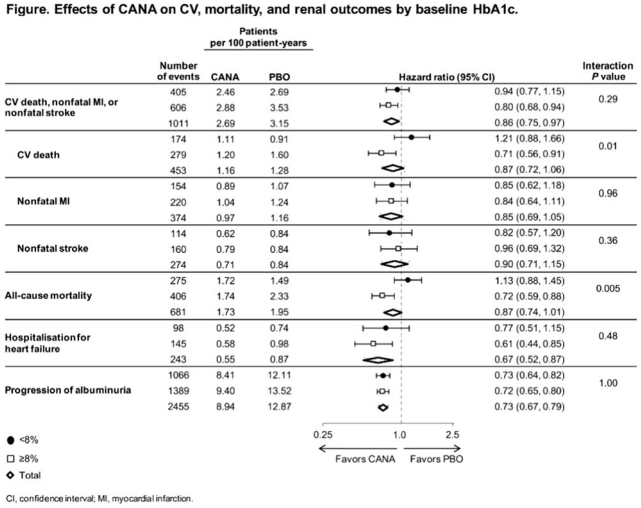
Relatively consistent effects of canagliflozin on outcomes regardless of baseline HbA_{1c} in the CANVAS Program

D.R. Matthews[1], J. Rosenstock[2], G. Bantwal[3], J. Wilding[4], R. Dumas[5], G. González-Gálvez[6], A. Slee[7], F. Vercruysse[8], K.W. Mahaffey[9], D. de Zeeuw[10], G. Fulcher[11];
[1]Oxford Centre for Diabetes, Endocrinology and Metabolism and Harris Manchester College, University of Oxford, Oxford, UK, [2]Dallas Diabetes Research Center at Medical City, Dallas, USA, [3]St. John's Medical College and Hospital, Bangalore, India, [4]University of Liverpool, Liverpool, UK, [5]Laval Clinic Research Center, Montreal, Canada, [6]Jalisco Institute of Diabetes and Obesity Research, Guadalajara, Mexico, [7]Axio Research, Seattle, USA, [8]Janssen Research & Development, Beerse, Belgium, [9]Stanford Center for Clinical Research, Department of Medicine, Stanford University School of Medicine, Stanford, USA, [10]University of Groningen, University Medical Center Groningen, Groningen, Netherlands, [11]The Royal North Shore Hospital and University of Sydney, Sydney, Australia.

Background and aims: The CANagliflozin cardioVascular Assessment Study (CANVAS) Program evaluated cardiovascular (CV) safety of canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, compared with placebo (PBO) in participants with type 2 diabetes mellitus (T2DM) and established CV disease (CVD) or with ≥2 CV risk factors. The primary composite outcome of CV death, nonfatal myocardial infarction, or nonfatal stroke was significantly reduced with CANA vs. PBO by 14% (hazard ratio [HR] 0.86; 95% confidence interval [CI], 0.75, 0.97; $P = 0.02$). In this prespecified analysis, the effects of CANA on the risk of CV, mortality, and renal outcomes were assessed in patients by baseline HbA1c.
Materials and methods: Outcomes were assessed in CANVAS Program participants by baseline HbA1c (<8% and ≥8%). The number of events, incidence rates, HRs, and 95% CIs were calculated for each outcome.
Results: Among CANVAS Program participants, 4,411 (43%) had baseline HbA1c <8% (mean HbA1c 7.4%; prior CVD 67%; age 64 y; body mass index [BMI] 32 kg/m^2; and blood pressure [BP] 136/77 mmHg) and 5,731 (57%) had baseline HbA1c ≥8% (mean HbA1c 8.9%; prior CVD 65%; age 63 y; BMI 32 kg/m^2; and BP 137/78 mmHg). The effects of CANA on CV and renal outcomes were similar overall in participants with baseline HbA1c <8% or ≥8%, but there was evidence of statistical heterogeneity between subgroups for CV death and all-cause mortality, where effects on these adverse outcomes were better in participants with HbA1c ≥8% (**Figure**).
Conclusion: CV and renal outcomes appeared better in CANA-treated participants regardless of HbA1c in this hypothesis-generating subanalysis with a suggestion of greater effects on lowering mortality risk in those with higher HbA1c levels at baseline.

Figure. Effects of CANA on CV, mortality, and renal outcomes by baseline HbA1c.



CI, confidence interval; MI, myocardial infarction.

Clinical Research, Department of Medicine, Stanford University School of Medicine, Stanford, USA, [9]University of Groningen, University Medical Center Groningen, Groningen, Netherlands, [10]Oxford Centre for Diabetes, Endocrinology and Metabolism and Harris Manchester College, University of Oxford, Oxford, UK.

Background and aims: The CANagliflozin cardioVascular Assessment Study (CANVAS) Program evaluated the cardiovascular (CV) safety of canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, compared with placebo (PBO) in patients with type 2 diabetes and established CV disease or with ≥2 CV risk factors. The results showed that CANA reduced the risk of CV and renal outcomes. Overweight and obesity are known risk factors for heart and kidney disease. In this prespecified analysis, the effects of CANA on the risk of CV, mortality, and renal outcomes were assessed in patients by baseline body mass index (BMI).
Materials and methods: Outcomes were assessed in the CANVAS Program participants (N = 10,142) by baseline BMI (<30 or ≥30 kg/m^2). The number of events, incidence rates, hazard ratios, and 95% confidence intervals were calculated for each outcome.
Results: At baseline compared to patients with BMI <30 kg/m^2, more patients with BMI ≥30 kg/m^2 had systolic blood pressure (BP) ≥140 or diastolic BP ≥90 mmHg (47.9% vs 40.3%) and were taking renin-angiotensin-aldosterone system (RAAS) inhibitors (83.8% vs 74.6%). Effects of CANA on the primary outcome (CV death, nonfatal myocardial infarction, or nonfatal stroke) and other CV outcomes were consistent between BMI subgroups (**Figure**). CANA decreased progression of albuminuria in both BMI subgroups with the effect appearing greater in patients with BMI ≥30 kg/m^2. Further statistical testing did not show a qualitative interaction (Gail-Simons P = 0.875). The comparative benefits of CANA on albuminuria in patients with higher BMI may be due to greater reductions in body weight (PBO-subtracted difference at 1 y: −2.1 and −2.8 kg for BMI <30 and ≥30 kg/m^2) and BP (systolic BP: −4.2 and −4.6 mmHg; diastolic BP: −1.0 and −1.7 mmHg for BMI <30 and ≥30 kg/m^2); HbA1c reductions were similar with BMI <30 and ≥30 kg/m^2 (−0.60% and −0.63%).
Conclusion: While small statistical heterogeneity may exist, BMI <30 versus ≥30 kg/m^2 does not appear to be a major determinant of the observed improvements in CV outcomes with CANA.

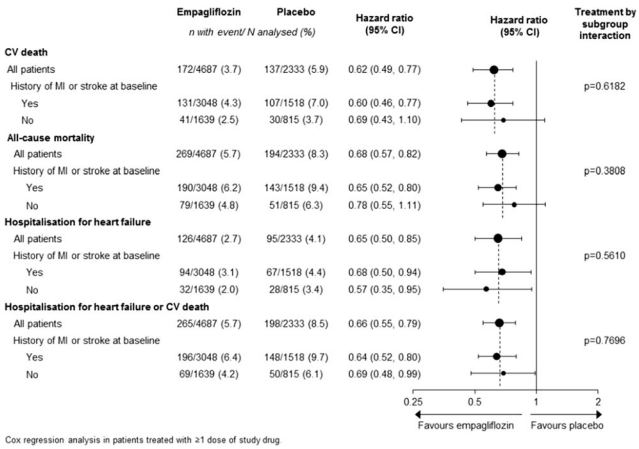
Empagliflozin reduces mortality and hospitalisation for heart failure in patients with or without a history of myocardial infarction or stroke at baseline

S. Sambevski[1], D. Fitchett[2], S.E. Inzucchi[3], S. Kaspers[1], E. Pfarr[1], J.T. George[1], B. Zinman[4];
[1]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [2]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [3]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [4]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Canada.

Background and aims: In the EMPA-REG OUTCOME trial, empagliflozin added to standard of care reduced cardiovascular (CV) death by 38% (HR 0.62 [95% CI 0.49, 0.77]), all-cause mortality by 32% (HR 0.68 [95% CI 0.57, 0.82]) and hospitalisation for heart failure (HHF) by 35% (HR 0.65 [95% CI 0.50, 0.85]) vs placebo in patients with type 2 diabetes and established CV disease. We investigated whether a history of myocardial infarction (MI) or stroke at baseline influenced the effect of empagliflozin on these outcomes.
Materials and methods: Patients were randomised to empagliflozin 10 mg, empagliflozin 25 mg, or placebo. Median observation time was 3.1 years. CV death, all-cause mortality, HHF and the composite of HHF or CV death were assessed for empagliflozin pooled vs placebo in subgroups by history MI or stroke at baseline using Cox regression analyses. P values for treatment by subgroup interaction were obtained from tests of homogeneity of treatment group differences among subgroups with no adjustment for multiple testing.
Results: Of 7020 patients treated, 65% in both treatment groups had a history of MI or stroke at baseline. Effects of empagliflozin on CV death, all-cause mortality, HHF and HHF or CV death were consistent in patients with and without MI or stroke.
Conclusion: Reductions in mortality and HHF with empagliflozin in patients with type 2 diabetes and established CV disease in the EMPA-REG OUTCOME trial were consistent in patients with or without a history of MI or stroke at baseline.



Cox regression analysis in patients treated with ≥1 dose of study drug.

Empagliflozin and kidney outcomes in patients with or without heart failure at baseline: insights from the EMPA-REG OUTCOME trial

J. Butler[1], F. Zannad[2], D. Fitchett[3], B. Zinman[4], A. Koitka-Weber[5,6], M. von Eynatten[7], U. Hehnke[7], J. George[7], M. Brueckmann[7], A.K. Cheung[8], C. Wanner[9];
[1]Dept of Medicine, University of Mississippi, Jackson, USA, [2]Institut Lorrain du Coeur et des Vaisseaux, Nancy, France, [3]St Michael's Hospital, University of Toronto, Toronto, Canada, [4]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital and Division of Endocrinology, University of Toronto, Toronto, Canada, [5]Boehringer Ingelheim International GmbH, Biberach, Germany, [6]Dept of Diabetes, Central Clinical School, Monash University, Melbourne, Australia, [7]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [8]University of Utah, Salt Lake City, USA, [9]Dept of Medicine, Division of Nephrology, Würzburg University Clinic, Würzburg, Germany.

Background and aims: Chronic kidney disease (CKD) is common and portends worse prognosis in patients with heart failure (HF), especially in the presence of type 2 diabetes (T2D). In the EMPA-REG OUTCOME trial, the sodium-glucose co-transporter 2 inhibitor empagliflozin (EMPA) significantly reduced the risk of cardiovascular (CV) death by 38% vs placebo (PBO) in patients with T2D and established CV disease (CVD). EMPA also reduced the risk of incident or worsening nephropathy by 39%, and slowed progression of CKD. Here, we report *post-hoc* kidney outcomes in patients with or without HF at baseline from EMPA-REG OUTCOME.
Materials and methods: Patients were randomised (1:1:1) to EMPA 10 mg, 25 mg or PBO. The composite kidney outcome of incident or worsening nephropathy (defined as progression to macroalbuminuria, doubling of serum creatinine, initiation of renal replacement therapy, or death from renal disease) and its components were analysed in subgroups of patients with or without HF at baseline. The incidence of first sustained decline in eGFR from baseline of ≥40% combined with initiation of renal replacement therapy, or renal death was also evaluated. Cox proportional hazards models were used to investigate the consistency of treatment effect across subgroups.
Results: Of 7020 treated patients, 706 (10.1%) had HF at baseline. For each of the four kidney outcomes, EMPA was associated with a consistent and lower relative risk versus PBO across the baseline HF subgroups (the *p* values for treatment by subgroup interaction across all kidney outcomes were >0.05) (Figure).
Conclusion: In EMPA-REG OUTCOME, EMPA reduced the risk of clinically relevant kidney events in patients with T2D and HF at baseline. The renoprotective effects were observed on a background of standard of care and were consistent with those reported for the overall study population. The potential of EMPA to slow CKD progression in patients with HF (with or without diabetes) is being further investigated in ongoing HF-trials (EMPEROR-trials).

Design of the EMPERIAL trials of empagliflozin in patients with chronic heart failure with reduced or preserved ejection fraction

W.T. Abraham[1], S.D. Anker[2], A. Salsali[3], B. Peil[4], C. Zeller[5], M. Brun[6], H. Macesic[7], M. Brueckmann[4], J. Lindenfeld[8], P. Ponikowski[9];
[1]The Ohio State University, Columbus, USA, [2]Charité University, Berlin, Germany, [3]Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, USA, [4]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [5]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany, [6]Boehringer Ingelheim France, Reims cedex, France, [7]Boehringer Ingelheim (Canada) Ltd, Burlington, ON, Canada, [8]Vanderbilt University Medical Center, Nashville, USA, [9]Wrocław Medical University, Wroclaw, Poland.

Background and aims: Besides increasing the risks of cardiovascular death and hospitalisation, chronic heart failure (HF) with either reduced (HFrEF) or preserved (HFpEF) ejection fraction is associated with a high symptom burden, and impaired physical functioning. Empagliflozin is a sodium-glucose cotransporter-2 inhibitor that was shown in the EMPA-REG OUTCOME trial to reduce the risk of cardiovascular events, hospitalisations and mortality in patients with type 2 diabetes and established cardiovascular disease. Two Phase III trials, EMPERIAL-reduced and EMPERIAL-preserved, have been initiated to investigate the effects of empagliflozin on functional outcomes in patients with HFrEF and HFpEF, respectively.
Materials and methods: The EMPERIAL trials (Effect of EMPaglifozin on ExeRcise ability and HF-symptoms, In patients with chronic heArt faiLure) are two randomised, double-blind, placebo-controlled trials designed to evaluate the effect of empagliflozin on exercise capacity and symptoms in patients with either HFrEF (left ventricular ejection fraction ≤40%) or HFpEF (left ventricular ejection fraction >40%). Inclusion criteria include 6-minute walk test (6MWT) distance of 100 m to ≤350 m and elevated N-terminal pro-brain natriuretic peptide (NT-proBNP) >600 pg/mL in HFrEF, or >300 pg/mL (>600 pg/mL with atrial fibrillation) in HFpEF, respectively. In addition, patients with HFpEF must present with structural heart disease (left atrial enlargement and/or left ventricular hypertrophy) documented by echocardiogram and/or hospitalisation for HF within the previous 12 months. Patients must be clinically stable and on appropriate medical therapy for HF consistent with current guidelines, with doses stable for ≥4 weeks (or ≥2 weeks

for diuretics). Approximately 300 patients in each trial will be randomised 1:1 to receive empagliflozin 10 mg or placebo once daily for 12 weeks. The primary endpoint is the change from baseline in 6MWT distance at week 12. Key secondary endpoints are changes from baseline in Kansas City Cardiomyopathy Questionnaire, total symptom score and in Chronic Heart Failure Questionnaire Self-Administered Standardized format dyspnoea score at week 12. Patient Global Impression of change questionnaires and change from baseline in NT-proBNP at week 12 are other secondary endpoints.

Results: Recruitment for this trial has started in 2018.

Conclusion: The findings of the EMPERIAL-reduced and EMPERIAL-preserved trials will determine the effects of empagliflozin on symptoms, exercise capacity and patient reported outcome in patients with heart failure. The effects of empagliflozin on cardiovascular death and hospitalisation for heart failure in patients with chronic heart failure are being investigated in the EMPEROR-reduced and EMPEROR-preserved trials.

Design and rationale of the EMPEROR trials of empagliflozin in patients with chronic heart failure with reduced or preserved ejection fraction

S.D. Anker[1], F. Zannad[2], J. Butler[3], G. Filippatos[4], A. Salsali[5], K. Kimura[6], J. Schnee[5], C. Zeller[7], S. Pocock[8], J.T. George[9], M. Brueckmann[9], M. Packer[10];
[1]Charité - Universitätsmedizin, Berlin, Germany, [2]Institut Lorrain du Coeur et des Vaisseaux, Nancy, France, [3]Department of Medicine, University of Mississippi, Jackson, USA, [4]University of Athens, Athens, Greece, [5]Boehringer Ingelheim Pharmaceuticals, Ridgefield, USA, [6]Boehringer Ingelheim Canada Ltd., Burlington, ON, Canada, [7]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany, [8]London School of Hygiene and Tropical Medicine, London, UK, [9]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [10]Baylor Heart and Vascular Institute, Dallas, USA.

Background and aims: Despite available therapies for heart failure (HF) with reduced ejection fraction (HFrEF), rates of hospitalization and mortality remain high. HF with preserved ejection fraction (HFpEF) increasingly contributes to HF hospitalizations with outcomes as poor as in patients with HFrEF, and there is no evidence-based therapy for HFpEF patients. In the EMPA-REG OUTCOME trial in patients with type 2 diabetes mellitus (T2DM) and established cardiovascular (CV) disease, the sodium-glucose co-transporter-2 (SGLT-2) empagliflozin reduced the risk CV mortality by 38% and the risk of HF hospitalizations (HHF) by 35%. Several mechanisms have been put forward to explain these benefits, which may go beyond the blood glucose lowering effect of empagliflozin. This raises the possibility of using empagliflozin as treatment for patients with established HF regardless of the presence of diabetes.

Materials and methods: Two phase III randomized, double-blind trials, EMPEROR-Reduced and EMPEROR-Preserved, will explore the efficacy and safety of once daily empagliflozin 10 mg compared with placebo, in patients with chronic HFrEF or HFpEF. The EMPEROR-Reduced trial includes patients with left ventricular ejection fraction (EF) ≤40% and elevated NT-proBNP levels (cut-offs for patients without/with atrial fibrillation are: NT-proBNP ≥2500/5000 pg/ml with EF 36–40%, ≥1000/2000 pg/ml with EF 31–35%, ≥600/1200 pg/ml with EF ≤30%). Alternatively, patients with EF ≤40% qualify, if they had a HHF within 12 months and present with NT-proBNP levels of ≥600 pg/ml (without AF) or ≥1200 pg/ml (with AF). In EMPEROR-Preserved, patients with chronic HFpEF with left ventricular EF >40% will be included. Patients are required to have elevated NT-proBNP levels (>300 pg/ml for patients without AF, or >900 pg/ml for patients with AF), and structural heart disease or documented HHF within 12 months. The composite primary endpoint in both trials is the time to first adjudicated CV death or HHF. Approximately 2850 and 4130 patients are planned to be randomized in EMPEROR-Reduced and EMPEROR-Preserved, respectively. The number of patients in these event-driven trials may be increased based on a blinded assessment of the primary event rate. The incidence of adjudicated HHF and the renal outcome of eGFR slope of change from baseline are key secondary endpoints.

Results: Recruitment for both trials started in 2017.

Conclusion: The EMPEROR-Reduced study evaluates empagliflozin in patients with chronic HF with reduced ejection fraction. As yet, EMPEROR-Preserved is the only phase III outcome study to evaluate an SGLT-2 inhibitor in patients with chronic HFpEF. Together, these trials are expected to deliver conclusive insights regarding the value of empagliflozin treatment for patients with heart failure.

Effect of empagliflozin on cardiovascular events including recurrent events in the EMPA-REG OUTCOME trial

S.S. Lund[1], D.K. McGuire[2], B. Zinman[3], S.E. Inzucchi[4], S.D. Anker[5], C. Wanner[6], S. Kaspers[1], J.T. George[1], U. Elsasser[1], H.J. Woerle[1], D. Fitchett[7];
[1]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [2]University of Texas Southwestern Medical Center, Dallas, USA, [3]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Canada, [4]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [5]Division of Cardiology and Metabolism – Heart Failure, Cachexia & Sarcopenia; Department of Cardiology (Campus CVK) & Berlin-Brandenburg Center for Regenerative Therapies (BCRT); Charité - Universitätsmedizin Berlin, Berlin, Germany, [6]Würzburg University Clinic, Würzburg, Germany, [7]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada.

Background and aims: In the EMPA-REG OUTCOME trial in patients with type 2 diabetes and established CV disease, empagliflozin reduced the risk of 3-point MACE (composite of CV death, MI, or stroke) by 14%, CV death by 38% and hospitalisation for heart failure (HHF) by 35% vs placebo in analyses of time to first event. We assessed the effect of empagliflozin on all (first and recurrent) CV events.

Materials and methods: Patients were randomised to receive empagliflozin 10 mg, empagliflozin 25 mg, or placebo in addition to standard of care. We assessed the effects of empagliflozin pooled vs placebo based on all adjudicated CV events using a negative binomial model with confidence intervals based on robust error variance estimators to account for within-subject correlation.

Results: A total of 7020 patients were treated (mean [SD] age 63 [9] years, 71% male, 47% with history of MI, 23% with history of stroke, 10% with HF). In analyses including all events, the event rate ratio (95% CI) with empagliflozin vs placebo was 0.78 (0.67, 0.91; $p = 0.0020$) for 3-point MACE, 0.79 (0.620, 0.998; $p = 0.0486$) for MI, 1.10 (0.82, 1.49; $p = 0.5248$) for stroke, 0.58 (0.42, 0.81; $p = 0.0012$) for HHF, 0.56 (0.45, 0.69; $p < 0.0001$) for the composite of CV death or HHF, and 0.80 (0.67, 0.95; $p = 0.0119$) for the composite of MI or coronary revascularisation. Results were consistent with analyses of first events (Figure).

Conclusion: Analyses of all (first and recurrent) CV events in the EMPA-REG OUTCOME trial complement previous analyses and confirm the consistency of the results.

PS 051 Tackling glucose and fat with novel agents

668

Liver directed FGF21 gene therapy reverses obesity and insulin resistance

C. Jambrina, V. Jimenez, E. Casana, V. Sacristan, S. Muñoz, S. Darriba, J. Rodó, M. Garcia, S. Marco, A. Ribera, I. Elias, A. Casellas, I. Grass, J. Ruberte, F. Bosch;
Universitat Autònoma de Barcelona, Bellaterra, Spain.

Background and aims: The prevalence of type 2 diabetes (T2D) and obesity is increasing worldwide. Currently available therapies are not suited for all patients in the heterogeneous obese/T2D population, and there is a need for novel treatments. Fibroblast growth factor 21 (FGF21) is considered a promising therapeutic agent for T2D/obesity. Native FGF21 has, however, poor pharmacokinetic properties, making gene therapy an attractive strategy to achieve sustained circulating levels of this protein. Thus, the aim of this study was to study the efficacy and safety of a gene therapy approach to overexpress native FGF21 in the liver, the main tissue from where circulating endogenous FGF21 is derived.
Materials and methods: We used adeno-associated viral vectors (AAV) and a liver specific promoter to genetically engineer the liver to achieve long-term FGF21 overexpression in two murine models of obesity and insulin resistance. Two-month-old ("Young adults") or seven-month-old ("Adults") C57Bl6 mice were fed either a chow or a HFD for 10 weeks and then administered intravenously with different doses of AAV vectors encoding a murine optimized FGF21 coding sequence or non-coding null vectors as controls. Following AAV delivery, mice were maintained on chow or HFD feeding for about 1 year, and body weight and metabolic parameters were monitored regularly. To further test the anti-obesogenic and anti-diabetic effects of FGF21 gene transfer to the liver, we performed a similar study in 8-week-old ob/ob mice.
Results: Treatment of animals fed a high-fat diet for a long time with AAV-FGF21 vectors resulted in marked reductions in body weight, adipose tissue hypertrophy and inflammation, hepatic steatosis, inflammation and fibrosis and insulin resistance for >1 year. This therapeutic effect was achieved in the absence of side effects on bones despite continuously elevated serum FGF21. Additionally, AAV treatment with AAV8-FGF21 vectors reduced the incidence of liver neoplasms associated to long-term-HFD-feeding. The therapeutic efficacy of FGF21 gene transfer to the liver was further confirmed in the genetically obese ob/ob mouse model.
Conclusion: Altogether, our results demonstrate that a single administration of AAV-FGF21 vectors to obese animals enabled a long-lasting increase in FGF21 levels in circulation, which resulted in sustained counteraction of obesity, insulin-resistance and NASH in the absence of adverse events. To the best of our knowledge, this is the longest follow up ever reported for an FGF21-based treatment in HFD-fed mice, and demonstrates both the efficacy and the safety of our therapeutic approach.

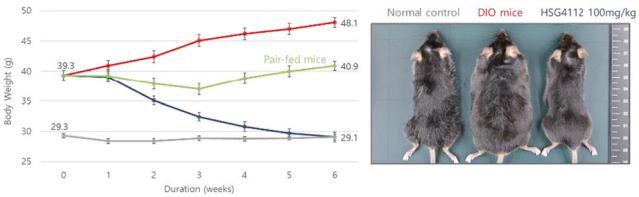
Efficacy and safety of HSG4112, a novel anti-obesity oral agent in diet-induced obesity (DIO) mice

K.-W. Lim, K. Kim, S.-K. Yoo, I. Jo;
Glaceum Inc., Suwon, Republic of Korea.

Background and aims: Obesity is defined by excess adipose mass and adipose tissue expansion, which occurs through adipocyte hypertrophy and hyperlasia. Hypertrophic adipocytes (sick fat) secrete pro-inflammatory cytokines, such as, TNF-α, IL-6, resistin and MCP1 etc., which lead to chronic inflammation that causes problems with triglyceride metabolism. The currently existing drugs for obesity are altering either appetite or absorption of calories. Yet, there are no approved drugs to solve the fundamental problem of triglyceride metabolism. The purpose of this study was to evaluate HSG4112 as a new drug candidate to resolve the fundamental energy metabolism in obesity.
Materials and methods: HSG4112 is a novel small molecule anti-obesity oral agent discovered and developed by Glaceum Inc. and its efficacy was tested in DIO mice. HSG4112 was given orally once daily for 7 days for 6 consecutive weeks (qd × 7 × 6). The test consisted of a normal control group (normal diet), a vehicle control group (high fat diet), a test group (HSG4112 100 mg/kg) and a pair-fed group.
Results: After 6 weeks, the total mean weight loss was 10.2 g (−26.0%) in the test group. The contribution made by reduced food intake was 38.0% and the energy expenditure effect was 62.0%. Increase of O_2 consuming and CO_2 generating rates and decrease of 5' Adenosine Monophosphate-activated Protein Kinase (AMPK) activity in hypothalamus after oral administration of HSG4112 to DIO mice were observed. Furthermore, enhanced browning effect with the characteristics of high mitochondria content was observed in scapular brown adipose tissue. As a result, lean and fit body shape was achieved in the test group. Single oral dose toxicity study of HSG4112 was performed with rat and dog. The Maximum Tolerated Dose (MTD) 2,000 mg/kg was observed from both rat and dog.
Conclusion: In nonclinical studies, HSG4112 demonstrated its weight reduction efficacy mainly by increased energy consumption with excellent safety profiles. These results suggest HSG4112 as a promising new drug candidate to resolve the fundamental energy metabolism in the treatment of obesity.



Disclosure: **K. Lim:** None.

Results of an interim analysis of a phase 2, randomised, double-blind, placebo-controlled clinical trial of ZGN-1061 in patients with obesity and type 2 diabetes

T. Kim, D. Zhuang, T.E. Hughes, D.D. Kim, K. Taylor;
Zafgen, Inc., Boston, USA.

Background and aims: ZGN-1061 (1061) is a methionine aminopeptidase 2 (MetAP2) inhibitor being developed to improve glycemic control in type 2 diabetes. This clinical trial investigated the effect of 12 weeks of 1061 (0.05, 0.3, 0.9 mg or placebo) administered s.c. every 3 days on A1C, safety, and tolerability. Stable noninsulin diabetes therapy was permitted.
Materials and methods: The study included 129 patients; an interim analysis was conducted prior to study completion on a subset of patients with Week 8 measurements ($N = 57$). Of these, 41 patients also had a Week 12 A1C measurement.
Results: Baseline characteristics of the interim intent-to-treat population ($N = 57$) were: 54% male, 77% white, (mean ± SD) age 54 ± 8 years, A1C 8.7 ± 1.0%, BMI 37.2 ± 6.4 kg/m^2. At Week 8, the least squares (LS) mean ± SE change in A1C for placebo was 0.2 ± 0.1% ($N = 13$) vs −0.4 ± 0.2% with 0.9 mg 1061 ($N = 13$, LS mean ± SE difference −0.6 ± 0.2%, $p < 0.02$). In patients with Week 12 measurements, the change in A1C was 0.4 ± 0.2 ($N = 12$) vs −0.5 ± 0.2 ($N = 8$, LS mean ± SE difference −0.9 ± 0.3, $p < 0.01$). There were trends for weight loss and improved fasting plasma glucose with 0.9 mg 1061 vs placebo as well as improvements in biomarkers, including hsCRP (Week 8 −2.1 ± 2.2 mg/L vs 1.0 ± 2.1, ns), adiponectin (1.0 ± 0.3 ug/mL vs −0.1 ± 0.3, $p < 0.05$), leptin (−6.9 ± 1.9 ng/mL vs 2.1 ± 1.7, $p < 0.05$), FGF21 (0.026 ± 0.014 ng/mL vs 0.000 ± 0.013; ns), and postprandial glucose AUC ($p < 0.01$). Improvements in efficacy measures with the lower doses of 1061 were variable. There were no serious or severe adverse events (AEs) and no subjects withdrew due to an AE. The most common AE (1061 > placebo) was upper respiratory tract infection. The 1061 pharmacokinetic profile indicated that exposure was within target levels for efficacy and safety and there were no changes in thrombosis markers (eg, D-dimer).
Conclusion: In this interim analysis, 1061 produced improvements in glycemic control and metabolic biomarkers that are consistent with MetAP2 inhibition. 1061 was also well tolerated with no safety signals in all doses tested. Week 12 results from the full analysis dataset will be presented.

ZGN-1061 improves metabolic parameters and hepatic pathology in an obese mouse model of diet-induced and biopsy-confirmed nonalcoholic steatohepatitis

J.E. Vath[1], M. Illemann[2], S.S. Veidal[2], M. Feigh[2], B.F. Burkey[1], T.E. Hughes[1];
[1]Zafgen, Inc., Boston, USA, [2]Gubra, Hørsholm, Denmark.

Background and aims: ZGN-1061 (1061) is a methionine aminopeptidase 2 (MetAP2) inhibitor being developed to improve glycemic control in type 2 diabetes. In diet-induced obese (DIO) mice, 1061 reduces fat mass and improves glycemic control, lipid metabolism, and other metabolic parameters.
Materials and methods: This study investigated 8 weeks of s.c. treatment with 1061 (0.3 mg/kg, $N = 11$) or vehicle ($N = 10$) on metabolic parameters, hepatic pathology, and nonalcoholic fatty liver disease (NAFLD) activity score (NAS; a composite measure of steatosis, inflammation, and ballooning degeneration; range 0–8) in male mice with diet-induced and biopsy-confirmed nonalcoholic steatohepatitis (DIO-NASH).
Results: At Week 8, there was a vehicle-corrected weight loss of 13.1% with 1061 ($p < 0.001$). 1061-treated mice had reduced liver weight (mean ± SE: 2.6 ± 0.4 g) vs vehicle (3.8 ± 0.8 g, $p < 0.001$) and a 21% reduction in liver triglyceride content ($p < 0.05$). There was no change in food intake. NAS was unchanged in vehicle-treated mice (baseline: 6.2 ± 0.1, Week 8: 6.4 ± 0.2, ns). 1061-treated mice had reduced NAS (baseline: 6.2 ± 0.2, Week 8: 5.0 ± 0.3, $p = 0.002$). Two of the NAS component measures improved: steatosis in vehicle-treated mice was unchanged (baseline: 3.0 ± 0.0, Week 8: 3.0 ± 0.0, ns), whereas 1061 reduced steatosis (baseline: 2.9 ± 0.1, Week 8: 2.5 ± 0.2, $p = 0.02$), and hepatocellular ballooning was unaffected in vehicle-treated mice (baseline: 0.7 ± 0.2, Week 8: 0.6 ± 0.2, ns), whereas 1061 significantly reduced ballooning severity (baseline: 0.6 ± 0.2, Week 8: 0.0 ± 0.0, $p = 0.006$). There was no treatment effect on fibrosis stage or liver collagen 1A. However, liver

galectin-3 was reduced with 1061 vs vehicle. 1061 produced a reduction in terminal plasma alanine aminotransferase and aspartate aminotransferase (AST) vs vehicle.

Conclusion: In DIO-NASH mice, 1061 markedly reduced body weight in conjunction with liver weight and triglyceride content. Importantly, 1061 improved liver function, steatohepatitis, and NAS composite score. These findings introduce 1061 as a promising therapy for obesity-related NASH.

672

ZGN-1061, a novel MetAP2 inhibitor, and liraglutide combine to improve glycaemic control and reduce body weight in a rat model of diet-induced obesity

B.F. Burkey[1], P.G.J. Pedersen[2], T.X. Pedersen[2], M. Feigh[2], J.E. Vath[1], T.E. Hughes[1];
[1]Zafgen, Inc., Boston, USA, [2]Gubra, Hørsholm, Denmark.

Background and aims: ZGN-1061 (1061) is a methionine aminopeptidase 2 (MetAP2) inhibitor being developed to improve glycemic control in type 2 diabetes. In diet-induced obese (DIO) mice, 1061 reduces fat mass and improves glycemic control, lipid metabolism, and other metabolic parameters.

Materials and methods: This study investigated 5 weeks of once-daily s.c. treatment with a submaximal 0.3 mg/kg dose of 1061, a maximal 0.4 mg/kg dose of liraglutide (lira), 0.3 mg/kg 1061 + 0.4 mg/kg lira (1061+lira), or vehicle ($N = 10$/group) on body weight, food intake/preference, and glycemic control in the Gubra DIO rat model (ad libitum access to standard chow and highly palatable high-fat, high-sugar [HFHS] diet). Fasting (4h) blood glucose was collected weekly and a semifasted (access to 50% of daily energy requirement in the prior 16 hours) OGTT was performed at Week 4.

Results: At Week 5 (Day 33), body weight changed by +1.7% with vehicle vs −6.0% with 1061, −9.1% with lira, and −16.9% with 1061+lira (all $p < 0.001$). Weight loss occurred earlier with lira (Day 1) than 1061 (Day 5). Starting at Day 6, intake of the HFHS diet was modestly reduced (15–30%) with 1061 vs vehicle. In contrast, lira and 1061+lira induced rapid and sustained 40–50% and 50–80% reductions in intake of the HFHS diet, respectively, over the first 8–9 days. Cumulative (Day 0–35) intake of the HFHS diet was reduced vs vehicle with 1061 (13.4%, $p = 0.07$), lira (17.8%, $p < 0.01$), and 1061+lira (38.2%, $p < 0.001$). Cumulative intake of standard chow was increased with 1061 and 1061+lira but not lira alone. There was a modest reduction in fasting glucose (mean Week 1–5) with 1061 vs vehicle ($p = 0.08$), a significant reduction with lira, and 1061+lira produced the largest reduction (both $p < 0.001$) that was significantly lower than either agent alone (both $p < 0.01$). In the OGTT, 1061 reduced the glucose AUC vs vehicle by 37% ($p = 0.07$), lira by 60% ($p < 0.001$) and 1061+lira by 80% ($p < 0.001$), achieving an AUC that was no different from lean rats.

Conclusion: In this DIO rat model, 1061 and lira had complementary effects on reducing body weight and normalizing glycemic control. Combination treatment with 1061 and liraglutide may yield greater weight loss and glycemic control than either agent alone in patients with type 2 diabetes.

Novel GPR40 agonist CPL207-280CA independently improves glycaemia and mitigates neuropathic pain in diabetic rodents

P. Buda, K. Bazydlo, M. Mach, F. Stelmach, R. Dzida, K. Dubiel, J. Pieczykolan, M. Wieczorek;
CelonPharma, Kielpin, Poland.

Background and aims: The new generation drug in type 2 diabetes (T2D) is expected to effectively control glycaemia, be safe, ensure infrequent dosage and, importantly, manage diabetic complications. GPR40 activation in pancreatic β-cells improves glycaemic control in T2D through enhancement of glucose-stimulated insulin secretion (GSIS). This process is mediated by Ca^{2+} release from intracellular stores. Similar mechanism was proposed in endogenous pain inhibitory system regulating pain sensation in the brain. These properties of GPR40 make its agonists promising agents acting on the frontier of both diabetes and its complication - neuropathy. However, the most clinically advanced GPR40 agonist fasiglifam was withdrawn from phase 3 due to high drug retention in the liver and bile acid transporters inhibition. In this study we aimed at designing more effective GPR40 agonist devoid of fasiglifam drawbacks. We also investigated its capacity to alleviate allodynia (exaggerated pain sensation) in diabetes-induced neuropathy.

Materials and methods: EC_{50} of CPL207-280CA was assessed in Ca^{2+} influx assay in CHO cells expressing human GPR40. Insulin secretion *in vitro* was measured in MIN6 cells treated with 20mM glucose. *In vivo* compound efficacy was assessed by intraperitoneal glucose tolerance test (IPGTT) in Wistar rats. In pharmacokinetic studies test compounds were administered p.o. and i.v. to C57BL6/cmdb mice and drug concentration in blood was measured at different time points up to 24h (assessed by mass spectrometry). Neuropathy was studied in STZ-treated (200 mg/kg) Albino Swiss mice, which developed diabetes (glucose >300 mg/dl) after 20 post-treatment days accompanied by allodynia manifestation (pain feeling threshold drop from 3.30 ± 0.20 to 1.75 ± 0.07 g). Mechanical allodynia in mice was assessed by paw withdrawal threshold in von Frey test.

Results: CPL207-280CA showed substantially higher efficacy as compared to fasiglifam in Ca^{2+} influx assay ($EC_{50} = 70$ vs 250 nM, respectively). Moreover, it also showed 3.9-times greater enhancement of GSIS in MIN6 cells (at 10 μM). Similarly, in glucose-challenged Wistar rats CPL207-280CA, compared to fasiglifam, improved GSIS 2.5-times and reduced glucose level 2-times without causing hypoglycaemia. Strikingly, the glucose lowering effect was present also during second glucose challenge performed 6 h later, indicating long-lasting activity of the compound allowing infrequent dosing. Pharmacokinetic studies in C57BL6/cmdb mice revealed different organ distribution of the compounds. In contrast to fasiglifam mostly penetrating to the liver, CPL207-280CA was present mainly in serum. Interestingly, only CPL207-280CA managed to pass blood-brain barrier reaching a concentration of 1.6 μM in the brain, well above its EC_{50}. When administered p.o. to neuropathic pain model STZ-mice, CPL207-280CA proved as effective as pregabalin (well acknowledged agent for neuropathic pain treatment) already after 1h treatment, presenting superior features to other glucose-regulating agents. Improved pain threshold (at the level of 2.30 ± 0.10 g) was observed at 10 mg/kg CPL207-280CA while full nominal pain sensation recovery was reached at 30 mg/kg.

Conclusion: We conclude that CPL207-280CA is a candidate for a potent new generation drug in T2D, which can safely and durably improve glucose control, and in parallel manage neuropathic pain, placing it well ahead among competitor drugs.

6-amino-6-deoxy paramylon improved obesity and glucose metabolism in a diet-induced obesity mouse model

S. Suzuki[1], T. Hashimoto[2], K. Shibata[3], M. Nakano[2], N. Onaka[4], G. Tsubouchi[4], M. Takahashi[4], A. Akashi[4], N. Hirawa[1], Y. Toya1[1], K. Ohashi[5], Y. Goshima[2], K. Tamura[1];
[1]Department of Cardiorenal Medicine, Yokohama City University School of Medicine, Kanagawa, [2]Department of Pharmacology, Yokohama City University School of Medicine, Kanagawa, [3]Artisan-ab Co.,Ltd, Kanagawa, [4]KOBELCO ECO-SOLUTIONS Co., Ltd., Hyogo, [5]Department of Pathology, Yokohama City University School of Medicine, Kanagawa, Japan.

Background and aims: Obesity and type 2 diabetes are preventable causes of death. Bile acid binding resins are beneficial for obesity and diabetes, but they are more likely to accompany abdominal distention and constipation. These side effects can be prevented by using dietary fiber. β-glucan is one of the dietary fiber and is reported to improve obesity and glucose metabolism. Barley or oat β-glucan increases fecal output of fat and bile acids synthesis from cholesterol in the liver. Paramylon is one of the component of green algae, Euglena, and consists of β-glucan. Besides barley or oat β-glucan, paramylon is reported to have no effect on hyperglycemia in diabetic rats. Here we generate cationized 6-amino-6-deoxy paramylon, which is just like bile acid binding resins. The effect of 6-amino-6-deoxy paramylon on obesity and glucose metabolism were examined in a diet-induced obesity mouse model.
Materials and methods: As an in vitro experiment, bile acids were incubated with 6-amino-6-deoxy paramylon in a fed state simulated human intestinal fluid. After that, the adsorption rate of bile acid was measured. Furthermore, in an experiment using animals, male C57BL/6J mice were fed high-fat (HF) diets supplemented with 6-amino-6-deoxy paramylon for 5 weeks. Body weight, blood sugar, serum LDL cholesterol, fecal bile acid composition and fecal lipid content were assessed. Hepatic small heterodimer partner (SHP) and cholesterol 7 alpha-hydroxylase (CYP7A1) gene expression levels were also analyzed to investigate the effect of 6-amino-6-deoxy paramylon on bile acids synthesis.
Results: Although paramylon barely absorbed bile acids, 6-amino-6-deoxy paramylon absorbed effectively in a simulated intestinal fluid. In mice, supplementation of 1% or 2% 6-amino-6-deoxy paramylon in a HF diet led to significant weight gain reduction (HF, 1%, 2%; +7.72 + 3.1, +4.16 + 1.4, +0.15 + 0.86 g). Significant decreases in concentrations of blood sugar (HF, 1%, 2%; 161 + 42, 138 + 23, 95 + 41 mg/dl) and serum LDL cholesterol (HF, 1%, 2%; 16.0 + 1.2, 9.4 + 2.1, 8.8 + 2.5 mg/dl) were shown. Strongly positive staining for Sudan IV in fecal smears indicated altered fat absorption when 6-amino-6-deoxy paramylon was supplemented in the HF diet. The composition of fecal bile acids were completely different, secondary bile acids were almost absent and primary bile acids like tauro-βmuricholic acids were dominated in feces of mice supplemented with 6-amino-6-deoxy paramylon. Moreover, decreased levels of SHP mRNA and increased levels of CYP7A1 mRNA were shown in the liver of mice supplemented with 6-amino-6-deoxy paramylon. 6-amino-6-deoxy paramylon had no effect on the food consumption and histology of digestive systems.
Conclusion: 6-amino-6-deoxy paramylon increased fecal output of fat and increases bile acids synthesis from cholesterol in the liver, thus improved obesity and glucose metabolism in a diet-induced obesity mouse model.

Improvement of type 2 diabetes in hypogonadal men with long-term testosterone therapy (TTh) is sustained for up to 10 years compared to untreated controls

U. Wissinger[1], A. Haider[2], K.S. Haider[2], G. Doros[3], A. Traish[4], F. Saad[5]; [1]Medical Affairs Established Products, Bayer AG, Berlin, Germany, [2]Private Urology Practice, Bremerhaven, Germany, [3]Boston University School of Public Health, Boston, USA, [4]Boston University School of Medicine, Boston, USA, [5]Medical Affairs Andrology, Bayer AG, Berlin, Germany.

Background and aims: Numerous experimental and clinical studies have shown beneficial effects of TTh in hypogonadal men with T2DM. In an ongoing registry study in a urological setting, men with T2DM were analysed as a subgroup.
Materials and methods: 805 men with hypogonadism (total testosterone ≤12.1 nmol/L) participate in an ongoing observational registry. Of 311 (38.6%) with T2DM which was diagnosed elsewhere, 141 men opted for TTh and received testosterone undecanoate (TU) injections 1000 mg every 12 weeks (T-group), 170 against TTh and served as controls (CTRL). Measurements were performed 1–4 times a year. Mean change over time between groups were compared by mixed effects model for repeated measures with random effect for intercept and fixed effects for time, group and their interaction and adjusted for age, weight, waist circumference, fasting glucose, blood pressure and lipids to account for baseline differences between groups.
Results: Mean follow-up: 7.5, median: 8 years. Mean age: 61.8 ± 5.3 (T-group), 63.5 ± 4.9 (CTRL). Fasting glucose decreased from 7.7 ± 1.2 to 5.3 ± 0.1 mmol/L at 10 years in the T-group with statistical significance vs. previous year for the first two years and increased from 6.3 ± 0.7 to 8.2 ± 2.7 mmol/L in CTRL. Estimated adjusted difference between groups: −3.6 mmol/L ($p < 0.0001$ for all). Mean HbA_{1c} decreased from 9.0 ± 1.2 to 5.9 ± 0.3% at 10 years in the T-group with statistical significance vs. previous year for the first 7 years and increased from 7.8 ± 0.7 to 10.6 ± 1.7% in CTRL. Estimated adjusted difference between groups: −6.2% ($p < 0.0001$ for all). At baseline, 61 patients in the T-group were on insulin at a mean dose of 34 ± 11.1 units/d, and 63 in CTRL at a mean dose of 30.7 ± 6 units/d. The mean dose requirement in the T-group declined to 19.9 ± 10.5 with statistical significance vs. previous year for the first 8 years. In CTRL, insulin dose was increased to 42.2 ± 8.5 units/d with statistical significance vs. previous year for the entire observation time. Estimated adjusted difference between groups: −33.1 units/d ($p < 0.0001$ for all). In the T-group, 113 patients (80.1%) achieved HbA_{1c} <6.5% and 128 (90.8%) <7.0% at last measurement. Men not reaching targets were those with the shortest treatment duration. In CTRL, no patient achieved either of the two targets. All men had an increase in HbA_{1c}. In the T-group, weight decreased from 113.4 ± 13.9 to 90.7 ± 8.6 kg at 10 years ($p < 0.0001$) with statistical significance vs. previous year for the first 9 years. Waist circumference decreased from 112.6 ± 10.7 to 99.6 ± 5.2 cm ($p < 0.0001$) with statistical significance vs. previous year for the first 9 years. In CTRL, weight and waist circumference remained stable. Since all injections were administered in the doctor's office and documented, there was a 100% adherence to TTh.
Conclusion: Long-term TTh with TU in hypogonadal men with T2DM improved glycaemic control which deteriorated in untreated controls. In patients in the T-group on insulin, the dose could be substantially reduced. Reductions of weight and waist circumference in the T-group may have contributed to the observed effects. Correcting hypogonadism in men with T2DM supports standard diabetes treatment.

A network meta-analysis for the best procedures of bariatric surgery for cure of diabetes

S. Kodama, K. Fujihara, C. Horikawa, D. Ishii, D. Ishiguro, M. Harada, Y. Matsubayashi, T. Yamada, S. Tanaka, H. Sone;
Niigata University Faculty of Medicine, Niigata, Japan.

Background and aims: There is strong evidence that bariatric surgery leads to a higher remission rate for type 2 diabetes mellitus (T2DM) than non-surgical treatment (NST). However, it remains unsolved which surgical procedure is most efficacious.This network meta-analysis aimed to compare and rank surgical procedures for the treatment of T2DM.
Materials and methods: Electronic literature searches were conducted for randomized controlled trials (RCTs) in which at least one surgical treatment was included among multiple arms and the diabetes remission rate was included in study outcomes. A random effects network meta-analysis was performed within a frequentist framework. The hierarchy of

treatments was expressed as an under the cumulative ranking curve (SUCRA) value.
Results: There were 25 eligible RCTs covering NST and 8 kinds of surgical treatments: biliopancreatic diversion with duodenal switch (BPD/DS), biliopancreatic diversion without duodenal switch (BPD), Roux-en Y gastric bypass (RYGBP), mini gastric bypass (mini-GBP), laparoscopic adjustable gastric banding (LAGB), laparoscopic sleeve gastrectomy (LSG), greater curvature plication (GCP), and duodenal-jejunal bypass (DJB). The surgical treatments except for DJB were significantly more efficacious than NST. BPD, BPD/DS, mini-GBP, RYGBP, and LSG were significantly more efficacious than LAGB and GCP. Mini-GBP was more efficacious than LSG (relative risk (RR) (95% confidence interval (CI)), 1.85 (1.15–2.97)) and was borderline more significantly efficacious than RYGBP (RR (95% CI), 1.64 (0.99–2.71)). Overall and sensitivity analyses indicated that BPD and mini-GBP had the highest SUCRA values of these 9 treatments.
Conclusion: BPD or mini-GBP is the best option among surgical treatments in terms of diabetes remission.

Improved time-in-range on continuous glucose monitor with Technosphere insulin compared to insulin Aspart in adults with type 1 diabetes: Stat study per protocol analysis

J. Snell-Bergeon[1], H.K. Akturk[1], E.A. Beck[1], L.J. Klaff[2], B.W. Bode[3], A. Peters[4], T.S. Bailey[5], S.K. Garg[1];
[1]Barbara Davis Center for Diabetes, University of Colorado AMC, Aurora, [2]Rainier Clinical Research Center, Renton, [3]Atlanta Diabetes Associates, Atlanta, [4]USC Westside Center for Diabetes, Beverly Hills, [5]AMCR Clinic, Escondido, USA.

Background and aims: Effective control of post-prandial hyperglycemia remains a challenge. In order to meet this challenge, a number of faster acting insulins have been developed for clinical use. However, inhaled Technosphere insulin (TI) has consistently shown a more rapid insulin absorption and clearance. This investigator-led, collaborative open-label pilot clinical trial evaluated the efficacy of TI in improving post-prandial blood glucose (PPBG), post-prandial glucose excursions (PPGE) and glucose Time-In-Range (TIR) (70–180 mg/dL) as measured by continuous glucose monitor (CGM) over a 4-week treatment period.
Materials and methods: Sixty patients with T1D on multiple daily injections were randomized in a multi-center study, stratified by A1c values (≤8% or >8%) to the control arm using aspart ($n = 34$) vs TI group ($n = 26$). Two patients in the TI arm discontinued from the study; and 2 had inadequate CGM data for analysis. Patients in the TI arm were instructed per protocol to take insulin doses pre-meal, and at 1 and 2 hours after meals based on observed PPBG values. Patients with at least 80% compliance with TI use were included in the PPT analysis ($n = 15$) and were compared to aspart treated individuals using usual mealtime administration guidelines and non-adherent TI users ($n = 7$). Baseline characteristics of the study group were compared to the randomization group using a student's t-test, and CGM data were analyzed using ANOVA models. Co-primary outcomes were TIR (70–180 mg/dl) and PPGE 1–4 hours after meals.
Results: Study participants did not differ on any baseline characteristic by randomization group, including: age, HbA1c, basal and bolus insulin doses, and forced expiration volume. Per protocol analysis, the TI-compliant group had significantly higher TIR (Figure) than both the aspart group and the TI-non-compliant group. The TI-compliant group also had lower PPGE 1–4 hours after meals than the aspart group (Least square mean ± SE = 113.5 ± 6.4 mg/dL vs. 133.8 ± 4.4 mg/dL, $p = 0.01$) but similar PPGE 1–4 hours after meals than the TI-non-compliant group (Least square mean ± SE = 115.9 ± 9.6 mg/dL, $p = 0.83$). Further, secondary endpoints including mean sensor glucose, SD for glucose, and time spent in hypoglycemic range (<70 mg/dL) were significantly lower in the TI-compliant when compared to the aspart group (all $p < 0.05$, data not shown).
Conclusion: These data uniquely demonstrate that the use of inhaled insulin (TI) with proper supplemental dosing significantly improves CGM measured TIR and lowers early PPGE values when compared to insulin aspart. In addition, the data suggests that TI can reduce time in hypoglycemia in adult patients with type 1 diabetes when compared to aspart.

Time of fat and carbohydrate intake affects substrate oxidation and adipokine secretion in subjects with impaired glucose metabolism

O. Pivovarova[1,2], K. Kessler[1,2], S. Hornemann[1,2], M. Markova[1,2], K.J. Petzke[3], M. Kemper[1,2], N. Rudovich[1,4], A. Kramer[5], A.F.H. Pfeiffer[1,2];
[1]Dept. of Clinical Nutrition, German Institute of Human Nutrition, Nuthetal, Germany, [2]German Center for Diabetes Research (DZD), München-Neuherberg, Germany, [3]Research Group Physiology of Energy Metabolism, German Institute of Human Nutrition, Nuthetal, Germany, [4]Spital Bülach, Bülach, Switzerland, [5]Laboratory of Chronobiology, Charité University of Medicine, Berlin, Germany.

Background and aims: We recently showed that a diet where fat is mainly eaten in the morning and carbohydrates mainly in the evening (compared to the reverse order) worsens glycemic control in people with prediabetes. Here, we investigated effects of the same dietary patterns on energy metabolism and daily profiles of circulating lipids, adipokines and inflammatory markers.
Materials and methods: In a randomized controlled cross-over trial, 29 non-obese men (with normal glucose tolerance (NGT) $n = 18$; or impaired fasting glucose/glucose tolerance (IFG/IGT) $n = 11$) underwent two isocaloric 4-week diets: (1) carbohydrate-rich meals until 13.30 and fat-rich meals between 16.30 and 22.00 (HC/HF) *versus* (2) inverse sequence of meals (HF/HC). After each intervention period, two meal tolerance tests were performed, at 09.00 and 15.40, respectively, according to the previous intervention. Substrate oxidation and levels of circulating lipids, adipokines and cytokines were assessed pre- and postprandially. Postprandial inflammatory response in leukocytes was analyzed ex vivo.
Results: Fasting levels of blood markers did not differ between diets. However, diurnal distribution of carbohydrates and fat modulated daily profiles of carbohydrate and lipid oxidation, as well as patterns of beta-hydroxybutyrate, triglycerides, LDL cholesterol, leptin, visfatin and of the LPS-induced inflammatory response in blood leukocytes. On the HF/HC diet, daily respiratory quotient was lower ($p = 0.026$) and lipid oxidation rate higher ($p = 0.008$) in IFG/IGT subjects compared to NGT subjects. The HF/HC diet decreased average daily leptin levels in the whole cohort ($p = 0.017$) and adiponectin in IFG/IGT subjects ($p = 0.037$).
Conclusion: The HF/HC diet induces a deterioration of metabolic flexibility in IFG/IGT subjects and affects adipokine secretion confirming the unfavorable effects of the HF/HC diet in subjects with impaired glucose metabolism.

Efficacy of low- and very-low-calorie diets in overweight and obese patients with type 2 diabetes: a meta-analysis of intervention studies

D.E. Kloecker, F. Zaccardi, M.J. Davies, M. Dario, K. Khunti, D.R. Webb;
University of Leicester, Leicester, UK.

Background and aims: In overweight and obese patients with type 2 diabetes mellitus recommendations based on calorie restriction with Very-Low-Calorie Diets (VLCD) are based mainly on evidence from observational studies. We undertook a comprehensive systematic review and meta-analysis of relevant intervention studies to clarify existing evidence about the effects of calorie restriction on body weight in type 2 diabetes.
Materials and methods: We electronically searched articles on MEDLINE, EMBASE, and CINAHL from inception to March 2018 to identify intervention studies (single or multiple arms) reporting the effect of Low-Calorie Diets (LCD; ≤1600 kcal/day) and VLCDs (≤800 kcal/day) on the outcomes body weight and body mass index (BMI) in people with type 2 diabetes. Given the non-linear effects of diets over time, we modelled outcomes using restricted cubic splines and accounting for study-specific estimate precision (inverse of study variance). Egger's test was used to assess publication bias.
Results: Of 803 records identified, 47 met the inclusion criteria comprising 55 study arms and 3883 participants (45% male); mean age was 51.9 (SD 7.0) and duration of diabetes 7.0 (3.8) years; mean weight and BMI before the interventions were 102.8 (11.7) kg and 36.6 (4.6) kg/m^2, respectively. The median duration of intervention was 56 (IQR 28–84; range 6–112) days and the mean daily target was 729 (SD 381, range 23.2–1600) kcal. Studies were published between 1978 and 2017 and were generally of low-moderate quality. There was a significant publication bias for body weight (Egger's $p < 0.001$) but not for BMI ($p = 0.057$). For 800 kcal/day, estimated reduction in body weight was already evident at 14 days (−5.8%; 95%CI: −9.5 to −2.2) and progressively increased at 60, 90, and 120 days while for 1200 kcal/day the effect was present only from 60 days onwards (Figure). Conversely, for 1600 kcal/day there was no effect at 14 and 60 days, a small reduction at 90 days, and an uncertain effect at 120 days. BMI followed the same pattern of body weight change.
Conclusion: Short-term efficacy of VLCDs and some LCDs is supported by evidence from reported intervention studies. Uncertainty remains over the true effect of diets on body weight and BMI due to a paucity of high-quality studies, the possibility of publication bias, and the relatively short duration of published interventions. This highlights a need for RCTs with larger sample size and longer duration to confidently quantify the efficacy of VLCDs and LCDs in overweight and obese people with type 2 diabetes.

Dietary patterns and non-alcoholic fatty liver disease in a Greek case-control study

I.P. Kalafati[1], D. Borsa[1], M. Dimitriou[1], K. Revenas[2], A. Kokkinos[3], G. Dedoussis[1];
[1]Dietetics and Nutritional Sciences, Harokopio University of Athens, Athens, [2]Radiology Department, Laiko General Hospital, Athens, [3]First Department of Propaedeutic Medicine, Laiko General Hospital, Athens, Greece.

Background and aims: Dietary patterns of non-alcoholic fatty liver disease (NAFLD) patients have not been defined yet. Up to now, there are only a handful of studies on the field and none in a European population.
Aims: We examined the relationship of a posteriori derived dietary patterns with NAFLD risk and NAFLD-related biomarkers in a Greek case-control study.
Materials and methods: A total of 351 individuals were recruited (134 NAFLD patients, 217 controls). Disease was diagnosed with abdominal ultrasound (U/S). Dietary intake data were collected with a 172 semi-quantitative Food Frequency Questionnaire (FFQ) and dietary patterns were derived by factor analysis. Consumption of dietary patterns was

divided into quartiles. Multivariate logistic and linear regression models were applied to investigate associations of dietary patterns with NAFLD risk and NAFLD-associated biomarkers.
Results: Four dietary patterns were identified. Adherence to the "Fast-food type" pattern was independently associated with higher odds for NAFLD. However, results were statistically significant only for the highest vs the lowest consumption (OR = 3.9, $p = 0.003$). On the contrary, individuals in the 2nd quartile of the "Unsaturated fatty acids" pattern had 55.7% reduced risk of developing NAFLD compared to those in the 1st quartile, after adjusting for the main confounders. The "Fast-food type" pattern was further associated with higher levels of CRP and uric acid and the "Unsaturated fatty acids" pattern with reduced levels of insulin and HOMAIR ($p < 0.05$). The "Prudent" dietary pattern was associated with triglycerides and uric acid levels (beta = −5.960, $p = 0.037$ and beta = −0.153, $p = 0.035$, respectively).
Conclusion: This is the first study to indicate associations of dietary patterns with NAFLD in a European population. More studies are needed in order to shed light on the exact role of diet in NAFLD development and treatment.

The effect of two energy- and macronutrient-matched meals on glucose metabolism and gastrointestinal hormones: a randomised cross-over study
H. Kahleova[1], M. Klementova[1], L. Belinova[1], M. Haluzik[1], R. Pavlovicova[1], M. Hill[2], T. Pelikanova[1];
[1]IKEM, Prague, [2]Institute of Endocrinology, Prague, Czech Republic.

Background and aims: Gastrointestinal hormones play a key role in glucose metabolism, energy homeostasis, and regulation of body weight.
Materials and methods: A randomized cross-over study was used to test the effects of two energy- (514 kcal) and macronutrient-matched plant-based and processed-meat meals (45% carbohydrates, 16% protein, and 39% lipids) on glucose metabolism, plasma concentrations of gastrointestinal hormones, and satiety in subjects with T2D ($n = 20$), obese subjects ($n = 20$) and healthy controls ($n = 20$). Plasma concentrations of glucose, immunoreactive insulin, C-peptide, GLP-1, GIP, amylin, and PYY, along with satiety, were determined at 0, 30, 60, 120 and 180 min. Repeated-measures ANOVA was used for statistical analysis.
Results: An increase in stimulated secretion of immunoreactive insulin was observed in T2D and obese subjects ($p = 0.005$, and $p = 0.045$, respectively) after the plant-based meal. We observed an increase in stimulated secretion of C-peptide in all groups after the plant-based meal ($p < 0.001$ for T2D, $p = 0.014$ for obese subjects, and $p = 0.001$ for healthy controls). An increase in post-prandial plasma concentrations of amylin was observed in T2D and healthy controls after the plant-based meal ($p < 0.001$ for both groups). An increase in stimulated secretion of GLP-1 was observed in T2D obese subjects and healthy controls ($p < 0.001$, and $p = 0.01$, respectively) after the plant-based meal. A decrease in peak concentrations of GIP (at 60 min.), and an increase in peak concentrations of PYY were observed in all groups after the plant-based meal. The participants in all groups reported greater satiety after the plant-based meal ($p = 0.004$ for T2D, $p < 0.001$ for obese subjects, and $p < 0.001$ for healthy controls).
Conclusion: Our study suggests that plant-based meals may be effective in increasing stimulated secretion of GLP-1, insulin, amylin, and PYY, as well as in promoting satiety.

Dietary intake and glycaemia in individuals with type 1 diabetes
A.J. Ahola[1,2], C. Forsblom[1,2], M. Saraheimo[1,2], P.-H. Groop[1,2];
[1]Folkhälsan Research Center, Helsinki, [2]Abdominal Center Nephrology, Helsinki University Central Hospital, Helsinki, Finland.

Background and aims: Dietary intake plays an important role in the glycaemic control of patients with type 1 diabetes. Current evidence in this field is, however, somewhat mixed. Importantly, in isoenergetic conditions an increase in the intake of one macronutrient is accompanied by a decrease in another macronutrient(s). Most of the previous studies have not taken the macronutrient substitution into consideration. Moreover, a number of studies have not adjusted their analyses for fibre intake, which may be important in glycaemic control. We investigated the association between dietary intake and glycaemia in a large population of individuals with type 1 diabetes taking part in the Finnish Diabetic Nephropathy Study.
Materials and methods: Food records from a minimum of 3 days were available from 1000 individuals (42% men, mean ± standard deviation age 48 ± 14 years). Along with reporting food and beverage consumption, in these records, participants also reported physical activity, insulin dosing, and self-monitored blood glucose (SMBG) values (median, interquartile range number of measurements, 3.8, 2.7–5.0). Daily average energy and nutrient intakes, and the mean and coefficient of variation (CV) of the reported SMBG measurements were calculated for each participant. The SMBG means and CVs were used as continuous variables in the generalised linear regression, where macronutrient substitution method was applied. Moreover, based on the median of the mean SMBG values and the median of the CVs, participants were divided into two respective groups. In these groups, the role of nutrient intake was investigated using logistic regression analysis.
Results: In the logistic regression analysis, adjusted for age, sex, BMI, triglyceride concentration, insulin dosing, physical activity, and other dietary variables, fibre intake (g/MJ) was associated with having mean SMBG (Exp(B), 95% CI, *P*, 1.403, 1.094–1.799, 0.008) below the median. In the multivariable macronutrient substitution analyses, mean SMBG values increased when energy intake from fats was increased at the expense of proteins. Similarly, increased consumption of saturated fatty acids, in place of either monounsaturated or polyunsaturated fatty acids, was associated with higher mean SMBG. After further adjustment with fibre intake, however, these observations were no longer significant. In the fully adjusted models, favouring the intake of proteins at the expense of either carbohydrates (−0.026, −0.013–0.040, <0.001), fats (−0.018, −0.004–0.033, 0.014), or alcohol (−0.026, −0.045–0.006, 0.010), or fats at the expense of carbohydrates (−0.009, −0.001–0.017, 0.030) were all associated with lower variability in the measured BG values.
Conclusion: Our observations highlight the important role of dietary fibre in the management of glycaemia. Moreover, even when adjusted for fibre intake, proteins, when consumed in place of excess carbohydrates, fats, or alcohol, or fats in place of carbohydrates, may reduce glycaemic excursions and thus impact glycaemia.

The immediate clinical effects of a carbohydrate-reduced high-protein diet on glycaemic variability in well-controlled type 2 diabetes: a randomised controlled study
M.N. Thomsen[1], M.J. Skytte[1], A. Astrup[2], C.F. Deacon[3], J.J. Holst[3,4], S. Madsbad[5], T. Krarup[1], S.B. Haugaard[1], A. Samkani[1];
[1]Dept. of Endocrinology, Copenhagen University Hospital, Bispebjerg, Copenhagen, [2]Dept. of Nutrition, Exercise and Sports, University of Copenhagen, Copenhagen, [3]Endocrinology Research Section, Dept. of Biomedical Sciences, University of Copenhagen, Copenhagen, [4]Section

for Translational Physiology, Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, [5]Dept. of Endocrinology, Copenhagen University Hospital, Amager Hvidovre, Copenhagen, Denmark.

Background and aims: High glycaemic variability (GV) is associated with late complications in Type 2 Diabetes (T2D). We hypothesized that a carbohydrate-reduced high-protein (CRHP) diet compared with a conventional diabetes (CD) diet would reduce GV acutely in patients with T2D.
Materials and methods: In this randomized, controlled, crossover study, 16 patients with metformin-treated T2D (median (IQR) age: 64.0 (58.8–68.0) yrs; HbA1c: 47 (43–57) mmol/mol; duration of T2D: 5.5 (2.8–10.3) yrs; mean ± SD BMI: 30.1 ± 4.4 kg/m^2) were randomly assigned to a CRHP diet (31E% carbohydrate, 29E% protein, 40E% fat) or an energy-matched CD diet (54E% carbohydrate, 16E% protein and 30E% fat) for two separate 48-hour intervention periods. Interstitial continuous glucose monitoring (CGM) was performed to assess measures of GV, i.e. standard deviation (SD); coefficient of variation (CV); mean amplitude of glucose excursions (MAGE); continuous overlapping net glycaemic action ($CONGA_n$) of observations n hours apart; and mean absolute glucose (MAG) change. Differences between diet interventions were compared using paired sample *t* tests or Wilcoxon signed-rank tests if assumptions of normality were not met.
Results: All indices of glycaemic variability (mean ± SD) were significantly reduced during CRHP diet compared with CD diet; including SD (1.6 ± 0.5 (CD) vs 1.0 ± 0.3 mmol/l (CRHP)), CV (19.3 ± 5.5 vs 12.3 ± 3.8%), MAGE (4.2 ± 1.3 vs 2.3 ± 0.9 mmol/l), $CONGA_1$ (1.5 ± 0.4 vs 0.8 ± 0.3 mmol/l), $CONGA_2$ (2.1 ± 0.7 vs 1.2 ± 0.4 mmol/l), $CONGA_4$ (2.5 ± 0.8 vs 1.4 ± 0.5 mmol/l), and MAG change (1.4 ± 0.4 vs 0.9 ± 0.3 mmol/l/h) ($p < 0.001$ for all). Compared with the CD diet, the CRHP diet improved the diurnal glucose profile by reducing 24-hour mean sensor glucose (MSG) (8.6 ± 2.0 vs 7.7 ± 1.6 mmol/l); postprandial glucose (PPG) levels after breakfast and lunch (10.1 ± 2.4 vs 8.5 ± 1.9 mmol/l and 9.4 ± 2.3 vs 8.0 ± 1.5 mmol/l, respectively); and total 24-hour peak levels (12.6 ± 2.5 vs 10.1 ± 2.0 mmol/l), ($p < 0.001$ for all), respectively. Patients spent significantly more time with blood glucose below 10 mmol/l (median (IQR)) (80.4% (62.2–96.7) vs 97.2% (94.5–100)) and correspondingly less time above 10 mmol/l (18.0% (3.1–37.8) vs 0.78% (0.0–5.5)) ($p = 0.003$ for both).
Conclusion: In T2D patients, two days of iso-energetic replacement of dietary carbohydrates by protein and fat reduced glycaemic variability when compared with a conventional diabetes diet. These data support reduction of carbohydrates as dietary advice for T2D patients.

The effect of three different types of diet on glycaemic control assessed by continuous monitoring in patients with type 1 diabetes on multiple daily insulin treatment

C. Dimosthenopoulos[1], S. Liatis[2], A. Tentolouris[2], E. Athanasopoulou[2], S. Driva[2], K. Makrilakis[2], N. Tentolouris[2], A. Kokkinos[2];
[1]Clinical Nutrition, Laiko General Hospital, Athens, [2]First Department of Propaedeutic Medicine, Medical School, National and Kapodistrian University, Laiko General Hospital, Athens, Greece.

Background and aims: Medical Nutritional Therapy (MNT) in diabetes is an essential part of the overall treatment. In recent decades, dietary recommendations have been greatly modified and various types of dietary patterns are currently recommended by large organisms. The aim of the present study was to compare the effects of three diets differing in the ratio of macronutrients, on glycemic variability and insulin needs in patients with type 1 diabetes (T1DM) undergoing multiple daily insulin (MDI) treatment.
Materials and methods: Patients with T1DM on MDI therapy were recruited from the outpatient diabetes clinic of Laiko General Hospital. They were adults, with an HbA1c <8%, and no hypoglycemia unawareness or clinically significant diabetic complications. Each participant followed three different isocaloric diets for three separate weeks, in a random order, and with a 7-day washout period between them: a reference (REF) diet corresponding to previous ADA recommendations 50% carbohydrate, 20% protein, 30% fat), a high protein-low carb (HPD) diet (20% carbohydrate, 40% protein, 40% fat), and a Mediterranean style/low GI (<60) (LGI) diet (40% carbohydrate 25% protein, 35% fat). The diets were tailored to the needs and preferences of each patient, but strictly defined and absolutely equivalent among patients regarding the proportion of macronutrients and the glycemic index. Glucose values were monitored with the iPro2 continuous glucose monitoring (CGM) device.
Results: Fifteen patients (5 males, mean age 26.1 ± 10 years, mean diabetes duration 12.4 ± 9.8 years, mean BMI 22.8 ± 3.8 kg/m^2) participated in the study. The mean percentage of time spent within the euglycemic range (70–140 mg/dl) differed significantly among the three diets (REF: 48.3 ± 13.7%, HPD: 55.7 ± 14.0% and LGI: 49.7 ± 12.6%, $p = 0.041$), the difference in *post hoc* analysis being statistically significant between the HPD and the REF diet ($p = 0.027$). Furthermore, glycemic variability, as expressed by the standard deviation of the mean interstitial tissue glucose value, was lower during the HPD as compared to the REF diet (46.1 ± 12.8 mg/dl vs. 52.7 ± 10.8 mg/dl, $p = 0.005$) but not to the LGI diet (51.4 ± 14.3 mg/dl, $p = 0.077$). In addition, the area under the curve (AUC) of time spent in the hypoglycemic range (<70 mg/dl) was lower during the HPD than during the REF diet (1.1 ± 1.0 vs. 2.4 ± 2.3, $p = 0.044$) but not the LGI diet (1.6 ± 1.9, $p = 0.76$). No significant differences were observed between the three diets regarding the mean interstitial tissue glucose value, the time spent or the AUC of time spent in the hyperglycemic range (>140 mg/dl) and the time spent in the hypoglycemic range. During the HPD, patients received less bolus insulin by 3.3 and 2.3 units per day compared to the REF and the LGI diet, respectively.
Conclusion: An HPD dietary pattern resulted in less hypoglycemic episodes, overall lower glucose, better glycemic variability, and less total insulin use vs a reference and a LGI dietary pattern. Modifying traditional dietary counseling by increasing protein intake improves glycemic indices and may be beneficial for people with T1DM. The use of CGM is useful in uncovering such differences which otherwise may had gone unnoticed.

A carbohydrate-reduced high-protein diet significantly reduces HbA_{1c}, diurnal and prandial plasma glucose in weight stable subjects with type 2 diabetes

M.J. Skytte[1], A.A. Samkani[1], A.D. Petersen[1], M.N. Thomsen[1], A. Astrup[2], E. Chabanova[3], J. Frystyk[4], J.J. Holst[5], H. Thomsen[3], S. Madsbad[6], T.M. Larsen[2], S.B. Haugaard[1], T. Krarup[1];
[1]Dept. of Endocrinology, Copenhagen University Hospital Bispebjerg, Copenhagen, [2]Dept. of Nutrition, Exercise and Sports, Copenhagen University, Copenhagen, [3]Dept. of Radiology, Copenhagen University Hospital Herlev, Copenhagen, [4]Dept. of Endocrinology and Internal Medicine, Aarhus University, Aarhus, [5]Center for Basic Metabolic Research, Copenhagen University, Copenhagen, [6]Dept. of Endocrinology, Copenhagen University Hospital Hvidovre, Copenhagen, Denmark.

Background and aims: The carbohydrate content of the diet has been proved to be of crucial importance for the increase in postprandial plasma glucose in subjects with type 2 diabetes mellitus (T2D). The long term metabolic effect of lowering the carbohydrate content in the diet has yet to be determined. The aim of the study was to investigate whether 6 weeks of fully controlled carbohydrate reduced high protein (CRHP) diet compared with 6 weeks of conventional diabetes (CD) diet improved metabolic control in well controlled, weight stable subjects with T2D.

Materials and methods: Twenty-eight patients with T2D, 20 males, age 64 (±7.7) years (mean ± SD), duration of T2D 7 (±5.4) years, BMI 30.1 (±5.2) kg/m², HbA1c 59.6 (±8.4) mmol/mol on oral antidiabetic agents were randomized to 6 weeks of CRHP or CD diet (carbohydrate 30/50 E%, protein 30/17 E%, fat 40/33 E%, respectively) followed by 6 weeks of the opposite diet. All meals were provided in accordance to participant estimated daily total energy expenditure based on a dual-energy X-ray absorptiometry scan and continuously adjusted to reinforce weight stability. At baseline, week 6 and week 12 metabolic measurements were performed. A linear mixed effects model was used to assess differences between diets adjusted for body weight loss.
Results: Compared with the CD diet, a significant reduction in HbA_{1c} was found on the CRHP diet (0.8 (±5.3) vs. 6.2 (±4.2) mmol/mol, $p < 0.01$, respectively) (Fig.). Furthermore, the CRHP vs. CD diet reduced 24 h mean glucose concentrations (8.02 (±1.2) vs. 9.24 (±1.9) mmol/L, $p < 0.01$), 4 hour meal tolerance test net area under curve (AUC) of glucose (1.25 (±1.1) vs. 3.1 (±1.3) mmol/L × 240 min, $p < 0.01$) and insulin (194.7 (±107) vs. 239.2 (±191) pmol/L × 240 min, $p = 0.04$), respectively. No difference in body weight loss was found between diets.
Conclusion: A CRHP diet significantly improved glycaemic control during a 6 week intervention with full diet provision in body weight stable patients with T2D compared with a CD diet. The improved glucose metabolism following a CRHP diet was not mediated by an increased insulin secretion.

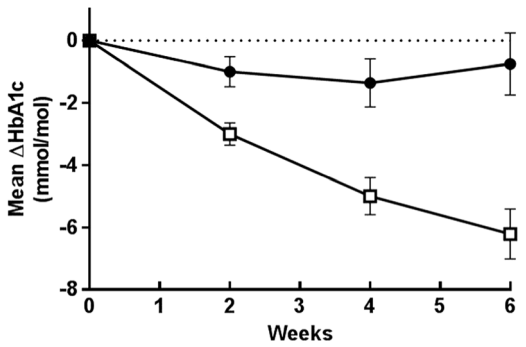

Figure. Effect of 6 weeks of conventional diabetes diet (●) and carbohydrate-reduced high-protein diet (□) on ΔHbA1c in 28 subjects with T2D. Values are means with standard error.

The common food additive carrageenan increases intestinal permeability without affecting whole-body insulin sensitivity in humans

R. Wagner[1], J. Buettner[2], M. Heni[1], L. Fritsche[1], S. Kullmann[3], M. Wagmüller[1], A. Peter[1], J. Machann[4], U.-F. Pape[5], G. Van Hall[6], P.S. Plomgaard[7], R. Klein[8], H.-U. Häring[1], A. Fritsche[1], N. Stefan[1];
[1]University Hospital Tübingen, Tuebingen, Germany, [2]Department of Hepatology and Gastroenterology, Charité Universitätsmedizin, Berlin, Germany, [3]Institute of Medical Psychology and Behavioral Neurobiology/fMEG Center, Eberhard Karls University Tübingen, Tuebingen, Germany, [4]Section on Experimental Radiology, Department of Diagnostic and Interventional Radiology, University Hospital Tübingen, Tuebingen, Germany, [5]Department of Hepatology and Gastroenterology, Charité Universitätsmedizin, Berlin, Berlin, Germany, [6]Department of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark, [7]Department of Clinical Biochemistry, Rigshospitalet, Copenhagen, Copenhagen, Denmark, [8]Division of Haematology, Oncology, Immunology, Rheumatology and Pulmonology, Department of Internal Medicine, University Hospital, Eberhard-Karls-University Tübingen, Tuebingen, Germany.

Background and aims: The increasing global diabetes epidemic is strongly associated with the western lifestyle. While increased intake of high-energy nutrients is a major dietary component of this lifestyle, it is not known whether food additives, such as the widely used carrageenan, also play a role in the pathogenesis of diabetes. Animal data suggest that increased carrageenan consumption causes insulin resistance and diabetes, mainly by interfering with hepatic insulin signaling. This is the first trial in humans that tested whether carrageenan added to the diet affects insulin sensitivity, inflammatory markers, body-fat distribution and intestinal permeability.
Materials and methods: We conducted a randomized, double-blind, placebo-controlled, cross-over trial. Healthy males ($N = 20$) were randomly allocated to 14 days of carrageenan (250 mg twice daily) or matching placebo. After a mean (±SD) washout-period of 30 ± 7 days they received the other compound. At the end of each treatment phase, subjects underwent an oral glucose tolerance test (OGTT), a hyperinsulinemic-euglycemic clamp with labeled glucose (6·6-$^2H_2$ glucose), whole-body MR tomography and ^{1}H-MR-spectroscopy measurements of body fat mass and distribution, liver fat content, blood immune cell phenotyping and a lactulose-mannitol test for investigating intestinal permeability.
Results: The subjects had a mean (±SD) age of 27.6 ± 4.8 years and a BMI of 24.4 ± 2.6 kg/m^2. Intestinal permeability significantly increased after carrageenan vs placebo exposure (lactulose-mannitol-ratio 0.0196 vs 0.015, $p = 0.03$). Whole-body insulin sensitivity did not differ between placebo and carrageenan exposure ($p = 0.5$ for both clamp-derived whole-body insulin sensitivity and OGTT-derived insulin sensitivity). No changes of hepatic fat content, body fat mass and distribution, liver transaminases, C-reactive protein and interleukin-6 levels were observed (all $p > 0.4$).
Conclusion: In young healthy males, carrageenan intake over a relatively short period of time resulted in an increased gut permeability, which was not accompanied by changes of whole-body insulin sensitivity, markers of subclinical inflammation, body fat mass and fat distribution and liver fat content.

Why resveratrol is effective in some but not all individuals: a combined data-analyses

M. de Ligt[1], E. Phielix[1], B. Havekes[2], V.B. Schrauwen-Hinderling[3], P. Schrauwen[1];

[1]Nutrition and Movement Sciences, Maastricht University, Maastricht, [2]Internal Medicine, Division of Endocrinology, Maastricht University Medical Center, Maastricht, [3]Radiology, Maastricht University, Maastricht, Netherlands.

Background and aims: Results from pre-clinical studies have suggested that resveratrol may have metabolic health effects and can prevent insulin resistance. However, the translation from animal to human studies turned out to be challenging. Even with similar treatment duration and dose of resveratrol, the efficacy differs between participant populations. Here we investigated which subject characteristics predict efficaciousness of resveratrol on a number of metabolic health parameters in humans.
Materials and methods: Data from three placebo-controlled, cross-over human clinical trials was combined. In all three clinical trials the same dose (150 mg/d) and treatment duration (30 days) was applied, but the populations varied from healthy obese men, to men at risk of type 2 diabetes (T2D) and to patients with T2D. Paired sample t-test was applied to evaluate effects of resveratrol treatment on a whole group basis. Pearson correlation coefficient analysis followed by stepwise linear regression was used to detect which baseline participant characteristics are determinants of resveratrol-induced changes in metabolic health outcome parameters.
Results: Overall, resveratrol had beneficial effects on systolic blood pressure (137 ± 1.8 upon placebo vs. 134 ± 1.8 mmHg upon resveratrol $p = 0.038$) and *ex vivo* mitochondrial function ($p < 0.001$, for all mitochondrial states) and decreased sleeping metabolic rate (7.71 ± 0.12 upon placebo vs. 7.51 ± 0.10 MJ/day upon resveratrol; $p = 0.029$), but not on plasma glucose or HOMA index. Remarkably, despite similar dosing, circulating plasma resveratrol levels were markedly different between the three groups ($p = 0.008$), but plasma resveratrol levels did not predict outcome. Baseline serum bilirubin was found to significantly predict resveratrol-induced change in diastolic blood pressure ($p = 0.044$), ALT ($p = 0.030$), intrahepatic lipid content ($p = 0.020$), and plasma glucose ($p = 0.004$). The latter was especially profound when also baseline serum albumin levels were taken into account ($p = 0.002$).
Conclusion: Baseline serum bilirubin was identified as the most relevant predictor of resveratrol-induced change in metabolic health outcome parameters. Thus, higher baseline serum bilirubin levels were associated with improvements in metabolic health upon resveratrol treatment. It has been suggested that bilirubin is a surrogate of UGT1A1 activity, which is an enzyme involved in glucuronidation of *trans*-resveratrol. Although speculative, our data may suggest that bilirubin levels reflect activity of glucuronidation enzymes, implying glucuronidation is important for efficacy of resveratrol. Further studies are needed to investigate the importance of glucuronidation of resveratrol.

Spirulina liquid extract prevents glucose intolerance and NAFLD in mouse

M. Coué[1,2], J. Falewee[1,3], A. Tesse[4], L. Fizanne[5], M. Krempf[1,2], J.-M. Pommet[6], O. Lépine[6], K. Ouguerram[1,3];
[1]INRA, UMR 1280, Physiopathologie des Adaptations Nutritionnelles, Nantes, [2]Centre de Recherche en Nutrition Humaine, Nantes, [3]Université de Nantes, Nantes, [4]INSERM, UMR 1087, Institut du Thorax, Nantes, [5]Université d'Angers, EA 3859, Laboratoire Intéraction Fibrose et Invasivité Tumorale Hépatique, Angers, [6]AlgoSource Technologies, Saint-Nazaire, France.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) concerns 85% of obese people and can progress to non-alcoholic steatohepatitis (NASH) and cirrhosis. Insulin resistance and oxidative stress are thought to play a pivotal role in the initiation and worsening of the disease spectrum. The aim of this work is to study the potential beneficial effect of supplementation with a liquid extract of Spirulina, a cyanobacteria rich in an antioxidant (AO) pigment, the phycocyanin (PC), on NAFLD establishment and its progression in mouse.
Materials and methods: C57Bl/6 male mice were submitted to western diet (WD) containing 23% of lipids and 2% of cholesterol and to drinking water rich in fructose (42 g/l). Supplemented group mice received the same diet but supplemented with a liquid extract of spirulina (WD-Spi) added in drinking water (10 mg PC/mouse/day). This protocol was conducted for 25 weeks. Mice were weighted once per week and different plasmatic and liver physiological parameters as well as expression of some key genes in glucose and lipid metabolisms were analyzed. Statistical tests were realized on 10 mice/group and data are presented as mean ± SEM.
Results: At 25 weeks of diet, body weight and subcutaneous adipose tissue were decreased in WD-Spi group by 20% ($p < 0.001$) and 52% ($p < 0.001$) respectively compared to WD group. The supplemented group ate significantly more food related to their body weight than WD mice (+19%) (WD: 0.076 ± 0.0008 and WD-Spi: 0.090 ± 0.0011; $p < 0.001$). Furthermore, spirulina supplementation improved fasting blood glucose (WD: 169 ± 3.7 mg/dl; WD-Spi: 153 ± 4.6 mg/dl; $p = 0.01$) and glycemic control reflected by area under the curve from glucose tolerance test ($p = 0.01$) compared to WD mice. This is accompanied by a reduced liver weight to body weight ratio (−25%, $p = 0.003$) and plasma aspartate amino transferase (−33%, $p = 0.004$) in WD-Spi group. These mice showed a lessening hepatic expression of sterol regulatory element-binding protein (SREBP-1), stearoyl-CoA desaturase-1 and of microsomal TG transfer protein. Hepatic expression of AO genes (catalase, glutathione peroxidase, superoxide dismutase) were diminished in WD-Spi mice.
Conclusion: Our data indicate that spirulina liquid extract protects against some deleterious effects of the WD known to affect liver function. We are now analyzing more specifically liver to unravel underlying mechanisms associated to spirulina effects.

Impact of isoflavones on several primary outcomes associated with diabetes: a meta-analysis of randomised controlled human trials

R. Menezes[1,2], A.F. Raimundo[1,2], F. Félix[1,2], A. Raimundo[3], A. Rodriguez-Mateos[4], A. González-Sarrías[5], B. Wang[4], C.N. Santos[1,2], I. Cruz[3], J.V.G. Lopes[6], M. Schär[7], M.-T. García-Conesa[5], R. Andrade[3], R.T. Ribeiro[3,8], P. Pinto[1,9];
[1]iBET - Instituto de Biologia Experimental e Tecnológica, Oeiras, Portugal, [2]ITQB-NOVA, Oeiras, Portugal, [3]APDP, Lisbon, Portugal, [4]King's College London, London, UK, [5]CEBAS-CSIC, Murcia, Spain, [6]CEDOC-FCM, Lisbon, Portugal, [7]University of Reading, Reading, UK, [8]iBiMed - UA, Aveiro, Portugal, [9]Instituto Politécnico de Santarém, Santarém, Portugal.

Background and aims: Isoflavones are naturally occurring isoflavanoids found in legumes, particularly in soybeans. As a phytoestrogen resembling human estrogen, isoflavones might provide many health benefits including antidiabetic properties. The reduction of blood glucose and insulin levels are some of the effects attributed to isoflavones, however, the association between isoflavones intake and diabetes remains inconclusive. Thus, this meta-analysis aimed to evaluate the effect of isoflavone-rich products intake on primary diabetes outcomes.
Materials and methods: A systematic search was conducted in several databases and articles were selected for meta-analysis based on the following criteria: human randomized controlled trials with diabetic or pre-diabetic patients; primary outcomes of diabetes such as glucose, insulin,

insulin resistance (HOMA-IR) and glycated hemoglobin (HbA1c), and intervention with a (poly)phenol. Selected articles were used for data extraction regarding the measured outcomes, individual factors of the participants and characteristics of the study, including quality. Results of meta-analysis are presented as standardized mean difference (SDM).

Results: This meta-analysis studied the effect of interventions with isoflavone-rich products, in diabetic and pre-diabetic patients. From eighty-nine interventions with different (poly)phenols, only eleven studies used isoflavones as the bioactive compound. Four studies were discarded: three due to inexistence of a proper control, and one did not measure any of the previously defined primary outcomes. Seven studies were selected for the meta-analysis, with 1208 participants (668 treated with isoflavones and 604 with placebo). Four outcomes were measured: glucose (6 studies), insulin (6 studies), Hb1Ac (4 studies) and HOMA-IR (5 studies). Results from the meta-analyses show a significant reduction in insulin (SDM = −0.26; 95% CI [−0.45, −0.07]; $p = 0.011$) and HOMA-IR (SDM = −0.25; 95% CI [−0.45, −0.06]; $p = 0.011$), but not on glucose (SDM = −0.16; 95% CI [−0.35, 0.03]; $p = 0.097$) and Hb1Ac (SDM = −0.33; 95% CI [−0.74, 0.09]; $p = 0.123$).

Conclusion: Based on the results of this meta-analysis, prolonged intake of isoflavone-rich products can contribute to reduce insulin resistance both in diabetic and pre-diabetic patients.

Vitamin D supplementation and body weight status in overweight or obesity: a systematic review and meta-analysis

J. Sun[1], C. Wu[2], L. Li[2];
[1]Shaoxing University Medical School, Shaoxing, [2]Department of Endocrinology, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China.

Background and aims: Our studies have found that vitamin D supplementation was associated with improved beta cell function and insulin sensitivity among persons who were at high risk for diabetes. Obesity has an increase in the risk for type 2 diabetes. Overweight and obese subjects typically have low circulating 25-hydroxyvitamin D [25(OH)D] levels. Although observational studies have suggested an increased risk of vitamin D deficiency in obese subjects, randomized controlled trials (RCTs) that evaluated the effects of vitamin D supplementation have produced inconsistent results. We evaluated whether vitamin D supplementation affects the body weight and composition. We conducted a systematic review and meta-analysis of randomized controlled trials (RCTs) involving vitamin D supplementation with or without calcium or caloric restriction on overweight or obesity.

Materials and methods: We used PubMed, Web of Science and the Cochrane Library to search for pertinent studies published through January 2017.

Results: Seven trials provided the required data, including body mass index (BMI), weight, and waist circumference. Vitamin D supplementation had no effect on BMI [standardized mean difference (SMD) −0.02 (−0.15 to 0.12), $P = 0.80$), weight (SMD −0.01 (−0.15 to 0.12), $P = 0.85$], and waist circumference [SMD 0.07 (−0.16 to 0.18), $P = 0.92$] of overweight or obese patients. According to the results of a meta-regression analysis, none of the potential moderating factors [age, gender, BMI, baseline 25(OH)D] was a significant predictor of changes in obesity measures.

Conclusion: Although Vitamin D supplementation could be effctive at improving glycemic control, it did not decrease measures of adiposity in overweight and obese subjects.

Effects of glutamine on gastric emptying of low- and high-nutrient drinks in healthy young subjects: impact on glycaemia

Y.T. Du[1,2], D. Piscitelli[1,3], S. Ahmad[1,3], L.G. Trahair[1], J.R. Greenfield[4], D. Samocha-Bonet[4], C.K. Rayner[1,5], M. Horowitz[1,5], K.L. Jones[1,5];
[1]The University of Adelaide, Adelaide, [2]Endocrine and Metabolic Unit, Royal Adelaide Hospital, Adelaide, [3]University of South Australia, Adelaide, [4]Garvan Institute of Medical Research, Sydney, [5]NHMRC Centre of Research Excellence in Translating Nutritional Science to Good Health, Adelaide, Australia.

Background and aims: Glutamine is a potent stimulus for the release of glucagon-like peptide-1 (GLP-1), which increases postprandial insulin secretion and slows gastric emptying. It has, accordingly, been suggested that glutamine may be useful in the management of type 2 diabetes. The rate of gastric emptying, which exhibits a substantial inter-individual variation, is a major determinant of postprandial glycaemic excursions in both health and diabetes. The aims of this study were to determine the effects of glutamine on the rate of gastric emptying, and glycaemic responses to, low- and high-nutrient drinks in healthy individuals.

Materials and methods: Eight healthy males (mean age 21.6 ± 0.7 years and BMI 22.9 ± 0.7 kg/m^2) were studied on 4 separate occasions on which they consumed both low- (beef soup; 18 kcal) and high-nutrient (75 g dextrose; 255 kcal) drinks, each with or without 30 g of glutamine (120 kcal), in a randomised, crossover design. Gastric emptying was measured using 2D ultrasound (to calculate the 50% emptying time; T50), and venous blood sampled for measurements of blood glucose and plasma insulin concentrations before and after each drink. Data are presented as mean ± SEM.

Results: Glutamine slowed gastric emptying of both low- (T50: 45 ± 3 min vs 26 ± 2 min, $P < 0.001$), and high-nutrient, (T50: 100 ± 5 min vs 77 ± 5 min, $P = 0.03$) drinks. However, there was no difference in gastric emptying of the high nutrient drinks when gastric emptying was expressed as kcal/min (3.39 ± 0.21 kcal/min vs 3.81 ± 0.20 kcal/min, $P = 0.25$) i.e. the prolongation of the T50 by glutamine reflected its caloric content. There was no change in blood glucose after the low-nutrient drinks with or without glutamine, despite a modest increase in plasma insulin with glutamine ($P = 0.007$). The rise in blood glucose following the high-nutrient drink ($P = 0.0001$) was attenuated during the first 60 min by glutamine (AUC^{0-60} 443 ± 17 mmol/L.min vs 473 ± 22 mmol/L.min, $P = 0.007$) without any difference in the plasma insulin response (AUC^{0-60} 1717 ± 233 mU/L.min vs 2250 ± 549 mU/L.min, $P = 0.19$).

Conclusion: In healthy subjects, glutamine in a dose of 30 g slows gastric emptying of both low- and high-nutrient drinks comparably and attenuates the rise in blood glucose after oral glucose, possibly via effects on gastric emptying.

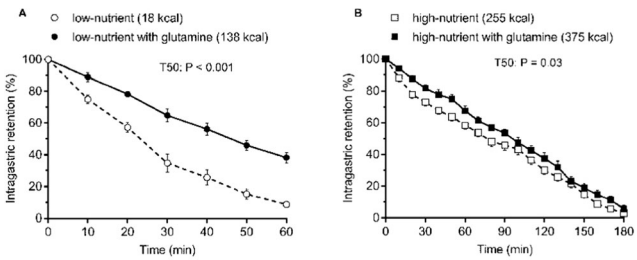

Figure: Gastric emptying of (A) low- and (B) high-nutrient drinks, with or without glutamine (30g)

Short-term dietary restriction of branched-chain amino acids (BCAA) decreases insulin secretion in type 2 diabetes

Y. Karusheva[1,2], T. van Gemert[1,3], M.-C. Simon[1,2], D. Markgraf[1,2], K. Strassburger[2,4], T. Jelenik[1,2], D. Schmoll[5], V. Burkart[1,2], K. Müssig[1,3], J. Szendroedi[1,3], M. Roden[1,3];
[1]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University, Düsseldorf, [2]German Center for Diabetes Research (DZD), München-Neuherberg, [3]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Düsseldorf, [4]Institute for Biometrics and Epidemiology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University, Düsseldorf, [5]Sanofi-Aventis Deutschland GmbH, Industriepark Hoechst, Frankfurt, Germany.

Background and aims: Serum levels of BCAA (valine, leucine, isoleucine) are elevated in insulin resistant animals and humans with type 2 diabetes (T2D) suggesting a role of BCAA in the development of insulin resistance. BCAA proved to reduce the serum levels of fibroblast-growth factor (FGF) 21, a novel metabolic regulator which improves glucose uptake in adipose tissue at the background of insulin resistance. We examined the hypothesis that reducing dietary BCAA for 1 week improves insulin sensitivity (IS) and oxidative phosphorylation in T2D and increases the levels of FGF 21 in humans.
Materials and methods: We designed a randomized, placebo-controlled, double-blinded cross-over study including 12 patients (8 male, 4 female; age 54 ± 4 years, body mass index 30.8 ± 2.8 kg/m^2, HbA1c 6.6 ± 0.9%, 49 ± 10 mmol/mol) with known T2D duration of <5 years. Patients were on a 4-week isocaloric diet with constant protein intake of 1 g/kg body weight. The diet consisted of either the complete amino acid set (BCAA$^+$) or a 60% reduction in BCAA (BCAA$^-$) for 1 week. Beta-cell function was assessed by mixed-meal tolerance tests (MMTT). Mitochondrial efficiency was assessed from the respiratory control ratio (RCR) measured by high-resolution respirometry in muscle and adipose tissue. FGF 21 serum levels were quantified by ELISA.
Results: MMTT showed lower increases in insulin and C-peptide after BCAA$^-$ than BCCA$^+$ diet (incremental insulin area under the curve: 21 ± 11 vs 29 ± 19 mU*ml^{-1}*4 h^{-1}, $p < 0.01$). The BCAA$^-$ diet also increased FGF 21 levels by 25.4% ($p < 0.05$). RCR in adipose tissue was 1.7-fold higher (1.2 ± 0.7 vs 2.1 ± 0.8, $p < 0.05$) after BCAA$^-$ diet but unchanged in skeletal muscle which points to improved mitochondrial efficiency in adipose tissue only.
Conclusion: Short-term dietary BCAA restriction decreases meal-induced insulin secretion, increases FGF 21 and stimulates adipose tissue mitochondrial efficiency.

Insulin influences mindset-induced brain response and behaviour on portion size selection for lunch

S. Kullmann[1], R. Veit[1], M. Heni[1,2], L. Horstman[1], M. Hege[1], P.J. Rogers[3], J.M. Brunstrom[3], H.-U. Häring[1,2], A. Fritsche[1,2], H. Preissl[1];
[1]Institute for Diabetes Research and Metabolic Diseases (IDM)of the Helmholtz Center Munich at the University of Tübingen, Tübingen, Germany, [2]Division of Endocrinology, Diabetology, Angiology, Nephrology and Clinical Chemistry, Department of Internal Medicine, Eberhard Karls University Tübingen, Tübingen, Germany, [3]Nutrition and Behaviour Unit, University of Bristol, Bristol, UK.

Background and aims: Food intake increases when people are served larger portion sizes. For decisions on the consumed portion size, attentional focus plays an important role. Currently, it is not known whether attentional modulation can influence pre-meal planning on portion size selection in overweight and obese individuals and whether these processes are influenced by insulin.
Materials and methods: In the current study, we asked normal-weight, overweight and obese participants ($n = 34$) how much they intent to consume for lunch prior to eating (free choice condition) whilst undergoing functional magnetic resonance imaging (fMRI). To investigate the important role of attentional focus, participants adopted different mindsets (eat with pleasure, considering health aspects and being full until dinner) while selecting their portion size for lunch. Blood samples were taken after fMRI measurement.
Results: Compared with a free choice condition, mindsets induced behavioral changes in portion size selection associated with specific neuronal processes. Both lean and obese participants reduced their portion size when considering health, which was accompanied by increased left prefrontal cortex activation. However, obese and overweight subjects chose larger portion sizes during the pleasure mindset compared to the lean group. This was related to an increased response in parts of primary gustatory cortex in overweight and obese participants. Moreover, insulin levels determined portion size selection when asked to choose with pleasure, leading to higher portion sizes with low insulin levels. Interestingly, activation of the right lateral prefrontal cortex, recently reported as vulnerable to insulin resistance, was related to individuals' plasma insulin levels when asked to choose a portion size while adopting the health mindset.
Conclusion: Mindsets induced specific behavioral and neural changes modulating portion size selection for lunch in an insulin dependent manner. Understanding these behavioral differences during pre-meal planning can inform the development of effective strategies for healthy weight management.

Coffee and tea consumption in relation to impaired glucose metabolism and diabetes

A.A.M. Berendsen, G. Abma, D. Sluik, E. Feskens;
Human Nutrition, Wageningen University & Research, Wageningen, Netherlands.

Background and aims: Earlier studies suggest that higher coffee and tea consumption are associated with a decreased diabetes incidence, however these associations are still controversial. In this research, we investigated the association between coffee and tea consumption, impaired glucose metabolism (IGM) and diabetes.
Materials and methods: The study population comprised participants from five population studies (Lifelines, the New Zealand Adult Nutrition Survey (NZANS), the Cardiovascular Risk in Young Finns Study (YFS), the Nutrition Questionnaires plus study (NQplus) and the Quebec Family Study (QFS)), which are included in the PREVIEW study. In our cross-sectional analyses, 144,452 participants were included. The prospective analyses on diabetes included 86,051 participants and the prospective analyses on impaired glucose metabolism included 60,419 participants. Each population was divided into categories of coffee (<1 (=ref.), 1–<4 and ≥4 cups/day) and tea (0 (=ref.), >0–<2 and ≥2 cups/day) consumption. Study-specific prevalence ratios (PR) and incidence ratios (IR) and 95% confidence intervals (95%CI) were calculated applying Cox regression with robust variance estimation. Results were adjusted for general characteristics, medical history, anthropometric measurements, lifestyle and dietary factors. Study-specific results for the highest compared to the lowest category of intake were combined in random effect meta-analyses.
Results: Results from our meta-analyses, cross-sectionally showed a lower diabetes prevalence (PR ≥4 cups/d vs. <1 cup/d = 0.79 [95% CI 0.71, 0.87]) and prospectively a decreased diabetes incidence (IR ≥4 cups/d vs. <1 cup/d = 0.75 [95% CI 0.59, 0.95]) for consumption of ≥4 cups of coffee per day compared to consumption of <1 cup per day. No overall association between diabetes and higher tea consumption was observed. Moreover, based on our meta-analyses, no cross-sectional and prospective associations between coffee and tea consumption and IGM were observed.
Conclusion: Combining results from the five studies in a meta-analysis, we showed that consumption of ≥4 cups of coffee per day compared to <1 cup per day was associated with a 21% lower diabetes prevalence and a 25% decreased diabetes incidence. No overall association between tea and diabetes was observed. We also showed no overall associations between higher coffee and tea consumption and IGM. Between-study heterogeneity limits the possibility to draw consistent conclusions. Further research is needed to study if the association between coffee consumption and diabetes is causal, to explore the associations for different types of coffee and tea and to study the impact of the preparation method.

Snacks at post-dinner increases the mean amplitude of glycaemic excursion whereas snacks at mid-afternoon decreases it in young healthy women

S. Imai[1], S. Kajiyama[2,3], A. Nitta[1], T. Miyawaki[1], S. Matsumoto[1], Y. Hashimoto[3], M. Tanaka[3], S. Kajiyama[3], N. Ozasa[4], M. Fukui[3];
[1]Kyoto Women's University, Kyoto, [2]kajiyama Clinic, Kyoto, [3]Graduate School of Medical Science, Kyoto Prefectural University of Medicine, Kyoto, , [4]Graduate School of Medicine, Kyoto University, Kyoto, Japan.

Background and aims: Postprandial hyperglycaemia and glycaemic spikes are associated with cardiovascular diseases even in people without diabetes. The best timing of eating snacks on postprandial glucose levels has not been extensively studied. The aim of this study was to evaluate the effect of consuming snacks at different time of the day on glycaemic parameters in Japanese young women without diabetes.
Materials and methods: This is a randomized controlled three-treatment crossover study. Seventeen women (21.2 ± 0.8 years, BMI 20.7 ± 2.5 kg/m^2, HbA1c 5.14 ± 0.15%: mean ± SD) wore continuous glucose monitors for 7 days. During the test period, each participant consumed identical test meals (total energy 2,060 kcal, protein 70.5 g, fat 70.5 g, carbohydrate 288 g) of breakfast at 07:00, lunch at 12:00, and dinner at 19:00 from the second to the sixth day. The energy ratio of test meals was 58, 13, and 29% from carbohydrates, proteins, and fat, respectively. The half of the participants consumed snack (baked cake 498 kcal, carbohydrate 53.6 g, protein 8.0 g, fat 28.0 g) at 12:30 (post-lunch) on the third day, at 15:30 (mid-afternoon) between lunch and dinner on the fourth day, and at 19:30 (post-dinner) on the fifth day at home. The rest of the participants consumed snacks at post-dinner on the third day, at mid-afternoon on the fourth day, and at post-lunch on the fifth day. The daily glucose parameters were compared during the study period.
Results: The standard deviation of glucose showed higher in consuming snacks at post-dinner than those at mid-afternoon (1.20 ± 0.11 vs. 0.92 ± 0.07 mmol/L, mean ± SE, $p = 0.002$), and the mean amplitude of glycaemic excursion (MAGE) was higher compared to those at post-lunch (3.54 ± 0.32 vs. 3.03 ± 0.27 mmol/L, $p = 0.049$) and at mid-afternoon (2.73 ± 0.20 mmol/L, $p = 0.013$), although mean glucose values did not differ among timings of eating snack (post-lunch, 5.81 ± 0.09; mid-afternoon 5.77 ± 0.11; post-dinner 5.80 ± 0.12 mmol/L). The incremental area under the curve for glucose (IAUC) 12:00–07:00 was higher in consuming snacks at post-dinner compared to that at post-lunch (986 ± 89 vs. 870 ± 112 mmol/L × min, $p = 0.049$) and at mid-afternoon (716 ± 88 mmol/L × min, $p = 0.013$). Additionally IAUC 07:00–10:00 (the following post-breakfast) in consuming snacks at post-dinner was not different from that at post-lunch (142 ± 17 vs. 105 ± 9 mmol/L × min, $p = 0.210$), but higher than that at mid-afternoon (104 ± 12 mmol/L × min, $p = 0.013$).
Conclusion: This study demonstrated that consuming snacks at post-dinner affects the MAGE and the postprandial glucose levels even in the following post-breakfast. On the other hand, consuming snacks at mid-afternoon could be a successful strategy for reduction of glucose excursions in healthy women.

Association between brown rice consumption and circulating microRNAs in Japanese subjects with prediabetes

H. Suzuki[1], R. Araki[2], K. Sasaki-Fukatsu[3], K. Fujie[2], M. Sekiya[1], Y. Nakagawa[1], T. Matsuzaka[1], Y. Nakata[2], N. Yahagi[1], K. Hashimoto[2], H. Shimano[1];
[1]Department of Internal Medicine (Endocrinology and Metabolism), Faculty of Medicine, University of Tsukuba, Tsukuba-shi, [2]Course of Clinical Research and Regional Innovation Donated by the Japanese Agriculture Ibaraki Publ, Faculty of Medicine, University of Tsukuba, Tsukuba-shi, [3]Department of Food Sciences, College of Life Sciences, Ibaraki Christian University, Hitachi-shi, Japan.

Background and aims: Consumption of whole grains like brown rice has beneficial effects for obesity and diabetes. MicroRNAs (miRNAs) are one type of non-coding RNA, which suppress target gene expression post transcriptionally. MiRNAs are detected in blood and could be useful biomarkers in many pathologies. The effects of whole grain consumption on circulating miRNA levels are not clear. The current study aimed at examining how whole grain consumption affects circulating miRNAs levels.
Materials and methods: This was a post-hoc analysis of a 12-week randomized controlled trial published previously. Middle age overweight participants with prediabetes ($n = 36$) were randomly allocated to receive either brown rice (BR) or white rice (WR). Serum miRNAs levels were analyzed by quantitative RT-PCR and the ΔΔCt method using miR-423 as a reference. Lipoprotein fractions were analyzed using HPLC.
Results: After the 12-week intervention period, the pooled serum levels of 51 circulating miRNAs of the BR group were significantly different compared to the WR group. Given their expression levels and their biological significance, we focused the analysis on miR-29a-3p and miR-92a-3p, which are known to inhibit lipogenesis in mouse liver and brown adipose tissue activity, respectively. The levels of miR-92a-3p in the WR group showed a trend of increase in comparison to the BR group (Table 1). However, ΔΔCt of miR-92a-3p levels were not significantly correlated with percentage of changes in body weight. Although miR-29a-3p levels were not significantly different between the two groups, the ΔΔCt of miR-29a-3p significantly correlated with percentage of changes in insulin levels ($r = -0.351$, $P = 0.045$), HOMA-IR levels ($r = -0.424$, $P = 0.014$), LDL cholesterol levels ($r = -0.505$, $P = 0.002$), number of large VLDL particles ($r = -0.364$, $P = 0.034$), number of total LDL particles ($r = -0.414$, $P = 0.015$), large LDL cholesterol levels ($r = -0.414$, $P = 0.015$) and medium LDL cholesterol levels ($r = -0.477$, $P = 0.004$).
Conclusion: BR consumption might increase circulating miR-92a-3p levels. Therefore, it is unlikely that brown adipose tissue activation is a cause of body weight reduction by BR consumption. miR29a-3p levels are associated with insulin resistance and apolipoprotein B containing lipoprotein metabolism.

Table 1. ΔCt and ΔΔCt of circulating levels of miR-29a-3p and miR-92a-3p

		Brown Rice	White Rice	*P*

Effect of meal composition on subsequent eating behaviour

G. Freckmann, D. Waldenmaier, S. Ulbrich, S. Pleus, C. Haug;
Institut für Diabetes-Technologie, Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Ulm, Germany.

Background and aims: An energy intake that exceeds the energy requirement promotes the progression of obesity. The intake of food with a low glycemic index (GI) might prevent the progression of obesity. This study examined the effect of meals with different GI on eating behavior at a subsequent meal in subjects without diagnosed diabetes mellitus.
Materials and methods: On two consecutive study days, 36 subjects received two standardized test meals, containing equal amounts of carbohydrate (50 grams) but differing in GI (high GI meal: "HGI", low GI meal: "LGI"), for breakfast and lunch. HGI mainly consisted of simple carbohydrates, whereas LGI contained complex carbohydrates and a high fat and protein content. On both study days, test meals were consumed in alternating sequence. For the subsequent dinner (unrestrictedly selected from a buffet), energy and macronutrient content were calculated. Before and after each meal, subjects rated their feeling of satiety on a scale ranging from −3 = extremely hungry to 3 = extremely full.
Results: The energy content of the dinner selected after LGI for breakfast and HGI for lunch (1270 ± 531 kcal) was on average 168 kcal higher than after the opposite test meal sequence (1102 ± 331 kcal; $p = 0.004$), although relative macronutrient composition was comparable. This difference corresponds to 8% of the calculated mean daily energy demand of the subjects. After test meal sequence LGI-HGI the feeling of satiety before dinner was on average −2.4, whereas after the opposite sequence the mean feeling was −1.6.
Conclusion: The composition of the previously consumed meal influenced meal selection at a subsequent meal more than the preceding cumulative energy intake. A low GI meal promoted the feeling of satiety for a longer time and decreased the risk of an increased energy intake at a subsequent meal.

Measurement of gastric emptying using scintigraphy and a ^{13}C-octanoic acid breath test with Wagner-Nelson analysis in type 2 diabetes

L.G. Trahair[1,2], M.A. Nauck[3], T. Wu[1,2], M.D.M. Buttfield[1,2], J.E. Stevens[4,2], S. Hatzinikolas[1,2], C.K. Rayner[1,2], J.J. Meier[3], M. Horowitz[1,2], K.L. Jones[1,2];
[1]Adelaide Medical School, The University of Adelaide, Adelaide, Australia, [2]NHMRC Centre of Research Excellence in Translating Nutritional Science to Good Health, Adelaide, Australia, [3]Diabetes Center Bochum-Hattingen, Medical Department I, St. Josef-Hospital, Bochum, Germany, [4]School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, Australia.

Background and aims: Disordered gastric emptying (GE) occurs frequently in diabetes. While scintigraphy remains the 'gold standard' measurement, GE of ^{13}C-labelled substrates has been applied widely in both clinical and research settings given the simplicity of the technique and lack of a radiation burden. A variety of mathematical approaches have been utilised to generate a GE curve from the % $^{13}CO_2$ measured in breath samples following a test meal, most simply, through the fitting of a non-linear exponential curve (conventional analysis). Wagner-Nelson (WN) analysis is another mathematical model that has been proposed; this method has hitherto not been assessed in a diabetic population. We compared WN analysis with (i) scintigraphy and (ii) conventional breath test modelling to evaluate GE in type 2 diabetes (T2DM).
Materials and methods: Thirteen patients with T2DM (age 68.1 ± 1.5 yr, BMI 31.0 ± 0.9 kg/m^2 duration of known diabetes 4.3 ± 0.9 yr, HbA1c

6.3 ± 0.2%) consumed a standardised mashed potato meal comprising 65 g powdered potato and 20 g glucose reconstituted with 250 ml water and an egg yolk labelled with 100 μL ^{13}C-octanoic acid, mixed with 20 MBq ^{99m}Tc-calcium phytate. Scintgraphic data were acquired and breath samples collected for 4 hours after meal ingestion, with the subject seated with their back against a gamma camera. Decay and attenuation-corrected GE curves were generated for the scintigraphic data. GE curves were derived from the breath test data using both WN analysis (with a range of values for the elimination constant (K_{el}) from 0.5–0.7) and conventional analysis. The 50% GE time (T50) and intragastric retention at 60 min were compared. Data are mean ± SEM.

Results: With WN analysis, a $K_{el} = 0.60$ best approximated the scintigraphic GE curve (Figure). There was a correlation between the T50 calculated with scintigraphy and the T50 calculated by $WN_{Kel=0.60}$ ($r^2 = 0.44$, $P < 0.05$) or conventional analysis ($r^2 = 0.44$, $P < 0.05$). Similarly, the intragastric retention at 60 min calculated with scintigraphy correlated with the $WN_{Kel=0.60}$ ($r^2 = 0.61$, $P < 0.01$) and conventional analysis ($r^2 = 0.51$, $P < 0.01$). The T50 calculated with scintigraphy (68.5 ± 4.8 min) and $WN_{Kel=0.60}$ (71.3 ± 4.5 min) were not different, whereas the T50 calculated by conventional analysis was much longer at 164.7 ± 6.0 min ($P < 0.001$).

Conclusion: In T2DM GE of a mashed potato meal assessed using a ^{13}C-octanoic acid breath test with $WN_{Kel=0.60}$ closely reflects measurements obtained with scintigraphy whereas, in absolute terms, the conventional breath test analysis does not.

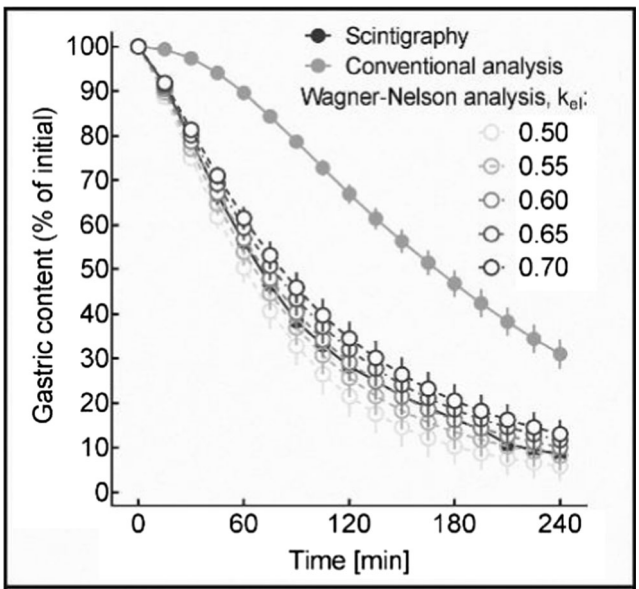

Figure: Gastric emptying of a mashed potato meal measured using scintigraphy and a breath test with both Wagner-Nelson analysis (with values for the elimination constant (Kel) ranging from 0.5-0.7) and a standard non-linear exponential model (conventional analysis) in n=13 type 2 patients.

Influence of dietary and haematobiochemical profile in patients with type 2 diabetes belong to Umbria clinic: "TOSCA.IT" study

A. Tantucci, A. Timi, G. Perriello;
University of Perugia, Perugia, Italy.

Background and aims: TOSCA.IT is a multicentre, randomised, open label, parallel-group clinical trial designed to compare the long-term effects of pioglitazone versus sulfonylureas, given in addition to metformin, on cardiovascular events in patients with type 2 diabetes mellitus. The aim of the study is to analyze the habitual diet of 138 partecipants of TOSCA.IT study (95 men and 43 women) belong to Umbria Clinics, to explore the association of different proportions of the various macronutrients of the diet within the ranges recommended by the various authorities and also to verify any gender differences

Materials and methods: First, subjects were administered two tests to assess the degree of knowledge of diabetes and its complications and to investigate physical health, psychological state, social and environmental context, relationships and quality of life; then, they performed a food interview. Anthropometric variables considered were body mass index and waist circumference. In addition, several blood parameters to evaluate the glycometabolic and cardiovascular state of patients were taken into consideration: glycosylated hemoglobin, total cholesterol, triglycerides, LDL and HDL cholesterol fractions, C-reactive Protein.

Results: Regarding lipid intake, the glycated hemoglobin is significantly higher ($p = 0.021$) in adherents men compared to non-adherents, while HDL are lower in adherents women compared to non-adherents ($p = 0.042$); as regards carbohydrate intake, glycated hemoglobin is higher in non-adherents men ($p = 0.007$) than in adherents and the HDL are lower in non-adherents women ($p = 0.02$) compared to adherents. As for the fiber, the HDL are lower in non-adherents men than in adherents ($p = 0.049$), the same situation regarding cholesterol for triglycerides ($p = 0.03$); very interesting data regarding the daily consumption of alcohol: in non-adherents women the weight and the BMI are higher compared to adherents women ($p = 0.006$ and $p = 0.03$ respectively), the same situation for PCR ($p = 0.042$).

Conclusion: Although nutritional therapy is a central point in diabetic pathology, it is difficult to achieve optimal adherence to recommendations, especially in the long term; our study, even if performed on a small cohort of people, shows that adherence or no-adherence to the nutritional recommendations can affect cardiometabolic and inflammatory risk factors, regardless the use of drugs and cigarettes. Despite of an ideal "diet" for the diabetic patient, it is necessary to "personalize" it according to who we are facing, following the DNSG/SID recommendations on the Mediterranean diet; therefore, we need interventional and not only observational studies to compare different dietetic strategies on diabetic patients, that involve a large cohort of people, representative the general diabetic population commonly present in the real clinical practice.

Orthodox religious fasting in practice: a comparative evaluation between Greek Orthodox general population fasters and Athonian monks

S.N. Karras[1], T. Koufakis[1], A. Petróczi[2], D. Folkerts[3,2], M. Kypraiou[1], H. Mulrooney[2], D.P. Naughton[2], P. Zebekakis[1], D. Skoutas[4], K. Kotsa[1];
[1]Division of Endocrinology and Metabolism, First Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, AHEPA University Hospital, Thessaloniki, Greece, [2]School of Life Sciences, Pharmacy and Chemistry, Kingston University London, London, UK, [3]Department of Sport Psychology, Institute of Sport and Exercise Sciences, University of Muenster, Muenster, Germany, [4]Sarafianos Private Hospital, Thessaloniki, Greece.

Background and aims: Orthodox religious fasting (OF), a periodical vegetarian subset of the Mediterranean diet, has been proven to exert beneficial effects on human health. Athonian fasting is a pescetarian OF variation, where red meat is strictly restricted throughout the year. Previous studies have examined the OF nutritional synthesis and health

impact in general population fasters (GF) and Athonian monks (AM), separately. This is the first study to comparatively evaluate the characteristics and effects of this nutritional advocacy between the two populations.

Materials and methods: 43 general population male fasters (aged 20–45 years) and 57 age-matched male monks following Orthodox fasting were included in the study. Dietary intake data were collected in both groups during a restrictive (RD) and a non-restrictive (NRD) day. Nutritional, cardiometabolic and anthropometric parameters were compared between the two cohorts.

Results: AM compared to GF, presented lower daily total caloric intake for both RD (1362.42 ± 84.52 vs 1575.47 ± 285.96 kcal, $p < 0.001$) and NRD (1571.55 ± 81.07 vs 2137.80 ± 470.84 kcal, $p < 0.001$). They also demonstrated lower Body Mass Index (23.77 ± 3.91 vs 28.92 ± 4.50 kg/m^2, $p < 0.001$), Body Fat mass (14.57 ± 8.98 vs 24.61 ± 11.18 kg, $p = 0.001$), Fasting Insulin concentrations (4.61 ± 3.16 vs 11.64 ± 9.21 μg/ml, $p < 0.001$) and Homeostatic Model Assessment for Insulin Resistance values (0.98 ± 0.72 vs 2.67 ± 2.19 mmol/l, $p < 0.001$), compared to GF. GF and AM demonstrated a comparable profile for Total Cholesterol (189.1 ± 45.08 vs 183.00 ± 40.87 mg/dl respectively, $p = 0.470$) and Low-Density Lipoprotein (120.68 ± 45.92 vs 119.97 ± 36.70 mg/dl respectively, $p = 0.930$), while High-Density Lipoprotein concentrations were in the low-normal range for both (43.20 ± 11.05 vs 47.83 ± 14.11 mg/dl respectively, $p = 0.061$). Secondary hyperparathyroidism (Parathyroid Hormone concentrations: 116.08 ± 49.74 pg/ml), as a result of profound hypovitaminosis D [25(OH)D: 9.27 ± 5.81 ng/ml], were evident in the AM group.

Conclusion: The results of the present study highlight the unique characteristics of Athonian Orthodox fasting and its value as a health-promoting diet. The impact of limitation of specific vitamins and minerals during fasting warrants further investigation.

Cardiometabolic markers in general population fasters and Athonian Monks

Biochemical Marker	Group 1 General population fasters	Group 2 Athonian monks	Test Statistics
CHOL (mg/dl)	189.1 ± 45.08	183.00 ± 40.87	t(99.758)= 0.725, d = 0.142, p = .470

Carbohydrate tolerance at near-normoglycaemia remission in obese African American patients with hyperglycaemic crises

P. Vellanki[1], D. Stefanovski[2], V. Narwani[1], I. Anzola[1], D.D. Smiley[1], L. Peng[3], G.E. Umpierrez[1];
[1]Emory University School of Medicine, Atlanta, [2]University of Pennsylvania, Atlanta, [3]Emory University, Atlanta, USA.

Background and aims: Many obese African American (AA) patients with new-onset DKA and severe hyperglycemia achieve near-normoglycemia remission (HbA1c <7%, fasting blood glucose [BG] <130 mg/dl) with intensive insulin treatment. Glycemic status at insulin remission varies from normal glucose tolerance (NGT), prediabetes or diabetes on oral glucose tolerance test (OGTT). We hypothesized that patients with NGT at near-normoglycemia remission will have higher insulin sensitivity (S_i) and insulin secretion, and longer hyperglycemia relapse-free survival.

Materials and methods: A total of 135 obese AA new-onset of diabetes presenting with DKA and severe hyperglycemia (BG >400 mg/dl without DKA) were consented. Seventy-eight patients (58%) achieved near-normoglycemia remission and 75 of these patients underwent 2-h 75-gm OGTTs a week after insulin remission and every 6 months till hyperglycemia relapse. After initial OGTT, subjects were randomized to metformin, sitagliptin, pioglitazone or placebo for a median of 336 days (range 19–1186). Because baseline characteristics did not differ significantly between DKA and severe hyperglycemia, data was combined for the analysis. S_i was calculated using the OGTT minimal model analysis. Insulin secretion was calculated as incremental area under the curve of insulin ($IncreAUC_i$) with insulin levels from OGTT. Disposition index (DI) was calculated as S_i x $IncreAUC_i$. Hyperglycemia relapse was defined as fasting BG ≥130 mg/dl, HbA1c >7% or 2 random BG ≥180 mg/dl.

Results: There were 33 patients with DKA and 42 with severe hyperglycemia. On initial OGTT, 12% had NGT, 45% had prediabetes and 43% had diabetes. There were no differences in baseline characteristics. DI was higher in patients with NGT vs prediabetes vs diabetes (1.88 ± 1.63 vs 1.05 ± 1.14 vs 0.35 ± 0.92, $p < 0.001$). The difference in DI was explained by higher S_i than $IncreAUC_i$ in NGT compared to prediabetes and diabetes (S_i: 4.2 ± 4.4 vs 2.4 ± 3.5 vs 1.2 ± 2.5 10^{-4}.(mU/l)$^{-1}$.min^{-1}, $p < 0.001$; $IncreAUC_i$: 6571 ± 3451 vs 6585 ± 4947 vs 4450 ± 3051, $p = 0.14$ mU/ml^2). At a median follow-up of 336 days, of the patients with NGT, 43% remained NGT, 43% and 14% developed prediabetes and diabetes respectively. Of the patients with prediabetes, 42% remained with prediabetes, 13% achieved NGT and 46% developed diabetes. Of the patients with diabetes, 79% remained with diabetes, 18% and 4% achieved prediabetes and NGT respectively. At last follow-up, DI was significantly higher in patients with NGT vs prediabetes and diabetes (2.49 ± 3.1 vs 1.21 ± 1.50 vs 0.61 ± 0.96, $p = 0.02$). S_i ($p = 0.17$) and $IncreAUC_i$ ($p = 0.25$) did not differ significantly among the groups at follow-up. Multivariate Cox regression adjusting for age, sex, DKA presentation and initial OGTT status showed that treatment with metformin, sitagliptin or pioglitazone was significantly associated with long-term relapse-free survival (Hazard ratio: 0.42, 95% confidence interval 0.20, 0.92) compared to placebo.

Conclusion: In obese AA patients, attaining NGT at near-normoglycemia remission is characterized by higher insulin sensitivity and disposition index rather than higher insulin secretion. However, none of these markers were associated with long-term hyperglycemia-free survival.

OCT1 is a target of metformin and regulates pancreatic stellate cell activity

C. Wu, S. Qiu, X. Zhu, L. Li;
Departmentof Endocrinology, affiliated ZhongDa Hospital of Southeast University, Nanjing, China.

Background and aims: Metformin treatment is reported to be associated with a lower incidence of and mortality from pancreatic cancer (PC) in type 2 diabetes patients. Activated pancreatic stellate cells (PSCs) are key stroma cells responsible for pancreatic fibrogenesis and PC progression. However, little research is about the influence of metformin on PSCs. Given the potential beneficial effects of metformin on PC, pancreatic tumour stroma is an important target for new therapeutics. We observed the effects of metformin on PSCs. We investigated the effects of metformin on human PSCs proliferation and the production of extracellular matrix (ECM) proteins.
Materials and methods: Cells were cultured with different concentrations of metformin (0–10 mmol/L). Cell proliferation was determined by immunofluorescence staining for nuclear Ki67 labelling. ECM production was studied by quantitative real-time polymerase chain reaction, immunoblotting and immunofluorescence microscopy. Adenosine monophosphate-activated protein kinase (AMPK), an important regulatory molecule responsible for metformin action, and the organic cation transporter member 1 (OCT1), which is believed to be the most important transporter for the pharmacological action of metformin, were investigated for their possible involvements in metformin-induced proliferation and ECM production.
Results: Our results showed that metformin inhibited PSCs proliferation and decreased the production of ECM proteins by activation of AMPK phosphorylation. Silencing of OCT1 expression resulted in a reduction in the effects of metformin on AMPK phosphorylation.
Conclusion: Collectively, the data indicate that OCT1 is important for metformin regulation of PSCs activity. OCT1 is a target of metformin in regulating PSCs activity.

Metformin-induced alterations of transcriptome profile in healthy individuals

M. Ustinova[1], I. Silamiķelis[1], I. Elbere[1], I. Kalniņa[1], L. Zaharenko[1], I. Radoviča-Spalviņa[1], V. Rovite[1], I. Konrāde[2], V. Pirags[1], J. Klovins[1];
[1]Latvian Biomedical Research and Study Centre, Riga, [2]Riga Stradins University, Riga, Latvia.

Background and aims: Metformin is the first-line antidiabetic agent used in pharmacotherapy of type 2 diabetes to improve glucose homeostasis. Nevertheless, additional therapeutic directions such as cancer prevention, treatment of polycystic ovary syndrome and neurodegenerative diseases have been highlighted lately justifying the pleiotropic effect of the drug. Despite the identification of AMP-activated protein kinase and mitochondrial respiratory-chain complex 1 as the major mediators of its effects, exact mechanisms of metformin action remain obscure. The aim of the study was to evaluate metformin-induced alterations of transcriptome profile, in order to identify novel mechanisms of action at the molecular level in non-diabetic individuals.
Materials and methods: The longitudinal study enrolled 25 healthy volunteers of European descent, receiving oral 850 mg dose of metformin twice-daily for 7 days. RNA was isolated from whole blood samples, collected at three consecutive time points: before metformin administration, 10 hours after the first dose and at the end of metformin treatment. RNA-seq was performed on Ion Proton™ System and Ion PI™ Chip. For bioinformatic analysis Trimmomatic 0.36, STAR 2.5.3a, edgeR and DAVID 6.8. tools were applied.
Results: In total 681 differentially expressed genes were identified (FDR <0.05), among them genes related to inflammatory responses, promoting enrichment of intestinal immune network for IgA production and cytokine-cytokine receptor interaction pathways. In addition, differential expression of four functional gene clusters were revealed after consideration of subject-specific effects, including upregulation of ribosomal genes, snoRNAs and genes relevant to insulin production (HNF1B, HNF1A, HNF4A, GCK, INS, NEUROD1, PAX4, PDX1, ABCC8, KCNJ11), and downregulation of genes contributing in cholesterol homeostasis (APOB, LDLR, PCSK9).
Conclusion: In healthy individuals universal metformin-induced alterations of global gene expression profiles in white blood cells are associated with immune responses, while subject-specific effects, which tendency to be more permanent are related to energy metabolism.

Physiological effects of pioglitazone and metformin in patients with ataxia-telangiectasia

L.J. McCreight[1], L. Coppin[2], N. Jackson[2], A.M. Umpleby[2], A. Mari[3], E.R. Pearson[1];
[1]University of Dundee, Dundee, UK, [2]University of Surrey, Guildford, UK, [3]National Research Council, Padova, Italy.

Background and aims: Ataxia telangiectasia (A-T) is a rare genetic condition associated with diabetes, caused by homozygous recessive loss of function of the A-T mutated (*ATM*) gene. OGTT data show that adults with A-T are insulin resistant, with normal fasting glucose and insulin, but large, prolonged excursions after a glucose load. *ATM*-ko mice have glucose intolerance, insulin resistance and abnormal fat distribution, which improved with TZD treatment. In people with diabetes, a SNP at a locus containing *ATM* was associated with greater response to metformin. Our study aimed to characterise the insulin resistance seen in A-T and to determine the physiological effects of pioglitazone and metformin in these patients.
Materials and methods: This open label, non-randomised, crossover study compared 8 non-diabetic people with A-T and 15 healthy controls over 17 weeks. The study consisted of two treatment periods, with one week washout, and three study visits: baseline, post-metformin and post-pioglitazone. At each visit, a dual tracer mixed meal test was used to measure fluxes in glucose, insulin, and c-peptide over 6 hours following a meal. Glucose absorption, beta cell function and insulin sensitivity were modelled.
Results: The groups were well matched for age, BMI and HbA1c. Adults with A-T are insulin resistant compared to controls, with higher fasting insulin secretion rate (ISR) (89.3 ± 13.3 v 58.1 ± 7.0 pmol/min/m^2, $p = 0.04$), despite comparable fasting glucose, glucose clearance (CL) and endogenous glucose production (GP). Post meal, they have greater total insulin secretion (96.1 ± 14.6 v 53.3 ± 6.1 pmol/L, $p = 0.005$) and glucose (6.4 ± 0.3 v 5.3 ± 0.1 mmol/L, $p = 0.001$). In the A-T group, metformin treatment resulted in increased CL (2.7 ± 0.2 v 2.5 ± 0.2 mmol/min/kg, $p = 0.04$) during fasting, in the context of reduced insulin (85.3 ± 33.9 v 99.5 ± 36.1, $p = 0.04$), and unchanged GP. Post-meal, metformin treatment caused a greater suppression in GP in the first hour compared to baseline (24 vs 4%, $p = 0.04$), in the absence of altered insulin or CL. After metformin treatment the control group had increased CL at fasting (3.1 ± 0.2 v 2.6 ± 0.1, $p < 0.001$), in the context of unchanged insulin. However, their fasting GP was increased (13.5 ± 0.8 v 11.2 ± 0.5 mmol/min/kg, $p = 0.001$). Post meal there was no significant difference in insulin, CL, or GP. Pioglitazone reduced fasting (58.2 ± 17.5 v 99.5 ± 36.1,

$p = 0.007$) and mean (522 ± 170 v 1065 ± 388, $p = 0.015$) insulin in the A-T group, in the context of unchanged fasting glucose but reduced mean glucose (5.9 ± 0.02 v 6.4 ± 0.3, $p = 0.02$), with unchanged CL or GP. In the controls, pioglitazone treatment had no significant effect on insulin or glucose concentration.

Conclusion: Metformin improves peripheral insulin sensitivity in the fasting state in both groups. In adults with A-T, there is increased suppression of EGP in the hour post-meal, in keeping with an improvement in hepatic insulin sensitivity. In contrast, the controls do not demonstrate any improvement in hepatic insulin sensitivity with metformin, but in fact have an increased EGP, which may represent compensation for an increase in fasting glucose clearance. Pioglitazone treatment in the A-T group improved both peripheral and hepatic insulin sensitivity. Pioglitazone reduced glucose excursion post-meal, where metformin did not. These data suggest that pioglitazone may be appropriate as first line treatment for diabetes in A-T.

Distribution of dose and up-titration patterns for patients initiating metformin monotherapy in the UK

K. Iglay[1], B. Sawhney[2], A.Z. Fu[2], G. Fernandes[1], M. Crutchlow[1], S. Rajpathak[1], K. Khunti[3];

[1]Merck & Co., Inc., Kenilworth, USA, [2]Complete HEOR Solutions (CHEORS), North Wales, USA, [3]Diabetes Research Centre, University of Leicester, Leicester, UK.

Background and aims: International guidelines recommend treatment with metformin as initial pharmacotherapy for patients with type 2 diabetes mellitus (T2DM). Dosing guidelines for metformin recommend starting with a low dose and up-titrating the dose over a period of 1–2 months to a maximally effective (~2000 mg/day) dose, unless tolerability-limited; however, the extent to which this occurs in the real world setting is unknown. To address this question, the current study sought to determine the dose distribution among new users of metformin monotherapy at initiation, 3, 6, and 12 months, as well as the pattern of up-titration following initiation of therapy.

Materials and methods: Patients ≥21 years of age with a T2DM diagnosis between 2012 and 2017 were identified using the Clinical Practice Research Datalink (CPRD) database. Patients with an HbA1c value in the 6 months prior to metformin monotherapy initiation, and continuous enrollment in the database 1 year prior and 15 months following metformin monotherapy initiation were included. Data were censored once patients discontinued metformin or added another diabetes medication if these occurred during the follow-up period. Descriptive statistics were used to describe dose distribution and up-titration patterns for patients on metformin monotherapy. Time to highest dose was estimated using a cumulative incidence function.

Results: Of the 6174 eligible patients, 42.7% were female, median age was 61 years, and median HbA1c prior to initiation was 7.8%. At 12 months post-initiation, 58.2% of the initial cohort remained on metformin monotherapy, while 41.8% were censored (33.8% discontinued metformin without initiating another anti-hyperglycemic agent (AHA) at the time of discontinuation, 4.8% had another AHA added to metformin, and 3.2% switched from metformin to another AHA). The table below describes the distribution of metformin dose and up-titration during the follow-up period. The majority (71.6%) of patients initiated metformin at ≤1000 mg/day. At 3, 6, and 12 months, 71.6%, 68.6% and 68.1% of metformin monotherapy patients, respectively, were on doses ≤1000 mg/day. Cumulatively, 0.03%, 6.7%, and 10.8% of patients were up-titrated from their initial dose at 3, 6 and 12 months, respectively. Among those who up-titrated during follow-up ($n = 667$), median (Q1, Q3) highest dose of metformin was 2000 mg/day (1000 mg/day, 2000 mg/day) and median (Q1, Q3) time to highest dose was 175 (162, 348) days.

Conclusion: Almost two-thirds of patients remained on metformin monotherapy 12 months after initiation. The majority were not up-titrated and remained on a sub-maximally effective dose of metformin at 12 months. Further research needs to determine potential reasons for failure to intensify metformin therapy.

Distribution of Dose and Up-titration Patterns for Patients on Metformin Monotherapy

Associations between metformin use and the risks of vitamin B_{12} deficiency, anaemia and neuropathy in patients with diabetes: a meta-analysis

W. Yang[1], X. Cai[1], H. Wu[2], L. Ji[1];

[1]Endocrinology and Metabolism, Peking University People's Hospital, Beijing, [2]Eisai China Inc., Shanghai, China.

Background and aims: Metformin is the first line therapy for patients with type 2 diabetes. However, numerous studies reported that metformin treatment led to decreased vitamin B12 level in patients, and clinically meaningful decrease in vitamin B12 level in patients could lead to diseases such as macrocrytic anemia and neuropathy. The aim of this meta-analysis was to find the associations between metformin use and the risks of vitamin B12 deficiency, anemia and neuropathy in patients with diabetes.

Materials and methods: The databases of PubMed, Web of Knowledge, Cochrane Library and Embase were searched to identify studies including all controlled studies on relationships between metformin use and vitamin B12, anemia or neuropathy in patients with diabetes, which were published in English prior to March 2018. The pooled risk ratio (RR) and 95% confidence interval (CI) were calculated with Cochrane Review Manager 5.3 (RevMan 5.3) to compare the risks of vitamin B12 deficiency, anemia and neuropathy in diabetic patients on metformin treatment vs those without metformin use. The mean difference (MD) and 95%CI were calculated to compare the levels and changes of serum vitamin B12 concentration (pmol/l) from baseline in diabetic patients on metformin treatment vs those without metformin use. A random-effect model was first used for the analyses, and a fixed effect model were used for those analyses with a low-to-moderate heterogeneity ($I^2 < 50\%$).

Results: A total of 30 studies were included in the analyses. Compared to patients without metformin use, patients with metformin treatment had significantly higher risk of vitamin B12 deficiency (RR = 2.28; 95% CI [1.63, 3.21]; $P < 0.001$; $I^2 = 62\%$), significantly lower levels of serum vitamin B12 concentration (MD = −64.71 pmol/l; 95% CI [−75.52, −53.91] pmol/l; $P < 0.001$; $I^2 = 87\%$), and significantly greater decrease in serum vitamin B12 concentration from baseline (MD = −14.68%; 95% CI [−17.98, −11.39]%; $P < 0.001$; $I^2 = 33\%$). Additionally, analyses of the few currently available studies did not reveal significant difference in risk

of anemia (four studies with 4070 patients, RR = 0.93; 95% CI [0.79, 1.09]; $P = 0.36$; $I^2 = 0\%$) and neuropathy (six studies with 1058 patients, (RR = 0.84; 95% CI [0.62, 1.13]; $P = 0.25$; $I^2 = 60\%$) between patients on metformin therapy vs those who were not.

Conclusion: Metformin use was significantly associated with the risk of vitamin B12 deficiency and the level of vitamin B12 was significantly lower in patients with metformin use compared with those without metformin use. As vitamin B12 deficiency could potentially have serious clinical consequences, affordable and non-toxic vitamin B12 supplement such as methylcobalamin is recommend to prevent and treat vitamin B12 deficiency in patients with diabetes on metformin therapy. In addition, more quality studies are needed to further elucidate whether metformin use was associated with anemia and neuropathy in patients with diabetes.

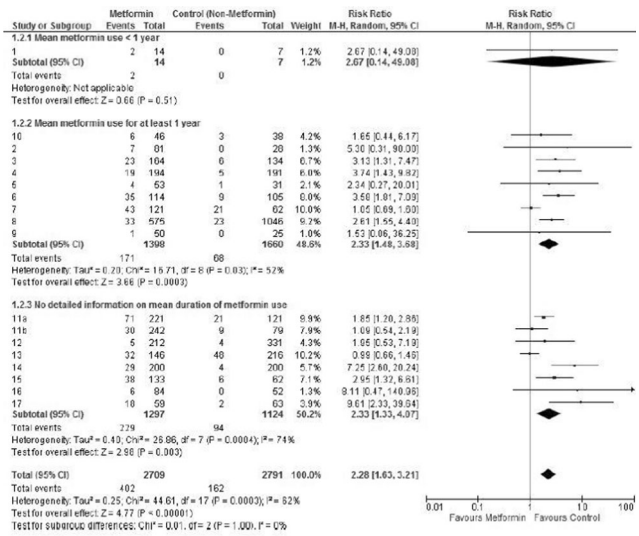

Figure 1 Risk of vitamin B12 deficiency between patients with metformin use vs controls (non-metformin use)

Trends in medication utilisation, glycaemic control and rate of severe hypoglycaemia among type 2 diabetes patients at a tertiary referral centre in Singapore from 2007 to 2017

Y.Z. Tan[1], M.H.H. Cheen[1], P.S. Lim[1], G.Y. Khee[1], J. Thumboo[2], S.-Y. Goh[3], Y.M. Bee[3];
[1]Pharmacy, Singapore General Hospital, Singapore, [2]Rheumatology & Immunology, Singapore General Hospital, Singapore, [3]Endocrinology, Singapore General Hospital, Singapore, Singapore.

Background and aims: Singapore has one of the highest prevalence of type 2 diabetes (T2DM) amongst developed countries, and this is estimated to rise from 11.3% in 2010 to 15.0% in 2050. Use of glucose-lowering medications has been a cornerstone in combating T2DM. Over the past decade, novel agents with more favourable adverse effects profiles have been introduced and subsequently incorporated into treatment guidelines. We report the temporal trends in the utilization of glucose-lowering medications, glycaemic control and rate of severe hypoglycaemia in T2DM patients managed at a tertiary referral centre in Singapore.

Materials and methods: We analysed data of 36,925 T2DM patients from the SingHealth Diabetes Registry seen at the Singapore General Hospital from 2007 to 2017. Annual age-, sex- and ethnicity-standardized proportions of patients (a) who were prescribed with each class of glucose-lowering agent; (b) who were on monotherapy with either an oral agent or insulin, a combination of oral agents, or on both insulin and oral agents(s); and (c) with glycated haemoglobin A1c (HbA_{1c}) of <6%, 6 to <7%, 7 to <8%, 8 to <9% and ≥9%, were estimated using logistic regression. Annual age-, sex- and ethnicity-standardized rates of severe hypoglycaemia were estimated using Poisson regression.

Results: Use of metformin (45.9% to 59.6%, from 2007 to 2017), insulin (24.4% to 57.9%, from 2007 to 2017), DPP-4 inhibitors (1.2% to 31.2%, from 2008 to 2017) and SGLT-2 inhibitors (0.50% to 7.4%, from 2014 to 2017) increased significantly, while utilization of sulphonylureas (52.0% to 44.9%, from 2007 to 2017) and acarbose (15.3% to 5.7%, from 2007 to 2017) decreased (all $p < 0.001$). Proportion of patients with a single oral agent decreased (40.1% to 18.0%), but increased for those on treatment regimen containing both insulin and oral agent(s) (17.2% to 46.0%; all $p < 0.001$). The proportion of patients with HbA_{1c} ≥9% increased (18.1 to 20.3%) and decreased for those with HbA_{1c} ≤7% (40.7% to 38.5%; all $p < 0.001$). The rate of severe hypoglycaemia increased (5.5 to 9.4 per 100 patient-years; $p < 0.001$) during the study period.

Conclusion: Medication utilization patterns have changed significantly over the past 11 years with a shift towards newer agents. Overall glycaemic control amongst those managed at our centre did not improve, and the rate of severe hypoglycaemia increased. Further analysis is required before causal relationships between medication utilization, glycaemic control and hypoglycaemia can be inferred.

Different sulfonylureas induce the apoptosis of proximal tubular epithelial cell differently via closing K_{ATP} channel

R. Zhang[1], X. Zhou[1], X. Shen[2], T. Xie[2], C. Xu[1], Z. Zou[1], J. Dong[3], L. Liao[1];
[1]Shandong provincial Qianfoshan hospital, Shandong university, Jinan, [2]Shandong university of Traditional Chinese Medicine, Jinan, China, [3]Qilu Hospital of Shandong university, Jinan, China.

Background and aims: Sulfonylureas (SUs) are widely prescribed for the treatment of type 2 diabetes (T2DM). Sulfonylurea receptors (SURs) are their main functional receptors. These receptors are also found in kidney, especially the tubular cells. However, the effects of SUs on renal proximal tubular epithelial cells (PTECs) were unclear. The aim of present study is to investigate if different SUs have different effects on the apoptosis of PTECs.

Materials and methods: HK-2 cells were exposed to SUs for 24 h prior to exposure to 30 mM glucose, the apoptosis rate was evaluated by Annexin/PI flow cytometry. Bcl-2, Bax and the ratio of LC3II to LC3I were also studied *in vitro*.

Results: Treatment with glibenclamide aggravated the apoptosis of HK-2 cells in high-glucose, as indicated by a significant decrease in the expression of Bcl-2 and increase in Bax ($P < 0.05$). Additionally, the decreased LC3II/LC3I reflects that the autophagy was inhibited by glibenclamide ($P < 0.01$). Similar but less pronounced change was found in glimepiride group, however, nearly opposite effects were found in gliclazide group ($P < 0.01$). Further, the effects of glibenclamide on apoptosis promotion and the decreased LC3II/LC3I were ameliorated obviously by treatment with 100 uM diazoxide ($P < 0.05$, $P < 0.01$). The potential protection effect of gliclazide was also inhibited after opening the K_{ATP} channel ($P < 0.05$).

Conclusion: The results suggest that, the effects of glibenclamide and glimepiride on PTECs apoptosis, especially the former, were achieved in part by closing the K_{ATP} channel. In contrast to glibenclamide and glimepiride, therapeutic concentrations of gliclazide showed an inhibitory effect on apoptosis of PTECs, which may have a benefit in the preservation of functional PTECs mass.

Comparison of medical resources, costs, and health utilities among patients with CHD and impaired glucose tolerance in the Acarbose Cardiovascular Evaluation Trial (ACE)

L. Mc Morrow[1], F. Becker[1], J. Leal[1], A.M. Gray[1], R. Coleman[2], H.C. Gerstein[3], L. Rydèn[4], R.R. Holman[5];
[1]Health Economics Research Centre, University of Oxford, Oxford, UK, [2]Diabetes Trials Unit, University of Oxford, Oxford, UK, [3]McMaster University, Hamilton, Canada, [4]Karolinska Institutet, Stockholm, Sweden, [5]DiabetesTrials Unit, Oxford Centre for Diabetes, Endocrinology and Metabolism, Diabetes Trials Unit, University of Oxford, Oxford, UK.

Background and aims: ACE assessed the effects of acarbose, an α-glucosidase inhibitor, in 6,522 patients with CHD and impaired glucose tolerance from 176 hospital outpatient clinics in China. This randomized, double-blind, placebo-controlled, phase-4 trial with a five year median follow-up showed acarbose did not reduce the risk of major adverse cardiovascular events, but reduced the incidence of diabetes by 18% ($p = 0.005$). We aimed to compare medical resource use, costs and health utilities between treatment arms.
Materials and methods: Medical resource use data were collected throughout the trial. Hospitalisations, medications and outpatient visits were valued using Chinese costs from, respectively, the China Health and Family Planning Statistical Yearbook (2016), the Beijing Medicine Sunshine Purchase Platform, and published studies. Medication use is represented as drug days, with all cardiovascular and diabetes drugs summed across the follow-up period for each patient. Health utilities were measured using the Euro-Qol-5-Dimension three level (EQ-5D-3L) questionnaire. An available-case analysis was performed using regression analyses (hierarchical generalized linear models) to compare resource use, costs, and health utilities accounting for between-site variation. Costs were discounted at 3% per annum.
Results: There were no significant differences in hospitalisations, inpatient days, outpatient visits or drug days between treatment arms. However, mean (standard error) diabetes drug days per patient (excluding study drug), as part of total drug days, were significantly lower in the acarbose group compared with the placebo group (91 ± 6.08 vs. 118 ± 6.99, $p = 0.04$). Costs over the trial period for inpatient care, outpatient care, medications and total costs (excluding study drug) did not differ significantly between groups. On average, the study drug (acarbose) cost ¥6,594 (€857, 1241 drug days) per patient during the trial follow-up period. Total costs per patient for the acarbose group were significantly higher than for the placebo group (Table). Health utilities were similar at baseline in the acarbose and placebo groups (0.94 ± 0.002 vs. 0.94 ± 0.002) indicating a trial population with few health problems. No significant between group differences in health utilities were detected during the trial ($p = 0.42$).
Conclusion: Total costs during the follow-up period were significantly higher in the acarbose arm once the study drug costs were added. Future research will explore the impact of acarbose on resource use, costs and quality adjusted survival over the lifetime horizon.

HbA_{1c} is highly variable in people with type 2 diabetes on stable therapy in both trial and real-world settings: implications for clinical practice

A. McGovern[1], J. Dennis[1], B. Shields[1], E. Pearson[2], A. Hattersley[1], A. Jones[1];
[1]University of Exeter, Exeter, [2]University of Dundee, Dundee, UK.

Background and aims: HbA1c is the measure most widely used to make decisions about changing treatment in people with type 2 diabetes (T2D). However within individuals HbA1c fluctuates considerably over time. It is unknown how much this noise in HbA1c obscures true deterioration or treatment response. A detailed understanding of how HbA1c fluctuates over time in people on stable therapy is essential for understanding how to interpret HbA1c changes at an individual level. We assessed the variability in HbA1c over time in people with T2D on stable treatment in a large randomised controlled trial and a large UK based real world cohort. We subsequently analysed the impact of clinical characteristics on HbA1c variability.
Materials and methods: We used data from the ADOPT randomised clinical trial ($n = 3380$) and a large UK primary care database (CPRD; Clinical Practice Research Datalink, $n = 82,439$) to analyse variation in HbA1c over time in people with non-insulin treated T2D on stable therapy. HbA1c variability was defined as the standard deviation (SD) of 4

measurements; measured every 3 months in ADOPT and 6 months in CPRD. Stable therapy was defined as no discontinuation or addition of any glycaemic lowering medication in the preceding six months or during follow up. The outcome SD in HbA1c was stratified by baseline HbA1c. We analysed the impact of age, gender, ethnicity, and body mass index (BMI), and drug class on glycaemic variability in multivariable regression after adjusting for baseline HbA1c.

Results: In ADOPT, SD of HbA1c was non-linearly correlated with baseline HbA1c, substantially increasing in those with the highest HbA1c (SD = 2.8 mmol/mol for baseline <48 mmol/mol, 3.5 mmol/mol for 48–64 mmol/mol, and 7.0 mmol/mol for >64 mmol/mol). Small but significant increases in SD were seen with younger age (0.33; 95%CI 0.24, 0.42 mmol/mol per decade), male gender (0.19; 95%CI 0.01, 0.38 mmol/mol), and Black race relative to White (0.63; 95%CI 0.39, 0.88 mmol/mol). Asian race was associated with less variation (−0.46; 95%CI −0.62, −0.30 mmol/mol). There was no association with BMI. Relative to metformin, glyburide had higher SD (0.42; 95%CI 0.21, 0.64 mmol/mol) and rosiglitazone lower (−0.28; 95%CI −0.49, −0.07 mmol/mol). In CPRD, the SD in HbA1c had a similar association with baseline HbA1c but was larger; (SD = 4.5 mmol/mol for baseline HbA1c <48 mmol, 5.4 mmol/mol for 48–64 mmol/mol, 7.9 mmol/mol for 64–86 mmol/mol, and 11.4 mmol/mol for >86 mmol/mol). Increases in SD were seen with younger age (0.42; 95%CI 0.39, 0.47 mmol/mol per decade), male gender (0.36; 95%CI 0.28, 0.46 mmol/mol), and Black race (0.63; 95%CI 0.38, 0.88 mmol/mol). There no association with BMI or Asian race relative to White. The lowest SD by drug class was with SGLT2 inhibitors (−1.71; 95%CI −1.98, −1.42 mmol/mol) and the highest with sulphonylureas (1.11; 95%CI 1.02, 1.21 mmol/mol) relative to metformin.

Conclusion: The amount of variability in HbA1c on stable therapy is large, particularly in patients with poor glycaemic control where it is similar to the HbA1c reductions expected from oral therapies. Therefore, a single post treatment HbA1c measure is unlikely to be sufficient to determine the effectiveness of a treatment, or need for therapy intensification for an individual. The high level of HbA1c variability was not substantially modified by any clinical characteristic.

Impact of proximal intestinal exclusion with EndoBarrier on key metabolic parameters and cardiovascular risk (UKPDS risk engine) in the first NHS-UK EndoBarrier service

E.N. Fogden[1], P. Sen Gupta[2], M. Yadagiri[2], S.P. Irwin[2], W. Burbridge[2], T. Bashir[3], R. Allden[1], J.P. Bleasdale[4], M.R. Anderson[1], R.E.J. Ryder[2]; [1]Gastroenterology, City Hospital, Birmingham, [2]Diabetes, City Hospital, Birmingham, [3]Dietetics, City Hospital, Birmingham, [4]Anaesthetics, City Hospital, Birmingham, UK.

Background and aims: Background and aims: The leading cause of death in patients with type 2 diabetes is cardiovascular disease (CVD). The United Kingdom Prospective Diabetes Study (UKPDS) CVD risk engine version 2.0 uses recognised risk factors to calculate future CVD risk. Our aim was to investigate the impact of proximal intestinal exclusion using EndoBarrier, a device implantable for up to 1 year, on 10 year CVD risk.

Materials and methods: We report the first 46 patients who have had their devices removed after (mean ± SD) 11.5 ± 2.2 months, of 62 who have so far received devices in our NHS service (2015–2018). We measured all factors utilised by the risk engine: age, duration of diabetes, sex, atrial fibrillation, ethnicity, smoking, systolic blood pressure, HbA1c, total cholesterol and HDL cholesterol.

Results: The table shows baseline characteristics of the patients and the impact on metabolic and CVD risk factors of EndoBarrier treatment. There were highly significant falls in all parameters involved in CVD risk assessment other than HDL cholesterol which remained unchanged. The UKPDS risk engine mean ± SD 10 year coronary heart disease (CHD) risk fell by 7.3 ± 8.3% from 17.1 ± 12.6% to 9.8 ± 6.9% ($p < 0.001$). 10 year fatal CHD risk fell by 6.1 ± 7.2% from 12.5 ± 10.6% to 6.3 ± 5.4% ($p < 0.001$). 10 year stroke risk fell by 0.94 ± 1.35% from 5.92 ± 4.27% to 4.98 ± 3.45% ($p < 0.001$). 10 year fatal stroke risk fell by 0.27 ± 0.41% from 0.93 ± 0.78% to 0.66 ± 0.49% ($p < 0.001$). Additionally, weight, which is not a factor utilised in the UKPDS risk engine, fell by 15.7 ± 8.8 kg from 124.0 ± 30.1 to 108.3 ± 31.3 kg ($p < 0.001$), and BMI by 5.6 ± 3.3 kg/m^2 from 41.9 ± 8.2 to 35.3 ± 8.5 kg/m^2 ($p < 0.001$); serum alanine-aminotransferase (marker of hepatic steatosis) fell by 13.6 ± 19.7 U/L from 32.5 ± 20.1 to 18.6 ± 10.5 U/L ($p < 0.001$). Median (IQR) total daily insulin dose reduced from 104 (60–140) to 40 (0–80) units ($p < 0.001$), $n = 27$. 7/27 (26%) insulin treated patients discontinued insulin.

Conclusion: In addition to reducing the requirement for insulin and a liver fat biomarker, EndoBarrier treatment reduced 10-year CVD risk by clinically useful amounts in patients with poorly controlled diabetes and obesity. These data suggest that EndoBarrier treatment in 100 patients could prevent between 8 and 9 events of CHD or stroke and save between 6 and 7 lives over the next 10 years, if effects were maintained. The results are likely to be an underestimate of the true reductions as the UKPDS risk engine does not take into account weight or BMI which were significantly impacted by EndoBarrier treatment.

Parameter	Baseline	At Removal	Difference	P value (n=46)

Preclinical effects of efpeglenatide, a long-acting glucagon-like peptide-1 receptor agonist, compared with liraglutide and dulaglutide

M. Trautmann[1], I. Choi[2], J. Kim[2], C. Sorli[3];
[1]ProSciento, Inc., Chula Vista, USA, [2]Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea, [3]Sanofi, Bridgewater, USA.

Background and aims: Efpeglenatide is a long-acting glucagon-like peptide-1 receptor agonist (GLP-1 RA) in development for the treatment of type 2 diabetes.
Materials and methods: The effects of efpeglenatide vs those of liraglutide and dulaglutide on glucodynamics and weight/lipid profiles were studied over 4 weeks in mouse models of diabetes (db/db) and obesity (diet-induced obesity [DIO]), respectively; doses tested were efpeglenatide 1.45, 2.89, or 4.35 nmol/kg once every 2 days (Q2D); twice-daily liraglutide 30 nmol/kg (db/db study) or 50 nmol/kg (DIO study); and dulaglutide 0.98 or 1.96 nmol/kg Q2D (human equivalent doses/key results in Table).
Results: At the highest doses tested, efpeglenatide was significantly more effective at lowering blood glucose (vs liraglutide and dulaglutide) and reducing the increase in HbA_{1c} from Day 0 (vs liraglutide) in db/db mice. Efpeglenatide also improved insulin sensitivity (vs liraglutide and dulaglutide) and postprandial glucose control (vs dulaglutide). In DIO mice, efpeglenatide significantly reduced body weight and mesenteric fat mass (vs dulaglutide), and cholesterol (vs liraglutide and dulaglutide; at highest doses).
Conclusion: Overall, efpeglenatide showed greater reductions in blood glucose, HbA_{1c} increase, weight, and cholesterol vs other GLP-1 RAs in mice. These effects may be due to the distinct receptor-binding properties of efpeglenatide, which enhance intracellular signalling and insulin release in β-cells. Further studies are needed to assess the clinical relevance of these findings.

Table. Summary of the effects of GLP-1 RAs on glycaemic, weight, and lipid endpoints in db/db and DIO mice

	Vehicle	Efpeg 4.35 nmol/kg, Q2D (HED: 6.0 mg/wk)	Lira 30 nmol/kg, BID (HED: 1.8 mg/day)	Dula 1.96 nmol/kg, Q2D (HED: 3.0 mg/wk)	Comparison between efpeg vs GLP-1 RA
Glycaemic effects in db/db mice over 28 days					
Non-fasting blood glucose AUC (mg/dL * days)[a]	12254.2	3678.8***	7370.5***	5799.0***	p<0.001 vs lira; p<0.05 vs dula
Increment in HbA_{1c} (%) from baseline[b]	4.03	0.12***	1.47***	1.12***	p<0.01 vs lira
ipITT AUC (% mg/dL vs 0 hr * hrs)[c]	144.3	84.9***	121.7	115.4**	p<0.001 vs lira; p<0.01vs dula
ipGTT AUC (Δ mg/dL vs 0 hr * hrs)[d]	897.1	307.2***	468.1***	521.4***	p<0.05 vs dula
	Vehicle	**Efpeg 4.35 nmol/kg, Q2D (HED: 6.0 mg/wk)**	**Lira 50 nmol/kg, BID (HED: 3.0 mg/day)**	**Dula 1.96 nmol/kg, Q2D (HED: 3.0 mg/wk)**	**Comparison between efpeg vs GLP-1 RA**
Weight and lipid effects in DIO mice over 28 days					
Body weight change (% vs baseline)	3.42	−22.18***	−18.55***	−7.15**	p<0.001 vs dula
Mesenteric fat mass at Day 28 (g)	0.88	0.44***	0.50***	0.67*	p<0.05 vs dula
Total cholesterol (mg/dL)	310	167***	206***	243***	p<0.05 vs lira; p<0.001 vs dula

P-value vs vehicle: *p<0.05, **p<0.01, and ***p<0.001
[a]Non-fasting blood glucose (mg/dL) was monitored every day for the first week and then twice weekly; AUC of blood glucose was calculated (mg/dL * days)
[b]HbA_{1c} was measured at Day 0 and again at Day 28; the increment of HbA_{1c} (Δ %) was obtained by subtracting the value at Day 0 (baseline) from the value at Day 28
[c]For ipITT, the % change of blood glucose from 0 hr (immediately prior to the ipITT) was calculated at several time points (0.5, 1, 2, and 4 hrs) and used to calculate the AUC of % change of blood glucose from 0 hr
[d]For ipGTT, change in blood glucose from 0 hr (just before glucose loading) was calculated at several time points (0.25, 0.5, 1, and 2 hrs) and used to calculate the AUC of change in blood glucose from 0 hr. Both ipITT and ipGTT were conducted at study end
AUC=area under the curve; BID=twice daily; dula=dulaglutide; efpeg=efpeglenatide; HED=human equivalent dose; hr=hour; ipGTT=intraperitoneal glucose tolerance test; ipITT=intraperitoneal insulin tolerance test; lira=liraglutide, wk=week

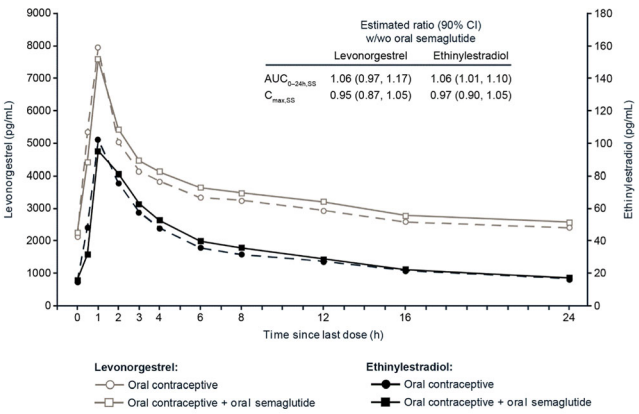
Oral semaglutide does not affect the bioavailability of the combined oral contraceptive, ethinylestradiol/levonorgestrel

A.B. Jordy[1], A. Breitschaft[2], E. Christiansen[1], C. Granhall[1], C.W. Hansen[1], A. Houshmand-Øregaard[1], T.A. Bækdal[1];
[1]Novo Nordisk A/S, Søborg, Denmark, [2]Parexel International GmbH, Berlin, Germany.

Background and aims: Semaglutide is a glucagon-like peptide-1 (GLP-1) analogue co-formulated with the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC), to allow oral administration. The effect of oral semaglutide on the pharmacokinetics of the combined oral contraceptive ethinylestradiol (0.03 mg)/levonorgestrel (0.15 mg) was assessed in an open-label, one sequence crossover trial.
Materials and methods: Healthy post-menopausal females ($n = 25$) received 8 days of oral contraceptive alone and 8 days of oral contraceptive with oral semaglutide (dose escalated to steady state at week 6: 1 week at 3 mg dose, 1 week at 7 mg dose, 4 weeks at 14 mg dose). Primary endpoints were total exposure to ethinylestradiol and levonorgestrel as measured by the areas under the plasma concentration-time curve during a dosing interval (0–24 h) at steady state ($AUC_{0-24h,SS}$). Secondary endpoints included other pharmacokinetic parameters, safety and tolerability.
Results: $AUC_{0-24h,SS}$ and maximum plasma exposure ($C_{max,SS}$) to ethinylestradiol and levonorgestrel appeared similar for oral contraceptive alone vs. oral contraceptive with oral semaglutide, and $AUC_{0-24h,SS}$ and $C_{max,SS}$ ratios were within the predefined no effect interval (0.8–1.25) (Figure). Adverse events with oral semaglutide at applied doses were consistent with previous trials and expected GLP-1 receptor agonist class effects.
Conclusion: These data indicate that oral semaglutide does not affect the bioavailability of the combined oral contraceptive ethinylestradiol and levonorgestrel.



For both $AUC_{0-24h,SS}$ and $C_{max,SS}$: no effect criterion is met if 90% CI is within the pre-defined interval 0.80–1.25.

A trial to investigate the effect of oral semaglutide on the pharmacokinetics of furosemide and rosuvastatin in healthy subjects

T.A. Bækdal[1], M. Albayaty[2], E. Manigandan[3], T.W. Anderson[1], S. Skibsted[1];
[1]Novo Nordisk A/S, Søborg, Denmark, [2]Parexel, London, UK, [3]Novo Nordisk, Bangalore, India.

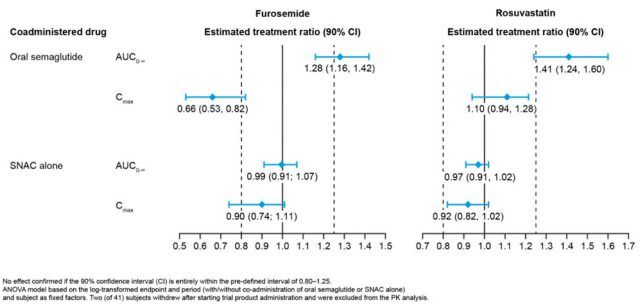
Background and aims: Oral semaglutide is a human glucagon-like peptide-1 (GLP-1) analogue co-formulated with an absorption enhancer,

sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC), for oral administration. *In vitro* assessments have indicated that SNAC may inhibit drug transporters (OAT1/3, BCRP, OATP1B1), potentially leading to increased plasma levels of transporter substrates such as furosemide (OAT1/3 substrate) or rosuvastatin (BCRP/OATP1B1 substrate). This open-label, one-sequence crossover trial investigated the effect of oral semaglutide and SNAC alone on the pharmacokinetics of furosemide and rosuvastatin.

Materials and methods: The trial consisted of three treatment periods during which 41 healthy subjects (39 of whom completed the trial) received single doses of furosemide 40 mg and rosuvastatin 20 mg alone, co-administered with SNAC 300 mg, and co-administered with oral semaglutide (dose escalated to steady state at week 6: 1 week at 3 mg dose, 1 week at 7 mg dose, 4 weeks at 14 mg dose). Primary endpoints were area under the furosemide or rosuvastatin plasma concentration-time curves from zero to infinity ($AUC_{0-\infty}$) after single doses. It was prespecified to conclude no effect of oral semaglutide or SNAC alone on exposure of furosemide or rosuvastatin if the 90% confidence interval (CI) for the treatment ratio (with/without oral semaglutide or SNAC alone) was entirely within the pre-defined interval (0.80–1.25). Secondary endpoints were other pharmacokinetic parameters, safety and tolerability.

Results: Co-administration of steady-state oral semaglutide with single-dose furosemide resulted in a 28% increase in total furosemide exposure ($AUC_{0-\infty}$) and a 34% decrease in maximum furosemide concentration (C_{max}). The no effect criterion was not met for either AUC or C_{max} (Figure). When co-administered with SNAC alone, there was no effect on the $AUC_{0-\infty}$ of single-dose furosemide while C_{max} decreased by 10%. Co-administration of steady-state oral semaglutide with single-dose rosuvastatin resulted in increases in both $AUC_{0-\infty}$ (41%) and C_{max} (10%) and the no effect criterion was not met for either endpoint. $AUC_{0-\infty}$ and C_{max} of rosuvastatin were not affected by co-administration of SNAC alone. The safety profile was as expected for the GLP-1 receptor agonist class and consistent with previous trials of oral semaglutide.

Conclusion: These data indicate that the SNAC component of oral semaglutide does not inhibit the transporters OAT1/3, BCRP or OATP1B1. Changes in exposure of furosemide and rosuvastatin when co-administered with oral semaglutide may be related to the known gastric emptying delaying effect of the GLP-1 component, which may influence both the rate and the extent of absorption of co-administered drugs. The observed changes in furosemide and rosuvastatin exposure are not expected to be clinically relevant.



No effect confirmed if the 90% confidence interval (CI) is entirely within the pre-defined interval of 0.80–1.25.
ANOVA model based on the log-transformed endpoint and period (with/without co-administration of oral semaglutide or SNAC alone) and subject as fixed factors. Two (of 41) subjects withdrew after starting trial product administration and were excluded from the PK analysis.

Investigations into tissue distribution and inhibition of food consumption with efpeglenatide

Y. Park[1], I. Choi[1], M. Trautmann[2], M. Hompesch[2], C. Sorli[3];
[1]Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea, [2]ProSciento, Inc., Chula Vista, USA, [3]Sanofi, Bridgewater, USA.

Background and aims: Efpeglenatide, a long-acting glucagon-like peptide-1 receptor agonist in development for type 2 diabetes, induces weight loss through satiety and reduced food intake. Studies in Sprague Dawley rats investigated how peripheral and central mechanisms contribute to the anorectic effects of efpeglenatide.

Materials and methods: Tissue distribution of efpeglenatide was assessed by whole-body autoradioluminography with ^{14}C-efpeglenatide. The contribution of vagal-nerve signalling to food-intake control was assessed in vagotomized rats treated with exenatide (0.15 or 0.45 nmol/kg twice daily) or efpeglenatide (0.71 or 2.1 nmol/kg every 2 days).

Results: Pharmacokinetic parameters of ^{14}C-efpeglenatide in selected organs/tissues are shown in the Table. Peak concentration (C_{max}) of ^{14}C-efpeglenatide was highest in the kidney cortex; C_{max} at all other sites was similar to/lower than in blood, relatively high in the intestine and pituitary, with below-quantifiable levels in the cerebellum/cerebrum. ^{14}C-efpeglenatide levels were highest in the kidney cortex at all time points (3, 24, 48, 144, 312, 480, 648, 888, and 1128 h). In blood, intestinal content, liver, lung, myocardium, pancreas, pituitary, and spleen, ^{14}C-efpeglenatide levels were below the limit of quantification or were not detected by 480 h. At all time points assessed, radioactivity levels in the cerebellum and cerebrum were below the limit of detection. Inhibition of food intake was not attenuated in vagotomized vs sham-operated rats at higher doses of efpeglenatide (3-day cumulative intake: 47.4 vs 49.4 g) or exenatide (54.9 vs 60.7 g), suggesting a non-vagal mechanism for these anorectic effects.

Conclusion: These findings suggest that central mechanisms are involved in the anorectic effects of efpeglenatide in this animal model; potential cell-signalling effects of efpeglenatide in the intestine and pituitary need to be investigated further.

Table. Pharmacokinetic parameters in select organs and tissues following single subcutaneous administration of radiolabelled efpeglenatide at a target dose level of 24 nmol/kg in male Sprague Dawley rats

Mono- and co-activation of the GIP and GLP-1 receptors inhibits bone resorption

N.C. Bergmann[1,2], A. Lund[1,3], S.M. Heimbürger[1], L.S. Gasbjerg[1,4], N.R. Jørgensen[5,6], L. Jessen[2], B. Hartmann[4], J.J. Holst[4], M.B. Christensen[1,7], T. Vilsbøll[1,8], F.K. Knop[1,8];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Gentofte Hospital, University of Copenhagen, Hellerup, [2]Zealand Pharma A/S, Glostrup, [3]Department of Medicine, Gentofte Hospital, Hellerup, [4]Department of Biomedical Sciences and Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, [5]Department of Clinical Chemistry, Rigshospitalet, University of Copenhagen, Glostrup, [6]OPEN, Odense Patient data Explorative Network, Odense University Hospital, Odense, [7]Department of Clinical Pharmacology, Bispebjerg Hospital, Copenhagen, [8]Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark.

Background and aims: This study investigated the effect of mono- and co-administration of the incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) on bone resorption and formation.
Materials and methods: Seventeen overweight/obese men without diabetes were included in a randomised, double-blinded, placebo-controlled, cross-over study and subjected to a 50 g OGTT and four isoglycaemic intravenous glucose infusions (IIGI), mimicking the glucose excursions from the OGTT, with concomitant infusions of GIP (4 pmol/kg/min), GLP-1 (1 pmol/kg/min), GIP+GLP-1 (4 and 1 pmol/kg/min, respectively) or placebo. Bone resorption and formation were assessed by measurements of carboxy-terminal type I collagen crosslinks (CTX), and procollagen type 1 N-terminal propeptide (P1NP), respectively.
Results: Suppression of CTX is shown in Fig. 1. During OGTT the baseline-subtracted AUC (bsAUC) was significantly lower than during IIGI+saline infusion (−9,117 ± 566 (mean ± SEM) vs −4333 ± 583% × min, $p < 0.0001$). Infusion of GLP-1 and GIP significantly potentiated CTX suppression to −10,751 ± 799% × min and −13,714 ± 440% × min, respectively. Co-administration of GIP+GLP-1 suppressed CTX to −15,466 ± 268% × min. P1NP levels were unaffected.
Conclusion: Our data suggest that GLP-1, like GIP, may be involved in bone homeostasis and that co-administration of GIP+GLP-1 inhibits bone resorption more than each hormone alone.

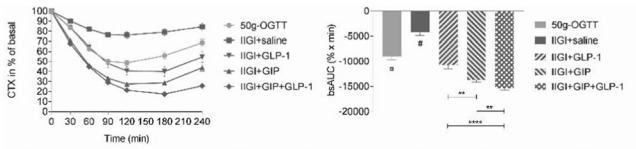

Figure 1. A) Carboxy-terminal type I collagen crosslinks (CTX) values in % of basal during 50g OGTT and four isoglycaemic intravenous glucose infusions (IIGI) with co-infusion of saline, glucagon-like peptide-1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP) and GIP+GLP-1, respectively. B) baseline-subtracted AUC values. Data are means±SEM, n=17. ¤The 50g OGTT differed from the other study days, $p<0.05$. # The IIGI−saline days differed from the other study days, $p<0.0001$. **$p<0.005$, ****$p<0.0001$

MEDI0382, a glucagon-like peptide/glucagon receptor dual agonist, in patients with type 2 diabetes: a multiple-ascending-dose study

D. Robertson[1], M. Stumvoll[2], M. Posch[3], T. Heise[4], L. Plum-Moerschel[5], G. Klein[6], L.-F. Tsai[7], M. Petrone[1], B. Hirshberg[7], C. Rondinone[7], V. Parker[1], L. Jermutus[1], P. Ambery[1];
[1]MedImmune, Cambridge, UK, [2]University Hospital Leipzig, Leipzig, Germany, [3]Charité Research Organisation GmbH, Berlin, Germany, [4]Profil, Neuss, Germany, [5]Profil, Mainz, Germany, [6]APEX GmbH, Munich, Germany, [7]MedImmune, Gaithersburg, USA.

Background and aims: MEDI0382 is a glucagon-like peptide 1 (GLP-1)/glucagon receptor dual agonist under development for the treatment of type 2 diabetes mellitus. and nonalcoholic steatohepatitis. This double-blind study evaluated MEDI0382 in patients with type 2 diabetes and a body mass index of 27–40 kg/m^2.
Materials and methods: Subjects ($n = 61$) were randomized to once-daily subcutaneous MEDI0382 or placebo at different dosing levels and uptitration schedules (100 μg [cohort 1], 150 μg [cohort 2], 200 μg [cohort 3], and 300 μg [2 uptitration schedules, cohorts 4 and 5]).
Results: Marked reduction in fasting and postprandial glucose was achieved with $a \approx 40\%$ decrease in glucose $AUC_{0\text{-}4h}$ after mixed-meal testing across all cohorts ($P \leq 0.0102$) (Table). Weight loss was observed at all dose levels and reached statistical significance ($P = 0.024$) at 300 μg (cohort 4) (Table). Ambulatory systolic blood pressure decreased nonsignificantly from baseline in the 300-μg cohort (cohort 4, −4.9 vs −6.5 mmHg; cohort 5, −9.1 vs −5.0 mmHg). Similar to other marketed GLP-1 analogs, MEDI0382 increased pulse rate vs placebo (cohort 4, 8.4 vs −2.4 bpm, $P = 0.0039$; cohort 5, 5.8 vs 0.2 bpm, $P = 0.0796$). Treatment-related adverse events occurred more often with MEDI0382 than with placebo (86% [36/42] vs 47% [9/19]); most events were mild or moderate in severity. Nausea and vomiting occurred more frequently with MEDI0382 vs placebo; however, their occurrence was not dose related.
Conclusion: In conclusion, MEDI0382 administered for up to 22 days showed a marked reduction in both fasting and postprandial glucose with weight reduction and an acceptable tolerability profile.

Table. Change from baseline in efficacy endpoints in subjects treated with MEDI0382 vs placebo

Cohort (days on treatment)	Glucose $AUC_{0\text{-}4h}$ post-MMTT (%)[a]	Body weight (kg)[b]	Fasting glucose (mg/dL)[a]
1 (8)	−41.9 vs −14.3 ($P = 0.0102$)	−2.1 vs −1.7 ($P = 0.6549$)	−73.6 vs −34.2 ($P = 0.0019$)
2 (12)	−37.1 vs −14.3 ($P = 0.0026$)	−1.5 vs −1.0 ($P = 0.4286$)	−60.5 vs −37.1 ($P = 0.0316$)
3 (16)	−37.0 vs −5.6 ($P = 0.0003$)	−4.5 vs −3.3 ($P = 0.3251$)	−54.2 vs −23.1 ($P = 0.0044$)
4 (22)	−41.7 vs −14.5 ($P = 0.0001$)	−3.4 vs −0.7 ($P = 0.0240$)	−53.6 vs −33.8 ($P = 0.0694$)

A novel combination of a long-acting GLP-1/GIP/Glucagon triple agonist and once weekly basal insulin offers improved glucose lowering and weight loss in diabetic animal model

J. Lee, J. Kim, J. Choi, S. Jung, S. Lee, I. Choi, S. Kim;
Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea.

Background and aims: Obesity is an established risk factor for the aggravation of pre-existing diabetes by negatively affecting lipid metabolism, insulin response, and eventually β-cell function. In this respect,

effective body weight loss (BWL) not only prevents or delays the onset of T2DM, but also enhances the response to conventional diabetes drugs including basal insulin in T2DM patients. Recently, we developed a novel long-acting GLP-1/GIP/Glucagon triple agonist, HM15211, which showed potent BWL in various obese animal models. Thus, we hypothesized that when combined with basal insulin, HM15211 could maximize the exogenous insulin response by providing potent BWL and following insulin sensitivity improvement. Here, we investigated the therapeutic potential of HM15211 and long-acting basal insulin combination for T2DM treatment by evaluating 1) drug-to-drug interaction (DDI) *in vitro* and *in vivo*, and 2) glycemic and BW control efficacy in diabetic animal models.

Materials and methods: *In vitro* human insulin receptor (hIR) phosphorylation potency by long-acting basal insulin (HM12460A) or its analog (HM12480) was evaluated in CHO cell stably expressing hIR in the presence or absence of HM15211. Similarly, cAMP accumulation potency by HM15211 was evaluated in CHO cells stably expressing respective receptors (human GLP-1R, GCGR, or GIPR) in the presence or absence of insulin counter partners. For PK assessment, HM15211 and/or HM12460A (or HM12480) were subcutaneously administered in SD rats. Blood samples were collected at indicated time points, and their blood concentration were determined using in-house established ELISA. To evaluate the *in vivo* efficacy, *db/db* mice and DIO/STZ rats were chronically administered with HM15211 and/or HM12460A (or HM12480), and blood glucose and BW were monitored. At the end of the treatment, HbA1c levels were measured to determine overall glycemic control efficacy.

Results: Firstly, hIR phosphorylation potency of either HM12460A or HM12480 was not affected by concomitant treatment of HM15211 (EC_{50} = 249.4 *vs.* 203.2 nM for HM12460A mono *vs.* COMBO, EC_{50} = 433.8 *vs.* 491.7 nM for HM12480 mono *vs.* COMBO). Similar results were also observed when cAMP accumulation potency of HM15211 was determined (EC_{50} = 0.027 *vs.* 0.030, and 0.030 nM for HM15211 mono *vs.* HM12460A COMBO, and HM12480 COMBO, for hGCGR/CHO cell activation). Secondly, both HM15211, HM12460A, and HM12480 showed favorable PK profiles as indicated by prolonged half-lives, and did not affect counter partners' PK properties in SD rats, demonstrating no DDI *in vivo*. Of note, compared to HM12460A, HM12480 showed more harmonized PK profiles with HM15211. Lastly, HM15211 combination either with HM12460A or HM12480 showed enhanced blood glucose lowering and more HbA1c reduction, compared to insulin mono treatment both in *db/db* mice and DIO/STZ rats. Most interestingly, HM15211 combination efficiently reduced BW, not just BW gain neutralization observed in insulin/GLP-1 combination, demonstrating their therapeutic benefits in BW control as well as glycemic control.

Conclusion: Based on these observations, we propose that HM15211 may be a novel combination partner of our long-acting basal insulin such as HM12460A and HM12480 by providing more favorable BW control as well as improved glycemic control in obese and T2DM patients.

PS 057 Lipids and fatty liver: What GLP1 receptor agonists can do

720

The effect of liraglutide treatment on postprandial remnant particles, apoCIII, liver fat and de novo lipogenesis in adequately controlled type 2 diabetes

N. Matikainen[1,2], S. Söderlund[2], K.H. Pietiläinen[2], E. Björnson[3], A. Hakkarainen[4], N. Lundbom[4], J. Borén[3], M.-R. Taskinen[2];
[1]Endocrinology, Helsinki University Hospital, Helsinki, Finland, [2]Research Programs Unit, Diabetes and Obesity, Helsinki, Finland, [3]Department of Molecular and Clinical Medicine, University of Gothenburg, Gothenburg, Sweden, [4]HUS Medical Imaging Center, Radiology, Helsinki, Finland.

Background and aims: Subjects with type 2 diabetes remain in high cardiovascular disease (CVD) risk despite of multifactorial interventions targeted against hyperglycemia, hyperlipidemia and hypertension. Incretin-based therapy with liraglutide reduces CVD risk by partly unexplained mechanisms. Previous data suggest that reversal of the incretin effect alleviates postprandial lipemia and may reduce liver fat. Here, we tested the combined effect of liraglutide on ectopic fat depots and postprandial lipid metabolism. To elucidate whether these metabolic effects are driven by weight reduction we aimed at similar weight loss in the liraglutide and placebo groups.

Materials and methods: We examined the effect of liraglutide on background of simvastatin and metformin therapy on 22 subjects with adequately controlled type 2 diabetes with mean HBA1c of 7% and 6.3% at baseline. Subjects were randomly allocated in 2:1 ratio to single-blinded liraglutide 1.8 mg o.d. or placebo treatments for 16 weeks. Subjects in placebo group received dietary counselling in order to lose 3 kg of body weight. Hepatic, intra-abdominal and subcutaneous fat depots, de novo lipogenesis (DNL), fat oxidation, postprandial lipids, apoproteins, glucose and insulin during a high-fat mixed meal were measured before and at the end of the treatment period.

Results: Weight loss at week 16 was similar between the two groups; −2.4 kg (−2.5%) in the liraglutide group and −2.1 kg (−2.2%) in placebo group. HBA1c improved by 0.6% in the liraglutide group (p = 0.006). Liver fat was reduced by 31% in liraglutide group and by 18% in the placebo group. Although liver fat decreased in both groups, no changes occurred in DNL or β-hydroxybutyrate level (a surrogate marker of fat oxidation). Despite similar weight loss, we found significant postprandial decreases of plasma, chylomicron and VLDL triglycerides and postprandial remnant particle cholesterol concentrations at week 16 in the liraglutide group. Both fasting and postprandial apoCIII concentrations were decreased at week 16 in the liraglutide group and these changes were closely related to improvement in glycemia. In relative importance analysis, less than 10% of changes in postprandial lipids were explained by improvements in weight, glycaemic control, insulin AUC or liver fat. Instead, reductions in apoCIII concentrations explained about 50% of the variation in these variables.

Conclusion: We report that treatment with liraglutide for 16 weeks produces multiple improvements in cardiometabolic risk factors not seen in the placebo group with similar weight loss. Importantly, liraglutide treatment resulted in a marked reduction of postprandial atherogenic remnant particles. The underlying mechanism is consistent with the hypothesis that improvement of glycaemic control leads to reduced expression of apoCIII, a key regulator of triglyceride metabolism in type 2 diabetes subjects.

Effect of the exenatide plus dapagliflozin combination on fatty liver index and insulin resistance in type 2 diabetes patients: the DURATION-8 trial

C. Guja[1], E. Repetto[2], J. Han[3], E. Hardy[2], S.A. Jabbour[4];
[1]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania, [2]AstraZeneca, Gaithersburg, USA, [3]Pharmapace Inc., San Diego, USA, [4]Thomas Jefferson University, Philadelphia, USA.

Background and aims: Type 2 diabetes mellitus (T2DM) is often associated with obesity and the risk of developing hepatic steatosis. Exenatide once weekly (ExQW) and dapagliflozin (DAPA) reduce glycaemia and body weight in T2DM patients. This analysis explored the effects of ExQW+DAPA vs ExQW+placebo (PBO) or DAPA+PBO on weight, fatty liver index (FLI) and insulin resistance in T2DM patients inadequately controlled by metformin.
Materials and methods: DURATION-8 was a multicentre, double-blind, randomized, phase 3 trial. Adults with T2DM and inadequate glycaemic control (baseline HbA_{1c} 8%–12%) despite stable metformin monotherapy were randomly assigned to receive ExQW 2 mg plus once daily oral DAPA 10 mg, ExQW with DAPA matched oral PBO or DAPA with ExQW matched PBO injections for 28 weeks. Patients entered a 24-week extension period where they continued to receive randomised active treatment. Changes in body weight, FLI (as determined by an algorithm based on body mass index, waist circumference, triglycerides and gamma-glutamyltransferase) and insulin resistance (homeostasis model assessment-insulin resistance [HOMA-IR]) from baseline to weeks 28 and 52 were studied and within-treatment and between-group comparisons were performed using analysis of covariance (ANCOVA). Correlations between FLI and HOMA-IR were evaluated.
Results: In total, 231, 230 and 233 patients received ExQW+DAPA, ExQW+PBO and DAPA+PBO, respectively. Baseline characteristics were similar across treatment groups (Table). ExQW+DAPA was significantly superior to either drug alone in achieving weight loss at 28 and 52 weeks ($P < 0.001$). Significant improvement in FLI was seen with ExQW+DAPA at week 28 (least square [LS {SEM}]: −6.81 [0.87], $P < 0.0001$) and was maintained at week 52 (LS [SEM]: −6.23 [1.02], $P < 0.0001$). HOMA-IR significantly improved in the ExQW+DAPA group at week 28 (geometric LS mean ratio to baseline [95% CI]: 0.81 [0.75–0.88], $P < 0.0001$) and week 52 (LS mean ratio to baseline [95%CI]: 0.80 [0.74–0.87], $P < 0.0001$). Changes in FLI (from baseline) correlated with HOMA-IR (ratio of week 28 or week 52 values to the baseline value) in all treatment groups (week 28: $r = 0.37$, 0.09 and 0.23; week 52: $r = 0.12$, 0.30 and 0.27 for ExQW+DAPA, ExQW+PBO and DAPA+PBO, respectively).
Conclusion: Combination of ExQW and DAPA has demonstrated efficacy in reducing body weight and other metabolic parameters in T2DM patients inadequately controlled on metformin. ExQW+DAPA also showed an improvement in FLI and insulin resistance that was sustainable up to 52 weeks.

Table. Study parameters at baseline, week 28 and week 52

Parameters		ExQW+DAPA (N=228)	ExQW+PBO (N=227)	DAPA+PBO (N=230)
Weight (kg)	Baseline	91.79 (22.24)	89.77 (20.22)	91.06 (19.71)
	Week 28	88.35 (20.57)[a]	87.62 (18.05)[b]	88.64 (18.90)[c]
	Week 52	89.44 (20.99)[d]	89.69 (18.00)[e]	89.49 (16.85)[f]

Liraglutide in combination with metformin reduces lipolysis and lipid oxidation in patients with well controlled type 2 diabetes and ischaemic heart disease

C. Anholm[1,2], P. Kumarathurai[3], L.R. Pedersen[3], A. Samkani[4], O.P. Kristiansen[3], O.W. Nielsen[3], M. Fenger[5], S. Madsbad[6], A. Sajadieh[3], R.C. Boston[7], S.B. Haugaard[4,2];
[1]Department of Internal Medicine, Copenhagen University Hospital, Glostrup, Glostrup, Denmark, [2]Department of Internal Medicine, Copenhagen University Hospital, Amager, Copenhagen, Denmark, [3]Department of Cardiology, Copenhagen University Hospital, Bispebjerg, Copenhagen, Denmark, [4]Department of Endocrinology, Copenhagen University Hospital, Bispebjerg, Copenhagen, Denmark, [5]Department of Clinical Biochemistry, Copenhagen University Hospital, Hvidovre, Hvidovre, Denmark, [6]Department of Endocrinology, Copenhagen University Hospital, Hvidovre, Hvidovre, Denmark, [7]Department of Clinical Studies–New Bolton Center, School of Veterinary Medicine,, Pennsylvania, USA.

Background and aims: Type 2 diabetes (T2DM) is associated with dyslipidemia which are a risk factor for cardiovascular disease and cardiovascular mortality. Elevated levels of non-esterified fatty acids (NEFA), i.e. lipotoxicity, plays a role in the development of insulin resistance, impaired beta-cell function and is also a major denominator of the abnormal atherogenic lipid profile characterizing obese T2DM. It is hypothesized that the GLP-1 receptor agonist liraglutide in combination with metformin may reduce lipolysis and, thereby improves insulin sensitivity and beta-cell function.
Materials and methods: A randomized, double-blind, placebo-controlled, cross-over trial in 12 + 12-week periods with ≥2-weeks wash-

out. Intervention: liraglutide/metformin vs. placebo/metformin. Based on plasma NEFA and glucose levels measured during a standard 180 minutes insulin modified frequently sampled intravenous glucose tolerance test, NEFA kinetics was estimated by the Boston NEFA minimal model. First phase insulin response (AIRg) and insulin sensitivity (Si) were estimated by MINMOD minimal model analysis.

Results: Of 41 patients randomized thirty completed all study visits, n = 28 had data sets available for minimal modelling and paired analysis. Liraglutide in combination with metformin reduced lipolysis by 30% from baseline 36.6 (10.4) μmol/L/min ($p < 0.001$). Metformin in combination with placebo increased lipid oxidation by 2.4 (0.9) %/min ($p < 0.001$) from baseline level 4.4 (0.8) %/min, however adding liraglutide to metformin halved lipid oxidation (−49%, $p < 0.001$). Insulin sensitivity Si did not differ while AIRg improved 3-fold with liraglutide treatment compared with placebo.

Conclusion: Liraglutide exerted a remarkable reduction in both lipolysis and lipid oxidation during an intravenous glucose tolerance test, which may be explained by improved insulin secretion. This mechanism of action of liraglutide may add to the explanation of the improved long-term outcome in in patients with ischaemic heart disease and T2DM treated with liraglutide.

The effect of efpeglenatide on lipid profiles and overall metabolism in patients with type 2 diabetes and obese patients without diabetes

K.-H. Yoon[1], J. Kang[2], I. Choi[2], M. Trautmann[3], M. Hompesch[3], C. Sorli[4], R. Pratley[5];
[1]The Catholic University of Korea, Seoul, Republic of Korea, [2]Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea, [3]ProSciento, Inc., Chula Vista, USA, [4]Sanofi, Bridgewater, USA, [5]Translational Research Institute for Metabolism and Disease, Florida Hospital, Orlando, USA.

Background and aims: Once-weekly (QW), subcutaneous efpeglenatide is a long-acting glucagon-like peptide-1 receptor agonist (GLP-1 RA) in development for type 2 diabetes (T2D). In a 12-week Phase 2 study in patients with T2D (EXCEED 203), treatment with efpeglenatide 3 and 4 mg QW was associated with significant ($p < 0.05$) reductions in HbA_{1c} (−1.41% [baseline: 7.82%] and −1.61% [baseline: 7.99%], respectively) vs placebo (−0.40% [baseline: 7.99%]). Fasting plasma glucose was also reduced in the efpeglenatide 3- and 4-mg groups (−2.25 mmol/L [baseline: 9.09 mmol/L] and −2.50 mmol/L [baseline: 9.15 mmol/L], respectively) vs placebo (−0.55 mmol/L [baseline: 9.06]). In a 20-week Phase 2 study in patients with obesity without diabetes (BALANCE 205), treatment with efpeglenatide 4 or 6 mg QW was associated with significant ($p < 0.05$) reductions in body weight (−6.63 kg [baseline: 100.81 kg] and −7.32 kg [baseline: 101.68 kg], respectively) vs placebo (−0.13 kg [baseline: 97.54 kg]).

Materials and methods: To assess whether these effects were associated with benefits on lipids, the effects of efpeglenatide QW on total cholesterol, LDL-cholesterol (LDL-C), HDL-C, VLDL-C, and triglycerides (TG) were assessed in patients from these Phase 2 trials (VLDL-C was measured in BALANCE 205 only).

Results: In the 12-week EXCEED 203 study in patients with T2D, efpeglenatide 4 mg QW led to significant ($p < 0.05$) reductions vs placebo in LDL-C and TG (Table). In the 20-week BALANCE 205 study in non-diabetic patients with obesity, efpeglenatide QW led to significant reductions vs placebo in total cholesterol, VLDL-C, TG (4-mg and 6-mg doses), and LDL-C and HDL-C (6 mg only). The safety profile of efpeglenatide in both trials was consistent with GLP-1 RAs; the proportions of patients who experienced any treatment-emergent adverse events were 62.2%, 66.7%, and 66.7% with placebo, efpeglenatide 3 mg, and efpeglenatide 4 mg, respectively, in EXCEED 203 and 80.0%, 86.4%, and 91.5% with placebo, efpeglenatide 4 mg, and efpeglenatide 6 mg, respectively, in BALANCE 205.

Conclusion: These findings suggest that loss of body weight and glycaemic effects with efpeglenatide are accompanied by significant benefits on lipid profiles, providing an overall improvement in the abnormal metabolic state associated with T2D.

Liraglutide and metformin may rock and roll the most atherogenic LDL fraction in patients with diabetes and ischaemic heart disease on stable statin therapy: a randomised trial

S.B. Haugaard[1,2], C. Anholm[3,2], P. Kumarathurai[4], L.R. Pedersen[4], A. Samkani[1], R.L. Walzem[5], O.P. Kristiansen[4], O.W. Nielsen[4], M. Fenger[6], S. Madsbad[7], A. Sajadieh[4];
[1]Department of Endocrinology, Copenhagen University Hospital, Bispebjerg, Copenhagen, Denmark, [2]Department of Internal Medicine, Copenhagen University Hospital, Amager, Copenhagen, Denmark, [3]Department of Internal Medicine, Copenhagen University Hospital, Glostrup, Glostrup, Denmark, [4]Department of Cardiology, Copenhagen University Hospital, Bispebjerg, Copenhagen, Denmark, [5]Department of Poultry Science and Faculty of Nutrition, Texas A&M University, College Station, USA, [6]Department of Clinical Biochemistry, Copenhagen University Hospital, Hvidovre, Hvidovre, Denmark, [7]Department of Endocrinology, Copenhagen University Hospital, Hvidovre, Copenhagen, Denmark.

Background and aims: Atherosclerosis in type 2 diabetes (T2DM) and obesity is multifactorial and associated with low-grade inflammation and dyslipidemias, especially small low dense lipoprotein particles are atherogenic. The glucagon-like peptide-1 receptor agonist, liraglutide, reduces cardiovascular events by unclear mechanisms. We investigated the effect of liraglutide combined with metformin on lipoprotein density profiles and low-grade inflammation and in patients with ischaemic heart disease and newly diagnosed well-controlled T2DM on stable statin therapy.

Materials and methods: A randomized, double-blind, placebo-controlled, cross-over trial in 12 + 12-weeks periods with ≥2-weeks washout. Intervention: liraglutide/metformin vs. placebo/metformin. Biochemical analysis was done at the beginning and end of each 12-weeks periods. Lipoproteins were separated by continuous density gradient ultracentrifugation and divided into HDL and LDL subfractions (5 each). The amount of particles in each subfraction was determined as the AUC of the density profile curve. Plasma C-reactive protein (CRP) and TNF-α were determined by the enzyme-linked immunosorbent-assay.

Results: Of 41 patients randomized thirty completed all study visits and were included in paired analysis, except from one patient, who had statin

dosage changed during the study. At baseline 95% of the patients were on statin therapy with LDL 2.3 (0.7) mmol/L (Friedwalds formula). LDL was divided in subfractions between 226–270 Å, considering particle sizes ≤255 Å as the most atherogenic. Liraglutide in combination with metformin reduced the most atherogenic subfraction LDL_5 by 17% ($p = 0.03$) from baseline level. Subgroup analysis comparing the "liraglutide-first" to "placebo-first" groups revealed that liraglutide significantly suppressed the LDL_5 fraction by 16% ($p = 0.03$) during treatment, but the subfraction rebounded significantly ($p = 0.03$) to pre-treatment value at the end of the wash-out period. HDL subfractions were not significantly affected by liraglutide combined to metformin. Markers of low-grade inflammation were at baseline slightly elevated, but the combination of liraglutide/metformin improved only CRP but not TNF-α.

Conclusion: Liraglutide in combination with metformin significantly improved the most atherogenic LDL subfraction and CRP in patients on stable statin therapy, with ischaemic heart disease and newly diagnosed well-controlled T2DM.

Effects of liraglutide versus placebo on gallbladder events: results from the LEADER trial

M.A. Nauck[1], H.A. Sævereid[2], M.L.M. Ghorbani[2], E. Kreiner[2], J. Buse[3], LEADER Publication Committee on behalf of the LEADER Trial Investigators;
[1]Diabetes Center Bochum-Hattingen, St Josef Hospital (Ruhr-Universität Bochum), Bochum, Germany, [2]Novo Nordisk A/S, Søborg, Denmark, [3]University of North Carolina School of Medicine, Chapel Hill, USA.

Background and aims: Patients with type 2 diabetes (T2D) have an increased risk of gallbladder disease. In the LEADER trial, cholelithiasis and cholecystitis were more frequent in patients with T2D randomised to liraglutide 1.8 mg vs placebo (PBO). The present post hoc analysis further explored the clinical features of the imbalance in gallbladder events in the liraglutide and PBO groups.

Materials and methods: In LEADER, 9340 patients with T2D and high cardiovascular (CV) risk were randomised 1:1 to liraglutide 1.8 mg or PBO, on top of standard of care, and followed for 3.5–5 years. Acute gallstone disease was a predefined area of special interest and events were systematically captured. Events were defined as gallbladder disease including biliary colic, symptomatic cholelithiasis and cholecystitis, and identified for analysis using predefined Medical Dictionary for Regulatory Activities (MedDRA) search criteria. All captured events were blind-reviewed post hoc by medically qualified persons, and grouped into 4 categories based on the clinical features described: uncomplicated gallbladder stones (gallbladder stones supported by imaging, but no cholecystitis, bile duct stones, pain or signs of cholestasis, invasive procedures or surgery), complicated gallbladder stones, cholecystitis (with/without gallbladder stones) or biliary obstruction. Cholecystectomy due to the events was also evaluated. Time to first event by treatment (liraglutide vs PBO) was analyses using Cox regression independently for all categories.

Results: The MedDRA search captured 275 events, most frequently reported as cholelithiasis (119), acute cholecystitis (59) and cholecystitis (26). Based on the post hoc review, 7 events (5 liraglutide, 2 PBO) were found to be unrelated to biliary disease and excluded from analyses.

No differences at baseline were seen in patients experiencing an event in the liraglutide group vs PBO with respect to weight, BMI, age, gender, diabetes duration, triglycerides or LDL cholesterol, and no apparent differences were observed in patients with an event vs those without. Overall, acute gallstone disease was more common with liraglutide vs PBO (141 patients [3.0%] vs 88 [1.9%]; HR 1.60, 95% CI 1.23–2.09), and more common with liraglutide vs PBO for all 4 categories: uncomplicated gallbladder stone (16 patients [0.3%] vs 5 [0.1%]; HR 3.19, 95% CI 1.17–8.70), complicated gallbladder stone (52 patients [1.1%] vs 40 [0.9%]; HR 1.30, 95% CI 0.86–1.96), cholecystitis (51 patients [1.1%] vs 33 [0.7%]; HR 1.54, 95% CI 0.99–2.39) and biliary obstruction (25 patients [0.5%] vs 16 [0.3%]; HR 1.56, 95% CI 0.83–2.91). Cholecystectomy was more common in patients treated with liraglutide vs PBO (81 patients [1.74%] vs 52 [1.11%]; HR 1.56, 95% CI 1.10–2.20).

Conclusion: These detailed post hoc analyses of gallbladder-related events in LEADER demonstrate increases in the incidence with liraglutide- vs PBO-treatment in 4 categories, representative of different clinical diagnoses. In addition, the increased incidence of cholecystectomies is correlated with the increase in gallbladder-related events. Further research should explore relevant mechanisms and measures to prevent gallbladder-related events with glucagon-like peptide-1 receptor agonists.

HbA_{1c} changes in subjects with obesity without diabetes receiving semaglutide for weight management

O. Mosenzon[1], J. Wilding[2], A.L. Birkenfeld[3], B. McGowan[4], S.D. Pedersen[5], S. Wharton[6], P. Auerbach[7], L. Endahl[7], C.G. Carson[7], P.M. O'Neil[8];
[1]Hadassah Hebrew University Hospital, Jerusalem, Israel, [2]University of Liverpool, Liverpool, UK, [3]University Clinic Dresden, Dresden, Germany, [4]Guy's and St Thomas NHS Foundation Trust, London, UK, [5]C-ENDO Diabetes & Endocrinology Clinic, Calgary, AB, Canada, [6]York University, Toronto, Canada, [7]Novo Nordisk, Søborg, Denmark, [8]Medical University of South Carolina, Charleston, USA.

Background and aims: Elevated HbA_{1c} below diabetic levels is common in obesity and associated with an increased risk of type 2 diabetes (T2D). Semaglutide (SEMA) is a human glucagon-like peptide 1 analogue approved for T2D and under evaluation for weight management. A randomised, placebo (PBO)-controlled phase 2 trial of once-daily SEMA (0.05, 0.1, 0.2, 0.3, or 0.4 mg s. c. following escalation every 4 weeks [q4w] or 2 weeks) in adults with obesity without diabetes (screening HbA_{1c} <6.5%) showed mean week 52 weight loss on q4w SEMA between −6.0% (0.05 mg) and −13.8% (0.4 mg), vs −2.3% on PBO. We report a *post hoc* analysis of HbA_{1c} changes in this study.

Materials and methods: Baseline (BL) to week 52 changes in HbA_{1c} and body weight (%-points) were evaluated for 0.3 and 0.4 mg/day q4w SEMA and the PBO group (overall $N = 341$), in subgroups with normal HbA_{1c} (<5.7%) or elevated HbA_{1c} (≥5.7%) at BL. All available on- or off-treatment data were used in an analysis of covariance model (treatment, region and sex as fixed factors). Missing data were imputed from the PBO group (jump-to-reference multiple imputation).

Results: At BL, 65% (222/341) had normal HbA_{1c} and 35% (119/341) elevated HbA_{1c}. Across the evaluated groups, median normal HbA_{1c} was 5.3–5.4% (range 4.3–5.6%), vs 5.8–5.9% (5.7–7.0%) for elevated HbA_{1c}. By week 52, 75–77% with elevated BL HbA_{1c} achieved normal HbA_{1c} on SEMA, vs 24% on PBO. Only 2–5% progressed from normal to elevated HbA_{1c} on SEMA, vs 9% on PBO (Table). SEMA-related changes in HbA_{1c} were larger in those with elevated BL HbA_{1c}. Estimated mean change in HbA_{1c} vs PBO for 0.3 and 0.4 mg SEMA was −0.32% (95% CI −0.47; −0.16) and −0.45% (−0.61; −0.29), respectively, in the elevated group, −0.18% (−0.27; −0.09) and −0.19% (−0.28; −0.10) in the normal group. Mean estimated body-weight change vs PBO for 0.3 and 0.4 mg SEMA was −9.2% (−12.6; −5.8) and −10.2% (−13.7; −6.7),

respectively, for elevated BL HbA_{1c}, −8.4% (−11.2; −5.5) and −12.2% (−15.0; −9.4) for normal BL HbA_{1c} (all $P \leq 0.0001$). Treatment was generally tolerated, with no severe or documented symptomatic hypoglycaemic episodes reported in these groups.

Conclusion: A third of individuals evaluated had elevated BL HbA_{1c}, and most treated with SEMA 0.3 or 0.4 mg achieved normal levels by week 52. HbA_{1c} reductions were greater in those with elevated HbA_{1c} than in those without, but this did not appear to correlate with differences in weight loss. Further studies are needed to determine whether SEMA reduces progression to T2D in people with obesity and elevated HbA_{1c}.

	Normal Baseline HbA_{1c} (<5.7%)		Elevated Baseline HbA_{1c} (≥5.7%)

MEDI0382, a glucagon-like peptide 1/glucagon receptor dual agonist, significantly reduces hepatic fat content in subjects with type 2 diabetes

M. Jain[1], L.-F. Tsai[2], D. Robertson[1], B. Hirshberg[2], P. Hockings[3], L. Johansson[3], P. Ambery[1];
[1]MedImmune, Cambridge, UK, [2]MedImmune, Gaithersburg, USA, [3]Antaros Medical AB, Molndal, Sweden.

Background and aims: MEDI0382 is a balanced glucagon-like peptide 1 (GLP-1)/glucagon receptor dual agonist in development for type 2 diabetes mellitus and nonalcoholic steatohepatitis. We investigated the effects of MEDI0382 on hepatic fat content in overweight/obese subjects with type 2 diabetes and a body mass index of 27–40 kg/m^2.

Materials and methods: In a phase 2a study, 51 subjects were randomized to receive MEDI0382 200 μg or placebo daily during a 41-day treatment period. Quantification of liver proton density fat fraction, subcutaneous adipose tissue (SAT), and visceral adipose tissue (VAT) was performed as an exploratory analysis in a subset of patients (MEDI0382, $n = 17$; placebo, $n = 21$) who had magnetic resonance imaging scans taken at baseline and on day 41.

Results: Mean (SD) liver fat content at baseline was 15.74% (8.97) and 18.07% (8.38) in the MEDI0382 and placebo groups, respectively. Patients treated with MEDI0382 showed a highly significant relative reduction from baseline in hepatic fat content versus placebo (Table). This was positively correlated with reductions in both body weight ($r = 0.49$, $P = 0.002$) and alanine aminotransferase ($r = 0.42$, $P = 0.009$). A significant decrease in liver volume with MEDI0382 vs placebo was also observed (Table). Treatment with MEDI0382 was also associated with reductions in both SAT and VAT versus placebo.

Conclusion: These data demonstrate the efficacy of MEDI0382 in reducing liver fat and its potential for the treatment of non-alcoholic fatty liver disease, including steatohepatitis.

Effect of GLP-1 receptor agonists on microvascular endpoints in type 2 diabetes: a systematic review and meta-analysis

I. Avgerinos[1], T. Karagiannis[1], K. Malandris[1], A. Liakos[1], M. Mainou[1], P. Andreadis[1], E. Bekiari[1], D.R. Matthews[2], A. Tsapas[1,3];
[1]Aristotle University of Thessaloniki, Thessaloniki, Greece, [2]Oxford Centre for Diabetes, Endocrinology and Metabolism, Churchill Hospital, Oxford, UK, [3]Harris Manchester College, University of Oxford, Oxford, UK.

Background and aims: Effect of GLP-1 receptor agonists (GLP-1 RAs) on microvascular outcomes in patients with type 2 diabetes (T2DM) is controversial. Aim of this systematic review and meta-analysis was to assess the effect of GLP-1 RAs on renal and eye-related outcomes in adult patients with T2DM.
Materials and methods: We searched PubMed, Embase, the Cochrane Library and grey literature sources. We included randomized controlled trials of at least 12 weeks' duration, comparing a GLP-1 RA with placebo or another antidiabetic agent in adults with T2DM. Outcomes included change from baseline in urinary albumin-to-creatinine ratio (UACR, mg/g), and incidence of diabetic retinopathy, macular oedema and vitreous haemorrhage. Two reviewers independently screened search results and extracted data from included studies. We calculated weighted mean differences (WMDs) for UACR and odds ratios (ORs) for retinopathy related outcomes.
Results: We included 55 studies ($n = 58,789$ patients) in the meta-analysis. Compared with placebo (13 studies, $n = 17,794$ patients), GLP-1 RAs slightly reduced UACR (WMD −2.25 mg/g, 95% CI −3.88 to −0.62), while no effect was evident when they were compared to other antidiabetic agents (WMD −5.03 mg/g, 95% CI −10.68 to 0.63, 13 studies, $n = 5769$). Treatment with GLP-1 RAs was not associated with an increase in the risk for diabetic retinopathy compared with placebo (OR 1.05, 95% CI 0.91 to 1.20, 13 studies, $n = 30,981$ patients) or against any other antidiabetic agents (figure). Similarly, GLP-1 RAs were safe regarding incidence of macular oedema (OR 0.89, 95% CI 0.47 to 1.69 against placebo, and OR 1.14, 95% CI 0.34 to 3.84 against active comparator). Finally, incidence of vitreous haemorrhage was higher in patients treated with GLP-1 RAs compared with placebo (OR 2.04, 95% CI 1.16 to 3.59, 6 trials, $n = 20,723$ patients).
Conclusion: Treatment with GLP-1 RAs is safe regarding albuminuria and overall incidence of diabetic retinopathy. However, caution is needed for incidence of vitreous hemorrhage.

Figure. Odds Ratios for diabetic retinopathy. GLP-1 RAs vs active comparator.

The effect of DPP-4 protected GLP-1 (7-36) on coronary microcirculation in obese adults

M. Nilsson[1], K. Bové[2], E. Suhrs[2], T. Hermann[2], S. Madsbad[3], J.J. Holst[4], E. Prescott[2], M. Zander[1];
[1]Department of Endocrinology, Bispebjerg Hospital, Copenhagen, [2]Department of Cardiology, Bispebjerg Hospital, Copenhagen, [3]Department of Endocrinology, Hvidovre Hospital, Copenhagen, [4]Department of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Recently, glucagon-like-peptide-1 (GLP-1) receptor analogues have been shown to reduce cardiovascular events in patients with type 2 diabetes. However, the mechanism behind is still unknown. We hypothesized that GLP-1 would improve coronary microcirculation. In the absence of stenosis in major coronary arteries, coronary flow velocity reserve (CFVR) reflects the function of the coronary microcirculation. Impaired CFVR is associated with type 2 diabetes and obesity as well as increased cardiovascular mortality. The aim of the study was to investigate the effect of native GLP-1 on coronary microcirculation in overweight adults with neither diabetes nor coronary artery disease.
Materials and methods: Twelve obese adults (7 male/5 female; mean age, 54 ± 9.7 years; BMI, 30.9 ± 2.9 kg/m^2) participated in this double-blinded randomized cross-over study. They underwent a treadmill exercise test with echocardiography, to exclude coronary macrovascular disease, prior to participation. Effects of infusions of native GLP-1 (1.5 pmol/kg/min) were compared with a saline infusion on separate days. A DPP-IV inhibitor (Januvia 100 mg) was administered the night before and in the morning of the examination day to block the degradation of intact GLP-1 (7–36) to the GLP-1 metabolite (9–36). Coronary microcirculation, assessed by CFVR, was measured before and after 2 hours of infusion. Blood samples were collected every 30 minutes for measurements of GLP-1 (intact and metabolite), insulin, glucagon and glucose.
Results: Plasma GLP-1 (7-36) was significantly increased during GLP-1 infusion compared to saline (AUC 15037 ± 977 vs. 36 ± 19 pmol/L × min, $p < 0.0001$) with a mean difference of 117 pmol/L between the two infusions just before CFR measurement. Plasma glucose decreased

during infusion with GLP-1 (AUC 691 ± 22 vs. 794 ± 24 pmol/L × min, $p < 0.0001$) with a mean difference in glucose concentrations between the two infusions of 0.5 mmol/L just before CFR measurement (4.9 vs 5.4 mmol/l). However, plasma glucose stayed within normal range throughout infusions. Plasma glucagon showed no significant changes (AUC 691 ± 97 vs. 804 ± 108 pmol/L × min, with GLP-1 and saline, respectively, $p = 0.132$) whereas C-peptide increased slightly with GLP-1 (AUC 95539 ± 12049 vs. 63379 ± 7340 pmol/L × min, $p = 0.0009$). No effect of GLP-1 infusion was found on CFVR compared to saline infusion (ΔCFVR 0.376 ± 0.267 vs. ΔCFVR 0.713 ± 0.298, $p = 0.349$).

Conclusion: We found no effect of acute infusion of GLP-1, protected from DPP-4 mediated degradation, on coronary flow velocity reserve in overweight adults without diabetes. Thus the effect of GLP-1 on cardiovascular function does not seem to be mediated through improvement in coronary microcirculation.

Neuroprotective property of liraglutide

A. Simanenkova, M. Makarova, L. Vasina, T. Vlasov, E. Shlyakhto; Pavlov First Saint-Petersburg State Medical University, Saint-Petersburg, Russian Federation.

Background and aims: Type 2 DM complications are main reasons of mortality and invalidity. Ischemic insult and chronic brain discirculation are much more frequent in type 2 DM. This requires a search for glucose-lowering drug having protective effect for the brain. Aim of the present study was to evaluate neuroprotecive effect of GLP-1 receptor agonist liraglutide (LIR).

Materials and methods: 45–75 aged type 2 diabetic patients ($n = 52$) with glycated hemoglobin (HbA1C) 7.5–9.0% on metformin (MET) therapy less than 2000 mg were included in the study. MET dose was titrated for 3 months until euglycemia or until 3000 mg. 3 months later patients who reached HbA1C less than 7.5% were included in group 1 and continued MET monotherapy for the following 6 months. Subjects with HbA1C more than 7.5% formed group 2 - they were co-administered LIR for next 6 months. At baseline, in 3, 6 and 9 months neuron-specific enolase (NSE) and S100 protein as neuroglial damage markers were evaluated.

Results: Baseline HbA1C level did not differ in groups 1 and 2 (8.4 (7.5; 9.0) % and 7.8 (7.54; 8.7) %, respectively). In 3 months 28 persons reached HbA1C less than 7.5% (6.75 (6.3; 7.2) %) and formed group 1, 24 patients were included in group 2 (HbA1C 8.2 (7.68; 8.68) %). In 6 months HbA1C remained satisfactory in group 1 (6.89 (6.45; 7.5) %) and demonstrated positive dynamics (decrease 0.5% and more for 3 months) in group 2 after LIR co-administration to metformin (7.6 (7.2; 8.3) %). In 9 months 3 patients in group 1 had worsening of glycemic profile (HbA1C 8.2 (7.6; 8.7) %), 25 still had HbA1C 6.7 (6.2; 7.0) %. Similarly, 5 patients in group 2 had increase of HbA1C (8.1 (7.75; 8.6) %), the rest 18 had further positive dynamics (7.35 (6.43; 7.75) %). Baseline level of NSE was higher in group 2, than in group 1 (26.55 (15.06; 43.95) mcg/L and 8.74 (4.52; 23.9) mcg/L, respectively, $p = 0.044$). S100 baseline level did not differ in group 1 (73.2 (21.98; 176.05) ng/L) and 2 (136.85 (79.55; 296.03 ng/L), $p = 0.246$, but prominently exceeded normal. No correlation was observed between neuroglial markers levels and/or DM duration, HbA1C. Glucose lowering in group 1 in 3 months led to NSE (6.81 (4.28; 12.0) mcg/L) and S100 (34.62 (19.45; 128.5) ng/L) normalization, they remained normal in 6 moths (NSE 6.67 (4.54; 10.28) mcg/L and S100 20.81 (13.1; 70.5) ng/L). In 9 months patients in group 1 with satisfactory glucose control had normal NSE (4.04 (3.39; 5.78) mcg/L) and S100 (19.2 (14.16; 59.52) ng/L), glycemia worsening led to NSE (6.43 (3.48; 6.43) mcg/L) and S100 (67.4 (19.33; 86.7) ng/L) increase. NSE (14.58 (7.42; 26.8) mcg/L) and S100 (38.8 (23.71; 82.6) ng/L) decreased in group 2 in 3 months even under unsatisfactory glycemic conditions, but this decrease was more prominent in 6 months after LIR administration, these parameters normalized (NSE 5.87 (4.18; 8.66) mcg/L and S100 44.28 (22.61; 69.15) ng/L). Importantly, NSE level did not differ in the part of group 2 having glycemia improvement (4.86 (3.5; 5.84) mcg/L) and worsening (4.58 (3.99; 6.53) mcg/L), $p > 0.05$. Similarly, S100 concentration remained normal and did not differ in patients having euglycemia under MET+ LIR therapy (29.54 (12.88; 45.24) ng/L) and having glycemic control worsening (23.2 918.19 (50.68) ng/l.

Conclusion: Type 2 DM leads to neuroglial damage not connected with glycemic control or disease duration, which manifests in NSE and S100 increase. Glycemic control improvement helps to decrease neuroglial damage. LIR has neuroprotective effect in type 2 DM not connected with its glucose-lowering action.

Disclosure: **A. Simanenkova:** None.

Liraglutide treatment fails to show neuronal repair or neuroprotective effects in patients with type 1 diabetes and diabetic symmetric polyneuropathy

C. Brock[1,2], C.S. Hansen[3], J.S. Karmitsholt[4,5], H.J. Møller[6], A.H. Juhl[7], A.D. Farmer[8], A.M. Drewes[1], S. Riahi[9], H. Lervang[4], P. Jakobsen[4,5], B. Brock[10,5];

[1]Mech-Sense, Department of Gastroenterology and Hepatology & Clinical Institute, Aalborg University Hospital, Aalborg, Denmark, [2]Department of Pharmacotherapy and Development, University of Copenhagen, Copenhagen, Denmark, [3]Complications research, Steno Diabetes Center Copenhagen, Gentofte, Denmark, [4]Department of Endocrinology, Aalborg University Hospital, Aalborg, Denmark, [5]Steno Diabetes Center North, Steno Diabetes Center North, Aalborg, Denmark, [6]Department of Clinical Biochemistry, Aarhus University Hospital, Aarhus, Denmark, [7]Department of Neurophysiology, Aalborg University Hospital, Aalborg, Denmark, [8]Centre for Neuroscience and Trauma, Blizard Institute, Wingate Institute of Neurogastroenterology, Barts and the London School of Medicine & Dentistry, Queen Mary University of London, London, UK, [9]Department of Cardiology, Aalborg University Hospital, Aalborg, Denmark, [10]Clinical research, Steno Diabetes Center Copenhangen, Gentofte, Denmark.

Background and aims: The pathogenesis of diabetic neuropathy is heterogenic and involves vascular-, metabolic-, immune-mediated - and inflammatory pathways. Studies have shown that glucagon-like-peptides-1 receptor agonists (GLP-1 RA) possess anti-inflammatory effects. The primary objective of this study was to evaluate the efficacy of treatment with the GLP-1 RA liraglutide on neuro inflammation and neuronal activity in a multi-level neurophysiological model.

Materials and methods: This randomized, double-blinded, single-centre, placebo-controlled trial carried out at Aalborg University Hospital comprised of 39 type 1 diabetes patients above 18 years, with HbA_{1c} >6.5 (48%) and confirmed neuropathy according to the Toronto criteria and assigned 1:1 to liraglutide (1.2–1.8 mg/day) or placebo. Primary outcome was in electrically evoked brain potentials at the motor threshold of the median nerve. Secondary outcomes were 24-h heart rate variability (HRV), sympatico-vagal balance; assessed by cardiac vagal tone (CVT) and cardiac sensitivity to the baroreceptor (CSB). Neurophysiological evaluation of peripheral sensory and motor nerves of upper and lower extremities was done. Pro-inflammatory cytokines; IL1β, TNF-α, IL6, IL-8 and IL-10 and macrophage markers sCD163 and sCD206 were assessed. Tertiary outcomes were alterations in HbA1C, insulin use and weight.

Results: In comparison to placebo, liraglutide elicited no differences in evoked potentials, peripheral nerve function, HRV parameters or measures of sympatico-vagal balance. Liraglutide reduced several inflammatory markers, only IL-6 was significantly reduced by −22.6% (95%CI: −38.1; −3.2; $P = 0.025$), and induced a weight loss of 3.38 kg (95%CI:

−5.29; −1.48, $P < 0.001$), but no change HbA1C: 1.18% (95%CI: −4.31; 6.98) or insulin use: −1.57% (95%CI: −18.14; 18.34) $P > 0.6$.

Conclusion: Liraglutide did not induce changes in evoked brain potentials, HRV parameters, measures of sympatico-vagal balance, nerve function of the peripheral nerves or glycaemic control. However liraglutide lowered levels of pro-inflammatory cytokines, however only significantly for IL-6, this independently of glycose metabolism. Liraglutide-induced reduction in neuro-inflammation may not have an effect on late-state neuropathy. Treatment effects on nerve function in patients with early-stage neuropathy remains to be explored.

Liraglutide with an effect on asymmetric dimethylarginine might be superior in nephroprotection compared to linagliptin and vildagliptin

A. Piljac[1], A. Jazbec[2], L. Duvnjak[1], S. Ljubic[1];
[1]Vuk Vrhovac University Clinic, Zagreb, [2]University of Zagreb, Zagreb, Croatia.

Background and aims: Incretins emerged as important in cardiovascular risk reduction in diabetes. As nitric oxide synthase inhibitor, asymmetric dimethylarginine (ADMA) is responsible for increased risk of angiopathy, it also predicts the progression of nephropathy. The significance of liraglutide in comparison to linagliptin and vildagliptin for nephroprotection was studied through an impact on factors of angiopathy.

Materials and methods: ADMA, BNP, ApN, some other markers of inflammation, BP, HbA1c and other cardiovascular (CV) risk factors were determined. A total of 243 type 2 diabetics divided into three groups treated with linagliptin (Group [Gr] 1), vildagliptin (Gr 2) and liraglutide (Gr 3) were studied during a 6-month follow-up period. Patients differed in their estimated GFR calculated using the CKD-EPI formula (Gr 1: eGFR >90, Gr 2: eGFR:90–60, and Gr 3: eGFR <60 ml/min/1.73 m^2), and albumin/cretinine ratio (ACR <2.5 and ≥2.5).

Results: A significant among-group difference was found in ApN (Gr 1 vs Gr 2 vs Gr 3 = 4.84 ± 1.81 vs 5.33 ± 1.74 vs 10.08 ± 2.82; ANOVA: F(2.36) = 14.06; $p < 0.0001$), ADMA (Gr 1 vs Gr 2 vs Gr 3 = 0.47 ± 0.07 vs 0.54 ± 0.05 vs 0.66 ± 0.16; F(2.38) = 13.05; $p < 0.0001$), and homocysteine (HCY) (Gr 1 vs Gr 2 vs Gr 3 = 12.92 ± 3.43 vs 14.4 ± 4.6 vs 21.03 ± 5.25; F(2.37) = 6.84; $p = 0.003$). Tukey post hoc test showed significant differences ($p < 0.05$) in ApN and HCY between Gr 1 and Gr 3, and Gr 2 and Gr 3, in ADMA between Gr 1 and Gr 3. No differences in variables according to ACR were dtermined (Mann Whitney test). Mean values for ADMA at the beginning of the study were 0.56 ± 0.14, 0.49 ± 0.07 and 0.54 ± 0.04 in the Gr 1, 2, 3 respectively, and were significantly reduced by 0.07 (95% CI: 0.02–0.14), 0.06 (95% CI: 0.02–0.1) and 0.04 (95% CI: 0.02–0.06) on average in all three groups, with greater reduction of Gr 3 in comparison with Gr 1 and 2. Mean values for high-sensitivity C-reactive protein (hs-CRP) at the beginning of the study were 3.86 ± 3.64, 2.67 ± 2.52 and 5.31 ± 2.37 in the Gr 1, 2, 3 respectively, and were significantly reduced by 0.63 (95% CI: 0.1–1.15), 1.35 (95% CI: −0.26–2.97) and 1.71 (95% CI: 0.57–2.84) on average in all three groups, with greater reduction of Gr 3 in comparison with Gr 2 (*t* paired test). HbA1c mean values at the beginning were 8.01 ± 0.79, 7.36 ± 0.87 and 8.01 ± 0.95 in the Gr 1, 2, 3 respectively, and were significantly reduced by 0.94 (95% CI: 0.73–1.15), 0.69 (95% CI: 0.05–1.32) and 1.15 (95% CI: 0.35–1.95) on average, with no difference between groups. BMI mean values in Gr 3 at the beginning were 39.3 ± 4.5 and were significantly reduced by 2.65 (95% CI: 1.35–3.94) on average, whereas SBP reduction was significant from baseline (137.5 ± 16.9) in Gr 2 by 9.0 (95% CI: −0.05–18.55). Postprandial C-peptide and triglycerides (TG) were reduced in Gr 3 by −0.32 (95% CI: −0.65–0.01) and 0.67 (95% CI: −0.09–1.43) on average, however, not significantly. ADMA correlated significantly with alanine aminotransferase ($r = -0.38$) and eGFR ($r = -0.64$) and ApN ($r = 0.43$).

Conclusion: ADMA, ApN and HCY accompanied impaired renal function. Liraglutide was superior in ADMA, hs-CRP, BMI and TG reduction, therefore it is credible to argue its advantage in diabetic angiopathy protection. Reducing ADMA, together with glycemic regulation, CRP, BMI and Tg reduction, liraglutide could be superior in nephroprotection.

Disclosure: **A. Piljac:** None.

Liraglutide reduces cardiovascular events and mortality in type 2 diabetes independent of LDL cholesterol and statin use: results of the LEADER trial

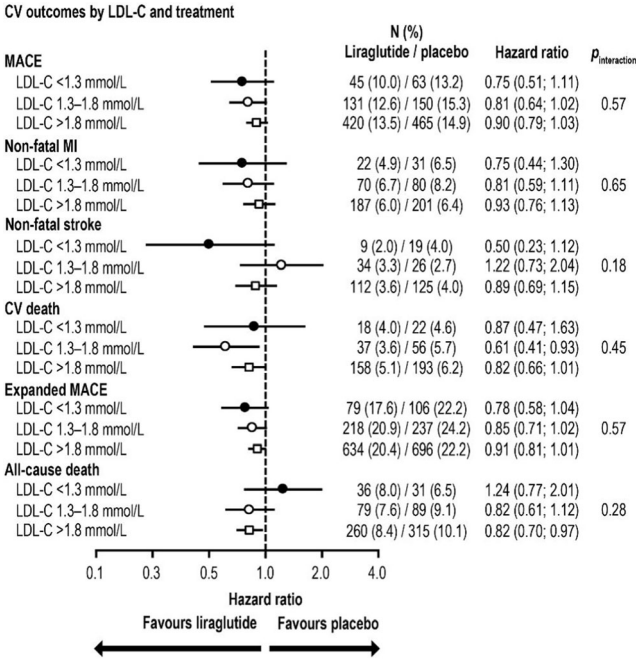
L.A. Leiter[1], S. Verma[2], C. Mazer[1], S.C. Bain[3], J. Buse[4], S. Marso[5], M.A. Nauck[6], B. Zinman[7], H. Bosch-Traberg[8], H. Frimer-Larsen[8], M.M. Michelsen[8], D.L. Bhatt[9], LEADER Publication Committee on behalf of the LEADER Trial Investigators;
[1]Li Ka Shing Knowledge Institute, St. Michael's Hospital and Univ. of Toronto, Toronto, Canada, [2]St. Michael's Hospital and Univ. of Toronto, Toronto, Canada, [3]Institute of Life Science, Swansea Univ., Swansea, UK, [4]Univ. of North Carolina School of Medicine, Chapel Hill, USA, [5]HCA Midwest Health Heart & Vascular Institute, Kansas City, USA, [6]Diabetes Center Bochum-Hattingen, St. Josef-Hospital (Ruhr-Universität Bochum), Bochum, Germany, [7]Lunenfeld Tanenbaum Research Institute, Mount Sinai Hospital, Univ. of Toronto, Toronto, Canada, [8]Novo Nordisk A/S, Søborg, Denmark, [9]Brigham and Women's Hospital Heart and Vascular Center and Harvard Medical School, Boston, USA.

Background and aims: The relationships among LDL cholesterol levels, statin use and cardiovascular (CV) outcomes are well established. In LEADER, the human glucagon-like peptide 1 analogue liraglutide reduced CV events in patients with type 2 diabetes (T2D) at high CV risk. This post hoc analysis evaluated liraglutide effects on CV outcomes by baseline LDL and statin use.

Materials and methods: LEADER studied liraglutide (1.8 mg or maximum tolerated dose) vs placebo, both in addition to standard care, in 9340 patients with T2D and high CV risk. Primary outcome: composite of CV death, non-fatal myocardial infarction, or non-fatal stroke (major adverse CV events, MACE). The key secondary expanded outcome (expanded MACE) also included hospitalisation for unstable angina or heart failure, or revascularisation. Cox regression evaluated liraglutide effect on CV outcomes by baseline LDL <1.3 mmol/L, 1.3–1.8 mmol/L and >1.8 mmol/L, and baseline statin use.

Results: In LEADER, 9187 patients had LDL measured: 926 (10.1%), 2021 (22.0%) and 6240 (67.9%) had baseline LDL <1.3 mmol/L, 1.3–1.8 mmol/L or >1.8 mmol/L, respectively. Baseline characteristics were relatively similar between the 3 groups, except that patients with LDL >1.8 mmol/L had lower statin use and lower proportion of CV events in their medical history. Within groups by LDL level, baseline characteristics were well-balanced across treatment groups. Liraglutide consistently reduced MACE vs placebo irrespective of baseline LDL (HR 0.75, 95% CI 0.51–1.11 vs HR 0.81, 95% CI 0.64–1.02 vs HR 0.90, 95% CI 0.79–1.03, *p* interaction = 0.57). Similarly for expanded MACE: HR 0.78, 95% CI 0.58–1.04 vs HR 0.85, 95% CI 0.71–1.02 vs HR 0.91, 95% CI 0.81–1.01, *p* interaction = 0.57) (Figure). The HR for MACE, with liraglutide vs placebo, was 0.83 (95% CI 0.73–0.94) in statin users (72%) and 0.97 (95% CI 0.79–1.20) in non-statin users (28%) (*p* interaction = 0.19). Results were similar in models adjusted for baseline characteristics.

Conclusion: In LEADER, liraglutide was associated with lower risk of major CV events in patients with T2D across LDL levels and statin use, with event reduction even in patients with lowest LDL.



N (%), number of patients with an event (as a proportion of the full analysis set). CV, cardiovascular; LDL-C, low-density lipoprotein cholesterol; MACE, major adverse cardiovascular event; MI, myocardial infarction

Semaglutide consistently reduces cardiovascular events in both male and female subjects with type 2 diabetes

I. Hramiak[1], C. DeSouza[2], J. Seufert[3], T. Hansen[4], J. Pettersson[4], D. Thielke[4], I. Lingvay[5];
[1]Western University, London, Canada, [2]University of Nebraska Medical Center, Omaha, USA, [3]Medical Faculty, University of Freiburg Medical Center, Freiburg, Germany, [4]Novo Nordisk A/S, Søborg, Denmark, [5]UT Southwestern Medical Center, Dallas, USA.

Background and aims: Semaglutide is a glucagon-like peptide-1 analogue for once-weekly treatment of type 2 diabetes (T2D). In the SUSTAIN 6 cardiovascular (CV) trial, subcutaneous semaglutide (0.5 mg and 1.0 mg) added to standard of care significantly reduced major adverse CV events (MACE: non-fatal myocardial infarction, non-fatal stroke or CV death) vs placebo over 2 years in subjects with T2D at high CV risk. This *post hoc* analysis assessed whether this CV risk reduction was consistent in male and female subjects.
Materials and methods: Endpoints analysed were MACE, the individual components of the MACE endpoint, first hospitalisation due to unstable angina, first hospitalisation due to heart failure, and first revascularisation. In total, 2,002 males and 1,295 females were randomised.
Results: MACE consistently occurred in fewer subjects with semaglutide vs placebo in both sexes, consistent with the overall study population ($p = 0.45$ for interaction): HR 0.68 (95% CI 0.50;0.92) in males, 0.84 (95% CI 0.54;1.31) in females and 0.74 (95% CI 0.58;0.95) in the total study population. Overall, this pattern was reflected across the individual MACE components, showing lower rates with semaglutide vs placebo regardless of sex, with the exception of CV mortality in female subjects (**Table**). In the overall trial population, there was no significant difference between semaglutide vs placebo for first hospitalisation due to unstable angina or heart failure: HR 0.82 (95% CI 0.47;1.44) and 1.11 (95% CI 0.77;1.61), respectively. These results were consistent in males (HR 0.66 [95% CI 0.33;1.34] and 1.18 [95% CI 0.75;1.86], respectively) and females (HR 1.17 [95% CI 0.45;3.03] and 0.93 [95% CI 0.49;1.76]) ($p = 0.35$ and $p = 0.55$ for interaction, respectively). Revascularisation was performed in significantly fewer subjects with semaglutide vs placebo (HR 0.65 [95% CI 0.50;0.86], $p = 0.003$). These results were consistent in males (HR 0.60 [95% CI 0.43;0.85], $p = 0.0035$) and females (HR 0.74 [95% CI 0.46;1.20], not statistically significant) ($p = 0.50$ for interaction). Adverse events were reported by similar proportions of males and females across treatments. The most frequent AEs reported were gastrointestinal, with higher rates in females than in males. The proportions of subjects prematurely discontinuing treatment due to AEs were comparable for males and females (**Table**).
Conclusion: The semaglutide-induced risk reduction in MACE and its components vs placebo seen in SUSTAIN 6 was consistent in both males and females. Numerically lower proportions of females than males reported MACE. The semaglutide treatment effect on the risk of secondary CV endpoints was also similar in both sexes.

Effect of liraglutide on ambulatory blood pressure in hypertensive patients with type 2 diabetes: randomised, double blind, placebo controlled trial

A. Liakos[1], K. Balampanis[2], E. Barmpa[3], E. Angeloudi[1], A. Katsoula[1], E. Athanasiadou[1], S. Gerou[4], V. Lampadiari[2], A. Bargiota[3], I. Avramidis[5], K. Kotsa[1], N. Tentolouris[2], E. Bekiari[1], A. Tsapas[1,6];
[1]Aristotle University Thessaloniki, Thessaloniki, Greece, [2]University of Athens, Athens, Greece, [3]University of Thessaly, Larisa, Greece, [4]Analysi Iatriki SA, Thessaloniki, Greece, [5]Papanikolaou General Hospital, Thessaloniki, Greece, [6]University of Oxford, Oxford, UK.

Background and aims: Arterial hypertension complicates most patients with type 2 diabetes further contributing to the increased cardiovascular risk. Liraglutide reduces incidence of cardiovascular events but the underlying mechanisms are yet poorly understood. We conducted an investigator-initiated, parallel group, randomised, double blind, multicentre trial assessing the effect of liraglutide on 24-h ambulatory blood pressure in patients with hypertension (pre- and stage 1 hypertension) and inadequately controlled type 2 diabetes (HbA_{1c} 7–10%).
Materials and methods: Eligible patients were on stable background antihyperglycemic therapy excluding insulin, glucagon-like peptide 1 receptor agonists and dipeptidyl-peptidase 4 inhibitors. Subjects were centrally randomized via a web-based system in a 1:1 ratio to receive either daily liraglutide 0.6 mg titrated to 1.2 mg after the first week or placebo for 5 weeks. Primary outcome was change in 24-h ambulatory systolic blood pressure (SBP). Secondary outcomes included change in ambulatory diastolic blood pressure (DBP) and heart rate as well as daytime and nighttime measurements. Analysis was based on the intention-to-treat principle.
Results: Of 87 subjects assessed for eligibility 62 patients (66% males) with mean age 60.2 years and BMI 33.8 kg/m^2 were allocated to liraglutide ($N = 31$) or placebo ($N = 31$). All participants received background therapy with metformin, whilst 35% were treated concomitantly with sulphonylurea and 15% with pioglitazone. Mean HbA_{1c} at baseline was 7.9% and mean duration of diabetes was 9.0 years. Compared with placebo liraglutide reduced 24-h SBP by 5.73 mmHg (95% CI −9.81 to −1.65) and had a neutral effect on 24-h DBP (mean difference −1.42 mmHg; 95% CI −4.25 to 1.40) whilst increasing 24-h heart rate by 6.16 beats/min (95% CI 3.25 to 9.07). Findings were consistent for daytime and nighttime measurements (Table). In each group two subjects discontinued treatment prematurely. Four patients (13%) in each arm experienced an adverse event. Of these, two patients in the placebo and one patient in the liraglutide arm discontinued the study drug due to an adverse event. No serious adverse events or deaths were reported.
Conclusion: Based on 24-h ambulatory measurements short term treatment with liraglutide had a favourable effect on systolic blood pressure whilst increasing heart rate.

Outcome	Change from baseline (SE)		Mean difference (95% CI)
	Liraglutide (N = 31)	Placebo (N = 31)	
24-h SBP, mmHg	–4.72 (1.43)	1.02 (1.43)	–5.73 (–9.81 to –1.65)
24-h DBP, mmHg	–0.58 (0.99)	0.84 (0.99)	–1.42 (–4.25 to 1.40)
24-h HR, beats/min	8.55 (1.03)	2.39 (1.03)	6.16 (3.25 to 9.07)
Daytime SBP, mmHg	–5.61 (1.47)	0.83 (1.47)	–6.43 (–10.63 to –2.24)
Daytime DBP, mmHg	–1.10 (1.02)	0.60 (1.02)	–1.70 (–4.60 to 1.20)
Daytime HR, mmHg	8.35 (1.06)	2.16 (1.06)	6.19 (3.19 to 9.18)
Nighttime SBP, mmHg	–1.67 (1.65)	1.77 (1.65)	–3.44 (–8.15 to 1.28)
Nighttime DBP, mmHg	–0.30 (1.07)	0.67 (1.07)	–0.97 (–4.03 to 2.09)
Nighttime HR, mmHg	9.25 (1.11)	3.09 (1.11)	6.17 (3.03 to 9.30)

SBP: systolic blood pressure, DBP, diastolic blood pressure, HR: heart rate.

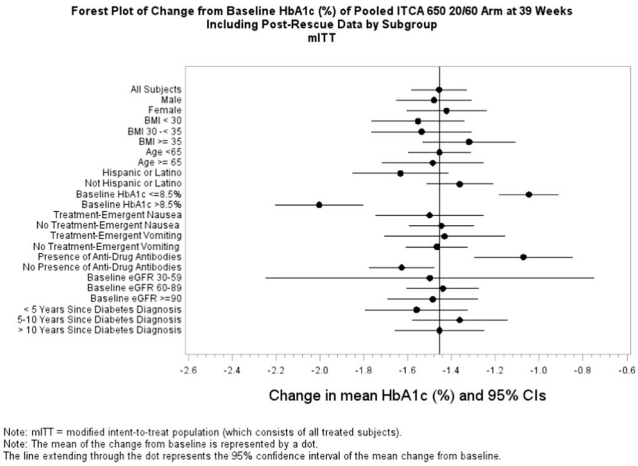
ITCA 650 provides consistent efficacy in type 2 diabetes irrespective of baseline characteristics: results of a pooled subgroup analysis

B. Schwartz, P. Prabhakar, L. Kjems, H. Huang, M. Baron;
Intarcia Therapeutics, Boston, USA.

Background and aims: ITCA 650 consists of a small titanium osmotic mini-pump that is subdermally placed in the abdominal wall during a brief in-office procedure. As an investigational product for the treatment of type 2 diabetes (T2D), ITCA 650 provides a continuous subcutaneous infusion of exenatide over 3 or 6 months.
Materials and methods: Pooled 39-week data from two double-blind, randomized, Phase 3 studies were used to evaluate the efficacy of ITCA 650 20/60 mcg/d in patients with T2D inadequately controlled by oral antidiabetic drugs (OADs). Results in the overall population ($N = 683$) and in subgroups according to age, gender, BMI, ethnicity, time since diagnosis, baseline HbA1c, GI adverse events, presence of anti-drug antibodies, and renal function are reported.
Results: As shown in the figure, the overall mean (standard deviation [SD]) reduction in HbA1c (%) was 1.5% (1.2) with clinically meaningful reductions in HbA1c consistently observed irrespective of age, gender, BMI, ethnicity, time from T2D diagnosis, eGFR and background OADs (data not shown). Patients with a higher baseline HbA1c had a greater response. Mean weight loss was 3.4 kg (SD 4.7), and 40.7% (95% CI 0.36–0.46) of patients achieved a composite endpoint of HbA1c/weight reduction of >0.5%/≥2 kg. Similar changes were likewise seen consistently across subgroups.
Conclusion: ITCA 650 demonstrated consistent efficacy across a wide spectrum of patients with T2D.



Note: mITT = modified intent-to-treat population (which consists of all treated subjects).
Note: The mean of the change from baseline is represented by a dot.
The line extending through the dot represents the 95% confidence interval of the mean change from baseline.

Efficacy and safety with exenatide once weekly: clinical trial results from 10 randomised trials (the DURATION programme)

O. Motawakel[1], P.S. Leigh[2], E. Hardy[1];
[1]AstraZeneca, Gaithersburg, USA, [2]AstraZeneca, Cambridge, UK.

Background and aims: Multiple clinical studies have investigated the glucagon-like peptide-1 receptor agonist (GLP-1RA) exenatide, a novel microsphere-based therapy once weekly administered s.c. (ExQW) or with an autoinjector with a miglyol diluent (ExQWS-AI), in patients with type 2 diabetes (T2D). This analysis summarises the efficacy of ExQW and ExQWS-AI across 10 comparator-controlled, phase 3, 24- to 30-week clinical studies from the DURATION clinical programme. The DURATION-1 study was extended to 7 years of follow-up; currently, this is the longest duration that any GLP-1RA has been studied in a clinical trial.
Materials and methods: Patients received ExQWS-AI or ExQW as monotherapy or in combination with other antidiabetic drugs (e.g. metformin, sulphonylurea, a thiazolidinedione [pioglitazone], dapagliflozin [DAPA] and insulin glargine). Efficacy and safety data were summarised from individual studies.
Results: In total, 2251 patients received ExQW 2 mg ($n = 1841$) or ExQWS-AI 2 mg ($n = 410$); 2870 patients received comparators (non-GLP-1RAs, $n = 1481$ [metformin, sitagliptin, pioglitazone, insulin glargine, and DAPA], ExBID [$n = 416$], liraglutide [$n = 450$], ExQW+DAPA [$n = 231$], or placebo [$n = 292$]). In the individual studies, the mean age of patients ranged from 52–58 years, and 48–65% were men. Mean duration of diabetes ranged from 5–11.3 years, except in a study of treatment-naïve patients (mean: 2.7 years). ExQW and ExQWS-AI reduced HbA1c in all trials from baseline to weeks 24–30 (mean change from baseline: −1.0% to −1.9%; **Figure**); proportions of patients achieving HbA1c ≤7.0% ranged from 27–77%. ExQW and ExQWS-AI resulted in fasting glucose reductions ranging from −0.7 to −2.5 mmol/L. Mean body weight reductions with ExQW and ExQWS-AI ranged from −1.0 to −3.7 kg. Efficacy has been observed in all patient subpopulations (e.g. by age, sex, baseline HbA1c, baseline body mass index, renal function and duration of diabetes) and diabetes therapy combinations studied to date. Overall, 67.5% and 64.1% of patients treated with ExQW or ExQWS-AI experienced ≥1 treatment-emergent adverse event (AE), respectively; 3.9% of patients discontinued treatment due to AEs, and 3.2% of patients had ≥1 serious AE with ExQW or ExQWS-AI. In patients receiving a comparator drug, 61.0% experienced ≥1 treatment-emergent AE. The most common AEs collectively with ExQW and ExQWS-AI were nausea, diarrhoea and vomiting, which occurred in 11.7%, 7.9%, and 3.6% of patients, respectively.
Conclusion: The 10 studies show consistent efficacy for ExQW (8 studies) and ExQWS-AI (2 studies) with HbA1c reductions of 1.0–1.9% at 24–30 weeks in patients with T2D with no new or unexpected safety findings in the integrated population. Consistent results were seen across clinical trials despite different patient populations, treatment settings, and medication combinations.

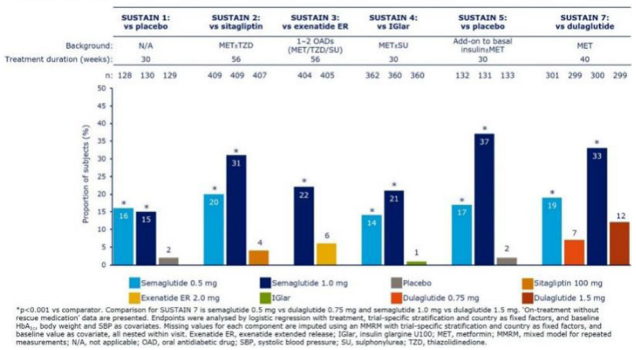
More subjects achieved composite reductions of ≥1% HbA_{1c}, ≥5% body weight and ≥5 mmHg SBP with semaglutide vs comparators across the SUSTAIN 1-5 and 7 trials

K.M. Dungan[1], V.R. Aroda[2,3], F.K. Knop[4], L.A. Leiter[5], N.L. Lausvig[6], S. Lindberg[6], J. Ferløv Schwensen[6], J.J. Meier[7];

[1]The Ohio State University, Columbus, USA, [2]Brigham and Women's Hospital, Boston, USA, [3]MedStar Health Research Institute, Hyattsville, USA, [4]Steno Diabetes Center Copenhagen, Gentofte Hospital, University of Copenhagen, Hellerup, Denmark, [5]Li Ka Shing Knowledge Institute, St Michael's Hospital, University of Toronto, Toronto, Canada, [6]Novo Nordisk A/S, Søborg, Denmark, [7]Diabetes Division, St Josef Hospital, Ruhr-University Bochum, Bochum, Germany.

Background and aims: Semaglutide is a glucagon-like peptide-1 (GLP-1) analogue for the once-weekly treatment of type 2 diabetes (T2D). Across the SUSTAIN clinical trial programme, subjects with T2D achieved greater reductions in three cardiovascular (CV) risk factors, HbA_{1c}, body weight (BW) and systolic blood pressure (SBP), with semaglutide vs placebo (SUSTAIN 1 and 5) or active comparators (sitagliptin [SUSTAIN 2], exenatide extended release [SUSTAIN 3], insulin glargine U100 [SUSTAIN 4] or dulaglutide [SUSTAIN 7]). The aim of this analysis was to evaluate to what extent subjects achieved clinically meaningful reductions in a composite of these three CV risk factors with semaglutide vs comparators in the SUSTAIN clinical trial programme.
Materials and methods: Six SUSTAIN trials (SUSTAIN 1–5 and 7; see figure for details) were assessed *post hoc* to determine the proportion of subjects who achieved clinically meaningful reductions in all three CV risk factors (composite endpoint: ≥1% decrease in HbA_{1c}, ≥5% BW loss, and ≥5 mmHg SBP reduction). Endpoints were analysed by logistic regression. Missing values for each component were imputed using a mixed model for repeated measurements.
Results: Across trials, mean baseline HbA_{1c}, BW and SBP ranges were 8.1–8.4%, 89.5–95.8 kg and 128.8–134.8 mmHg, respectively. Significantly more subjects achieved the composite endpoint with semaglutide (0.5 mg: 14–20%; 1.0 mg: 15–37%) vs comparators (1–12%; $p < 0.001$ for all comparisons; **Figure**). Evaluation of the two trials vs GLP-1 receptor agonists (GLP-1RAs) showed that the composite endpoint was achieved by a significantly greater proportion of subjects treated with semaglutide (0.5 mg: 19%; 1.0 mg: 22–33%) vs exenatide extended release 2.0 mg (6%; SUSTAIN 3) or dulaglutide (0.75 mg: 7%; 1.5 mg: 12%; SUSTAIN 7) ($p < 0.001$ for all comparisons; **Figure**).
Conclusion: With semaglutide, a significantly greater proportion of subjects achieved clinically meaningful improvements in the composite endpoint of HbA_{1c}, BW and SBP reductions vs comparators (including other GLP-1RAs), which may promote an improved overall CV risk profile with semaglutide vs comparators.

Figure. Proportion of subjects achieving the composite endpoint of ≥1% HbA_{1c}, ≥5% body weight and ≥5 mmHg SBP reduction across the SUSTAIN 1–5 and 7 trials



*p<0.001 vs comparator. Comparison for SUSTAIN 7 is semaglutide 0.5 mg vs dulaglutide 0.75 mg and semaglutide 1.0 mg vs dulaglutide 1.5 mg. 'On-treatment without rescue medication' data are presented. Endpoints were analysed by logistic regression with treatment, trial-specific stratification and country as fixed factors, and baseline HbA_{1c}, body weight and SBP as covariates. Missing values for each component are imputed using an MMRM with trial-specific stratification and country as fixed factors, and baseline value as covariate, all nested within visit. Exenatide ER, exenatide extended release; IGlar, insulin glargine U100; MET, metformin; MMRM, mixed model for repeated measurements; N/A, not applicable; OAD, oral antidiabetic drug; SBP, systolic blood pressure; SU, sulphonylurea; TZD, thiazolidinedione.

Efficacy and safety of ITCA 650, an injection-free GLP-1 RA, in patients with type 2 diabetes: a pooled analysis of phase 3 studies

M. Baron, L. Kjems, P. Prabhakar, B. Schwartz, H. Huang;
Intarcia Therapeutics, Inc., Boston, USA.

Background and aims: ITCA 650 consists of a small titanium osmotic mini-pump that is subdermally placed in the abdominal wall during a brief office procedure. As an investigational product for the treatment of type 2 diabetes (T2D), ITCA 650 provides a continuous subcutaneous infusion of exenatide over 3 or 6 months.
Materials and methods: An integrated analysis of efficacy and safety was conducted from 2 double-blind, randomized, Phase 3 studies, which evaluated pooled data with ITCA 650 20/60 mcg/d vs. placebo or sitagliptin for the treatment of patients with T2D, inadequately controlled on antidiabetic drugs. The efficacy endpoints were mean change from baseline at Week 39 for HbA1c, body weight, composite endpoints of HbA1c and weight loss, and proportion achieving HbA1c <7%. The incidence of treatment-emergent adverse events (TEAEs) was also reported.
Results: Significant and clinically meaningful improvements at 39 weeks were observed with ITCA 650 20/60 mcg/d for all these endpoints. The higher incidence of TEAEs with ITCA 650 vs. comparators was explained by the higher incidence of GI TEAEs. Similar proportions of patients in each group discontinued for TEAEs.
Conclusion: The results are consistent with results observed from individual Phase 3 studies, which demonstrated that ITCA 650 is effective for lowering HbA1c and weight, for achieving a composite of HbA1c/weight reduction and target HbA1c <7%, and is well tolerated.

Table. Baseline characteristic, outcomes, and adverse events from pooled analysis

	ITCA 20/60 mcg/d N=418	Placebo N=154	Sitagliptin 100 mg/d N=265
Age, years	55.1 ± 9.7	54.7 ± 9.1	54.6 ± 10.3
Baseline HbA1c, % [a]	8.5 ± 0.9	8.5 ± 0.8	8.7 ± 0.9
Baseline weight, kg [a]	94.2 ± 19.5	98.2 ± 21.9	92.4 ± 21.3
Background therapy			
Metformin only	326 (78%)	66 (42.9%)	265 (100%)
Metformin + sulfonylurea	65 (15.6%)	64 (41.6%)	1 (0.4%)
HbA1c, % [b]	-1.4 ± 0.06	0.05 ± 0.15	-0.9 ± 0.07
Weight, kg [b]	-3.5 ± 0.25	-1.6 ± 0.50	-1.1 ± 0.28
HbA1c/weight decreased >0.5%/≥2 kg [c]	156 (37.3%)	17 (11%)	43 (16.2%)
HbA1c/weight decreased >1%/≥3 kg [c]	115 (27.5%)	10 (6.5%)	26 (9.8%)
HbA1c <7% [c]	165 (39.5%)	13 (8.4%)	59 (22.3%)
Any treatment-emergent AE (≥ 5%)	264 (63.2%)	69 (44.8%)	133 (50.2%)
Nausea	131 (31.3%)	15 (9.7%)	36 (13.62%)
Vomiting	88 (21.1%)	3 (1.9%)	14 (5.3%)
Minor hypoglycemia	21 (5.0%)	4 (2.6%)	5 (1.9%)
Serious TEAEs	21 (5.0%)	5 (3.2%)	20 (7.5%)

Only within treatment group comparisons were performed. Between treatment group comparisons were not performed because placebo or sitagliptin was not used in both studies in this analysis.
Background therapy included various oral agents in FREEDOM-1 and metformin only in FREEDOM-2. Excluded post rescue data.
[a] Mean ± standard deviation
[b] LS mean ± standard error change at Week 39
[c] Percentage was based on all treated patients from each group. Patients with missing Week 39 values were considered as non-achievers.

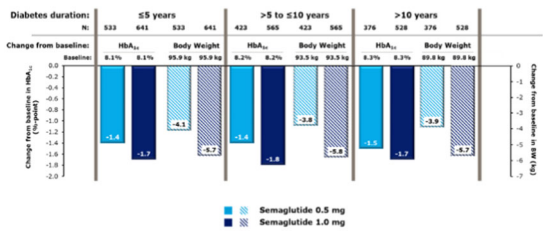
Consistent HbA_{1c} and body weight reduction with semaglutide independent of diabetes duration: SUSTAIN 1–5 and 7 patient-level meta-analysis

S. Madsbad[1], S.C. Bain[2], L. Chaykin[3], J. Lüdemann[4], J. Kjærulff Furberg[5], J. Rask Larsen[5], E. Yildirim[5], J. Rosenstock[6];
[1]Hvidovre Hospital, University of Copenhagen, Copenhagen, Denmark, [2]School of Medicine, Swansea University, Swansea, UK, [3]Meridien Research, Bradenton, USA, [4]Diabetes-Falkensee, Diabetes Centre and Centre for Clinical Studies, Falkensee, Germany, [5]Novo Nordisk A/S, Søborg, Denmark, [6]Dallas Diabetes Research Center at Medical City, Dallas, USA.

Background and aims: Achieving glycaemic targets is challenging. Over time, people with type 2 diabetes (T2D) have declining beta-cell function and may become less responsive to therapies. Semaglutide, a once-weekly glucagon-like peptide-1 (GLP-1) analogue for T2D treatment, showed superior reductions in HbA_{1c} and body weight in the SUSTAIN 1–5 and 7 clinical trials vs placebo or active comparators. This meta-analysis assessed the effect of semaglutide 0.5 mg and 1.0 mg on HbA_{1c} and body weight by baseline T2D duration.
Materials and methods: Efficacy and safety data from SUSTAIN 1–5 and 7 were pooled. For efficacy, 3,066 subjects receiving either semaglutide 0.5 mg or 1.0 mg were analysed by baseline T2D duration: ≤5 years (n = 1,174), >5 to ≤10 years (n = 988), >10 years (n = 904). Safety analyses by baseline T2D duration evaluated semaglutide 0.5 mg (n = 1332) and 1.0 mg (n = 1734) arms vs 2,032 subjects in the comparator arms: ≤5 years (n = 766), >5 to ≤10 years (n = 643), >10 years (n = 622). Patients were randomised and exposed to at least one dose of trial product. Proportions of subjects experiencing at least one adverse event (AE) were Cochran-Mantel-Haenszel adjusted.
Results: Semaglutide consistently reduced HbA_{1c} by 1.4–1.8 percentage-points from baseline to week 30 or 40 across subgroups by T2D duration (**Figure**). Reductions in body weight from baseline to week 30 or 40 were also consistent across subgroups (semaglutide 0.5 mg and 1.0 mg: ≤5 years, −4.1 and −5.7 kg; >5–≤ 10 years, −3.8 and −5.8 kg; >10 years, −3.9 and −5.7 kg; respectively). The proportions of subjects on semaglutide (both doses) reporting AEs were generally similar vs comparators: ≤5 years, 69.6 vs 65.9%; >5–≤ 10 years, 69.9 vs 70.8%; and >10 years, 73.5 vs 69.0%. Serious AEs were reported by 6.2 vs 6.6%, 7.2 vs 6.0% and 8.3 vs 6.3% of subjects, respectively. Nausea was reported by 20.5 vs 9.3%, 20.7 vs 9.1% and 20.1 vs 9.5%; and vomiting by 9.4 vs 4.5%, 7.2 vs 4.2% and 8.7 vs 4.3% of subjects receiving semaglutide vs comparators; premature treatment discontinuation due to AEs was reported by 7.7 vs 3.6%, 7.9 vs 3.6% and 8.5 vs 4.6% of subjects treated with semaglutide vs comparators.
Conclusion: Semaglutide consistently reduced HbA_{1c} and body weight, regardless of baseline T2D duration. The safety profile of semaglutide was as expected and appeared to be unaffected by diabetes duration.

Figure. Estimated change from baseline in HbA_{1c} and body weight to week 30 or 40 by diabetes duration in the SUSTAIN 1–5 and 7 clinical trials



On-treatment without rescue medication data were pooled on the basis of all subjects contributing to the full analysis sets in SUSTAIN 1–5 and 7. Data presented are estimated change from baseline to week 30 or 40 based on a meta-analysis across the six trials. These analyses were based on week 30 data for SUSTAIN 1 to 5, and on week 40 data for SUSTAIN 7 because the protocol did not include visits at week 30. BW, body weight.

Predictors of glucose-lowering response to treatment with glucagon-like peptide-1 receptor agonists in patients with diabetes and obesity
M.V. Amosova, O.Y. Gurova, V.V. Fadeev;
Federal State Autonomous Educational Institution of Higher Education I.M. Sechenov First Moscow State Medical University of the Ministry of Health of the Russian Federation, Moscow, Russian Federation.

Background and aims: Glucose-lowering response to glucagon-like peptide-1 receptor agonists (GLP-1 RA) varies significantly among patients with type 2 diabetes mellitus (T2DM). The mechanism of this variability has not been determined yet. On the ground of this study we would like to identify the most valued characteristics that have influence on treatment outcomes in patient with T2DM and obesity.
Materials and methods: We conducted a 24-week, prospective, open-label, randomized trial including 58 patients with T2DM and obesity (body mass index (BMI) 37,7 (35;42,1)), at the age from 35 to 71 years, receiving basal insulin (BI) + metformin+ one of the other glucose-lowering medication. Baseline glycosylated hemoglobin (HbA1c) was 9,5%(8,6;10,95%). Patients were randomized into two groups: 1) short-acting GLP-1 RA + BI + metformin; 2) long-acting GLP-1 RA + BI + metformin. The potential predictors that we analyzed in this study were type of eating behavior (according to the data from The Dutch Eating Behavior Questionnaire (DEBQ)), diabetes duration, age of the patient, C-peptide level, BMI, baseline level of HbA1c, fasting blood glucose (FPG) and postprandial glucose (PPG). We used the Spearman correlation analysis to assess association between this characteristics and glycemic response (HbA1c change 0 to 6 months).
Results: Glycemic response to GLP-1 RA was associated with diabetes duration, baseline levels of HbA1c, FPG, PPG and type of eating behavior. Diabetes duration: in patients with a history of diabetes more than 10 years, there was less reduction of HbA1c (−2.05% >10 years; −2.8%. <10 years, p = 0.02)), which, however, does not associate with the c-peptide level (p = 0.38). HbA1c: the most significant reduction was observed in patients with higher baseline HbA1c level (−3.2% (>10%) vs −1.8% (<10%) (p = 0.016). FPG: among patients with higher levels of FPG, long-acting GLP-1-RA were more effective than short-acting GLP-1-RA (−4.3 mmol/l vs −2.6 mmol/l, p = 0.039). In contrast, among patients with higher level of PPG the short-acting GLP-1-RA demonstrated greater glycemic control (−5.6 mmol/l vs −3.9 mmol/l, p = 0.002). BMI: there was no influence of the baseline BMI on the glycemic control. (p = 0.4). Eating behavior: in this cohort of patients, emotional (32%), and mixed eating model prevailed (45%). If this form of eating disorders was present the HbA1c and body weight decreased more significantly. In patients without eating disorders less effectiveness of the GLP-1-RA in reduction of HbA1c (−3.6% with disorders vs without −2.05%) and body mass (−16 kg with disorders vs without −4.5 kg) was noted.
Conclusion: In this study, we identified that certain characteristics such as diabetes duration, eating behavior, HbA1c, FPG and PPG baseline levels associated with an effective response to GLP-1-RA therapy. Identifying the predictors of a therapeutic response to the use of GLP-1-RA is the basis for rational personalization in the selection of the optimal medication. However, some aspects of this work require conducting of further research.

Comparison of the efficacy of insulin degludec/liraglutide (IDdegLira) and insulin glargine/lixisenatide (iGlarLixi) fix combinations: a meta-analysis
B.A. Domján[1], M.M. Svébis[1], B.D. Lovász[1], A.G. Tabák[1,2];
[1]Semmelweis University, Budapest, Hungary, [2]University College London, London, UK.

Background and aims: Fix combinations of glucagone-like peptide 1 (GLP-1) receptor agonists and basal insulins are emerging as feasible alternatives to basal-bolus insulin regimens according to recent literature. The efficacy of the 2 commercially available fix combinations of GLP-1 agonists and basal insulins (insulin degludec/liraglutide [IDegLira] and insulin glargine/lixisenatide [iGlarLixi]) has been evaluated in two meta-analysises that reached differing conclusions with the use of questionable methods. Thus our aim was to compare the efficacy of these 2 fix combinations by an indirect meta-analysis and meta-regression based on randomised controlled trials.
Materials and methods: We searched PubMed and ClinicalTrials.gov for randomised-controlled trials conducted with IDegLira and iGlarLixi published until 09/JAN/2018. Baseline characteristics of participants, active and comparator medications, mean differences between treatment arms in HbA1c, fasting glucose, and bodyweight, as well as the number of patients with hypoglicaemic events were recorded. Results were analysed using random effect model indirect meta-analysis, and indirect meta-regression adjusted for relevant baseline and treatment parameters.
Results: Altogether 9 randomised controlled trials fulfilled inclusion criteria (2 double-blind and 7 open-labelled). Mean age was 55–60 years (range), duration of diabetes was 6.3–12.1 years, mean HbA1c at the time of randomization 7.7–8.8%, 26–76% of the participants were male. According to the meta-regression with adjustment for relevant clinical parameters IDegLira treatment was associated with a 0.2% lower (95% CI −0.1–0.5%, $p = 0.17$) HbA1c-level (adjusted for the number of comparator medications and baseline bodyweight), a 0.24 mmol/l (95% CI −0.33–0.81 mmol/l; $p = 0.34$) lower fasting glucose (adjusted for the presence of basal insulin), and a 0.21 kg (95% CI −1.90–2.31 kg; $p = 0.83$) lower body weight (adjusted for the effect of comparator on body weight) compared to iGlarLixi. All these differences were statistically non-significant. IDegLira was associated with a non-significantly increased risk of hypoglycaemia (OR 1.29; 95% CI 0.66–2.53; $p = 0.39$) compared to iGlarLixi.
Conclusion: We were unable to prove a statistically significant difference in the efficacy of IDegLira and iGlarLixi based on the meta-analysis of published randomised controlled trials, although due to the wide confidence intervals clinically significant differences may still be present between these medications. Longer studies with direct comparisons are needed to more precisely compare the efficacy of IDegLira and iGlarLixi.

Robust glucose control and weight loss after 6 weeks of treatment with MEDI0382, a balanced GLP-1/Glucagon receptor dual agonist, in patients with type 2 diabetes

P. Ambery[1], M. Stumvoll[2], M. Posch[3], T. Heise[4], L. Plum-Moerschel[5], L.-F. Tsai[6], D. Robertson[1], M. Petrone[1], C. Rondinone[6], V. Parker[1], B. Hirshberg[6], L. Jermutus[1];
[1]MedImmune, Cambridge, UK, [2]University Hospital Leipzig, Leipzig, Germany, [3]Charité Research Organisation GmbH, Berlin, Germany, [4]Profil Institut, Neuss, Germany, [5]Profil Institut, Mainz, Germany, [6]MedImmune, Gaithersburg, USA.

Background and aims: MEDI0382 is under development for the treatment of type 2 diabetes mellitus and nonalcoholic steatohepatitis.
Materials and methods: In a double-blind study, 51 patients with type 2 diabetes and a body mass index of 27–40 kg/m^2 were randomized (1:1) to a daily subcutaneous dose of MEDI0382 200 μg or placebo.
Results: Based on an analysis of covariance model adjusting treatment and baseline values, MEDI0382 markedly reduced fasting glucose (change from baseline at day 41, −49.9 vs −19.2 mg/dL; $P < 0.0001$) and postprandial glucose in a mixed-meal tolerance test (percent change from baseline in glucose $AUC_{0\text{-}4h}$, −32.8 vs −10.2; $P < 0.0001$) (Figure) with no increase in hypoglycemia. HbA1c levels decreased −0.9% with MEDI0382 and −0.6% with placebo ($P = 0.0004$). Weight loss was 3.8 kg vs baseline (1.7 kg vs placebo; $P = 0.0008$); 92% of MEDI0382 patients lost >2 kg. Mean reduction in ambulatory systolic blood pressure was −4.2 for MEDI0382 vs −1.5 mmHg for placebo (P = ns). As with marketed GLP-1 analogs, a mean pulse increase of 6.8 bpm was seen for MEDI0382, vs a fall of 2.0 bpm for placebo ($P < 0.0001$). Treatment-related adverse events such as decreased appetite, vomiting, and headache were seen in more patients on MEDI0382 (20 [80.0%] vs 15 [57.7%]); none were grade >3 severity, 3 led to study discontinuation for MEDI0382 vs 1 for PBO, and 1 serious adverse event in the placebo arm.
Conclusion: Overall, MEDI0382 normalized fasting and postprandial blood glucose, significantly reduced body weight, and had an acceptable safety profile over 41 days of dosing in obese/overweight patients with type 2 diabetes mellitus.

PS 060 GLP1 receptor agonists: How good are they in real practice?

744

Effectiveness of the switch from insulin to incretin therapy in patients with long-lasting type 2 diabetes: a 6-month longitudinal, real-life study

R. Citarrella, M. Di Vittorio, A. Bonfiglio, S. Speciale, D. Ruggirello, G. Castellino, R. Chianetta, D. Nikolic, C. Mannina, G. Montalto;
DIBIMIS, University of Palermo, Italy, Palermo, Italy.

Background and aims: The effects beyond glycemic control including cardiovascular (CV) benefits of incretin-based therapies (IBTs), such as glucagon-like peptide 1 (GLP-1) receptor agonists, are well documented in type 2 diabetes mellitus (DMT2) treatment. However, several studies directly investigated the replacement of insulin by IBTs in diabetes care. Here we investigated glycemic and non-glycemic effects of GLP-1 receptor agonists compared to insulin therapy in order to reach the following objectives: 1) to demonstrate non-inferiority of IBT versus insulin in improving glycemic control and 2) to demonstrate an improvement in overall cardio-metabolic profile after the switch form insulin to GLP-1 receptor agonists.
Materials and methods: Sixty patients (32 men and 28 women; age: 61 ± 8 years) with long-lasting T2DM, treated over the 6-year period with basal-bolus insulin therapy in addition to oral hypoglycemic agents (OHA) and with poor adherence and were included in the present study. The study population was subdivided in 2 groups: 1) Group A ($n = 30$): switching from insulin to IBTs was performed (liraglutide was given to 25 patients at dose of 1.2 mg/day) and 2) Group B $n = 30$) included patients who continued and intensified the insulin therapy (average insulin dose 0.74 ± 0.31 U/kg per day). The Visceral Adiposity Index (VAI), a gender-specific mathematical model for assessing cardiometabolic risk associated with visceral obesity, was calculated. Statistical analysis was performed using Wilcoxon or the Mann-Whitney *U* test.
Results: The only statistically significant difference between 2 groups at baseline was found for triglyceride levels that was higher in group A ($p = 0.030$). After 6 months of the therapeutic switch in the group A statistically significant changes were found in all measured parameters, with the exception of total-, LDL-cholesterol and triglycerides (Table 1). In the group B, the only HbA1c changed significantly ($p = 0.004$). Comparing the 2 groups, after 6 months of follow-up from the therapeutic switch, a statistically significant difference was observed in reduction of HbA1c ($p < 0.001$), waist circumference ($p = 0.010$) and body weight ($p = 0.023$), in favor of Group A. The VAI reduced significantly ($p = 0.017$) only in the group A, as well as blood pressure (PAS $p = 0.003$ and PAD $p = 0.039$) and aminotransferases (AST $p = 0.004$ and ALT $p < 0.001$).
Conclusion: After 6-month of the therapeutic switch, GLP-1 receptor agonists were found to be more effective compared to insulin in improving glyco-metabolic compensation, promoting the reduction of anthropometric parameters. Overall, such effects may reduce progression of the complications of diabetes, including the risk of CV events and mortality rate as it has been shown in recent CVOTs.

Parameters	Mean (ds)		p-value
	Baseline	After 6 moths	
PAS (mmHg)	134.8 (15.3)	127.7 (14.1)	**0.003**

Comparative glycaemic effectiveness of dulaglutide vs liraglutide and exenatide once weekly in a US real-world setting

R. Mody[1], Q. Huang[2], M. Yu[3], H. Patel[1], R. Zhao[2], M. Grabner[2], L. Fernández Landó[1];
[1]Eli Lilly and Company, Indianapolis, USA, [2]HealthCore, Inc., Wilmington, USA, [3]Eli Lilly and Company, Toronto, Canada.

Background and aims: The objective of this retrospective observational study was to compare 6-month and 1-year real-world glycaemic effectiveness among patients initiating GLP-1 receptor agonists (GLP-1RA), dulaglutide (DULA) vs. liraglutide (LIRA) or DULA vs. exenatide QW (EQW), using US claims data from the HealthCore Integrated Research Database (HIRD®) between November 2014 and May 2016 (index date = earliest GLP-1RA fill date).
Materials and methods: Patients ≥18 years old with T2DM, no claim for any GLP-1RA in the 6 months pre-index period (baseline), continuous enrolment 6 months pre- and 1-year post-index, ≥1 $HbA1_c$ result pre-index and 1-year post-index were included. DULA users were propensity-matched 1:1 to LIRA (585 pairs) or EQW (422 pairs) users and the matched cohorts were balanced in baseline patient characteristics including mean $HbA1_c$.
Results: The mean age of all cohorts was 53 years and approximately 50% were males. Among the DULA vs. LIRA matched cohorts, 59% and 41% initiated on DULA 0.75 mg and 1.5 mg QW, respectively, and 44% and 56% initiated on LIRA 0.6/1.2 mg and 1.8 mg QD, respectively. The key effectiveness results are included in the table.
Conclusion: At both 6-month and 1-year post-index, patients initiating DULA experienced a greater reduction in $HbA1_c$ compared to LIRA or EQW initiators ($P < 0.05$). In all cohorts, patients adherent to their GLP-1RA treatment had greater reductions in $HbA1_c$ than non-adherent patients ($P < 0.05$).

Table: Real-world glycaemic effectiveness outcomes among GLP-1RA initiators

6-Month post-index outcomes[1], n	Matched DULA vs. LIRA cohorts		Matched DULA vs. EQW[2] cohorts	
	DULA 420	LIRA 433	DULA 307	EQW 296
$HbA1_c$ Outcomes, mean (SD) (mmol/mol)				
Pre-index $HbA1_c$ result[3]	71.69 (19.24)	71.25 (18.91)	72.23 (19.24)	70.92 (19.79)

Time to treatment intensification with GLP-1 receptor agonists for patients with type 2 diabetes in the UK: medical record review study

K. Norrbacka[1], D. Stein[2], L.S. Matza[3], J.B. Jordan[3], L.-E. García-Pérez[4], S.W. Hassan[4], K.S. Boye[4];
[1]Eli Lilly Finland, Helsinki, Finland, [2]Evidera, London, UK, [3]Evidera, Bethesda, USA, [4]Eli Lilly and Company, Indianapolis, USA.

Background and aims: Patients with type 2 diabetes (T2D) who fail to meet recommended glycemic control targets are at increased risk of diabetes complications. The National Institute for Health and Care Excellence (NICE) guidelines recommend drug intensification in patients not able to maintain HbA1c levels ≤7.0% (53 mmol/mol). For patients who cannot maintain glycemic control on oral medication, one recommended option is to add an injectable glucagon-like peptide-1 receptor

agonist (GLP-1 RA) to their treatment regimen. This is the first known study to examine time to treatment intensification with GLP-1 RA, including the duration of time that patients did not maintain glycemic control with oral medication.

Materials and methods: This was a medical record review conducted in the UK via an online physician survey from Jul to Oct 2017. Participating physicians represented three medical specialties: endocrinologists/diabetologists (specialists), general practitioners (GPs) with special interest in diabetes (GPwSIs), and GPs with no special diabetes interest (GPs). Patients eligible to have their records reviewed were required to be ≥18 years of age, have a confirmed T2D diagnosis, and have newly initiated GLP-1 RA for T2D in the prior 6 months. All HbA1c within 5 years prior to GLP-1 RA initiation were collected. Duration of poor glycemic control since most recently added oral regimen (oral±injectable) was calculated based on consecutive HbA1c values >7.0% (53 mmol/mol) prior to GLP-1 RA initiation.

Results: 113 physicians (38.9% Specialists, 20.4% GPwSIs, 40.7% GPs) contributed data for 1096 patients (Specialists: 437, 39.9%, GPwSIs: 216, 19.7%, GPs: 443, 40.4%). Patient mean (SD) age at GLP-1 RA initiation was 55 (12), 607 were male (55.4%), and 782 were white/Caucasian (71.4%); mean (SD) BMI was 35.2 (6.0) and mean (SD) number of HbA1c assessments/year was 1.9 (0.8). Most common diabetes treatment regimen prior to GLP-1 RA was oral (918, 83.8%) followed by oral+injectable (145, 13.2%). Median time from T2DM diagnosis to GLP-1 RA initiation was 6.1 years. Median time from most recently added oral diabetes regimen (oral ± injectable) to GLP-1 RA initiation was 3.0 years; majority of patients on oral regimens had ≥1 uncontrolled HbA1c prior to GLP-1 RA initiation (1047, 98.5%). Median consecutive time patients on oral regimens were not under control prior to GLP-1 RA initiation was 13.5 months (Specialists: 11.0, GPwSIs: 16.2, GPs: 17.0 months) (Figure).

Conclusion: Results suggest that treatment intensification is often delayed despite consistently poor glycemic control for more than 12 months, contrary to treatment guideline recommendations. Findings from this study highlight that there may be T2D patients who would benefit from more rapid treatment intensification, thereby reducing the risk for many short and long-term health complications.

[1]Hull Royal Infirmary, Hull, UK, [2]Northern HSC, Antrim, UK, [3]The Ulster Hospital, Dundonald, UK, [4]Kingston Hospital, London, UK, [5]City Hospitals, Sunderland, UK, [6]Kings College Hospital, London, UK, [7]Pennine Acute Hospitals, Manchester, UK, [8]St John's Hospital, Livingston, UK, [9]School of Medicine and Pharmacology, Perth, Australia, [10]City Hospital, Birmingham, UK.

Background and aims: Liraglutide has been shown to reduce cardiovascular outcomes in patients at high cardiovascular disease (CVD) risk (LEADER study). Uncertainty exists regarding the impact of liraglutide on CVD risk in routine clinical care. The United Kingdom Prospective Diabetes Study (UKPDS) CVD risk engine version 2.0 uses recognised risk factors to calculate future CVD risk. Our aim was to investigate the impact of liraglutide in routine use on 10 year CVD risk.

Materials and methods: We used data from the Association of British Clinical Diabetologists (ABCD) nationwide liraglutide audit which assesses liraglutide in routine clinical practice (6959 patients, 163 centres, 2009–2017). For this analysis we included all patients with all the factors utilised by the risk engine (age, duration of diabetes, ethnicity, systolic blood pressure, HbA1c, total cholesterol and HDL cholesterol) measured before and at the earliest return to clinic between 3 and 9 months after commencing liraglutide. As we did not have data on atrial fibrillation or smoking these were assumed to be absent for the purposes of the analysis.

Results: The table shows baseline characteristics of the 747 patients and the early impact of liraglutide treatment on CVD risk factors. There were highly significant falls in all parameters involved in CVD risk assessment other than HDL cholesterol which was unchanged. The UKPDS risk engine mean ± SD 10 year coronary heart disease (CHD) risk fell by 2.7 ± 7.6% from 18.7 ± 13.0% to 16.1 ± 11.6% ($p < 0.001$). 10 year fatal CHD risk fell by 0.3 ± 2.8% from 7.9 ± 8.7% to 7.6 ± 8.3% ($p < 0.001$). 10 year stroke risk fell by 0.94 ± 1.35% from 5.92 ± 4.27% to 4.98 ± 3.45% ($p = 0.003$). 10 year fatal stroke risk fell by 0.1 ± 0.7% from 1.2 ± 1.4% to 1.1 ± 1.3% ($p = 0.001$). Weight, which is not a factor utilised in the UKPDS risk engine was assessed in the 3535 patients in the audit with weight and BMI data during the same time interval. Weight fell by 2.8 ± 6.1 kg from 110.0 ± 22.3 to 107.9 ± 22.1 kg ($p < 0.001$), and BMI by 0.98 ± 2.2 kg/m^2 from 38.7 ± 7.0 to 37.8 ± 6.9 kg/m^2 ($p < 0.001$).

Conclusion: Starting liraglutide reduced 10-year CVD risk. These data suggest that liraglutide used in routine clinical care in 100 patients could prevent 3 events of CHD or stroke and save 2 or more lives over the next 10 years. As this represented the earliest assessment after commencement of liraglutide it is possible that the impact would be greater with longer follow up. The results are likely to be an underestimate as the UKPDS risk engine does not take into account BMI which is also reduced by liraglutide.

Parameter	Baseline	At 3-9 months	Difference	P value
Age (years)	56.6±10.3			
Sex (%male)	56.2			
Ethnicity: % White % Afro-Caribbean % Asian-Indian	89.2 2.9 7.9			
Diabetes Duration (Median (IQR) years)	9.0 (6.0-13.0)			
HbA1c (mmol/mol)	77.2±18.0	67.4±18.6	-9.8±17.9	<0.001
HbA1c (%)	9.2±1.6	8.3±1.7	-0.9±1.6	<0.001
Systolic Blood Pressure (mm Hg)	136.8±16.6	133.3±17.3	-3.5±17.7	<0.001
Serum total cholesterol (mmol/L)	4.22±1.57	3.97±1.01	0.25±1.45	<0.001
Serum HDL cholesterol (mmol/L)	1.10±0.32	1.12±0.79	-0.02±0.78	0.39
Weight (kg) (n=3535)	110.0±22.3	107.9±22.1	-2.8±6.1	<0.001
BMI (kg/m^2) (n=3535)	38.7±7.0	37.8±6.9	-0.98±2.2	<0.001

Table: Baseline characteristics of the 747 patients who returned to clinic between 3 and 9 months after starting liraglutide and the change in cardiovascular risk parameters at the return visit as mean±SD or median (interquartile range [IQR]). Weight and BMI measurements in 3535 patients during the same time interval. P-values reflect change from baseline.

COMBINATION study: COMbined Behavioural/INcretin Action sTudy In Obese/diabetic persoNs

L. Montesi[1], A. Mazzotti[1], L. Brodosi[1], M.T. Caletti[1], F.A. Barbanti[1], P. Di Bartolo[2], G. Marchesini[1];
[1]Department of Medical and Surgical Sciences (DIMEC), University of Bologna, Bologna, Italy, [2]Diabetes Clinical Network, Romagna Local health Authority, Ravenna, Italy.

Background and aims: Cognitive-behavior therapy (CBT) and drug treatment show multiplicative effects in obesity treatment. We aimed to test the reinforcing effects of CBT in patients with type 2 diabetes mellitus (T2DM), newly-treated with glucagon-like peptide-1 receptor agonists (GLP1-RAs).
Materials and methods: The anthropometric and clinical data of 207 T2DM patients (93 F, 114 M; mean age 56 ± SD 10.3) who shifted to GLP-1RAs in the period 2013–6 were retrospectively analyzed and weight loss trajectories were reconstructed to determine the effects of new treatment in relation to the participation in structured lifestyle intervention programs. The primary outcome was weight loss (≥10% initial body weight); secondary endpoint was A1c target reach (<53 mmol/mol - 7%). According to our protocol, behavior therapy is offered to all cases first attending our institution. Behavioral treatments were carried out within 6 months of GLP-1RA treatment and were classified either as elementary nutritional education (ENE, 5 group sessions) or as more intensive lifestyle interventions (CBT treatment, 12 group sessions). 147 cases (68 F, 79 M) received liraglutide, 35 exenatide BID (14 F, 21 M), 20 exenatide-LAR (6 F, 12 M) and only 5 the most recent GLP-1RA, dulaglutide (2 F, 3 M). 151 case did not receive behavior therapy (CONT-Group A; 64 F, 87 M); 56 cases participated in educational programs during the pre-specified temporal window (Group B, divided into ENE - B1 ($n = 20$) and CBT - B2 ($n = 36$)).
Results: In the whole group, 38 cases (19%) reached the primary end-point (weight loss ≥10%) and 122 cases (61%) reached the secondary end-point (A1c <7%) at 12-month follow-up. Among the different sub-groups, weight loss was larger in Group B compared with Group A: after 6 months the average weight loss was −3.2 ± 4.4% in Group A and −6.4 ± 2.6% e −7.7 ± 5.9% in ENE and CBT, respectively. The trend was maintained after 12 months: −3.7 ± 6.0% in Group A, −5.6 ± 4.5% in ENE e −6.8 ± 7.4% in CBT ($P < 0{,}0001$). No significant differences among groups were measured in the A1c end-point ($P = 0.195$). At logistic regression analysis, the participation into CBT increased the probability of weight loss target reach (OR, 2.59; 95% CI, 1.24-5-41; $p = 0.011$). The secondary end point reach (HbA1c <7%) was associated with baseline metabolic control and the achievement of the primary end-point (OR, 3.47; 1.44–8.36). In both analyses BMI at GLP-1RA shifting, sex and age did not change the association with outcome reach.
Conclusion: The results suggest that initial GLP1-RA treatment may be effectively summed up to behavior therapy to enhance weight loss in T2DM. Initial treatment with GLP-1RAs may be a crucial point to implement effective, successful behavioral treatment.

GLP-1 RA treatment: a benefit-risk analysis from a retrospective cohort study

E. Konstantara, A.P. McGovern, W. Hinton, R. Coyle, M. Feher, N. Munro, S. de Lusignan;
Department of Clinical and Experimental Medicine, University of Surrey, Guildford, UK.

Background and aims: Glucagon-like peptide-1 receptor agonists (GLP-1 RAs) are an established drug class of injectable non-insulin treatments for type 2 diabetes (T2D). Benefits include reductions in HbA_{1c} and weight, and low hypoglycaemia risk. A predominant limiting factor of widespread use of GLP-1 RAs is gastrointestinal side-effects. We aimed to identify which people are most likely to benefit from GLP-1 RAs with the lowest risk of adverse effects.
Materials and methods: We performed a retrospective cohort study using routine data from a primary care sentinel network in England (Royal College of General Practitioners Research and Surveillance Centre). People with T2D were identified if they had been prescribed GLP-1 RA therapy (Exenatide, Lixisenatide, Liraglutide, Albiglutide or Dulaglutide) between 1 January 2005 and 31 July 2016. Using regression modelling, factors associated with improvement in HbA_{1c}, weight reduction, presence of gastrointestinal side-effects (nausea, vomiting, and diarrhoea) were identified. Treatment discontinuations over 1 year from the first GLP-1 RA prescription were also recorded. Adjustments were made for; gender, age, ethnicity, socioeconomic status, BMI, duration of diabetes, and HbA_{1c} at initiation.
Results: From 144,427 people with T2D, 3.8% ($n = 5515$) were initiated on GLP-1 RA. Mean HbA_{1c} at GLP-1 RA initiation was 76.05 mmol/mol (SD 18.86) with mean HbA_{1c} improvement −4.99 mmol/mol (SD 18.90). Mean BMI at initiation was 37.98 kg/m^2 (SD 7.03) with mean BMI improvement −1.19 (SD 3.18). After adjusting for baseline HbA_{1c}, people 55+ years old had a greater reduction in HbA_{1c} at 1 year, compared to those <55 years (55–74 years: −2.63; 95% CI −4.25 to −1.02; 75+ years: −5.12; 95% CI −7.61 to −2.63). Females, compared to males, showed a greater HbA_{1c} reduction (−1.89 mmol/mol; 95% CI −3.21 to −0.56). People of black ethnicity showed a smaller reduction in HbA_{1c} at 1 year, compared to people of white ethnicity (6.54 mmol/mol; 95% CI 2.38 to 10.71); no other ethnic differences were identified. People who had diabetes for 10+ years had a smaller reduction in HbA_{1c}, compared to people who had diabetes for under a year (3.44 mmol/mol; 95% CI 1.23 to 5.65). Socioeconomic status and BMI were not associated with glycaemic improvement. Side effects were almost twice as frequently reported by females (OR 1.79; 95% CI 1.27 to 2.51). There were no other associations with reporting of adverse effects. Weight reduction was greater in those with the highest initial BMI (−0.13 kg/m^2; 95% CI −0.14 to −0.11). There were no other associations identified. Treatment discontinuation was less common in those who had T2D for 1–3 years (OR 0.49; 95% CI 0.37 to 0.67) and more common in those diagnosed 10+ years ago (OR 1.73; 95% CI 1.45 to 2.05) compared to those with T2D for 4–6 years. Treatment discontinuation was also less likely in those with a high HbA_{1c} at initiation (73.9+ mmol/mol) (OR 0.61; 95% CI 0.49 to 0.74) compared to those with a lower HbA_{1c} (47.6–57.4 mmol/mol); and more likely for those with a BMI ≥40 kg/m^2 (OR 1.54; 95% CI 1.21 to 1.97) compared to those with BMI 25.0–29.9 kg/m^2.
Conclusion: Older people and those with diabetes of short duration achieve the greatest glycaemic benefit from GLP1 RAs. Females also have greater HbA_{1c} reduction despite reporting more adverse effects. Weight loss appears to be consistent across all groups. These findings will help develop a targeted approach to GLP-1 RA prescribing in individuals with T2D.

Lifetime cost-effectiveness simulation of exenatide once-weekly in type 2 diabetes: evidence from the EXSCEL trial

F. Becker[1], H. Dakin[1], S.D. Reed[2], Y. Li[2], J. Leal[1], S.M. Gustavson[3], B. Kartman[4], E. Wittbrodt[3], A.M. Gray[1], A.F. Hernandez[2], R.R. Holman[5]; [1]Health Economics Research Centre, Oxford, UK, [2]Duke Clinical Research Institute, Durham, USA, [3]AstraZeneca Research and Development, Gaithersburg, USA, [4]AstraZeneca, Mölndal, Sweden, [5]Diabetes Trials Unit, Oxford, UK.

Background and aims: The Exenatide Study of Cardiovascular Event Lowering (EXSCEL) assessed the effect of branded exenatide 2 mg once-weekly (EQW) vs placebo added to usual care in 14,752 patients with type 2 diabetes (T2D), with or without previous cardiovascular disease. This pragmatic, randomized, double-blind, placebo-controlled, event-driven trial demonstrated a statistically non-significant reduction in major adverse cardiovascular events and a nominally significant reduction in all-cause mortality with allocation to EQW. We assessed the lifetime cost-effectiveness of EQW added to usual care, compared with usual care alone.

Materials and methods: Medical resource use and EuroQol 5-Dimension (EQ-5D) data were collected throughout the study. Within-trial results were extrapolated to a lifetime horizon using the UKPDS Outcomes Model version 2 after accounting for missing within-trial data. Cost-effectiveness was evaluated separately for US and UK settings, with costs assessed from a healthcare perspective and outcomes measured by quality-adjusted life-years (QALYs). The base case analyses extrapolated the 9% annual discontinuation rate observed in the trial forward for the first 10 years of the extrapolated period. In the US setting, a 23.1% discount on the wholesale acquisition price of branded EQW was applied. Further analyses were performed using pre-specified patient sub-groups and assuming patients who were still receiving EQW at the end of the trial remained on branded EQW during lifetime.

Results: Branded EQW plus usual care was estimated to gain 0.151 QALYs ($p < 0.001$) over a lifetime horizon at an additional cost of USD34,410 ($p < 0.001$) per patient, compared with usual care in a US setting. The incremental cost-effectiveness ratio (ICER) was estimated as USD230,429/QALY (base case; Table). In a UK setting, the estimated net gain was 0.141 QALYs ($p < 0.001$) at an additional cost of GBP4,566 ($p < 0.001$) with an ICER of GBP32,782/QALY. The base case ICERs exceeded the standard cost-effectiveness thresholds of USD100,000 and GBP20,000 per QALY, respectively. However, the ICERs for different sub-groups were found to be considerably lower, with an ICER of USD88,608 for patients enrolled in US sites and an ICER of GBP16,319 for patients aged 65 years and older in the UK setting.

Conclusion: Branded EQW added to usual care was associated with greater QALY gain and additional costs compared with usual care alone during a lifetime. The base case ICERs exceeded standard cost-effectiveness thresholds. However, EQW was cost-effective in specific sub-groups of the trial population, such as patients enrolled in US sites and (in the UK setting) patients aged 65 years and older.

Table 1: Lifetime cost-effectiveness of exenatide once-weekly vs placebo – base case, sensitivity and sub-group analyses

	n	US			UK

Efficacy and safety of semaglutide in elderly subjects with type 2 diabetes: a post hoc analysis of the SUSTAIN 7 trial

V.R. Aroda[1,2], D. Sugimoto[3], D. Trachtenbarg[4], M. Warren[5], A. Navarria[6], G. Nayak[6], M. Abildlund Nielsen[6], V. Woo[7];
[1]Brigham and Women's Hospital, Boston, USA, [2]MedStar Health Research Institute, Hyattsville, USA, [3]Cedar Crosse Research Center, Chicago, USA, [4]University of Illinois College of Medicine at Peoria, Peoria, USA, [5]Physicians East, Greenville, USA, [6]Novo Nordisk A/S, Søborg, Denmark, [7]University of Manitoba, Winnipeg, Canada.

Background and aims: The SUSTAIN 7 trial investigated efficacy and safety of semaglutide, a glucagon-like peptide-1 analogue, vs dulaglutide in subjects with type 2 diabetes (T2D). The aim of this *post hoc* analysis was to compare the efficacy and safety of semaglutide and dulaglutide in elderly (≥65 years old) vs non-elderly (<65 years old) in the SUSTAIN 7 trial.
Materials and methods: Subjects with T2D were randomised to once-weekly subcutaneous semaglutide or dulaglutide for 40 weeks. As pre-specified in SUSTAIN 7, semaglutide 0.5 mg was compared with dulaglutide 0.75 mg; semaglutide 1.0 mg with dulaglutide 1.5 mg. For this analysis, subjects were stratified by age (≥65 and <65 years old). Post-baseline data were analysed using a mixed model for repeated measurements.
Results: This analysis comprised 1,199 subjects (260 elderly and 939 non-elderly; mean ages 69.3 and 51.9 years, respectively). Mean baseline HbA_{1c} and body weight were lower in elderly vs non-elderly subjects (**Table**). Across treatment arms, reductions from baseline were similar between elderly and non-elderly subjects for HbA_{1c} (interaction p value: $p > 0.05$) and body weight (interaction p value: $p > 0.05$). Reductions in HbA_{1c} and body weight were greater with semaglutide vs dulaglutide in all subgroups (**Table**). The proportions of subjects achieving HbA_{1c} <7.0% and ≤6.5% were higher in elderly than non-elderly subjects across all treatment arms, and were higher with semaglutide vs dulaglutide across subgroups (**Table**). This is consistent with lower baseline HbA_{1c} in elderly vs non-elderly subjects and similar reductions in HbA_{1c} between age groups. More elderly than non-elderly subjects reported adverse events (AEs) with semaglutide 1.0 mg and dulaglutide 1.5 mg. More elderly than non-elderly subjects reported serious AEs across all treatment arms except semaglutide 1.0 mg. Most AEs were mild to moderate in severity. A higher proportion of elderly than non-elderly subjects discontinued semaglutide 1.0 mg due to AEs. The proportion of subjects discontinuing treatment due to AEs in other treatment arms was similar between elderly and non-elderly subjects (**Table**).
Conclusion: In the SUSTAIN 7 trial, reductions in HbA_{1c} and body weight were comparable in both elderly and non-elderly subjects, and were greater with semaglutide vs dulaglutide across most subgroup comparisons. These improvements in glycaemic control in elderly subjects were not associated with a higher incidence of hypoglycaemia. The overall safety profile for semaglutide was in line with the SUSTAIN 1–5 trials and these results may help guide treatment in elderly patients with T2D.

Table. Changes in HbA_{1c} and body weight, and AEs, in elderly vs non-elderly subjects in SUSTAIN 7

Efficacy and safety of lixisenatide as add-on in patients with type 2 diabetes aged ≥70 years uncontrolled on basal insulin in the GetGoal-O study

G. Dailey[1], T. Dex[2], M. Roberts[2], G. Meneilly[3];
[1]Scripps Whittier Diabetes Institute, La Jolla, USA, [2]Sanofi, Bridgewater, USA, [3]Department of Medicine, University of British Columbia, Vancouver, Canada.

Background and aims: Patients aged ≥70 years with type 2 diabetes (T2D) are often excluded from clinical trials. The GetGoal-O trial specifically enrolled elderly, nonfrail patients with T2D uncontrolled on their current therapy. This analysis assesses the efficacy and safety of lixisenatide as add-on therapy to basal insulin (BI) in these patients with or without renal insufficiency.
Materials and methods: A post hoc subgroup analysis was performed in nonfrail patients ≥70 years, randomized to receive once-daily 20 μg lixisenatide or placebo on a background of BI ± oral antidiabetic drugs for 24 weeks. Patients were stratified by background antidiabetic therapy and presence of renal insufficiency (defined as having an estimated glomerular filtration rate [eGFR] of 30≤eGFR<60 or eGFR ≥60 mL/min/1.73 m^2) at screening.
Results: In total, 108 patients met the inclusion criteria, of whom 36 had 30≤eGFR<60 mL/min/1.73 m^2. Average BI dose at baseline was 0.47 U/kg, indicating that most patients were approaching a point where they would require postprandial glucose control. Overall, patients randomized to lixisenatide, compared with placebo, had significantly greater reductions in HbA1c, 2-h postprandial glucose (2-h PPG), average 7-point self-monitored plasma glucose (SMPG), and weight. No significant differences between treatment arms were observed for change in fasting plasma glucose (FPG), eGFR, or daily BI dose by weight. Treatment-emergent adverse events (TEAEs) occurred more frequently in the lixisenatide

group. Incidence of documented symptomatic hypoglycemia (<60 mg/dL) was low in both groups: 5.7% of lixisenatide and 12.7% of placebo-treated patients. There were no instances of severe symptomatic hypoglycemia in either treatment group. Significantly more patients treated with lixisenatide achieved >0.5% reduction in HbA1c with no documented symptomatic hypoglycemia compared with the placebo group (P = 0.002) (Table). Although reduction in HbA1c also remained significantly greater in lixisenatide-treated patients regardless of baseline eGFR, the difference was slightly greater in those with renal insufficiency (−0.68% vs −0.55%). No significant differences for other efficacy outcomes were observed between patients stratified by baseline eGFR; insufficient numbers were available for a meaningful analysis of hypoglycemia or TEAEs.

Conclusion: This post hoc analysis suggests that adding lixisenatide in nonfrail patients with T2D aged ≥70 years uncontrolled with BI is efficacious and has a good safety profile. Furthermore, despite small expected increases in exposure and a very small sample size, this treatment approach suggests similar efficacy of lixisenatide in patients with mild-to-moderate renal insufficiency, with no dose adjustments required.

Table

	Placebo (N=55)	Lixisenatide (N=53)
Age, years	74.7±4.4	73.8±4.1
Duration of BI treatment, years	3.81±3.38	4.32±4.97

Dulaglutide has favourable outcomes in elderly or renal impairment patients with type 2 diabetes

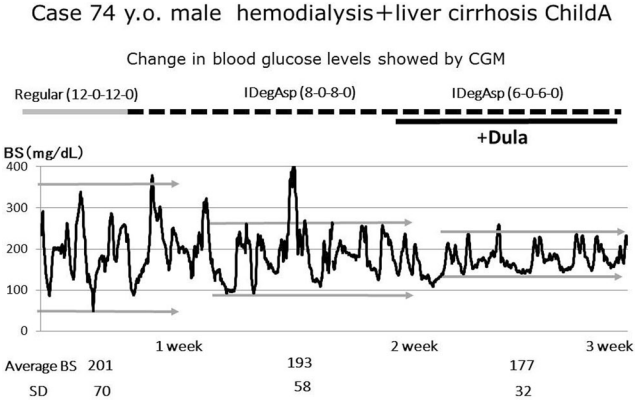
M. Kadoya, Y. Ueda, Y. Tahara, S. Kaneko;
Takatsuki Red Cross Hospital, Takatsuki, Osaka, Japan.

Background and aims: Japan is becoming a super-aged society. Additionally, dialysis is being performed in one out of 400 people. Therefore, safe, effective and convenient therapies for elderly or renal impairment type 2 diabetic patients (T2D) including those undergoing dialysis are needed. We investigated the long-term efficacy and safety of a new once weekly GLP1RAg dulaglutide (Dula) on glycemic control in the above.

Materials and methods: We conducted two different retrospective analyses of the efficacy and safety of Dula in T2D for 2 years according to; 1) subgroups stratified by ages (≤70 years old or >71 years old), 2) renal impairment including those undergoing dialysis**.**

Results: Regarding 1), Of a total of 360 T2D, 180 elderly T2D (>71 years old, 94 males, 78.2 ± 5.0 years old, disease duration of 7.6 ± 7.4 years, HbA1c 8.3 ± 1.8%, BMI 24.1 ± 4.1) and 180 younger T2D (≤70 years old, 113 males, 60.4 ± 9.7 years old, disease duration of 5.6 ± 5.6 years, HbA1c 7.9 ± 1.4%, BMI 25.5 ± 4.4) were newly administered Dula weekly. Elderly and younger T2D treated with Dula achieved 7.0 ± 0.9% and 7.2 ± 0.9% in HbA1c after 2 years respectively. 20 elderly T2D were injected with help from a carer due to cognitive impairment. Three patients discontinued Dula due to intolerance. Nocturnal hypoglycemia never occurred. Regarding 2), 33 patients with renal impairment (Impairment group) (69.6 ± 9.7 years old, HbA1c 7.7 ± 1.1%, BMI 23.8 ± 3.7, eGFR 39.7 ± 10.2 mL/min/1.73 m^2), 8 patients undergoing dialysis (Dialysis group) (6 hemodialysis and 2 peritoneal dialysis) and 1 patient who received a kidney transplant (Transplant group) were administered Dula weekly. The levels of HbA1c in Impairment group maintained <7% and their levels of eGFR remained as they were at the start of Dula therapy. Only one patient in Dialysis group discontinued Dula due to vomiting. In the remainder of Dialysis group and in Transplant group, there were no complications due to administration of Dula and good blood glucose levels were maintained.

Conclusion: Weekly GLP-1RAg provides more effective and safer glycemic control in elderly T2D with/without renal impairment irrespective of whether dialysis was being performed. In addition to relieving patient burden due to weekly injections, the administration of Dula might be expected to reduce the risk of hypoglycemia and lower the burden on carers in an aging society. It might also be expected to improve the QOL of patients due to a reduction in the overall burden of taking medicines (i.e. by switching from daily to weekly injections) and a reduction in the incidence of hypoglycemia. Carers' burdens in aiding elderly patients, compounded by a labor force shortage, will also be lessened. The net result could also be a reduction in medical costs.



Disclosure: **M. Kadoya:** None.

Effect of liraglutide on cardiovascular outcomes in elderly patients in the LEADER trial

M.P. Gilbert[1], S.C. Bain[2], E. Franek[3], E. Jodar-Gimeno[4], M.A. Nauck[5], R.E. Pratley[6], R. Réa[7], J. Saraiva[8], S. Rasmussen[9], K. Tornøe[9], B. von

Scholten[9], J. Buse[10], LEADER Publication Committee on behalf of the LEADER Trial Investigators;
[1]The Robert Larner, M.D. College of Medicine at The University of Vermont, South Burlington, USA, [2]Institute of Life Science, Swansea University, Swansea, UK, [3]Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland, [4]Quirónsalud Madrid University Hospital, Madrid, Spain, [5]Diabetes Center Bochum-Hattingen, St. Josef-Hospital (Ruhr-Universität Bochum), Bochum, Germany, [6]Florida Hospital Translational Research Institute, Orlando, USA, [7]Clinical Hospital of the Federal University of Paraná (SEMPR), Curitiba, Brazil, [8]Pontifícia Universidade Católica de Campinas, Campinas, Brazil, [9]Novo Nordisk A/S, Søborg, Denmark, [10]University of North Carolina School of Medicine, Chapel Hill, USA.

Background and aims: The burden of chronic diseases such as type 2 diabetes (T2D) and associated comorbidities increases with ageing, making the elderly more vulnerable to potential side effects of medical treatment. Information about the effect of antihyperglycaemic therapy on cardiovascular (CV) events in the elderly is limited. Liraglutide reduced the risk of CV events in the LEADER trial compared with placebo, and this post hoc analysis assesses risk of CV events and all-cause mortality in elderly patients with T2D.
Materials and methods: In the LEADER trial, 9340 patients with T2D at high risk for CV events were randomised 1:1 to liraglutide or placebo, both on top of standard of care, and followed for up to 5 years. The primary composite outcome was defined as time to first occurrence of death from CV causes, non-fatal myocardial infarction (MI) or non-fatal stroke. Secondary outcomes included the expanded composite outcome and all-cause mortality. In this analysis, outcomes were assessed in patients aged ≥75 years.
Results: Among those aged ≥75 years, baseline characteristics were well matched between treatment arms ($N = 418$ for both treatment arms). Compared with placebo, liraglutide significantly reduced the risk of the primary composite outcome, expanded composite outcome, non-fatal MI, coronary revascularisation, death from any cause and death from non-CV causes (Table).
Conclusion: In the LEADER trial, liraglutide treatment reduced the risk of CV events and all-cause mortality in elderly patients with T2D.

Table: Risk of cardiovascular events in patients aged ≥75 years

Outcome	Liraglutide (N=418)		Placebo (N=418)		HR (95% CI)	*p*-value (test for HR=1)
	N (%)	Events/ 100 PYO	N (%)	Events/ 100 PYO		
Primary composite endpoint	77 (18.4)	4.9	106 (25.4)	7.0	0.69 (0.51–0.92)	0.012
Expanded composite endpoint*	108 (25.8)	6.9	140 (33.5)	9.2	0.73 (0.56–0.93)	0.013
CV death	34 (8.1)	2.2	42 (10.0)	2.8	0.78 (0.50–1.23)	0.291
Non-fatal MI	30 (7.2)	1.9	51 (12.2)	3.4	0.56 (0.36–0.88)	0.011
Non-fatal stroke	19 (4.5)	1.2	22 (5.3)	1.5	0.84 (0.45–1.55)	0.577

Efficacy and safety of semaglutide in subjects with type 2 diabetes by race and ethnicity: a post hoc analysis of the SUSTAIN trials

C. Desouza[1], S. Garg[2], B. Cariou[3], J.K. Furberg[4], A. Navarria[4], G. Nayak[4], V. Fonseca[5];
[1]University of Nebraska Medical Center, Omaha, USA, [2]Barbara Davis Center for Diabetes, University of Colorado Denver, Denver, USA, [3]CHU de Nantes, L'Institut du Thorax, Department of Endocrinology, Nantes, France, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Tulane University Health Sciences Center, New Orleans, USA.

Background and aims: The SUSTAIN clinical trials investigated the effects of semaglutide, a glucagon-like peptide-1 analogue for the treatment of type 2 diabetes (T2D). This *post hoc* analysis compared efficacy and safety of semaglutide in race and ethnicity subgroups pooled from SUSTAIN 1–5 and 7.
Materials and methods: Subjects with T2D were randomised to once-weekly subcutaneous semaglutide 0.5 or 1.0 mg (only 1.0 mg in SUSTAIN 3) vs placebo (SUSTAIN 1 and 5; 30 weeks), sitagliptin (SUSTAIN 2; 56 weeks), exenatide extended release (SUSTAIN 3; 56 weeks), insulin glargine (SUSTAIN 4; 30 weeks) or dulaglutide (SUSTAIN 7; 40 weeks). Efficacy (change from baseline in HbA_{1c} and body weight) and safety (adverse event [AE]) data at week 30 (SUSTAIN 1–5) or 40 (SUSTAIN 7) were pooled and analysed by race (Asian, Black/African American, Caucasian, Other) and ethnicity (Hispanic, non-Hispanic).
Results: The analysis included 3,066 subjects who received semaglutide 0.5 or 1.0 mg, pooled from SUSTAIN 1–5 and 7. 'Other' race subgroup data are not reported due to low subject numbers ($n = 25$ [semaglutide 0.5 mg]; $n = 50$ [semaglutide 1.0 mg]). Estimated changes from baseline in HbA_{1c} and body weight by race and ethnicity are shown in the table. HbA_{1c} reductions ranged from 1.4 to 1.5% with semaglutide 0.5 mg. With semaglutide 1.0 mg, HbA_{1c} was reduced by 1.6–2.0%; Asians had greater reductions than Black/African Americans or Caucasians despite similar baseline HbA_{1c}. Body weight reductions in Caucasians were 4.2 and 6.0 kg with semaglutide 0.5 and 1.0 mg, respectively, and ranged from 3.3 to 5.3 kg in remaining race groups. Reductions were smallest in Asians, who also had the lowest baseline weight. Body weight reductions were greater in non-Hispanics vs Hispanics (4.2 vs 2.6 kg and 6.1 vs 4.1 kg with semaglutide 0.5 and 1.0 mg). The proportions of subjects experiencing AEs, gastrointestinal AEs and AEs leading to treatment discontinuation are shown in the table. The proportion of Caucasian, Black/African American and Asian subjects reporting serious AEs were 6.8, 5.1 and 4.1% with semaglutide 0.5 mg, and 7.7, 7.6 and 4.3% with semaglutide 1.0 mg. The proportion of Hispanics and non-Hispanics reporting serious AEs were 6.6 and 4.7% with semaglutide 0.5 mg, and 7.9 and 5.1% with semaglutide 1.0 mg.
Conclusion: Semaglutide provided clinically relevant reductions in HbA_{1c} (1.4–2.0%) and body weight (2.6–6.1 kg) in subjects with T2D across SUSTAIN 1–5 and 7 regardless of race and ethnicity. The safety profile in each subgroup was similar to that of all subjects in the SUSTAIN clinical trial programme, with slight variations in safety across race and ethnicity groups.

Table. Estimated change from baseline to 30 or 40 weeks in HbA_{1c} and body weight, and AEs by race and ethnicity subgroups across SUSTAIN 1–5 and 7

			Baseline	Number of subjects	Semaglutide 0.5 mg	Number of subjects	Semaglutide 1.0 mg
HbA_{1c} (%)	Race	Caucasian	8.2	982	−1.4 (0.03)	1,328	−1.7 (0.02)
		Asian	8.2	243	−1.5 (0.05)	232	−2.0 (0.05)
		Black/African American	8.3	82	−1.4 (0.09)	124	−1.6 (0.07)

		Asian	75.3	243	−3.3 (0.28)	232	−4.6 (0.29)
		Black/African American	94.9	82	−3.3 (0.48)	124	−5.3 (0.39)
	Ethnicity	Hispanic	88.1	208	−2.6 (0.31)	324	−4.1 (0.24)
		Non-Hispanic	94.4	1,124	−4.2 (0.13)	1,409	−6.1 (0.12)
AEs (%)	Race	Caucasian	-	982	69.0	1,328	69.8
		Asian	-	243	76.6	232	73.3
		Black/African American	-	82	63.4	124	67.4
	Ethnicity	Hispanic	-	208	67.7	324	62.0
		Non-Hispanic	-	1,124	70.5	1,410	72.5
GI AEs (%)	Race	Caucasian	-	982	39.4	1,328	40.6
		Asian	-	243	48.9	232	49.7
		Black/African American	-	82	32.8	124	32.9
	Ethnicity	Hispanic	-	208	42.5	324	37.0
		Non-Hispanic	-	1,124	40.3	1,410	42.5
AEs leading to PTD (%)	Race	Caucasian	-	982	6.4	1,328	8.0
		Asian	-	243	10.0	232	13.4
		Black/African American	-	82	5.1	124	6.9
	Ethnicity	Hispanic	-	208	6.0	324	7.7
		Non-Hispanic	-	1,124	7.0	1,410	8.8

Efficacy analyses included pooled 'on-treatment without rescue medication' data from all subjects contributing to the full analyses sets from SUSTAIN 1–5 and 7. Data from the 'Other' race subgroup are not included due to low subject numbers. These analyses were based on week 30 data for SUSTAIN 1–5, and week 40 data for SUSTAIN 7 (due to the visit schedule not including week 30). Presented HbA_{1c} and body weight data are estimated change from baseline (standard error of the estimate) based on a meta-analysis across the six trials. Safety summaries included pooled 'on-treatment' data from all subjects in the safety analysis sets. AE data are presented as proportion of subjects experiencing an AE. AE, adverse event; GI, gastrointestinal; PTD, premature treatment discontinuation.

Relationship between HbA_{1c} reduction and postprandial glucose change with once weekly dulaglutide in Chinese patients with type 2 diabetes

T. Hong[1], X. Liu[2], W. Zhao[2], F. Wang[2], L. Gu[2];
[1]Peking University Third Hospital, Beijing, [2]Lilly Suzhou Pharmaceutical Co. Ltd., Shanghai, China.

Background and aims: A post-hoc analysis was conducted on two randomized trials of dulaglutide, a once weekly GLP-1 receptor agonist to assess the relationship between HbA1c reduction and postprandial glucose (PPG) change in Chinese patients with type 2 diabetes mellitus (T2DM) after 26 weeks of treatment with dulaglutide 1.5 mg or 0.75 mg vs glimepiride or insulin glargine.
Materials and methods: Patients in the dulaglutide vs glimepiride study (GBCG, $n = 556$) were treatment-naive or discontinued from monotherapy with oral anti-diabetic drugs; those in the dulaglutide vs glargine study (GBDK, $n = 591$) continued on metformin and/or sulfonylurea. Analyses were conducted based on mixed-models repeated measures using modified intent-to-treat population, by trial rather than by pooling, due to difference in background therapies and baseline characteristics.
Results: The superiority of dulaglutide 1.5 mg vs. glimepiride or glargine was achieved in the two studies. In GBCG study, least-squares (LS) mean changes from baseline in HbA1c were −1.46%, −1.25%, and −0.92%; and the LS mean changes in PPG (2-hr post-morning meal, mmol/L) measured by SMBG was −4.07, −3.28, and −2.71 in dulaglutide 1.5 mg, 0.75 mg, and glimepiride groups, respectively. In GBDK study, LS mean changes from baseline in HbA1c were −1.67%, −1.31%, and -1.11%; and the LS mean changes in PPG was −3.41, −3.12, and −2.74 in dulaglutide 1.5 mg, 0.75 mg, and insulin glargine groups, respectively. In the two studies, 92%–97% and 86%–92% of patients treated with dulaglutide 1.5 mg and 0.75 mg, respectively, demonstrated HbA1c reduction, vs 83% and 88% with glimepiride and insulin glargine. Among the patients with HbA1c reduction, 82%–87% and 76%–80% of patients treated with dulaglutide 1.5 mg and 0.75 mg also experienced PPG reduction, vs 69% and 71% with glimepiride and glargine. Correlation was observed between HbA1c reduction and PPG change in dulaglutide 1.5 mg and its comparator in both GBCG ($R = 0.393$ for dulaglutide, $R = 0.333$ for glimepiride) and GBDK ($R = 0.593$ for dulaglutide, $R = 0.448$ for glargine) studies.
Conclusion: Dulaglutide is an effective treatment option for Chinese patients with T2DM, resulting in significant HbA1c reduction. In addition, the association between HbA1c reduction and PPG change further supports a strong effect of dulaglutide on PPG, besides the known effect on fasting glucose.

Safety and efficacy of lixisenatide vs sulfonylurea added to basal insulin in patients with type 2 diabetes who fast during Ramadan (LixiRam): a randomised controlled trial

M.M. Hassanein[1], K. Hafidh[2], N. Shehadeh[3], S. Azar[4], W. Hanif[5], H. Li[6], K. Djaballah[7], R. Sahay[8];
[1]Dubai Hospital, Dubai, United Arab Emirates, [2]Rashid Hospital, Dubai, United Arab Emirates, [3]Rambam Medical Center, Haifa, Israel, [4]American University of Beirut Medical Center, Beirut, Lebanon, [5]University Hospital Birmingham, Birmingham, UK, [6]Sanofi-Aventis (China), Beijing, China, [7]Sanofi, Paris, France, [8]Osmania Medical College, Hyderabad, India.

Background and aims: Some type 2 diabetes (T2D) people who fast during Ramadan are at increased risk of hypoglycaemia. This is more so for those treated with insulin. Lixisenatide (Lixi) is a once-daily prandial glucagon-like peptide-1 receptor agonist (GLP-1 RA) with a relatively low risk of hypoglycaemia. This is the first randomized controlled trial (RCT) comparing the efficacy and safety of Lixi vs sulphonylurea (SU), both combined with basal insulin (BI), in T2D people fasting during Ramadan.
Materials and methods: Adults with T2D, diagnosed for ≥1 year with insufficient glycaemic control with BI + SU intending to fast during Ramadan, were randomized 1:1 to receive BI + SC Lixi or oral SU at optimal doses in this phase IV, 12–22-week trial. Primary endpoint: % of people with ≥1 documented symptomatic hypoglycaemia event (plasma glucose ≤70 mg/dL; 3.9 mmol/L) during the Ramadan fast. Secondary endpoints included HbA_{1c}, weight, BI dose, and safety.
Results: In total, 184 people were randomized (Lixi [$n = 92$]; SU [$n = 92$]; safety population). Primary endpoint: for Lixi vs SU, respectively, 3.3% (3/91) vs 8.9% (8/90) of people had ≥1 documented symptomatic hypoglycaemia event (intent-to-treat population [$n = 181$]; Lixi [$n = 91$]; SU [$n = 90$]; OR: 0.34; 95% CI: 0.09, 1.35) during Ramadan. Secondary safety: for Lixi vs SU, respectively the % of people with any hypoglycaemia event was 3.3% vs 15.2% (OR: 0.17 [95% CI: 0.05, 0.61]; difference: −0.12 [95% CI: −0.20, −0.04]) during the pre-Ramadan period and 4.3% vs 17.4% (OR: 0.22 [95% CI: 0.07, 0.68]; difference: −0.13 [95% CI: −0.22, −0.04]), during Ramadan. For Lixi vs SU, respectively, no severe hypoglycaemia was reported during pre-Ramadan, and 0% vs 1.1% during Ramadan. Total people with any hypoglycaemia during the entire observation period were 15.8% overall with 5.4% vs 26.1% (OR: 0.16 [95% CI: 0.06, 0.44]) for Lixi vs SU, respectively. Secondary efficacy: least squares mean (standard error) absolute change from baseline to post-Ramadan for Lixi vs SU, respectively: HbA_{1c} (%), −0.43 (0.11) vs −0.49 (0.11); weight (kg), −2.1 (0.27) vs −1.4 (0.27); and BI dose (units), 2.44 (0.63) vs 3.24 (0.64). Any treatment-emergent adverse events (TEAEs) for Lixi vs SU, respectively, were 17.4% vs 16.3% during Ramadan; no treatment-emergent serious adverse events were reported and TEAEs leading to discontinuation were 1.1% vs 0%. No deaths were reported.
Conclusion: In this first RCT exploring treatment with a GLP-1 RA + BI in T2D people fasting during Ramadan, the % of people experiencing ≥1 symptomatic hypoglycaemia event during Ramadan was numerically lower with Lixi. Any hypoglycaemia was clinically and statistically significantly lower in Lixi added to BI compared to SU added to BI. HbA_{1c} and weight fell despite a slight increase in BI dose in both arms. No specific safety concerns were raised.

Physicians' intention and actual pattern of treatment in drug-naive patients with type 2 diabetes in the real-world setting in Japan

H. Murayama[1], K. Imai[1], M. Bauer[2], M. Odawara[3];
[1]Medical Division, Novartis Pharma K.K, Tokyo, Japan, [2]Real World Data Analytics, Novartis Global Service Center, Dublin, Ireland, [3]Department of Diabetes, Endocrinology, Metabolism, and Rheumatology, Tokyo Medical University, Tokyo, Japan.

Background and aims: The Japanese guidelines for type 2 diabetes mellitus (T2DM) don't define tailored first-line therapy. Few reports show physicians' intentions for treatment choice and real-world treatment patterns of anti-diabetes drugs (AD) for drug-naive patients. We conducted a web-survey and database analysis to address these evidence gaps.
Materials and methods: We conducted a multiple choice question web-survey to physicians across eight regions in Japan. The primary endpoint was treatment factors and patient characteristics that influenced treatment choice for drug-naive patients. We also conducted a secondary data analysis of patients diagnosed with T2DM from October 2012 to September 2016 in the Medical Data Vision database. The primary endpoint was proportion of T2DM patients receiving each type of AD as first-line therapy. Secondary endpoints were features of drug-naive T2DM patients treated with the first and second most frequently used AD and requiring additional T2DM treatment during 180 days post-outpatient first-line (O-1L) treatment initiation.
Results: A total of 491 physicians participated in the web survey. Dipeptidyl peptidase-4 inhibitors (DPP-4is) were the most preferred first-line AD by both diabetes specialists and non-specialists, followed by metformin (54% and 39% of total ADs, respectively). Regression analysis revealed the dominant factor for choice of DPP-4is over metformin was its ease of use in patients with renal impairment, while metformin was chosen over DPP-4is for improved insulin resistance and low cost. The key patient characteristics driving the choice of DPP-4is over metformin as first-line AD and treatment intensification by physicians were similar for both groups. Post prandial glucose and renal function for DPP-4is; age, BMI, insulin resistance, and renal function for metformin.In the database analysis, 224,761 drug-naïve patients received O-1L T2DM treatment: 58,933 (26.2%) and 16,029 (7.1%) patients were treated with DPP-4is or metformin, respectively; 78,709 (35.0%) or 20,877 (9.3%) patients were treated with AD-combination therapy and any insulin therapy, respectively. Regression analysis revealed higher body mass index (OR: 0.90), diabetic retinopathy (OR: 0.74), liver disease (OR: 0.96) and higher HbA1c level (OR: 0.83) were patient characteristics influenced treatment choice of metformin over DPP-4is whereas male (OR: 1.10), age (OR: 1.06), renal disease (OR: 4.20), coronary heart disease and stroke (OR: 2.22) and clinic visits (OR: 1.31) influenced choice of DPP-4is over metformin. Male (OR: 1.03), diabetic retinopathy (OR: 1.33), diabetic neuropathy (OR: 1.05). diabetic nephropathy (OR: 1.08), higher baseline HbA1c level (OR: 1.45) and clinic visits (OR: 1.15) were positively associated with receiving additional T2DM treatment during 180 days post index date, while age (OR: 0.98), liver disease (OR: 0.88), renal disease (OR: 0.94) and coronary heart disease and stroke (OR: 0.73) were negatively associated.
Conclusion: We found similarities and differences between physicians' intention and actual prescription of drugs among drug-naive T2DM patients in Japan. These findings may help establish a treatment algorithm for T2DM, which may be especially useful for non-DM specialists.

Patient reported outcomes following initiation of glucagon-like peptide-1 receptor agonists (GLP-1 RA) in patients with type 2 diabetes: PROGRESS-DIABETES study

R.E. Brown, A. Abitbol, H.S. Bajaj, H. Khandwala, R. Goldenberg, S. Abdel-Salam, R. Aronson;
LMC Diabetes & Endocrinology, Toronto, Canada.

Background and aims: Patient-reported outcomes (PRO's) can offer a unique patient perspective on the effectiveness of a therapy. The objective of this study was to better understand the influence of GLP-1 RA on patient reported outcomes in patients with type 2 diabetes (T2D) in a real-world clinical setting.
Materials and methods: This prospective, observational cohort study evaluates PRO's in patients initiating GLP-1 RA therapy in a diabetes specialist practice in Canada. Patients with T2D initiating GLP-1 RA therapy as part of their usual treatment approach were enrolled from Ontario-based LMC Diabetes & Endocrinology clinics. Patients completed questionnaires assessing diabetes medication satisfaction (Diab-Med Sat), diabetes device satisfaction (TRIM-D Diabetes), and diabetes medication adherence (ARMS-D) at baseline and at follow-up (3–6 months). Standard clinical outcomes were collected.
Results: Of the subjects who have enrolled into this study, 186 initiated once-weekly dulaglutide (DULA), 119 initiated once-daily liraglutide (LIRA), and 24 switched from LIRA to DULA. At baseline, PRO's and clinical measures were similar between cohorts (mean age 54.7 ± 9.7 years; mean HbA1c 8.4 ± 1.4%; mean body weight 99.3 ± 23.2 kg). In this interim analysis of completers to date who did not prematurely discontinue therapy (mean follow up 3.9 months), DULA completers (N = 135) and LIRA completers (N = 78) had similar improvements in the diabetes medication satisfaction and device satisfaction scores. There was a trend for DULA to have a greater improvement in diabetes medication adherence scores (Figure). To-date, DULA subjects had a 1.0 ± 1.1% reduction in HbA1c and 2.1 ± 3.0 kg reduction in weight. The LIRA subjects showed similar trends (0.9 ± 1.1% reduction in HbA1c and 2.8 ± 3.0 kg reduction in weight).
Conclusion: Interim analysis of this real-world, specialist-led registry of patients initiating GLP-1 RA therapy showed similar improvements in PRO's and clinical outcomes, with a trend for greater improvement in medication adherence in the DULA cohort compared to the LIRA cohort.

Dulaglutide has higher adherence and persistence than liraglutide and exenatide QW: 1-year follow-up from US real-world data

L. Fernández Landó[1], R. Mody[1], Q. Huang[2], M. Yu[3], R. Zhao[2], H. Patel[1], M. Grabner[2];
[1]Eli Lilly and Company, Indianapolis, USA, [2]HealthCore, Inc., Wilmington, USA, [3]Eli Lilly and Company, Toronto, Canada.

Background and aims: The objective of this retrospective real-world observational study was to compare 1-year adherence and persistence among patients initiating GLP-1 receptor agonists (GLP-1RA), dulaglutide (DULA) vs. liraglutide (LIRA) or DULA vs. exenatide QW (EQW) in the US, using claims data between November 2014 and May 2016 (index date = earliest GLP-1RA fill date) from the HealthCore Integrated Research Database (HIRD®).
Materials and methods: Patients ≥18 years old with T2DM, no claim for index drug in the 6 months pre-index period and continuous enrolment 6 months pre- and 1-year post-index were included. DULA users were propensity-matched 1:1 to LIRA (2,427 pairs) or EQW (1,808 pairs) users, and the matched cohorts were balanced in baseline characteristics.
Results: The mean age was 54 years with around 52% males. The key adherence and persistence outcomes are included in the table. At 1 year, DULA users were more likely to be adherent (Proportion of Days Covered [PDC] ≥80%) than LIRA (odds ratio [OR] = 1.76, 95% CI = [1.56, 1.99]) or EQW users (OR = 2.31, 95% CI = [2.00, 2.66]). Cox regression showed that DULA users were less likely to discontinue therapy than LIRA (hazard ratio [HR] = 0.75, 95% CI = [0.69, 0.81]) or EQW users (HR = 0.58, 95% CI = [0.53, 0.63]).
Conclusion: At 1-year follow-up, patients initiating DULA had higher medication adherence, and were more persistent to their treatment compared to patients initiating either LIRA or EQW.

Table: 1-Year Follow-up Adherence and Persistence Outcomes Among GLP-1 RA Initiators

	Matched DULA vs. LIRA Cohorts			Matched DULA vs. EQW[1] Cohorts		
	DULA	LIRA	P-value[2]	DULA	EQW[1]	P-value[2]
	N=2,427	N=2,427		N=1,808	N=1,808	
Proportion of Days Covered (PDC), mean (SD) in %	67.3% (32.1)	59.5% (32.6)	<0.001	66.8% (32.2)	51.3% (34.6)	<0.001
Adherence (PDC ≥80%), %	51.2%	38.2%	<0.001	50.7%	31.9%	<0.001
Patients who discontinued therapy, %	51.1%	62.0%	<0.001	51.1%	70.9%	<0.001
Persistence[3], mean (SD) days	251.9 (135.7)	217.3 (143.0)	<0.001	250.5 (136.8)	191.6 (139.3)	<0.001

[1]The study included only exenatide QW pen users.
[2]P-values for categorical variables were obtained using Chi-square tests; P-values for continuous variables were obtained using Wilcoxon rank sum tests.
[3]The number of days of continuous index GLP-1 RA therapy since initiation, allowing for a maximum gap (between fills) of 45 days. Patients who were censored at the end of the 1-year follow-up period were included.

Semaglutide improves health-related quality of life vs placebo when added to standard-of care in patients with type 2 diabetes at high risk (SUSTAIN 6)

E. Jódar[1,2], W. Polonsky[3], R. Réa[4], M. Warren[5], T. Vilsbøll[6,7], J. Håkan-Bloch[8], H. Vrazic[8], S. Lindberg[8], S.C. Bain[9];
[1]Hospital Universitario Quirón Salud Madrid, Madrid, Spain, [2]Facultad de Ciencias de la Salud, Universidad Europea de Madrid, Madrid, Spain, [3]University of California, San Diego, USA, [4]Federal University of Paraná, Paraná, Brazil, [5]Physicians East, PA, Greenville, USA, [6]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [7]University of Copenhagen, Copenhagen, Denmark, [8]Novo Nordisk A/S, Søborg, Denmark, [9]School of Medicine, Swansea, UK.

Background and aims: The Short Form-36 health survey, version 2 (SF-36v2®) is a validated, widely used tool to assess health-related quality of

life (HRQoL) in patients with many different diseases. Research has shown that a 1-point increase in the physical component summary (PCS) score of the SF-36v2® is associated with clinical benefits, including reduced risk of mortality and hospitalisation. Semaglutide is a glucagon-like peptide-1 (GLP-1) analogue for the treatment of type 2 diabetes (T2D). In SUSTAIN 6, a 2-year cardiovascular (CV) outcomes trial ($N = 3297$), semaglutide significantly reduced the risk of the primary outcome (CV death, non-fatal myocardial infarction or non-fatal stroke) vs placebo, when added to standard of care, in patients with T2D at high CV risk. This analysis examined the effect of semaglutide vs placebo on SF-36v2® in SUSTAIN 6.

Materials and methods: SF-36v2® was assessed from baseline to Week 104. A *post hoc* analysis evaluated SF-36v2® scores in patients who had a primary outcome event ($n = 254$) vs those who did not ($n = 3043$).

Results: At baseline, all domain scores were similar across treatment groups. Changes from baseline to Week 104 in PCS (1.74 vs 0.35) and mental component summary (MCS) (0.86 vs −0.11) scores were significantly greater for semaglutide 1.0 mg vs placebo 1.0 mg ($p = 0.0004$ and $p = 0.0489$, respectively; **Figure**) in the overall study population; semaglutide 1.0 mg showed significant improvements across all subcategories, except 'role emotional', vs placebo 1.0 mg (**Figure**). For PCS and MCS scores with semaglutide 0.5 mg vs placebo 0.5 mg, a similar trend was observed, although this did not reach significance; of the associated domains, only improvement in 'general health' was significant ($p = 0.0350$). There was a negative effect on change from baseline in PCS and MCS scores in patients who had a primary outcome event vs those who did not (PCS: −0.36 vs 0.81, $p = 0.0460$; MCS: −1.44 vs 0.29, $p = 0.0170$).

Conclusion: In SUSTAIN 6, after 104 weeks, HRQoL was consistently improved with semaglutide 1.0 mg vs placebo 1.0 mg, added to standard of care, in patients at high CV risk. A similar, non-significant, trend was observed for the low dose comparison. HRQoL was improved in patients who did not have a primary outcome event vs those who did.

Figure: Change from baseline in SF-36v2® PCS and MCS scores, and their associated domain scores, after 104 weeks in the SUSTAIN 6 trial

Exploring two dose regimens of ITCA 650 to switch from stable liraglutide therapy in patients with type 2 diabetes

N. Rasouli[1], J. Rosenstock[2], S. Nakhle[3], B. Schwartz[4], P. Prabhakar[4], S. Kruger[4], H. Huang[4], M. Baron[4];
[1]University of Colorado School of Medicine, Aurora, [2]Dallas Diabetes Research Center at Medical City, Dallas, [3]Southern Hills Hospital and Medical Center, Las Vegas, [4]Intarcia Therapeutics Inc., Boston, USA.

Background and aims: ITCA 650 is an investigational titanium osmotic mini pump that is subdermally placed in the abdominal wall during a brief office procedure to continuously deliver exenatide over 3 and 6-month periods and has the potential to improve medication adherence because patients do not self-administer.
Materials and methods: In this 26 week, open-label phase 3b study, 136 patients with T2D receiving liraglutide (1.2 to 1.8 mg/d) and metformin (≥1000 mg/d) were randomized to either the standard ITCA 650 dose regimen used in phase 3 trials of 20 mcg/d for 13 weeks followed by a 60 mcg/d maintenance dose (for 13 weeks in this study) or starting directly with the maintenance dose of 60 mcg/d for 26 weeks. The last injection of liraglutide occurred 2 days prior to randomization. The primary endpoint compared the incidence of nausea (N) and vomiting (V) between the two dose regimens.
Results: Switching from liraglutide to either dose regimen of ITCA 650 had a similar incidence of transient mild to moderate N/V (Table). Of note, 3 sites, which recruited 25% of the study population, accounted for 47% and 68% of the total N/V seen in the study. 4 patients discontinued due to GI AEs. Glycemic control remained stable in both groups. At Week 26, significant weight reduction was observed in both groups ($p < 0.05$ vs. baseline).
Conclusion: Patients on stable liraglutide therapy can be switched to ITCA 650 60 mcg/d without the need for up-titration from a lower dose.

Table. Baseline Characteristics and Clinical Outcomes*

Parameter	ITCA 650 20/60 mcg/d N=67	ITCA 650 60 mcg/d N=68
Baseline Characteristics		
Age, years[a]	60.0 ± 10.1	58.7 ± 9.7
Weight, kg[a]	95.9 ± 19.2	92.8 ± 18.4
Body mass index, kg/m^2 [a]	33.9 ± 5.5	33.1 ± 5.6
Baseline HbA1c (%)[a]	7.0 ± 1.1	6.9 ± 1.0
Duration of diabetes, years[a]	10.7 ± 6.6	10.0 ± 6.8
Duration of liraglutide use, days[a]	751 ± 663	589 ± 575
Liraglutide dose, mg/d[a]	1.6 ± 0.3	1.6 ± 0.3
Metformin dose, mg/d[a]	1716 ± 428	1687 ± 483
Clinical Outcomes		
LS Mean (SE) change HbA1c (%) at Week 26	-0.13 (0.10) p=0.241 [b]	0.05 (0.11)
LS Mean (SE) change in weight, kg at Week 26	-1.9 (0.51) p=0.237 [b]	-1.0 (0.52)

Evaluating clinical outcomes of changing type 2 diabetes patients from other DPP-4 inhibitor therapy to alogliptin in a primary care setting

W.D. Strain[1], P. McEwan[2], H. Howitt[3], S.B. Meadowcroft[3];
[1]Diabetes and Vascular Research Centre University of Exeter Medical School, Exeter, [2]Health Economics & Outcomes Research Ltd, Cardiff, [3]Takeda UK Ltd, High Wycombe, UK.

Background and aims: Guidelines increasingly recommend considering cost-effectiveness when choosing agents within a class of drugs. As a result, several UK regions initiated a within-therapy class switch policy, aiming to switch dipeptidyl peptidase-4 inhibitors (DPP-4i) with a higher tariff to alogliptin. Clearly such policy is only appropriate if it can be verified that glycaemic control is not attenuated when switching therapies. We aimed to assess the impact of switching from a higher tariff DPP-4i to alogliptin on glycaemic control.
Materials and methods: We worked with six clinical commissioning groups (CCGs) that had recommended to its primary care teams an active switch program for all patients on DPP-4 inhibitors to alogliptin based on the potential savings of at least £6,518 per 100 patient years treatment. Using the primary care electronic records, we performed a retrospective, observational cohort study using individual patient-level routine data collated from before and after the switch. Only people prescribed DPP-4i according to licensed indications were included in this analysis. Index was defined as the point that the switch took place. Unadjusted mean HbA1c values were compared to assess changes in HbA1c from the most recent value prior to index to the first HbA1c recorded ≥2.5 months after index.
Results: Data were available for 865 people with Type 2 diabetes mellitus (T2DM) switched from a DPP-4i (mainly sitagliptin) to alogliptin. The mean age was 64.35 years (SD = 11.19) and 63.7% were male. Pre-index mean (SD) HbA1c was 8.44% (1.52) at median of 58 days pre-switch (interquartile range (IQR) 137–21). HbA1c remained effectively unchanged at 8.42% (1.62) at 167 days (IQR 112–245) post-index. There was little difference in the distribution of individual HbA1c values pre and post switch (figure 1). At 6 months, the majority of people (80.8%) remained on alogliptin; a small proportion (4.1%) reverted to an alternative DPP-4i, whilst only 4.5% of people underwent other changes to their glycaemic medication.
Conclusion: A policy of switching from a higher tariff DPP-4i to alogliptin was well tolerated, as evidenced by a high persistence of therapy and was not associated with any deterioration in glycaemic control over a 6-month period. Such policy has the potential to generate significant cost savings without detriment to the diabetic control of people with T2DM.

Comparison of the incidence of hospital admissions for severe hypoglycaemia in type 2 diabetes patients treated with different dipeptidyl peptidase-4 inhibitors

C.-M. Chang[1], J. Wang[2], K.-L. Chien[2], J.-F. Chen[1];
[1]Kaohsiung Chang Gung Memorial Hospital, Kaohsiung City, [2]Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei City, Taiwan.

Background and aims: Dipeptidyl peptidase-4 inhibitors (DPP4Is) have been shown to provide a wide spectrum of glycemic *effects* with lower

risk of hypoglycemia in patients with type 2 diabetes mellitus (T2DM). We aimed to compare the incidence of hospital admissions for hypoglycemia in patients with T2DM exposed to the combinations of oral anti-hyperglycemic drugs (OADs) with DPP4Is versus without DPP4Is, and to examine whether a class-effect or difference for DPP4Is on the incidence of hospitalization for hypoglycemia exist.

Materials and methods: This study was based on the *National Health Insurance* (NHI) program, which is a compulsory healthcare insurance system in Taiwan. All patients newly diagnosed with diabetes mellitus (DM) after 2008, when DPP4I was first approved in Taiwan, and before July 2013 were included. Patients with a history of hypoglycemia were excluded. In dataset 1, we investigated the correlation between DPP4Is exposure and the incidence of hospitalization for hypoglycemia. The participants were stratified into four different groups by the numbers of OAD types, and DPP4Is users and non-users were included in each group. In dataset 2, we investigated the incidence of hospitalization for hypoglycemia between the 3 types of DPP4Is. We calculated the incidence rate by dividing the numbers of hospitalization for hypoglycemia events by the total follow-up person-years (events per 1,000 person-years) within each group. Univariate and multivariate regression analyses were subsequently utilized to estimate the HRs and 95% CIs based on Cox proportional hazards model in order to assess the risk of hospitalization for hypoglycemia due to DPPI4s use. The other OADs users (dataset 1) or sitagliptin users (dataset 2) served as the reference. The full models was adjusted for age, sex, residence, comorbidities, and medications.

Results: A total 2,036,531 DM patients were identified between 2007 and 2013. 680,992 and 303,890 DM patients were enrolled to dataset 1 and dataset 2 respectively. We observed DPP4I user was associated with significant lower incidence of hospitalization for hypoglycemia compared to non-DPP4I user among using two and three types OAD patients (HR 0.65; 95% CI, 0.54 to 0.78; HR 0.79; 95% CI, 0.72 to 0.88, respectively).After adjusting for age, gender, comorbidities, and medications, we found the significant lower risk of hospitalization for hypoglycemia in DPP4Is group among using one, two and three types OAD population (HR 0.26; 95% CI, 0.14 to 0.51; HR 0.46; 95% CI, 0.36 to 0.55; HR 0.73; 95% CI, 0.66 to 0.81, separately).Compared with Sitagliptin, Vildagliptin and Saxagliptin had significant lower incidence of hospitalization for hypoglycemia (HR 0.69; 95% CI, 0.61 to 0.78; HR 0.82; 95% CI, 0.73 to 0.92, respectively). The results were consistent after adjusting for confounding factors (vildagliptin vs sitagliptin: HR 0.69; 95% CI, 0.61 to 0.78; saxagliptin vs sitagliptin: HR 0.78; 95% CI, 0.69 to 0.87).

Conclusion: Incidence of hospital admissions for severe hypoglycemia was significantly less in T2DM patients exposed to DPP4Is, when treated with combination therapies of no more than three types OADs. Within DPP4I class, compared with sitagliptin, vildagliptin and saxagliptin may provide lower risk of hospitalization for hypoglycemia.

Disclosure: **C. Chang:** None.

765

Minimal contribution of nausea or vomiting to superior semaglutide-mediated weight loss vs exenatide and dulaglutide in type 2 diabetes

I. Lingvay[1], R. de la Rosa[2], M. Marre[3], M. Nauck[4], V. Woo[5], T. Hansen[6], J.R. Larsen[6], E. Yildirim[6], J. Wilding[7];
[1]University of Texas Southwestern Medical Center, Dallas, USA, [2]Four Rivers Clinical Research, Paducah, USA, [3]Hôpital Bichat-Claude Bernard, Paris, France, [4]Diabetes Center Bochum-Hattingen, St. Josef-Hospital, Ruhr-University, Bochum, Germany, [5]University of Manitoba, Winnipeg, Canada, [6]Novo Nordisk A/S, Søborg, Denmark, [7]University of Liverpool, Liverpool, UK.

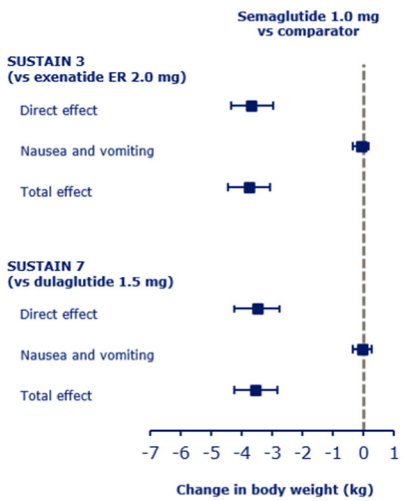
Background and aims: Semaglutide, a glucagon-like peptide-1 (GLP-1) analogue for the treatment of type 2 diabetes (T2D), showed superior HbA_{1c} and body weight reductions vs comparators in the SUSTAIN clinical trials. Gastrointestinal adverse events are common with GLP-1 receptor agonists (GLP-1RAs). A previous analysis showed the contribution of nausea or vomiting to the superior body weight loss with semaglutide in SUSTAIN 1–5 was small. This *post hoc* analysis assessed the contribution of nausea or vomiting to the greater weight loss with semaglutide vs once-weekly GLP-1RAs, exenatide extended-release (ER) and dulaglutide, in SUSTAIN 3 and 7.

Materials and methods: Subjects with T2D were randomised to once-weekly semaglutide 1.0 mg vs exenatide ER 2.0 mg in SUSTAIN 3 or once-weekly semaglutide 1.0 mg vs dulaglutide 1.5 mg and semaglutide 0.5 mg vs dulaglutide 0.75 mg in SUSTAIN 7. Subjects were grouped based on the occurrence of nausea or vomiting. A mediation analysis was done to determine how much of the estimated treatment differences (ETDs) in weight loss was due to direct effects of semaglutide vs nausea or vomiting.

Results: In SUSTAIN 3 ($N = 813$), proportions of subjects experiencing nausea or vomiting were 24.0 (semaglutide) vs 14.1% (exenatide ER). In SUSTAIN 7 ($N = 1201$), proportions were 24.0 vs 23.1% (semaglutide 1.0 mg vs dulaglutide 1.5 mg), and 25.2 vs 16.1% (semaglutide 0.5 mg vs dulaglutide 0.75 mg). In SUSTAIN 3, mean changes in body weight from baseline were −6.9 (semaglutide) and −2.7 kg (exenatide ER) in subjects with nausea or vomiting vs −5.4 and −1.6 kg in those without. In SUSTAIN 7, mean changes were −7.6 vs −3.9 kg (semaglutide 1.0 mg vs dulaglutide 1.5 mg) and −5.4 vs −3.3 kg (semaglutide 0.5 mg vs dulaglutide 0.75 mg) in those with nausea or vomiting, and −6.2 vs −2.7 kg (semaglutide 1.0 mg vs dulaglutide 1.5 mg) and −4.3 vs −2.1 kg (semaglutide 0.5 mg vs dulaglutide 0.75 mg) in those without. In SUSTAIN 3 and 7 (high-dose comparison), ETDs [95% CI] for body weight reductions favoured semaglutide and the contribution of nausea or vomiting was small (**Figure**). Similarly, the SUSTAIN 7 low-dose comparison led to a significant ETD [95% CI] for body weight reduction (−2.3 [−2.91; −1.59]); 0.03 kg of this difference was due to nausea or vomiting.

Conclusion: In SUSTAIN 3 and 7, body weight reductions were significantly greater with semaglutide vs exenatide ER and dulaglutide in subjects with and without nausea or vomiting. Nausea or vomiting contributed minimally to the superior weight reductions, thus treatment differences were largely mediated by direct effects of semaglutide.

Figure. Mediation analysis of direct (due to treatment) and indirect (due to nausea or vomiting) effects on weight loss for subjects treated with semaglutide 1.0 mg in SUSTAIN 3 and 7.



Data are ETD [95% CI] for the change from baseline in body weight based on the full analysis set using 'on-treatment without rescue medication' data. Post-baseline responses were analysed using a mixed model for repeated measurements that included the interaction of treatment and any nausea or vomiting. ETD, estimated treatment difference.

Changes in serum calcitonin concentrations and incidence of adjudicated medullary thyroid carcinoma in the EXenatide Study of Cardiovascular Event Lowering (EXSCEL)

B. Katona[1], M.A. Bethel[2], R. Patel[2], V.P. Thompson[3], S.M. Gustavson[1], P. Ohman[1], N. Iqbal[1], J.B. Buse[4], A.F. Hernandez[3], R.R. Holman[2], for the EXSCEL Study Group;
[1]AstraZeneca, Gaithersburg, USA, [2]Diabetes Trials Unit, Oxford, UK, [3]Duke Clinical Research Institute, Durham, USA, [4]University of North Carolina School of Medicine, Chapel Hill, USA.

Background and aims: Serum calcitonin concentration is used as a tumour marker for neoplasia of the thyroid C-cells, including medullary thyroid carcinoma (MTC), which has been associated with glucagon-like peptide-1 (GLP-1) receptor activation in pre-clinical studies. EXSCEL was a multinational, randomised, double-blinded, pragmatic cardiovascular outcomes trial evaluating exenatide, a once-weekly GLP-1 receptor agonist, versus placebo on the background of usual care in type 2 diabetes. We report changes in serum calcitonin concentrations in exenatide- and placebo-treated participants and incidence of MTC in EXSCEL over a median 3.2-year follow-up period.
Materials and methods: Participants (n = 14,752) in EXSCEL were randomised 1:1 to exenatide 2 mg once-weekly or placebo. Serum calcitonin concentration was measured in participants at baseline (ineligible for trial if >40 ng/L) and annually throughout follow-up (trial medication discontinued if ≥50 ng/L). A repeated measures mixed model analysis was performed, including serum calcitonin concentrations only from participants with a baseline and at least one post-baseline value. Median serum calcitonin concentration for treatment groups was calculated at baseline and at yearly intervals thereafter. Thyroid malignancies, including MTC, were collected prospectively throughout the trial and adjudicated using pre-specified criteria by an independent committee, blinded to treatment assignment.
Results: In the intention-to-treat population at baseline, 52 (30 exenatide, 22 placebo) participants had a serum calcitonin concentration >40 ng/L, and during follow-up 23 participants (15 exenatide, 8 placebo) had a serum calcitonin concentration ≥50 ng/L (excluding those with serum calcitonin concentration >40 ng/L at baseline). Median (IQR) baseline serum calcitonin concentration was 1.7 ng/L (1.7, 4.3) in the exenatide group and 1.7 ng/L (1.7, 4.2) in the placebo group. Serum calcitonin concentrations were unchanged over 36 months in both groups, with a median (IQR) change from baseline of 0.0 (−0.4, 0.0) in the exenatide group and 0.0 (−0.5, 0.0) in the placebo group. Confirmed MTC occurred in 3 participants (2 exenatide, 1 placebo), all of whom had elevated serum calcitonin concentrations at baseline (413, 422 and 655 ng/L).
Conclusion: Treatment with exenatide 2 mg once-weekly did not result in an increase in serum calcitonin concentrations, with no evidence of a difference in serum calcitonin concentrations between exenatide- and placebo-treated participants over a median 3.2-year follow-up period. All 3 confirmed cases of MTC in EXSCEL occurred in participants who had an elevated serum calcitonin at baseline, prior to administration of trial medication.

PS 063 DPP4 inhibitors: new regiments and new comparisons

767

A Comparative head-to-head study of the effect Of three different DPP-4 Inhibitors (CODI24) during 24h, in metformin-treated type 2 diabetes individuals

W. Alsalim[1], O. Göransson[2], B. Ahrén[1];
[1]Department of Clinical Sciences, Lund University, Lund, [2]Department of Experimental Medical Science, Lund University, Lund, Sweden.

Background and aims: Control of glycemia in treatment of type 2 diabetes (T2D) involves normalization of fasting and post-prandial blood glucose. It is known that DPP-4 inhibitors (DPP-4i) have effects on both fasting and postprandial glucose, but the extent of the glucose effect over the entire day after DPP-4 inhibition and whether DPP-4i differ are not known. Such comprehensive knowledge is important for clinical decision, particularly since discrepancies between DPP-4i are possible due to differences in chemical structure, mode of enzyme inhibition and half-life. In this study, we therefore compared the effect of three different DPP-4i (sitagliptin (SITA), vildagliptin (VILDA), saxagliptin (SAXA)) versus placebo (PBO) on glucose and insulin levels over an entire day with controlled and standardized meal ingestion (breakfast, lunch and dinner) in metformin-treated and well controlled T2D subjects.
Materials and methods: After an overnight fast, twenty-four metformin-treated T2D subjects (12 male, 12 female, mean age 63 yrs, BMI 31.0 kg/m^2 , HbA1c 44.7 mmol/mol = 6%) underwent four tests in random order ingesting either SITA; 100 mg, VILDA; 50 mg, SAXA; 10 mg, or PBO followed by ingestion of a standardized breakfast (525 kcal), lunch (780 kcal) and dinner (560 kcal) at specific time points. SITA and SAXA were ingested 30 min before breakfast while VILDA was ingested 30 min before breakfast and dinner. Blood samples were taken for analysis of glucose and insulin; their suprabasal 180 min areas under the curve (AUC) were calculated.
Results: SITA, VILDA, and SAXA suppressed the rise in glucose levels after all three meals (Fig. 1A), compared to the PBO, and the $AUC_{glucose180min}$ were significantly reduced by DPP-4i (SITA; 29, 41 and 22%, VILDA; 24, 34 and 24%, SAXA; 22, 25 and 16% after breakfast, lunch and dinner respectively (Fig. 1B). The fasting blood glucose levels the day after ingestion of DPP-4i did not differ significantly compared to PBO. The insulin levels increased after meal ingestion without significant differences between DPP-4i and PBO (Fig. 1C, D). There were no significant differences in glucose or insulin levels between the three DPP-4i.
Conclusion: Based on these data we conclude that in metformin-treated and well controlled T2D subjects; 1) DPP-4i reduced postprandial glucose levels, compared to placebo, 2) DPP-4i had the same effect after breakfast, lunch and dinner, 3) insulin levels increased after each meal with no significant difference between placebo and DPP-4i, and 4) there was no significant difference between the three DPP-4is. Therefore, we suggest that different DPP-4i have the same glucose-reducing effect over the day. Moreover, DPP-4 inhibition is associated with unchanged insulin levels compared to PBO, in spite of lower postprandial glycemia, as a sign of improved beta-cell function.

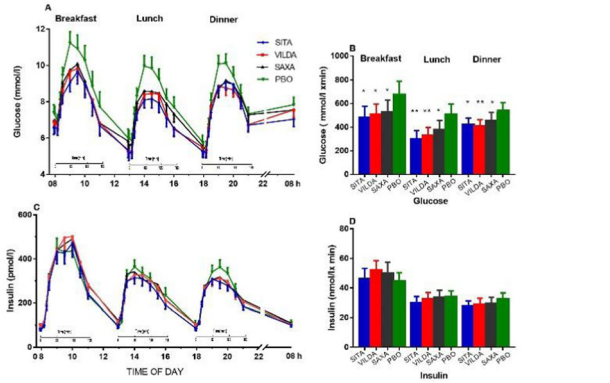

Figure 1. Plasma levels and suprabasal area under the curve (180 min) of glucose (A,B) and insulin (C,D) after ingestion of breakfast (525kcal), lunch (780kcal) and dinner (560kcal) with sitagliptin (SITA;100mg), vildagliptin (VILDA; 50mg b.i.d), saxagliptin (SAXA; 10mg) and placebo (PBO) in well controlled and metformin treated T2D subjects. Mean±SEM are shown. SITA, VILDA and SAXA compared to BPO; *$p \leq 0.05$ and **$p \leq 0.01$.

Comparative efficacy of saxagliptin combination therapy with acarbose, or gliclazide modified release, or metformin in drug naive patients with type 2 diabetes

X.P. Chen[1], H.M. Li[2], H.Y. Kuang[3], L. Chen[4], J.H. Ma[5], Q. Zhang[6], T.R. Pan[7], J. He[8], W.Y. Yang[1];
[1]China–Japan Friendship Hospital, Beijing, China, [2]China Meitan General Hospital, Beijing, China, [3]The First Affiliated Hospital of Harbin Medical University, Harbin, China, [4]Qilu Hospital of Shandong University, Jinan, China, [5]Nanjing First Hospital Affiliated to Nanjing Medical University, Nanjing, China, [6]The First Affiliated Hospital of Anhui Medical University, Hefei, China, [7]The Second Hospital of Anhui Medical University, Hefei, China, [8]Tulane University, New Orleans, USA.

Background and aims: Newly diagnosed type 2 diabetic patients whose HbA1c more than 9% associated with hyperglycemia symptoms can implement short term intensive insulin therapy by AACE and Chinese guideline. Initiate metformin-based combination therapy for newly diagnosed T2DM with high HbA1c and no hyperglycemia symptoms is recommended in AACE guideline. However, less information exists about dipeptidyl peptidase-4 inhibitor based dual therapy in these patients. This is a 24-week, multicenter, randomized, open-label, parallel group study to assess the efficacy and safety of saxagliptin initial combination with acarbose or gliclazide modified release (MR), or metformin therapy in drug naïve patients with T2DM.
Materials and methods: 648 subjects aged ≥18 and ≤80 years old were enrolled in the study and mean HbA1c was 9.2%. Patients were randomized to saxagliptin plus acarbose ($n = 216$), or saxagliptin plus gliclazide MR ($n = 216$), or saxagliptin plus metformin ($n = 216$). Saxagliptin was given 5 mg once daily during entire trial and the trial included 4-week drug dose titration period. Acarbose was titrated up to 300 mg/d, metformin was up to 2000 mg/d, and gliclazide MR was up to maximum tolerated dose over 4-week.
Results: 583 patients started the intended study drug. HbA1c reduction at week 24 was −2.63% in the acarbose group, −2.77% in the gliclazide MR group and −2.92% in the metformin group. The proportion of patients with HbA1c less than 7.0% was 74.4% (acarbose), 80.3% (gliclazide MR) and 84.9% (metformin) at 24 weeks. The proportion of patients with HbA1c of 6.5% or less was 60.3% (acarbose), 63.6% (gliclazide MR) and 73.1% (metformin) at 24 weeks. At week 24, the HbA1c reduction difference was 0.29 (95% CI 0.07 to 0.52, $p = 0.1748$) for Acarbose, 0.15 (95% CI −0.07 to 0.37, $p = 0.0134$) for Gliclazide MR, compared to metformin, respectively. The mean change in body weight from baseline to endpoint in treatment groups was −1.5 kg for acrabose, 1.0 kg for gliclazide MR and −1.6 kg for metformin, respectively. Hypoglycemic events, almost all are mild, were reported during treatment period in acrabose (0.38%), gliclazide MR (1.42%), and metformin (0.68%).
Conclusion: The findings of this study provides evidence that remarkable efficacy and safe profile of initial saxagliptin combination therapy with acarbose, or gliclazide MR, or metformin in drug naïve Chinese T2DM patients with high HbA1c level. In addition to insulin intensive treatment, saxagliptin-based combination therapy is also one of optimal options for drug naive T2DM patients with high HbA1c level.

Glycaemic efficacy and safety of linagliptin compared to basal bolus insulin regimen in non-cardiac surgical patients with type 2 diabetes: Linagliptin-Surgery trial

G. Umpierrez[1], P. Vellanki[1], N. rasouli[2], D. Baldwin[3], S. Alexanian[4], I. Anzola[1], M. Urrutia[1], P. Gomez[1], S. Cardona[1], H. Wang[1], F. Pasquel[1];
[1]Emory University School of Medicine, Atlanta, [2]Medicine, University of Colorado, Denver, [3]Rush University, Chicago, [4]Medicine, Boston Universty, Boston, USA.

Background and aims: Effective hospital and post-discharge regimens are needed for the management of general surgery patients with type 2 diabetes. We compared the safety and efficacy of linagliptin with a basal-bolus insulin regimen in the hospital, and determine the efficacy of an HbA1c-based algorithm to guide post-discharge diabetes therapy.
Materials and methods: This prospective, multicenter open-label study enrolled non-cardiac surgery patients with type 2 diabetes, blood glucose (BG) between 7.8–22.2 mmol/l and treated with diet, oral agents, or insulin at a total daily dose (TDD) ≤0.5 units/kg. Subjects were randomized to either linagliptin 5 mg daily ($n = 128$) or basal-bolus insulin regimen ($n = 122$). Insulin treated subjects were started at a TDD of 0.4 U/kg/day or 0.5 U/kg/day for randomization BG between 7.8 11.1 mmol/l or >11.1–22.1 mmol/l, respectively. If GFR <45 ml/min/1.73 m^2, TDD was reduced by 50%. Both groups received correction doses of rapid-acting insulin for BG >7.8 mmol/l before meals or every 6 hours if NPO. The discharge algorithm was based on admission HbA1c. If HbA1c <7% (<53 mmol/mol), 221 subjects were discharged on linagliptin or preadmission oral agents; patients with HbA1c 7% and 9% and those >9% were discharged on linagliptin with glargine at 50% or 80% of the hospital daily dose, respectively. The primary outcome was difference in mean hospital daily BG between groups. Secondary outcomes were inpatient hypoglycaemia and changes in HbA1c at 3 months after discharge.
Results: Difference in mean daily hospital BG between groups was 0.6 mmol/l. Linagliptin resulted in fewer hypoglycemic events (1.6% vs.11%, $p = 0.001$, relative risk reduction of 86%) and in lower number of daily insulin injections (2.0 ± 3.3 vs 3.1 ± 3.3, $p < 0.001$) compared to basal-bolus. In patients with a randomization BG <11.1 mmo/l (observed in 63% of overall cohort), linagliptin resulted in similar mean daily BG (8.9 ± 2.3 vs. 8.7 ± 2.3 mmol/l, $p = 0.43$); however, patients with BG ≥11.1 mmol/l treated with linagliptin had higher BG compared to basal-bolus (10.9 ± 2.6 vs. 9.2 ± 2.2 mmo/l, $p < 0.001$). There were no differences in length of hospital stay or in the rate of perioperative complications between treatment groups. Three months after discharge, HbA1c decreased from $7.9 \pm 2.0\%$ to $7.1 \pm 1.5\%$, $p < 0.0001$ using the discharge algorithm.
Conclusion: Linagliptin is an effective alternative to basal-bolus insulin regimen in general surgery patients with type 2 diabetes with mild to

moderate hyperglycemia. Our results indicate that in patients with BG <11.1 mmol/l, treatment with linagliptin resulted in similar improvement in glycemic control and in significantly lower rates of hypoglycemia compared to the basal-bolus insulin regimen. However, basal-bolus insulin regimen was superior to linagliptin in patients with BG ≥11.1 mmol/l. The proposed HbA1c-based hospital discharge algorithm with the use of linagliptin, with or without basal insulin, showed efficacious glycemic control after discharge.

Efficacy and safety of continuing sitagliptin when initiating insulin therapy in subjects with type 2 diabetes

R. Roussel[1], S. Duran-Garcia[2], Y. Zhang[3], S. Shah[3], C. Darmiento[3], R.R. Shankar[3], E.A. O'Neill[3], G.T. Golm[3], R.L.H. Lam[3], I. Gantz[3], K.D. Kaufman[3], S.S. Engel[3];

[1]Groupe Hospitalier Bichat, Paris, France, [2]Valme University Hospital Medical School, Seville, Spain, [3]Merck & Co., Inc., Kenilworth, USA.

Background and aims: DPP-4 inhibitors (DPP4is) are often discontinued with initiation of insulin therapy but the impact of this discontinuation on efficacy and hypoglycemia has not been studied. In this double-blind trial the safety and efficacy of initiating insulin while continuing sitagliptin (SITA) was evaluated.

Materials and methods: Eligible patients had inadequately controlled T2DM on metformin (MET, ≥1500 mg/day) in dual or triple combination therapy with a DPP-4i and/or sulfonylurea. Those on MET + SITA (100 mg/day) directly entered the trial; all others were switched to MET + SITA and stabilized during a run-in period. Subjects were randomized to continuing SITA or discontinuing SITA and switching to matching placebo, with both groups initiating insulin (LANTUS®), which was titrated based on fasting glucose.

Results: 746 subjects (mean HbA1c = 72.6 mmol/mol [8.8%], mean disease duration of 10.6 years) were randomized. After 30 weeks, continuing SITA was superior to discontinuing SITA in reducing HbA1c ($p < 0.001$). Patients who continued SITA had a lower event rate of documented symptomatic hypoglycemia (blood glucose ≤3.9 mmol/L) and daily insulin dose compared to patients who discontinued SITA. Summary adverse event measures and change in body weight (Week 30) were similar in the 2 treatment groups.

Conclusion: With the initiation of insulin therapy, continuation of SITA resulted in superior glycemic efficacy and less documented symptomatic hypoglycemia.

Efficacy and safety of linagliptin and metformin combination compared with metformin alone on stratified approach of type 2 diabetes treatment

Y. Shi[1], S.V.D. Walt[2], L. Miao[3];

[1]Department of Endocrinology and Metabolism, Changzheng Hospital, Shanghai, China, [2]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [3]Lilly (Shanghai) Management Co.,Ltd., Shanghai, China.

Background and aims: To evaluate the efficacy and safety of linagliptin and metformin combination versus metformin alone according to different baseline HbA1c level and individualized HbA1c target.

Materials and methods: Two phase 3 clinical trials evaluating efficacy and safety of initiated linagliptin/metformin combination or monotherapy in T2DM were included in this *post hoc* analysis. Patients were drug-naïve or pretreated with 1 OAD.The trials comprised a washout period (for patients pretreated with OAD) followed by placebo run-in period (all).Then, patients received 24 weeks of treatment period. For patients randomized to metformin 1000 mg bid, two weeks titration was applied with titration from 500 to 1000 mg bid. Pool I included all patients who randomized to metformin 500 mg bid (Met500), metformin 1000 mg bid (Met1000), linagliptin 2.5 mg + metformin 500 mg bid (Lina2.5/Met500) and linagliptin 2.5 mg + metformin 1000 mg bid (Lina2.5/Met1000). Pool II involved drug-naïve patients from Pool I.

Results: In pool I, 289 patients received Met500[mean HbA1c (SD) 8.68 (0.98)%], 291 received Met1000 [8.57 (0.93)%],290 received Lina2.5/Met500 [8.68 (0.94)%] and 290 received Lina2.5/Met1000 [8.71 (1.02)%]. At 24 week, in the category of baseline HbA1c <7.5%, there was no statistical difference between groups [lina2.5/Met500 vs Met500, lina2.5/Met1000 vs Met1000, $P > 0.05$ for both] on the proportion of patients who achieved HbA1c <7.0%. However, in the group of Lina2.5/Met1000, the proportion of patients who achieved HbA1c ≤6.5% was significantly higher than Met1000. For baseline HbA1c ≥7.5–9.0% population, a higher proportion of patients on initial dual therapy achieved HbA1c <7.0% or ≤6.5%,compared with monotherapy at 24 week. In the baseline HbA1c >9.0% population, the proportion of patients achieved HbA1c <7.0% or ≤6.5% in Lina2.5/Met1000 were highest at 24 week. The proportion of patients achieved HbA1c <7.0% in Lina2.5/Met1000 is significantly higher than Met1000 ($P = 0.0174$), but the proportion of patients achieved HbA1c ≤6.5% was non-significantly different with Met1000. In Met500, Met1000, Lina2.5/Met500 and Lina2.5/Met1000, 51.6%, 54.6%, 50.3% and 53.4% of patients experienced AEs. In pool II, we observed similar results.

Conclusion: For the patients whose baseline HbA1c is <7.5%, if the individualized glucose target is 7.0%, monotherapy or dual therapy are both appropriate. However, if the target is 6.5%, physicians can select Lina2.5/Met1000. For the patients whose baseline HbA1c level is ≥7.5–9.0%, regardless of the individualized HbA1c target is 6.5% or 7.0%, Lina2.5/Met1000 can make more patients achieve glucose target. For the patients whose baseline HbA1c level is >9.0%, if the individualized HbA1c target is 7.0%, Lina2.5/Met1000 maybe the best choice. However, if the target is 6.5%, triple-therapy may be needed.

Table1: At 24 week, the proportion of patients achieving HbA1c target in different baseline HbA1c categories

Baseline HbA1c level	Treatment group	n	At 24 week, the proportion of patients achieved HbA1c<7.0% (%)	P value (lina2.5/Met500 vs Met500)	P value (lina2.5/Met1000 vs Met1000)	At 24 week, the proportion of patients achieved HbA1c≤6.5% (%)	P value (lina2.5/Met500 vs Met500)	P value (lina2.5/Met1000 vs Met1000)

Early initiation of sitagliptin during metformin up-titration in treatment of patients with type 2 diabetes

J.P. Frias[1], Z. Zimmer[2], R.L.H. Lam[2], G. Amorin[2], C. Ntabadde[2], C. Iredale[2], E.A. O'Neill[2], S.S. Engel[2], K.D. Kaufman[2], H. Makimura[2], M.F. Crutchlow[2];
[1]National Research Institute, Los Angeles, [2]Merck & Co., Inc., Kenilworth, USA.

Background and aims: Metformin (MET) is widely used as the first-line antihyperglycemic agent (AHA) for patients with T2DM; it is usually initiated at a low dose and up-titrated based on tolerability and glycemic response. For many patients not at glycemic goal on a sub-maximal MET dose, MET dose maximization does not result in attainment of HbA1c goal. To better understand the optimal thresholds for early addition of a second-line AHA, the safety and efficacy of MET maximization with simultaneous addition of sitagliptin (SITA) were compared to MET maximization alone in participants not at HbA1c goal on a sub-maximal dose of MET.
Materials and methods: Participants at baseline had inadequate glycemic control on no AHA or on monotherapy with MET at 1000 mg/day or on another AHA. Prior to randomization, all participants continued or transitioned to MET 1000 mg/day for a 6–10 week stabilization period, followed by a 2-week single-blind placebo (PBO) run-in. Those with HbA1c 58 to 97 mmol/mol [7.5 to 11.0%] prior to the run-in were eligible for randomization. At randomization, participants were assigned (1:1) to SITA 100 mg/day or matching PBO. The MET dose was to be increased from 1000 mg/day to 2000 mg/day by study Week 2 and continued through Week 20. Primary objectives were to compare the effect of up-titration of MET with and without addition of SITA on reduction from baseline in HbA1c after 20 weeks of treatment and to assess the overall safety and tolerability of these regimens. Secondary objectives included the effects of treatment on the percentage of patients at the HbA1c goal of <53 mmol/mol (<7%) and reduction from baseline in fasting plasma glucose (FPG) after 20 weeks.
Results: Treatment groups were well balanced at baseline ($n = 229$/group, mean HbA1c = 71.1 mmol/mol [8.7%], mean FPG = 10.2 mmol/L). At Week 20, LS mean changes from baseline HbA1c were greater with SITA vs. PBO (Table), $p < 0.001$. At Week 20, the HbA1c goal of <53 mmol/mol (<7.0%) was more likely to be met with SITA than with PBO overall (Table) (Relative Risk 1.7, $p = 0.001$), and in the pre-specified subgroup with baseline HbA1c ≥69 mmol/mol (8.5%) (Table; Relative Risk 2.4, $p = 0.026$). At Week 20, LS mean changes from baseline in FPG were greater with SITA vs. PBO, $p = 0.002$. Both treatment regimens were well tolerated, with no notable between-group differences in safety or tolerability.
Conclusion: In this study of T2DM patients with inadequate glycemic control on MET 1000 mg/day, early initiation of SITA, simultaneous with MET dose maximization, was well tolerated and increased HbA1c goal attainment. These data support that initiation of SITA concomitantly with MET up-titration may be a preferred treatment-intensification strategy for many T2DM patients not at HbA1c goal on a sub-maximal dose of MET.

At Week 20	MET maximization + SITA	MET maximization + PBO
Change from baseline in HbA1c, mmol/mol (%)	-12.1 (-1.1)	-7.6 (-0.7)
Between group difference (95% CI)		
mmol/mol	-4.5 (-6.5, -2.5)	----
%	-0.4 (-0.6, -0.2)	----

Efficacy and safety of saxagliptin and glimepiride in patients with type 2 diabetes inadequately controlled with metformin monotherapy: results from the SPECIFY study

T. Gu, L. Zhu, Q. Niu, C. Li, Y. Bi, D. Zhu;
Department of Endocrinology, Nanjing Drum Tower Hospital affiliated to Nanjing University Medical School, Nanjing, China.

Background and aims: There is no consensus on the preference of oral anti-diabetic agents when metformin fails in Type 2 diabetes (T2D). In this 48 weeks, multicentre, open-label, randomized, parallel trial, we aimed to compare the efficacy and safety profile of saxagliptin with glimepiride in T2D patients uncontrolled with metformin monotherapy.
Materials and methods: Patients were 1:1 randomized to saxagliptin (5 mg daily) add-on to metformin or glimepiride (initial with 1 mg, titrated 1 mg if fasting blood glucose >6.1 mmol/L till 6 mg daily) add-on to metformin. The primary endpoint was the achievement of HbA1c <7.0%, without hypoglycemia and weight gain (defined as plasma glucose <3.9 mmol/L with or without symptoms and weight gain <3.0%) after 48 weeks treatment.
Results: Of 388 patients randomized, 325 (83.8%) patients completed the study (163 in saxagliptin and 162 in glimepiride). The patients' mean (±SD) age was 53.3 ± 9.4 years, mean T2D duration was 5.0 ± 4.3 years, mean HbA1c was 8.0 ± 0.7% and mean BMI was 25.5 ± 2.5 kg/m^2, in the full analysis set. Over 48 weeks, greater proportion of patients achieved the primary endpoint with saxagliptin plus metformin versus glimepiride (mean dose 2.5 mg/day) plus metformin (43.3% in saxagliptin *versus* 31.3% in glimepiride; odds ratio 1.38, 95%CI 1.05, 1.82; $p = 0.019$). Mean reduction in HbA1c was similar in two treatment groups at Week 48 (−0.94% in saxagliptin *versus* −0.98% in glimepiride, $p = 0.439$). Bodyweight decreased with saxagliptin plus metformin (−0.7 ± 2.6 kg), but increased with glimepiride plus metformin (0.9 ± 2.8 kg) from similar mean baseline values (69.8 ± 9.6 kg *versus* 69.9 ± 10.1 kg); the treatment difference was −1.6 kg ($p < 0.001$). The proportion of patients experiencing hypoglycemia was much less with saxagliptin plus metformin (3.1% in saxagliptin *versus* 12.8% in glimepiride, $p < 0.001$). Furthermore, subgroup analysis demonstrated that the proportion of patients with baseline HbA1c levels <8.0% or T2D duration <5 years achieving the composite primary endpoint was significantly higher with saxagliptin, compared with glimepiride (54.5% in saxagliptin *versus* 39.3% in glimepiride, $p = 0.042$; and 54.0% in saxagliptin *versus* 37.1% in glimepiride, $p = 0.021$, respectively).
Conclusion: This study provides evidence that saxagliptin is similar to glimepiride in efficacy, with reduced body weight and a significantly lower risk of hypoglycemia in patients with T2D inadequately controlled with metformin monotherapy, especially in patients with moderate hyperglycemia and relatively shorter diabetes duration.

Safety and efficacy of sitagliptin compared with dapagliflozin in patients with type 2 diabetes, mild renal impairment, and inadequate glycaemic control on metformin ± a sulfonylurea

A. Raji[1], R. Scott[2], J. Morgan[1], Z. Zimmer[1], R.L.H. Lam[1], E.A. O'Neill[1], K.D. Kaufman[1], S.S. Engel[1];
[1]Merck & Co., Inc., Kenilworth, USA, [2]Christchurch Hospital, Christchurch, New Zealand.

Background and aims: While choice of AHAs may be modified in patients with T2D and moderate or severe renal insufficiency, this is generally not the case in patients with mild renal insufficiency. Clinical trial data focused on this population, which represents ~40% of patients with T2D, are lacking. In a randomized, double-blind, active comparator-controlled clinical trial, the safety and efficacy of adding sitagliptin (SITA) (100 mg qd) or dapagliflozin (DAPA) (10 mg qd) to treatment of patients with eGFR ≥60 and <90 mL/min/1.73 m^2 and HbA1c ≥53 and ≤80 mmol/mol (≥7.0% and ≤9.5%) while on metformin ± a sulfonylurea were assessed.
Materials and methods: The primary efficacy endpoint was change from baseline HbA1c at Week 24 (analyzed with a longitudinal data analysis model), with a primary hypothesis of non-inferiority of SITA to DAPA based on the prespecified criterion of the upper bound of the between-treatment difference 95% CI (SITA minus DAPA) <0.3%; if the upper bound was <0.0%, SITA would be declared superior.
Results: Treatment groups were well balanced at baseline ($n = 307$ and 306, mean HbA1c, mmol/mol, [%] = 60.9 [7.7] and 61.2 [7.8], mean eGFR, mL/min/1.73 m^2 = 79.4 and 76.9 for SITA and DAPA, respectively). At Week 24, LS mean changes from baseline HbA1c, mmol/mol (%) were −5.6 (−0.5) (SITA) and −3.9 (−0.4) (DAPA); between-group difference (95%CI) = −1.7 (−2.9, −0.5) (−0.2 [−0.3, −0.0]), $p = 0.006$, confirming both non-inferiority and superiority of SITA vs. DAPA. The pre-specified analysis of 2 hr post-prandial glycemic excursion showed no significant difference between groups. The HbA1c goal of <53 mmol/mol (<7%) was met by 43% (SITA) and 27% (DAPA) of patients. Treatments were well tolerated; there were significantly fewer patients with drug-related adverse events (AEs) with SITA than with DAPA, but summary AE profiles were otherwise similar.
Conclusion: SITA treatment over 24 weeks resulted in greater glycemic efficacy and greater % of patients at HbA1c goal than DAPA in patients with T2D and mild renal impairment who were inadequately controlled on metformin ± a sulfonylurea.

Efficacy of dapagliflozin plus saxagliptin vs insulin glargine at 52 weeks in patients with type 2 diabetes inadequately controlled by metformin with or without sulfonylurea

T. Vilsbøll[1], E. Ekholm[2], E. Johnsson[2], R. Garcia-Sanchez[3], N. Dronamraju[3], S.A. Jabbour[4], M. Lind[5];
[1]Steno Diabetes Center, Copenhagen, Denmark, [2]AstraZeneca, Mölndal, Sweden, [3]AstraZeneca, Gaithersburg, USA, [4]Thomas Jefferson University, Philadelphia, USA, [5]University of Gothenburg, Gothenburg, Sweden.

Background and aims: Metformin (MET) is recommended as a first-line treatment of type 2 diabetes (T2D). Many patients (pts) on MET continue to demonstrate inadequate glycaemic control. Combination agents may provide better glycaemic control in pts with HbA_{1c} ≥64 mmol/mol (≥8.0%). Although insulin therapy is effective in pts on MET, it may lead to hypoglycaemia and body weight gain. We recently showed in a randomized trial over 24 weeks (w) that co-administration of dapagliflozin (DAPA) and saxagliptin (SAXA) was non-inferior to insulin glargine (INS) in achieving HbA_{1c} reductions, with a reduced risk of body weight gain and hypoglycaemia in pts with T2D inadequately controlled on MET ± sulfonylurea (SU). Here the efficacy and tolerability of DAPA+SAXA vs INS up to 52w with regards to HbA_{1c}, body weight and hypoglycaemia are compared.
Materials and methods: In this international, multicentre, randomised, parallel-group, phase 3, 24w (short-term) study with a 28w extension (long-term), pts ≥18y with T2D (HbA_{1c} 64–108 mmol/mol or 8.0–12.0%) on MET ≥1500 mg/day ±SU ≥50% maximal dose received DAPA 10 mg/day + SAXA 5 mg/day or INS 100 units/mL/day. Fasting plasma glucose goal for INS titration was ≤100 mg/dL (5.5 mmol/L). Week 52 endpoints: Change in HbA_{1c} and body weight, and proportion of pts achieving therapeutic glycaemic response without hypoglycaemia (plasma glucose ≤70 mg/dL) were considered exploratory.
Results: Overall, 1,163 pts were enrolled, 707 entered the short-term phase, 643 received treatment, 600 (306, DAPA+SAXA; 294, INS) entered the long-term phase and 557 (284, DAPA+SAXA; 273, INS) completed treatment. Mean (SD) HbA_{1c} (%) at baseline was comparable for the 2 treatment groups: DAPA+SAXA, 9.04 (1.023) and INS, 9.04 (1.054); other patient characteristics were balanced. Number of pts requiring rescue medication during treatment was 76 (23.5%) and 97 (30.4%) in DAPA+SAXA and INS groups, respectively. Mean total daily INS dose at 52w was 37.9 units. At 52w, the adjusted mean (SE) reduction in HbA_{1c} (%) was greater in pts on DAPA+SAXA [−1.51 (0.07)] vs INS [−1.26 (0.07)] (**Table**). There was a reduction in total body weight expressed as adjusted mean (SE) change from baseline with DAPA+SAXA [−1.83 (0.27) kg] vs weight gain with INS [+2.75 (0.28) kg] (**Table**). More pts on DAPA+SAXA (17.6%) vs INS (9.1%) achieved HbA_{1c} <53 mmol/mol (7.0%) without hypoglycaemia than INS.
Conclusion: Oral treatment with DAPA+SAXA improved glycaemic control and reduced mean body weight vs INS 52w after treatment initiation. A larger proportion of pts on DAPA+SAXA achieved therapeutic glycaemic control without hypoglycaemia vs INS. DAPA+SAXA can be a useful add-on to MET and MET+SU in T2D pts with inadequately controlled glycaemia.

PS 064 Incretin-based therapies: new mechanistic insights

776

The reduction in postprandial glucose by sitagliptin is related to the rate of gastric emptying in type 2 diabetes

K.L. Jones[1], J.E. Stevens[2], M. Buttfield[3], T. Wu[1], S. Hatzinikolas[1], H. Pham[1], K. Lange[1], C.K. Rayner[1], M. Horowitz[1];
[1]Adelaide Medical School, University of Adelaide, Adelaide, [2]School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, [3]School of Health Science, University of South Australia, Adelaide, Australia.

Background and aims: Dipeptidyl peptidase-4 (DPP-4) inhibitors are used widely, and for the main part, empirically in the management of type 2 diabetes (T2DM) and reduce fasting and postprandial glucose. The rate of gastric emptying (GE), which exhibits a substantial inter-individual variation in health and T2DM, is a major determinant of postprandial glycaemic excursions and the stimulation of glucagon-like peptide-1 (GLP-1). The latter relationship is non-linear e.g. the GLP-1 response is disproportionately greater when glucose delivery to the small intestine is 4 kcal/min when compared to 1–2 kcal/min. Therefore, while the effect of DPP-4 inhibitors on GE, if any, is modest, it is intuitively likely that postprandial glucose-lowering by DPP-4 inhibitors will be greater in T2DM patients with relatively more rapid GE. We have evaluated the relationship between the effect of sitagliptin on postprandial glucose and the rate of GE in T2DM.
Materials and methods: Fourteen subjects with T2DM (9M, 5F; age: 67.8 ± 1.5 yr; BMI: 31.2 ± 0.9 kg/m^2; duration of known diabetes: 4.2 ± 0.9 yr; HbA_1c: 6.35 ± 0.2%), managed by diet ± metformin, underwent concurrent measurements of GE and plasma glucose for 240 min after a mashed potato meal (368.5 kcal) labelled with 20 MBq ^{99m}Tc-Calcium Phytate, on two separate occasions. Participants received sitagliptin (100 mg) or placebo in randomised, double-blind, crossover fashion on 2 consecutive days; the last dose was given 60 min before the meal. Data are mean values ± SEM.
Results: There was no difference in the 50% GE time (T50) between the 2 days (sitagliptin: 71.5 ± 3.9 vs placebo: 71.1 ± 4.3 min). Sitagliptin had no effect on plasma glucose immediately before the meal ($t = -5$ min) (sitagliptin: 6.7 ± 0.4 vs placebo: 6.7 ± 0.3 mmol/L). The overall postprandial plasma glucose response was reduced by sitagliptin ($iAUC^{0–240}$ min: sitagliptin: 548 ± 79 vs placebo: 700 ± 96 mmol/L*min; $P < 0.005$) with a reduction in peak plasma glucose (sitagliptin: 11.4 ± 0.7 vs placebo: 12.7 ± 0.6 mmol/L; $P < 0.01$). The plasma glucose at 60 min was inversely related to the T50 on placebo ($r = -0.62$, $P = 0.01$), but not on sitagliptin ($r = -0.35$, $P = 0.22$). The magnitude of postprandial glucose-lowering by sitagliptin (change in $iAUC^{0–240}$ between placebo and sitagliptin) was related directly to the rate of GE (expressed as kcal/min) on placebo ($r = 0.68$, $P = 0.008$; *Figure*).
Conclusion: In T2DM, the acute effect of sitagliptin to reduce postprandial glucose is related to the baseline rate of GE, probably reflecting relative postprandial increases in both glucose and GLP-1. DPP-4 inhibitors may, accordingly, have greater therapeutic efficacy in T2DM patients with faster GE, providing a potential rationale for routine measurement of GE prior to the initiation of treatment.

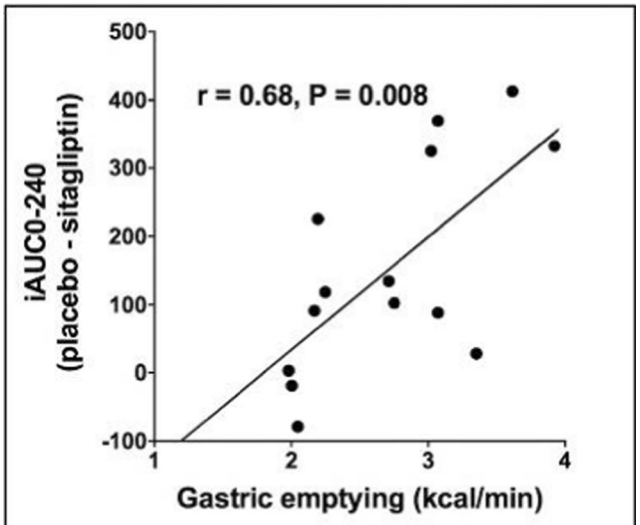

Figure: Relationship between the change in $iAUC^{0-240}$ min for plasma glucose from placebo to sitagliptin and the rate of GE (kcal/min) of a mashed potato meal on placebo in T2DM (n=14).

Effects of DPP-4 inhibitors on BNP, GLP-1, NPY, SP and global longitudinal strain measurements in type 2 diabetes patients

S. Güllü[1], E. Asfuroğlu Kalkan[1], B.I. Aydogan[1], S. Canlar[1], A. Gökçay Canpolat[1], I. Dinçer[2];
[1]Department of Endocrinology and Metabolism, Ankara University Faculty of Medicine, Ankara, [2]Department of Cardiology, Ankara University Faculty of Medicine, Ankara, Turkey.

Background and aims: Previously, a significant relationship between saxagliptin treatment and increased rate of hospitalization for congestive heart failure was reported. Echocardiographic global longitudinal strain (GLS) is a new and effective method in detecting myocardial damage and subclinical cardiac dysfunction even when left ventricular ejection fraction (LVEF) is normal. We aimed to investigate effects of vildagliptin and saxagliptin on brain natriuretic peptide (BNP), neuropeptide Y, substance P (SP), glucagon like peptide-1 (GLP-1) levels and left ventricular global longitudinal strain (GLS), assessed by 3-dimensional speckle tracking echocardiography in uncontrolled type 2 Diabetes Mellitus (T2DM).
Materials and methods: Thirty seven inadequately controlled type 2 DM (HbA1c ≥7.5%) patients who were recently prescribed to either vildagliptin 50 mg BID ($n = 21$) or saxagliptin 5 mg QD ($n = 16$) and completed the study period were included in this study. Exclusion criteria were; 1-Patients who received insulin (recent/previous), 2-Patients with known heart failure and/or coronary heart disease and/or hypertension. Informed consent forms were obtained from all patients and study was approved by Ethical Committee. Body mass index, HbA1c, Hb, creatinine, ALT, AST,BNP, NPY, SP, GLP-1 levels were measured at

admission, 1st and 3rd months of treatment. Global longitudinal strain (GLS) was measured at admission and 3rd month.

Results: Age, BMI, gender, HbA1c, ALT, AST and lipid profiles were not different between treatment groups. In whole group, AST, ALT and HbA1c levels decreased significantly at 3rd month of treatment ($p < 0.001$, $p = 0.002$, $p = 0.004$ respectively) while BNP and NPY values increased significantly ($p < 0.001$, 0.004; respectively). In the vildagliptin group, BNP and NPY values increased significantly at 3rd month of treatment (median = 10.06 (5.22–36) vs. 20.54 (6.4–60.89), $p = 0.020$ and 9.6 (4.3–27.7) vs. 17 (3.92–42.1), $p = 0.047$, respectively). In the saxagliptin group only BNP levels increased significantly (median = 8.5 (3.71–44) vs. 18.38 (2.36–50), $p = 0.015$). In both treatment groups; SP,GLP-1 levels and GLS measurements did not change significantly during follow-up period. Basal and 3rd month mean GLS were -16.34 ± 2.83 vs. -15.82 ± 2.40 in vildagliptin group and -16.41 ± 2.80 vs. -16.72 ± 2.83 in saxagliptin groups, respectively. All measured parameters were similar at the 1.st and 3rd. months of treatment. None of the patients required hospitalization for heart failure during follow-up.

Conclusion: The current study demonstrated that treatment with DPP-4 inhibitors, saxagliptin and vildagliptin, was associated with increased levels of BNP and NPY levels. However no evidence of subclinical myocardial damage or cardiac dysfunction could be detected by GLS measurements assessed by 3-dimensional speckle tracking echocardiography after three months of therapy. Since our study population had no previous clinical cardiac disorders, increases in BNP and NPY levels with these two DPP4 inhibitors can be considered as a safety signal. In order to clarify this, further studies including patients with known heart problems are needed.

Effects of MEDI0382, a glucagon-like peptide 1/glucagon receptor dual agonist, on pancreatic and incretin hormones

L. Jermutus[1], L.-F. Tsai[2], D. Robertson[1], M. Petrone[1], C. Rondinone[2], H. Boaz[2], P. Ambery[1], V. Parker[1];
[1]MedImmune, Cambridge, UK, [2]MedImmune, Gaithersburg, USA.

Background and aims: MEDI0382, a glucagon-like peptide 1 (GLP-1)/glucagon dual-receptor agonist, is being developed for the treatment of type 2 diabetes mellitus and nonalcoholic steatohepatitis. GLP-1 receptor agonists promote glucose-dependent insulin release, suppress glucagon, and increase or have minimal effect on glucose-dependent insulinotropic polypeptide (GIP); however, knowledge of the effect on GLP-1 is limited. We characterized fasting and postprandial hormone profiles associated with MEDI0382 therapy.

Materials and methods: In a phase 2a study, 51 subjects with type 2 diabetes and a body mass index of 27–40 kg/m^{2}received MEDI0382 (uptitrated to 200 μg) or placebo daily for 41 days. Glucose, insulin, glucagon, GIP, and GLP-1 were measured at baseline (day -1) and day 41 during a liquid mixed-meal tolerance test.

Results: MEDI0382 significantly reduced fasting glucose (−49.9 vs −19.2 mg/dL for placebo; $P < 0.0001$) and glucose $AUC_{0\text{-}4h}$ (−32.8 vs −10.2% for placebo; $P < 0.0001$) in association with increased fasting insulin (2.2 mU/L vs −3.9 mU/L for placebo; $P = 0.0164$), but postprandial insulin AUC was unchanged. In contrast, fasting and postprandial endogenous glucagon, GIP (Figure), and active and inactive GLP-1 were suppressed, and a delay in their kinetics was observed after MEDI0382 therapy.

Conclusion: The results suggest that MEDI0382 is insulinotropic and might also cause delayed gastric emptying. The effects of MEDI0382 on GIP have not been observed with GLP-1 receptor monoagonists and may represent a footprint of dual GLP-1/glucagon receptor agonism in this complex hormone signaling network.

Comparison of therapy in which incretin action compatibility was considered in basal insulin therapy using continuous glucose monitor: randomised triple crossover study

S. Takeishi, H. Tsuboi, S. Takekoshi;
General Inuyama Chuo Hospital, Inuyama-city, Japan.

Background and aims: We investigated combinations of agents with incretin action used together with basal insulin to ascertain which was the most compatible combination. Vildagliptin can reduce postprandial and fasting glucose levels properly; metformin enhances the effect of long-acting insulin and endogenous insulin secreted from vildagliptin; and miglitol is effective at reducing postprandial glucose levels. We examined the following combinations using a continuous glucose monitor: vildagliptin 100 mg (V) +metformin 500 mg (M), V+miglitol 150 mg (α) or M+α.

Materials and methods: We calculated a required sample size of 30. 30 type 2 diabetic patients were randomly allocated to three groups. On admission, Group 1: Patients took V+M (VM) and glucose level were stabilized (not exceeding 180 mg/dL for 3 days) by insulin glargine 300 U/ml (Glargine300); next, patients wore a continuous glucose monitoring (FreeStyle Libre Pro) device and glycemic variability (GV) was evaluated on days 3 and 4; VM was then switched to V+α (Vα), and GV was evaluated on days 8 and 9; finally, Vα was switched to M+α (Mα) and GV was evaluated on days 13 and 14. Group 2: Patients took in the order of Vα, Mα, and VM, following the same regimen. Group 3, Patients took in the order of, Mα, VM and Vα, following the same regimen. V and M was taken at 08:00 and 18:00, α was taken at 08:00, 12:00, and 18:00. Glargine300 (the same dose as during the FreeStyle Libre Pro measurement period) was injected at 08:00. Data collected on the second evaluation day were analysed (mean amplitude of glycaemic excursion (MAGE), mean of daily differences (MODD) and average daily risk range (ADRR): on all evaluation days). Test meals were given.

Results: 24-h percentage of time in target range (70–140 mg/dL), 24-h mean absolute glucose (MAG), 24-h glycemic variability percentage, mean glucose level (24-h, 00:00–06:00), coefficient of variation (24-h, 00:00–06:00, 08:00–24:00), and high blood glucose index were significantly lower in patients on VM, Vα, and Mα, in that order (Friedman's test). The difference between groups (Δ = VM − Vα) in MAG significantly correlated to body mass index (BMI) ($r = -0.38$, $p = 0.04$). ΔMAGE also significantly correlated to BMI ($r = -0.4$, $p = 0.03$). Mean absolute relative difference compared to 9-point self-monitoring of blood glucose (SMBG) in patients on VM, Vα, and Mα was 10.2%,

10.0%, and 9.7%, respectively. FreeStyle Libre Pro values significantly correlated to SMBG values before and after breakfast, before and after lunch, before and after dinner, at bedtime and at 04:00 (9-point SMBG time) in patients on VM, Vα, and Mα ($r = 0.68$~0.95, $p < 0.0001$). FreeStyle Libre Pro values and SMBG values were not significantly different at 9-point SMBG time in patients on VM, Vα, and Mα.

Conclusion: Vildagliptin and metformin is the most compatible combination to improve GV in basal insulin therapy.

	a: Vildagliptin 100 mg + metformin 500 mg	b: Vildagliptin 100 mg + miglitol 150 mg	c: Metformin 500 mg + miglitol 150 mg	p	p (a vs. b)	p (b vs. c)	p (a vs. c)

Urinary proteomics may unmask the renal potential of the dipeptidyl peptidase (DPP)-4 inhibitor linagliptin in patients with diabetic kidney disease (DKD)

J. Siwy[1], H. Mischak[1], T. Klein[2], M. von Eynatten[3];
[1]mosaiques-diagnostics GmbH, Hannover, [2]Boehringer Ingelheim, Biberach, [3]Boehringer Ingelheim, Ingelheim, Germany.

Background and aims: DKD is a serious complication of hyperglycaemia and novel treatments to preserve renal function are needed. DPP-4 inhibitors are commonly used glucose-lowering drugs in type 2 diabetes (T2D) patients. Among these, linagliptin (LINA) has previously been suggested to have renal potential independent of its effects on hyperglycaemia. We aimed to characterise the urinary proteomic profile (UPP) before and after treatment with LINA in T2D patients at early stages of DKD.

Materials and methods: Samples were derived from the previously reported MARLINA-T2D™ trial. In brief, T2D patients ($n = 360$) with prevalent albuminuria (urinary albumin creatinine ratio [UACR] ≥30 mg/g) despite stable background renin-angiotensin system blockade were randomised 1:1 to receive double-blind, oral treatment with LINA 5 mg or placebo for 24 weeks. Urine samples were collected at baseline and after treatment. Capillary electrophoresis coupled with mass spectrometry was performed to assess UPP and a previously developed CKD273 score.

Results: Urine samples were available for 88.8% of the study population ($n = 320$). At baseline, the CKD273 score showed a strong correlation with UACR (rho = 0.54) and estimated glomerular filtration rate (eGFR) (rho = −0.41), respectively (both $p < 0.0001$). In addition, baseline CKD273 ($p = 0.027$) and baseline eGFR ($p = 0.015$), but not baseline UACR, were associated with eGFR decline per year in the placebo group. LINA treatment was not associated with a significant overall difference in eGFR compared to placebo at study end. However, after stratification of the study population according to low and high risk for renal disease progression (based on CKD273 score) we identified numerically less renal function loss in high risk patients with LINA (median GFR: 90.0 ml/min/1.73 m² at study end) as compared to placebo (median GFR: 65.0 ml/min/1.73 m² at study end; $p = 0.06$). No differences in eGFR at study end between the LINA and placebo groups were observed in the low risk group. We further compared the UPP before and after treatment with LINA ($n = 164$). We identified 993 peptides potentially affected by LINA and sequenced 314. The majority of sequenced peptides were increased after LINA. This finding was expected based on the protease feature of DPP-4. Consequently, out of the 95 most altered peptides, 53 had the amino acid proline in the penultimate position. This sequence is compatible with the DPP-4 active site, known to cleave X-proline dipeptides from the N-terminus. Therefore, the UPP after LINA was enriched for peptides containing the N-terminal X-proline, and consequently peptides lacking the DPP-4 signature dipeptide were decreased. We were able to identify such pairs of peptides. Finally, we found a significant ($p < 0.05$) negative correlation between the urinary concentration increase with reduced plasma DPP-4 activity for 20 peptides.

Conclusion: This sub-study of the MARLINA-T2D™ trial confirms previous evidence of the CKD273 score to be associated with markers of DKD. A novel finding was that CKD273 could not only identify patients at high risk for DKD progression but may also be indicative for the potential of LINA to slow renal function loss. Furthermore, our comprehensive assessment of the UPP revealed a significant impact of LINA on urinary peptides with a pattern reflective of the specific protease fingerprint of the DPP-4 enzyme.

DPP-4 inhibitor teneligliptin attenuates high glucose induced beta cell dysfunction via cAMP-Sirt1 pathway

S. Elumalai[1], U. Karunakaran[2], J. Moon[2], K. Won[2];
[1]Institute of Medical Science, Yeungnam University College of Medicine, Buk-gu, Daegu, [2]Department of Internal Medicine, Yeungnam University College of Medicine, Buk-gu, Daegu, Republic of Korea.

Background and aims: Teneligliptin, a newer DPP-4 inhibitor provides a narrative clinical efficacy and oral tolerability with a unique chemical structure amongst currently available DPP-4 inhibitors. A very recent study shows that DPP-4 is expressed in human pancreatic beta cells and there is no study about the effect of Teneligliptin in the pancreatic beta cells. Herein we investigated the direct effect of Teneligliptin, on beta-cell function and survival in response to high glucose conditions.

Materials and methods: We subjected INS-cells and human 1.1b4 pancreatic beta cells to high glucose (30mM) for 48 hours in the absence or presence of DPP-4 inhibitor Teneligliptin. Insulin secretion was assessed by Millipore ELISA Kit. P66Shc phosphorylation and mitochondrial translocation was measured by western blot and immunofluorescent analysis. Reactive oxygen species were measured by using DCFDA. Apoptosis was determined by TUNEL In-Situ cell death detection kit. The protein expression level of GLP1R, Sirt1, JNK and cleaved caspase-3 signaling and SERCA2B ubiquitination in response to high glucose was assessed by western blot analysis.

Results: Exposure of INS-1 cells or human 1.1b4 pancreatic beta cells to high glucose (30mM) downregulated GLP1R expression and induce beta cell apoptosis. Interestingly, Teneligliptin treatment stabilized GLP1R protein and increased the intracellular cAMP production ($p < 0.005$) and potentiate glucose stimulated insulin secretion (GSIS) ($p < 0.05$). In parallel, Teneligliptin treatment correlated with the up-regulation of Sirt1 expression. Further, Teneligliptin treatment significantly decreased the

high glucose induced reactive oxygen species (ROS) production ($p < 0.05$) and reduce the JNK mediated p66Shc serine 36 phosphorylation and its mitochondrial translocation and cleaved caspase-3 activation. Moreover, Teneligliptin counteracted the high glucose induced ubiquitination of SERCA2b and lowers the ER stress markers. Interestingly, cAMP pathway inhibition by H89 (PKA inhibitor) blocked the teneligliptin protective effects against the high glucose induced beta cell apoptosis.

Conclusion: Teneligliptin stabilizes GLP1R protein and increasing the cAMP dependent antioxidant response (Sirt1 activation) and its downstream signaling lead to β-cell function (GSIS) and survival under high glucose conditions. Teneligliptin ameliorates high glucose-induced endoplasmic reticulum stress by reducing the ubiquitination of SERCA2b. Collectively, our results unveil a direct effect of Teneligliptin on beta-cell function and survival.

DPP-4 inhibitor reduces the risk of developing hypertrophic scars and keloids in diabetic patients: analysis using the National Database of Health Insurance Claims of Japan

H. Suwanai[1], R. Watanabe[2], M. Sato[1], H. Matsumura[1];
[1]Tokyo Medical University, Tokyo, Japan, [2]Kanagawa University of Human Services, Kanagawa, Japan.

Background and aims: Hypertrophic scars and keloids, abnormalities due to hyperplasia of collagen fibers, often occur in surgical wounds, but their exact cause and preventive measures are unknown. The administration of dipeptidyl peptidase-4 (DPP-4) inhibitors to humans is expected to suppress fibrosis in wounds and minimise hypertrophic scar and keloid formation. This study aimed to verify the suppressive effect of DPP-4 inhibitors on the formation of hypertrophic scars and keloids in diabetic patients using data from the National Database of Health Insurance Claims and Specific Health Checkups of Japan (NDB).

Materials and methods: We extracted data from NDB between April 2013 and March 2015 and performed retrospective cohort study. NDB includes approximately 3.3 billion claims. Patients who underwent median sternotomy in April 2014 were included in the study based on their claimed surgical codes. Exclusion criteria included median sternotomy during the preceding or subsequent 1-year period, "scars" or "keloids" within 1 year prior to the procedure, and death during the study period. Subjects who were prescribeDPPP-4 inhibitors between April 2013 and March 2014 comprised the treatment group; subjects who were not prescribed or administereDPPP-4 inhibitors during that period comprised the non-treatment group. Subjects included 5430 patients throughout Japan (3509 men: mean age, 65.1 years; 1921 women: mean age, 66.0 years).

Results: Of the 446 subjects who were treated with DPP-4 inhibitors within 1 year before the procedure, six (1.35%) developed either hypertrophic scars or keloids within 1 year of the procedure. Of the 4984 subjects who were not treated, 152 (3.05%) were at significantly lower risk for developing hypertrophic scars and keloids (risk ratio, 0.696; $p = 0.04$). Logistic regression analysis was performed to adjust for confounding factors, with history of hypertrophic scar formation as the explained variable anDPPP-4 inhibitor treatment, age, sex, diabetes mellitus status, and steroid treatment as explanatory variables. Treatment with DPP-4 inhibitors minimised the development of hypertrophic scars and keloids, although it was not statistically significant (treatment odds ratio, 0.512; $p = 0.12$).

Conclusion: Treatment with DPP-4 inhibitors in diabetic patients minimised the risk of hypertrophic scars and keloids in humans. These results prove a cause-and-effect relationship and are highly generalisable to Japanese people.

Liraglutide treatment in obese diabetic patients modulates gut microbiota

S. Moffa[1], V. Tesori[2], V.A. Sun[1], T. Mezza[1], C.M.A. Cefalo[1], F. Impronta[1], F. Cinti[1], G.P. Sorice[1], F. Scaldaferri[2], G. Cammarota[2], A. Gasbarrini[2], A. Giaccari[1];
[1]Center for Endocrine and Metabolic Diseases, Policlinico Gemelli, Rome, [2]Gastroenterology Division and Internal Medicine Institute, Policlinico Gemelli, Rome, Italy.

Background and aims: Liraglutide, a glucagon-like peptide-1 (GLP-1) analogue, acts by stimulating glucose-dependent insulin secretion and by slowing gastric emptying. Recent studies in mouse models have shown that Liraglutide is able to modulate the composition of the intestinal microbiota suggesting that this may be one of the factors favoring the drug-induced weight loss. We here aimed to observationally evaluate the effect of Liraglutide on gut microbiota composition in obese diabetic humans.

Materials and methods: Eight obese diabetic subjects (age 61.7 ± 10.5; HbA1C 8.1 ± 1.4%; weight: 102.6 ± 11.9 kg), candidates to receive GLP1-analogs therapy, were included in the study. All subjects underwent, before (B) and after 6 weeks of treatment (PT) with Liraglutide 1.2 mg, metabolic evaluation including BMI, glucose, HbA1c and LDL-cholesterol. Lactulose Breath Test (LBT) was performed to characterize gut microbiota, measuring hydrogen (H2) and methane (CH4) production; while gastric emptying time (t/2) was assessed by Octanoic Acid Breath Test.

Results: All subjects experienced a significant weight loss (4% of the basal body weight; BMI B: 35.7 ± 3.3 kg/m^2, BMI PT: 34.9 ± 2.8 kg/m^2, $p = 0{,}03$), as well as a significant reduction of fasting plasma glucose (FPG) (FPG B: 153.7 ± 34.3 mg/dl, FPG PT: 135 ± 37.3 mg/dl $p = 0.02$), Hb1Ac (HbA1C B: 8.1 ± 1.4%, HbA1C PT: 7.2 ± 0.9% $p = 0.004$) and LDL-cholesterol (LDL B: 84.8 ± 42.1 mg/dl; LDL PT: 67.3 ± 26.6 mg/dl, $p = 0.005$). Methane and Hydrogen production (AUC) were significantly reduced by Liraglutide in the post-treatment group (H2 B: 7140 ± 12.5 ppm, H2 PT: 1831.8 ± 1130 ppm, $p = 0.0008$; CH4 B: 1663.5 ± 161.6, CH4 PT: 600 ± 366 ppm, $p = 0.001$); moreover, the LBT revealed that Liraglutide is able to significantly slow down the Oro-cecal Transit Time (OTT). As expected, gastric emptying was significantly reduced after Liraglutide treatment (t/2 B: 49.7 ± 12.5 min, t/2 PT: 88 ± 13.4 min $p = 0.002$).

Conclusion: These results confirm the effect of Liraglutide in delay gastric emptying and show also the effect in reducing the OTT. We, here, show that Liraglutide also induces a reduction in the intestinal gases production, which is an indirect measure of changes in gut microbiota. In conclusion, we highlight the close relationship between glucose lowering effect of Liraglutide and the intestinal microbiota composition, suggesting that the treatment effect may be potentially mediated by changes in gut microbiota, which could in turn represent a new therapeutic target for treatment of type 2 diabetes.

Liraglutide and glimepiride in type 2 diabetic patients with failure to oral hypoglycaemic agents: effects on beta cell function

E. Salutini[1], S. Del Guerra[2], S. Barone[2], G. de Gennaro[2], S. Del Prato[2], C. Bianchi[3];
[1]Hospital of Pistoia, Pistoia, [2]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, [3]University Hospital of Pisa, Pisa, Italy.

Background and aims: GLP-1 analogues have been claimed to prevent beta-cell loss and ensure a more sustained glycaemic control. However, whether this is related to duration of diabetes is presently unclear. We, therefore, compared the effect of liraglutide as compared to a sulphonylurea in sustaining beta-cell function in patients with Type 2 diabetes (T2DM) and secondary failure to oral agents after restoration of strict glycaemic control with insulin.
Materials and methods: Fifteen type 2 diabetic patients (age 66 ± 1 yrs; BMI 29.9 ± 1.5 Kg/m^2; mean ± SE) with poor glycaemic control (HbA1c 8.2 ± 0.2%) with metformin+sulfonylurea therapy were randomly assigned to liraglutide (LIR; $n = 8$) or glimepiride (GLI; $n = 7$) after the restoration of strict glycaemic control with basal insulin (Figure). Fasting and OGTT (75 g) plasma glucose, and insulin, were measured at entry and after completion of each of the 4-phases of intervention.
Results: After 24 wk insulin therapy HbA1c improved in both groups (LIR 7.5 ± 0.2 vs. GLI 7.5 ± 0.2; $p > 0.05$ vs. basal). LIR (1.4 ± 0.2 mg/day) or GLI (3.8 ± 0.4 mg/day) add-on therapy further lowered HbA1c (LIR 6.4 ± 0.1 vs. GLI 6.7 ± 0.2; $p > 0.05$). Insulin withdrawal was associated with only marginal and not different HbA1c increase (LIR 6.8 ± 0.2 vs. GLI 7.1 ± 0.2) with no changes 2 wks after LIR and GLI discontinuation (LIR 6.8 ± 0.2 vs. GLI 7.1 ± 0.3). With LIR the AUCins/AUCglucose increased at wk48 (basal 0.05 ± 0.01; wk48: 0.15 ± 0.04) and remained higher after insulin discontinuation (0.14 ± 0.04) and after LIR withdrawal (0.10 ± 0.03; all $p < 0.05$ vs. basal). GLI also was associated with an increase in the AUC ratio that was significant only after insulin discontinuation (Basal 0.03 ± 0.01; 48wk: 0.10 ± 0.05; 64wk 0.06 ± 0.01, $p > 0.05$ vs basal; 66wk 0.05 ± 0.01). HOMA-IR was not significantly affected in both treatment arms. Disposition index (DI) was calculated as the Insulinogenic Index adjusted by HOMA-IR x 100. In both arms, DI improved after initial insulin treatment (Basal: 0.3 ± 0.2; wk24, LIR 1.6 ± 0.2, GLI 3.9 ± 1.5) to return to baseline in the ensuing time points.
Conclusion: In T2DM patients with failure to oral agents restoration of glycaemic control with insulin is associated with an improvement of beta-cell function that seems to persist to a better extent with continuation of glucose lowering therapy with liraglutide than with glimepiride.

HbA_{1c} target attainment in patients with type 2 diabetes receiving iGlarLixi who reach postprandial glucose and fasting plasma glucose targets in the LixiLan-L trial

J. Davidson[1], J. Chao[2], A. Saremi[3], T. Dex[3], L. Leiter[4];
[1]Touchstone Diabetes Center, Dallas, USA, [2]Xinyi, Inc., Bridgewater, USA, [3]Sanofi US, Inc., Bridgewater, USA, [4]St. Michael's Hospital, Li Ka Shing Knowledge Institute, Toronto, Canada.

Background and aims: Treatments that reduce HbA_{1C} levels often do not reflect improvements in both fasting and postprandial hyperglycaemia.
Materials and methods: Data from 731 patients with type 2 diabetes uncontrolled on basal insulin ± oral antidiabetes drugs in the LixiLan-L trial were used to investigate the association between achieving fasting plasma glucose (FPG)/postprandial glucose (PPG) targets and HbA_{1C} target attainment after 30 weeks of treatment with a titratable once-daily fixed-ratio combination of basal insulin and lixisenatide (iGlarLixi; $n = 366$), or insulin glargine (iGlar; $n = 365$). Outcomes were HbA_{1C} target attainment, HbA_{1C} change from baseline, and mean HbA_{1C} at Week 30 in patients achieving both FPG and PPG targets, FPG target only, PPG target only, or neither, using American Diabetes Association (ADA) glycaemic targets.
Results: The proportion of patients reaching PPG only, or both FPG and PPG targets, was numerically higher for iGlarLixi, while the proportion reaching FPG target only was numerically higher for iGlar **(Table)**. iGlarLixi-treated patients reaching both FPG and PPG targets, or FPG target only, showed statistically significant greater HbA_{1C} changes from baseline, lower end-of-trial HbA_{1C}, and a higher proportion reaching HbA_{1C} target than iGlar-treated patients **(Table)**. Despite a numerically higher proportion of patients reaching FPG target only in the iGlar arm, HbA_{1C} outcomes were in favour of patients receiving iGlarLixi.
Conclusion: In conclusion, the complementary actions of iGlarLixi on both fasting and postprandial hyperglycaemia were associated with better HbA_{1C} target attainment compared with iGlar alone, which mainly targets fasting hyperglycaemia.

Table: FPG and PPG target attainment, mean HbA_{1C} at week 30, HbA_{1C} change from baseline, and HbA_{1C} target attainment in iGlarLixi- or iGlar-treated patients according to ADA targets (2-hour PPG <180 mg/dL; FPG <130 mg/dL; HbA_{1C} <7.0%).

		Glycaemic Targets

Propensity-matched patient-level comparison of iGlarLixi and basal-bolus regimen in patients with type 2 diabetes

J. Meier[1], J. Anderson[2], C. Wysham[3], F.J. Tinahones[4], A. Saremi[5], P. Stella[5], M. Liu[6], A.G. Tabak[7];
[1]St Josef Hospital, Ruhr-University Bochum, Bochum, Germany, [2]The Frist Clinic, Nashville, USA, [3]Rockwood Clinic, Spokane, USA, [4]University of Malaga, Malaga, Spain, [5]Sanofi, Bridgewater, USA, [6]BDM Consulting, Somerset, USA, [7]Semmelweis University Faculty of Medicine, Budapest, Hungary.

Background and aims: Given the progressive nature of type 2 diabetes (T2D), glycaemic control is expected to become insufficient with basal insulin-supported oral therapy (BOT) in T2D and intensification with

prandial insulin may be required. However, the high injection burden, weight gain, increased risk of hypoglycaemia, and the complexity of basal-bolus (BB) regimens are barriers in real-world practice. iGlarLixi, a once-daily titratable fixed-ratio combination of insulin glargine 100 U/mL and the glucagon-like peptide-1 receptor agonist lixisenatide, may offer a simple alternative to BB regimens to provide glycaemic control while mitigating weight gain and hypoglycaemia in patients with T2D.

Materials and methods: In this post hoc analysis, patients randomized to iGlarLixi in the LixiLan-L trial were matched (using propensity scores based on the covariates of age, race, diabetes duration, baseline BMI, HbA_{1c} and fasting plasma glucose) to patients randomized to BB insulin in the GetGoal Duo-2 trial, yielding 328 pairs. In addition, in a sensitivity analysis, 192 pairs were matched with baseline basal insulin dose added to the pool of matched covariates. Changes from baseline were compared by mixed-effect models using repeat measurements with treatment groups, randomization strata of HbA_{1c} (<8.0% or ≥8.0%) at screening, metformin use (yes/no), and country as fixed effects; and visit, baseline*visit interaction, and treatment*visit interaction as covariates.

Results: In the primary analysis (Figure), greater proportions of patients in the iGlarLixi group reached the individual endpoints of HbA_{1c} <7%, no weight gain and no hypoglycaemia, as well as composite endpoints (this was also the case in patients further matched for baseline insulin dose). In addition, a greater reduction in HbA_{1c} (least squares [LS] mean −0.28% [standard error (SE) 0.06]) was achieved in the iGlarLixi group versus the BB group ($p < 0.0001$). The LS mean (SE) differences in change from baseline total insulin dose (BB insulin vs iGlarLixi) were 3.31 (1.48) U and 5.08 (1.34) U in patients unmatched and matched for baseline dose, respectively ($p < 0.05$).

Conclusion: iGlarLixi offers an effective alternative to BB insulin, with lower rates of hypoglycaemia and weight gain in patients with T2D inadequately controlled with a BOT at a moderate basal insulin dose.

Impact of type 2 diabetes duration on response to iGlarLixi vs iGlar: a subanalysis of LixiLan-L

L. Blonde[1], L. Berard[2], A. Saremi[3], Y. Huang[4], V.R. Aroda[5], D. Raccah[6]; [1]Frank Riddick Diabetes Institute, Ochsner Medical Center, New Orleans, USA, [2]Wellness Institute Seven Oaks General Hospital, Winnipeg, Canada, [3]Sanofi, Bridgewater, USA, [4]BDM Consulting, Somerset, USA, [5]Brigham and Women's Hospital, Boston, USA, [6]University Hospital Sainte-Marguerite, Marseilles, France.

Background and aims: Glucagon-like peptide-1 receptor agonists such as lixisenatide have insulin-independent effects, which may allow benefit for patients with a longer duration of type 2 diabetes (T2D) and greater loss of β-cell function.

Materials and methods: We assessed the effects of insulin glargine U100 (iGlar) vs fixed-ratio iGlar plus lixisenatide (iGlarLixi) by T2D duration in the LixiLan-L trial ($N = 736$). Changes in glycated haemoglobin (HbA_{1c}), weight, and insulin dose from baseline to Week 30, as well as hypoglycaemia rates, were analysed in patients divided into quartiles by recorded baseline T2D duration (<7.3, 7.3–<10.7, 10.7-15.7, and >15.7 yrs). Patients were also grouped by both duration and baseline insulin dose, both of which may relate inversely to β-cell function.

Results: Baseline HbA_{1c} was higher in longer-duration quartiles but similar with iGlarLixi vs iGlar. iGlarLixi reduced HbA_{1c} more vs iGlar across all duration quartiles (Figure). The difference was greatest in patients in the longest duration quartile (least squares mean difference [standard error], −0.62 [0.13]; $p < 0.0001$). Mean (SD) weight change across quartiles ranged from −0.95 (3.50) to −0.11 (3.65) with iGlarLixi and from 0.43 (2.81) to 1.13 (2.83) with iGlar ($p < 0.0001$, 0.0053, <0.0001, and 0.3281 for between-group differences, in lowest to highest duration quartiles). In both treatment groups, patients in the shortest duration quartile had the greatest mean insulin dose change from baseline to Week 30 (11.91 and 14.36 U for iGlarLixi and iGlar, respectively, versus 8.84 and 8.90, respectively, in the longest duration quartile). The difference in hypoglycaemia (iGlarLixi vs iGlar) was greatest in patients in the longest duration quartile (3.3 vs 6.9 events/patient-yr; $p < 0.0001$). In patients grouped by T2D duration and insulin dose, those with both long duration (≥15.7 yrs) and high dose (≥42 U) showed the greatest difference in HbA_{1c} lowering with iGlarLixi vs iGlar.

Conclusion: In LixiLan-L, iGlarLixi lowered HbA_{1c} more vs iGlar regardless of T2D duration, with the greatest difference in those with the longest duration.

Effects of sustained treatment with lixisenatide on gastric emptying and glucose metabolism in type 2 diabetes

C.K. Rayner[1,2], L.E. Watson[1], L.K. Phillips[1,2], M.J. Bound[1], J. Grivell[1], T. Wu[1,2], K.L. Jones[1], M. Horowitz[1,2], E. Ferrannini[3], D. Trico[3], S. Frascerra[3], A. Mari[4], A. Natali[3];
[1]University of Adelaide, Adelaide, Australia, [2]Royal Adelaide Hospital, Adelaide, Australia, [3]University of Pisa, Pisa, Italy, [4]Institute of Neuroscience, Padua, Italy.

Background and aims: Slowing of gastric emptying is a key mechanism by which 'short-acting' glucagon-like peptide-1 receptor agonists (GLP-1RAs) lower postprandial glycaemia in type 2 diabetes (T2DM). We examined the effects of sustained use of a standard clinical dose of lixisenatide (20mcg daily) on gastric emptying and postprandial glucose metabolism, measured using the 'gold standard' techniques of scintigraphy and double glucose tracers, in patients with T2DM.
Materials and methods: 18 metformin-treated T2DM patients (age 67 ± 1 years, HbA1c 7.1 ± 0.1%) consumed a 75 g glucose drink labelled with ^{99m}Tc-calcium phytate and [U-^{13}C]glucose during IV infusion of 6,6-[$^{2}H_2$]glucose. Gastric emptying (scintigraphy) and glucose fluxes were monitored for the next 240min. Patients were then randomised to receive 8 weeks daily lixisenatide (titrated up to 20mcg in the first 2 weeks) or placebo in a double blind parallel design, before the 75 g oral glucose study was repeated. Data are presented as mean values ± SEM.
Results: Gastric emptying did not differ between the groups at baseline, or after 8 weeks of placebo, but was markedly slower after 8 weeks of lixisenatide when compared to both baseline and placebo ($P < 0.0001$, figure). Compared to placebo, lixisenatide was associated with a much lower (i) incremental area under the postprandial glucose curve (349 ± 155 vs 1389 ± 82 mmol.L^{-1}.min), (ii) area under the [U-^{13}C] glucose curve (465 ± 165 vs 1516 ± 95), and (iii) rate of appearance of [U-^{13}C] glucose (all $P < 0.0005$). In patients receiving lixisenatide, the decrements in both blood glucose and plasma [U-^{13}C] glucose at 90 and 120 min, compared to baseline, were strongly related to the reduction in the proportion of oral glucose emptied from the stomach at each time point (r = 0.94 and 0.77 for blood glucose, $r = 0.86$ and 0.78 for plasma [U-^{13}C] glucose, all $P < 0.05$).
Conclusion: 8 weeks treatment with lixisenatide in T2DM is associated with sustained slowing of gastric emptying and marked reductions in postprandial glycaemia and appearance of ingested glucose. 'Short-acting' GLP-1 RAs therefore represent an effective long-term therapy for specifically targeting postprandial glucose excursions.

The effect of lixisenatide on post-prandial blood glucose and glucagon in type 1 diabetes

C. Ballav[1], A. Dhere[1], O. Agbaje[2], I. Kennedy[2], R.R. Holman[2,3], K.R. Owen[1,3];
[1]Oxford Centre for Diabetes Endocrinology and Metabolism, Oxford, [2]Diabetes Trial Unit, Oxford, [3]Oxford Biomedical Research Centre, Oxford, UK.

Background and aims: The glucagon-like peptide-1 receptor agonist, Lixisenatide (Lix), suppresses glucagon and reduces hyperglycaemia in type 2 diabetes. We studied the effect of Lix on post-prandial blood glucose (PPBG) and glucagon in type 1 diabetes (T1D).
Materials and methods: In a double-blinded, placebo-controlled, cross-over study, 25 patients with T1D (13 females, mean ± SE HbA_{1C} 65.6 ± 8.1 mmol/mol, BMI 27.0 ± 3.6 Kg/m^2) received treatment in random order with Lix and placebo (Plac) in addition to their usual insulin therapy for four weeks, with a four week washout period in between. Participants had continuous glucose monitoring (CGM) for at least 3 days before and at the end of each treatment period, as well as post treatment standard mixed meal tests (MMT; Fortisip 360 Kcal) and hyperinsulinaemic hypoglycaemic clamps (target glucose 2.5 mmol/L). (See Figure). The primary outcome was defined as the proportion of CGM readings in the range 4 to 10 mmol/L during the 3-hour post-prandial period.
Results: The mean ± SE percentage of PPBG CGM readings in range was similar before and after treatment and for each meal for Lix compared with Plac (breakfast 45.4 ± 6.0 vs. 44.3 ± 6.0, $p = 0.9$, lunch 45.5 ± 5.8 *vs.* 50.6 ± 5.3, p = 0.6, and dinner 43.0 ± 6.7 *vs.* 47.7 ± 5.6, $p = 0.6$). Mean HbA1c did not change during treatment periods and was similar between Lix and Plac (64.7 ± 1.6 *vs.* 64.1 ± 1.6 mmol/mol, $p = 0.3$). The overall daily prandial insulin dose post-treatment was significantly less after Lix compared with Plac (−0.7 ± 0.6 *vs.* +2.4 ± 0.7 units/day, $p = 0.004$), but the total insulin dose was not different between treatments. The post MMT mean ± SE 120 minute glucose area under the curve (AUC) was lower with Lix compared with Plac (392.0 ± 167.7 *vs.* 628.1 ± 132.5 mmol/L × min, $p < 0.001$), as was the corresponding glucagon AUC (140.0 ± 110.0 *vs.* 304.2 ± 148.2 nmol/L × min, $p < 0.001$). Glucagon values at a blood glucose level of 2.4 mmol/L during the hypoglycaemic clamp, were similar for Lix compared with Plac (3.1 ± 3.7 *vs.* 2.6 ± 1.7 nmol/L, p = 0.7). Mean adrenaline, noradrenaline, cortisol and pancreatic polypeptide values did not differ during the clamp between Lix and Plac.
Conclusion: Lixisenatide suppresses glucagon and may reduce post prandial glycaemia without compromising counter-regulatory responses during hypoglycaemia in T1D.

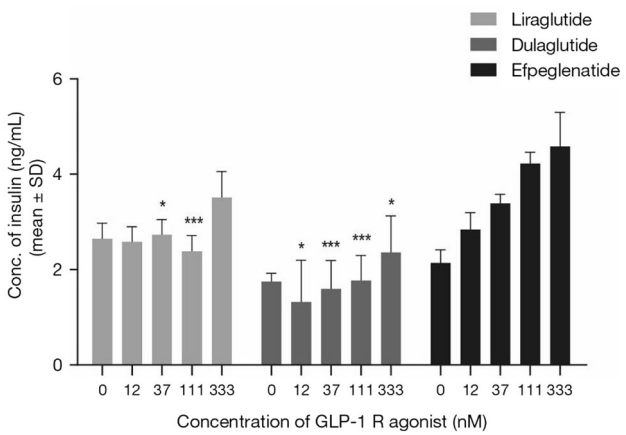
In vitro studies to evaluate the receptor kinetics of efpeglenatide versus other glucagon-like peptide-1 receptor (GLP-1 R) agonists

I. Choi[1], M. Moon[1], M. Trautmann[2], M. Hompesch[2], C. Sorli[3];
[1]Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea, [2]ProSciento, Inc., Chula Vista, USA, [3]Sanofi, Bridgewater, USA.

Background and aims: Efpeglenatide is a long-acting GLP-1 R agonist in development for the treatment of type 2 diabetes. Efpeglenatide's effects on the GLP-1 R suggest that it is a superagonist: a ligand that leads to greater maximal signalling and stimulation compared with the endogenous ligand.
Materials and methods: *In vitro* studies evaluated the superagonistic effects of efpeglenatide and compared them to the effects of liraglutide (lira) and dulaglutide (dula) on GLP-1 R-binding kinetics and internalization, and cell signalling/desensitization.
Results: Efpeglenatide had a higher dissociation constant vs lira or dula (360.7 vs 58.7 and 39.4 nmol/L, respectively) indicating a lower binding affinity for GLP-1 R (~6.1 fold vs lira, ~9.2 vs dula) and faster dissociation vs lira (~3.6 fold; $p < 0.001$) or dula (~2.9 fold; $p < 0.001$). At 100 nM, efpeglenatide led to less receptor internalization vs lira or dula (% of initial internalized receptor: 140% vs 1191% and 714%, respectively; $p < 0.001$ each) and lower proportions of receptor lost from the cell surface (32% vs 74% and 69%; $p < 0.001$). After pretreatment for 4 h, efpeglenatide led to significantly greater insulinotropic activity vs lira or dula (Figure). After pretreatment for 24 h, significantly greater accumulation of cyclic AMP was observed with efpeglenatide vs lira or dula.
Conclusion: The superagonistic effect of efpeglenatide on the GLP-1 R may be due to its specific binding characteristics, allowing more cell-surface receptor availability for intracellular signalling. The clinical relevance of these findings should be assessed further.

Figure. Reduced *in vitro* GLP-1 R desensitization with efpeglenatide vs other GLP-1 RAs



Cells were pretreated with 10 nM GLP-1 R agonist for 4 h and insulin release was measured after retreatment with 0–333 nM GLP-1 R agonist for 1 h

Effects of dulaglutide and trelagliptin on beta cell function in patients with type 2 diabetes: a randomised controlled study: DUET-beta study

Y. Kondo[1], S. Satoh[2], Y. Terauchi[1];
[1]Department of Endocrinology and Metabolism, Graduate School of Medicine, Yokohama City University, Yokohama, [2]Department of Endocrinology and Metabolism, Chigasaki Municipal Hospital, Chigasaki, Japan.

Background and aims: Some studies with glucagon-like peptide 1 receptor agonists (GLP-1-RA) and dipeptidyl peptidase-4 inhibitors (DPP-4-I) have suggested positive effects on the beta-cells. But the direct comparison between weekly GLP-1-RA: dulaglutide (Dula) and weekly DPP-4-I: trelagliptin (Trela) effects on beta-cell function has not yet been clarified. Therefore, we compared the effects of Dula and Trela on beta-cell function in patients with type 2 diabetes (T2D) in open-label, parallel-group, randomized controlled trial.
Materials and methods: In this trial, subjects received Dula 0.75 mg/week or Trela 100 mg/week for 24 weeks. Beta-cell function was assessed by glucagon stimulation test (GST) based disposition index (DI = area under the curve of C-peptide during 6 min GST ÷ HOMA2-IR). The primary endpoint was the difference between the two groups of change in DI over the 24-weeks treatment period. Body composition was also assessed by bioelectrical impedance method.
Results: Fifty metformin ± basal insulin-treated patients with T2D were randomized to Dula or Trela. Forty-eight patients completed 24 weeks of weekly administration of Dula ($n = 23$) or Trela ($n = 25$). The primary outcome of change in DI during 24 weeks was not different between both groups (Dula: +0.34 ± 0.49, Trela: +0.57 ± 0.47, $p = 0.74$). However, change in HOMA2-%β was higher in Dula group than Trela group (Dula: +50.6 ± 9.9% vs. Trela: +7.5 ± 9.5%, $p = 0.003$). HbA1c was decreased in greater extent with Dula group (Dula: −0.77 ± 0.07%, Trela: −0.57 ± 0.07%, $p = 0.04$). Severe hypoglycemia was not observed in both groups. Body weight was reduced more in Dula group than Trela group (Dula: −1.4 ± 0.3 kg vs. Trela: −0.3 ± 0.3 kg, $p = 0.02$). Body fat mass was reduced more in Dula group than Trela group (Dula: −1.2 ± 0.3 kg vs. Trela: −0.3 ± 0.2 kg, $p = 0.02$). However, change in skeletal muscle mass did not differ between the groups (Dula: −0.2 ± 0.1 kg vs. Trela: −0.1 ± 0.1 kg, $p = 0.66$). Dula did not reduce skeletal muscle mass from baseline (−0.2 ± 0.1 kg, $p = 0.31$).
Conclusion: The effects of Dula and Trela on beta-cell function were not different in GST-based DI. However, Dula increased HOMA2-%β level more than Trela. Dula reduced body fat mass without skeletal muscle mass loss.

Rescue therapy with linagliptin to improve glucose metabolism and pancretic beta cell function in patients with prediabetes with no response to metformin

S. Salazar-Lopez[1], M. Alvarez-Canales[1], D. Farfan[1], L. Jimenez-Ceja[1], M. Montes de Oca[1], F. Angulo-Romero[1], M. Reyes-Escogido[1], E. Durán-Pérez[2], A. Aguilar-García[1], R. Guardado-Mendoza[1,2];
[1]Metabolic Research Laboratory, University of Guanajuato, Leon, Guanajuato, [2]Hospital Regional de Alta Especialidad del Bajío, Leon, Guanajuato, Mexico.

Background and aims: Patients with prediabetes have a high risk to develop T2DM. Lifestyle modifications and metformin are therapeutic options in these patients with limited results. The goal of this work was to evaluate the effect of adding linagliptin to metformin on glucose metabolism and beta cell function in patients with prediabetes with no response to metformin alone during the previous 12 months
Materials and methods: Patients with impaired glucose tolerance (IGT) were previously on metformin therapy 1700 mg/day during 12 months plus a lifestyle program and those that showed no improvement on glucose metabolism were selected for the present study; they had a metabolic evaluation including oral glucose tolerance test (OGTT) with insulin measurements, body composition, lipid profile and HbA1c, and were randomized to: *i) linagliptin 2.5 mg/metformin 850 mg twice daily (**LM group**, n = 15)*, or *ii) continue with metformin alone 850 mg twice daily* (***M group***, $n = 10$), with monthly follow-up and a 6 month metabolic evaluation. Insulin sensitivity and pancreatic beta cell function were calculated from the OGTT. The protocol was approved by the Ethical Committee. Inter and intragroup differences were analyzed with a T test.
Results: All patients had IGT at the beginning of the study, and there were not basal differences in age (53 vs 50 y) and body weight (75 vs 75 kg) between the LM and M group. After 6 months of treatment, the LM group had better improvements in weight (−2.0 vs −0.26 kg, p 0.096), glucose during the OGTT at 0′(−12 vs 0.3 mg/dl, p 0.013), 30′(−36 vs −5 mg/dl, p 0.056), 60′(−57 vs −7 mg/dl, p 0.012), 90′(−43 vs −8 mg/dl, p 0.020) and 120′(−46 vs −5 mg/dl, p 0.011), and $AUCglucOGTT_{0\text{-}120}$ −4675 vs −711 mg/dl/120 min, p 0.015, HbA1c (−0.20 vs 0.26%, p 0.003), insulin sensitivity (Matsuda index +2.0 vs −1.4, p 0.008), and beta cell function (Disposition index +0.77 vs −0.12, p 0.001, and Oral disposition index +0.11 vs −0.01, p 0.036).
Conclusion: Adding linagliptin to metformin, together with a lifestyle program, improved better glucose metabolism, insulin sensitivity, insulin secretion and beta cell function in patients with IGT previously treated and not improved with metformin alone for 12 months. This could be a useful preventive strategy in patients with prediabetes with no response to metformin and a high risk of T2DM

PS 066 Multiple facets of continuous glucose monitoring

793

Real-time decoding of endogenous islet algorithms and their use in a type 1 diabetes simulator

M. Raoux[1], M. Jaffredo[1], L. Olçomendy[2], A. Pirog[2], B. Catargi[3], S. Renaud[2], J. Lang[1];
[1]CNRS UMR 5248, CBMN, Univ. Bordeaux, Bordeaux, [2]CNRS UMR 5218, IMS, Bordeaux INP, Univ. Bordeaux, Bordeaux, [3]Hôpital Saint-André, Bordeaux University Hospital, Bordeaux, France.

Background and aims: Pancreatic islets continuously sense and process multiple nutritional and neuro-hormonal inputs by "endogenous algorithms" to precisely adapt insulin secretion dynamics. New non-invasive and high-resolution sensors are needed to decipher these natural algorithms. Electrical signals are the first readout integrating multiple physiological inputs and they can be monitored extracellularly with multi-electrode arrays (MEAs). Whereas action potentials (APs) translate single-cell activity, the so-called slow potentials (SPs) reflect physiologically important coupling among islet β cells. Here we asked whether both signals can (i) be recorded simultaneously, (ii) be analyzed online and in real-time (iii) and can qualify as signals to drive an insulin pump during continuous monitoring.
Materials and methods: Intact mouse or human islets were cultured on MEAs in which the electrodes were covered with an electroactive polymer, PEDOT:CNT. Electrical signals were recorded with a high sampling rate (10,000 Hz) and analyzed i) offline with the commercial software MC_Rack (Multichannel Systems) and ii) online and in real-time on custom digital integrated circuits (Field-Programmable Gate Array, FPGA). To test their capacity driving an insulin pump, data were introduced via a Python program in the UVA/Padova T1DM Simulator, an FDA-approved model of T1D patients, in a three-meal 24 h scenario.
Results: Mouse islets were exposed to physiological glucose elevation (3–8.2 mM; 1h30). Electrodes covered with the polymer detected SPs and APs with a significant amelioration in comparison with classical non-polymer electrodes (42.5 ± 3.7 vs $69.8 \pm 6.3\%$ of electrodes with detectable SPs and APs; $p < 0.05$; $N = 7$ independent preparations). In this setting, our integrated circuit was able for the first time to automatically and simultaneously analyze in real-time (<40 μs) three relevant electrical parameters: SPs' frequency and amplitude as well as APs' frequency. The FPGA-based hardware linked to MEAs clearly detected a biphasic electric profile of islet activation with the same efficiency as offline analysis by commercial software ($n = 70$ electrodes; $N = 3$). Long-term monitoring with the set-up showed signal stability for at least up to 25 days. The system also detected and analyzed simultaneously SPs and APs generated by human islets ($N = 6$ pancreata). Biosensor data were modeled and introduced in the whole human body UVA/Padova T1DM Simulator. The introduction of the biphasic electrical component resulted in glycemic profiles in these in-silico T1D patients similar to those observed in healthy subjects and without the use of further algorithms. Furthermore, this approach was exempt of hypoglycemic incident and maximal post-prandial glucose levels were similar to healthy subjects.
Conclusion: Electrical activity of islets as recorded by MEAs parallels known secretion patterns. The in-silico validation shows that the device qualifies as efficient CGM system for the control of insulin delivery in closed-loop configurations. The bio-electronic sensor developed here will also serve to further decode islet's "endogenous algorithms" in response to physiological combinations of nutrients and hormones.

794

New insight into evaluation of continuous glucose monitoring index using continuous wavelet transformation

Y. Nakamura[1], S. Furukawa[2];
[1]Specified Clinic of Soyokaze CardioVascular Medicine and Diabetes Care, Matsuyama, [2]Department of Epidemiology and Preventive Medicine, Ehime University Graduate School of Medicine, Toon, Japan.

Background and aims: Continuous glucose monitoring (CGM) has recently become available to select a therapeutic strategy for poorly controlled diabetes. However, CGM is not yet a gold standard marker since many glucose data are manipulated and daily glucose value changes occur due to feeding behavior etc. Continuous wavelet transformation (CWT) which extracts valid information from time and frequency domains, is used in the cardiology field. We hypothesized that CWT could contribute to sourcing glucose changes based on patient background, as such change would be converted to a waveform.
Materials and methods: 126 sets of daily glucose data were evaluated in 7 type 2 diabetic patients (T2DM) (59 ± 5 years) and 3 type 1 patients (T1DM) (54 ± 13 years). Data were obtained from subcutaneous tissue every 15 min over 2 weeks. If data were lost due to sensor error, that day's data were excluded. Complete data were assessed via CWT with Morlet wavelets ($n = 7$) as the mother waveform. The CGM sensor was also attached to 10 healthy volunteers (60 ± 14 years). Daily glucose data showing levels of 69–146 mg/dl were used as controls.
Results: CGM data were obtained from 116 diabetics, 23 controls. Hemoglobin A1c was 9.8 ± 0.9% in T2DM, 8.9 ± 0.4% in T1DM and 5.4 ± 0.1% in control. Average glucose levels were 212 ± 76 mg/dl, 156 ± 71 mg/dl, 101 ± 14 mg/dl, respectively ($p < 0.0001$). Maximum glucose levels in T2DM were higher than for T1DM (333 ± 77 mg/dl vs 274 ± 72 mg/dl, $p < 0.0001$). In contrast, minimum data showed no significant difference (72 ± 34 mg/dl vs 117 ± 34 mg/dl, NS). Variations in daily glucose changes in T1DM and T2DM were also similar. CWT was visualized as a contour map with x-axis; time, y-axis; frequency and z-axis; scalogram (Fig). A high frequency (75 ± 6 Hz) wave (HW)(P1) at midnight disappeared in T1DM and T2DM, though it was present in all controls (22%, 9%, 0%, respectively, $p = 0.0251$). Evening HW (P3) in T1DM and T2DM was also significantly decreased compared to control (24%, 8%, 0%, respectively, $p = 0.00649$). Power values of the scalogram obtained from CWT were lower than in control (P1;0.047 ± 0.012, 0.049 ± 0.008, 0.057 ± 0.005, respectively, $p = 0.0001$, P2; 0.053 ± 0.009, 0.054 ± 0.008, 0.064 ± 0.004, respectively, $p < 0.0001$, P3; 0.049 ± 0.008, 0.048 ± 0.009, 0.058 ± 0.004, respectively, $p < 0.0001$). Low frequency small waves (LW) (30 ± 2 Hz) such as P9–P12 emerged in T2DM from midnight to noon (14% in P19, $p = 0.00859$, 19% in P10, $p = 0.003$, 20% in P11, $p = 0.0118$, 19% in P12, $p = 0.0353$). LW appeared in the afternoon area and night time showed no significant differences among groups. Also, super-high frequency (98 ± 8 Hz) waves were amplified in 8 maps (22%) in T1DM, 6 maps (8%) in T2DM but not in control ($p = 0.0167$).
Conclusion: CWT differentiated specificity of each group at a point distinct from that of previous markers. This method may contribute to selection of therapeutic strategies such as choice and combination of drugs or evaluation of pathogenesis.

Avoidance of glucose excursions with predictive alerts in the Guardian™ Connect CGM system: real-world paediatric data

O. Cohen[1], S. Abraham[2], C. McMahon[2], P. Agrawal[2];
[1]Medtronic, Tolochenaz, Switzerland, [2]Medtronic, Northridge, USA.

Background and aims: The Guardian™ Connect continuous glucose monitoring (CGM) system allows users to view sensor glucose (SG) data directly on a smartphone. The Guardian™ Connect system has built-in glucose threshold alerts to notify users about low and high glucose excursions. The system also includes predictive glucose threshold alerts that notify users 10–60 minutes before a low or high glucose excursion. The real-world rates of alerts and outcomes of Guardian™ Connect system users, from January 2, 2017-March 13, 2018, were evaluated. These results were compared to a control dataset where alerts were disabled.
Materials and methods: De-identified CareLink™ sensor data from 1,183 children ≤15 years old with >5 days of sensor data were analyzed. Excursions were defined as ≥3 consecutive SG values beyond the preset low threshold range (2.2–21.6 mmol/L [40–390 mg/dL]) and high threshold range (2.8–22.2 mmol/L [50–400 mg/dL]). The low and high SG thresholds for control were marked during the periods when no alerts were enabled and when the SG level crossed 4.0 mmol/L (73 mg/dL) and 12.9 mmol/L (233 mg/dL), respectively. Both levels were based on the median low and high SG threshold settings of the users. The low and high predictive alerts for control were marked when the SG level would have crossed the low SG threshold and high SG threshold (17.5 minutes and 12.5 minutes before the user-established median settings, respectively). For analyses, the window of evaluation for excursion start times was within 60 minutes following an alert and the excursion duration following an alert was segmented into: avoided, ≤20 min, 20–60 min, and >60 min.
Results: The table shows the percentage of each alert resulting in an excursion, which are stratified per excursion duration. Users who received predictive alerts avoided 59% of low events and 37% of high events. The percentage point improvement for excursions avoided was 31% and 28% following predicted low and predicted high alerts, respectively, compared to control. The percentage point reduction for excursions >60 min was 14% and 25% following predicted low and predicted high alerts, respectively, compared to control.
Conclusion: Guardian™ Connect CGM system users who enabled predictive alerts avoided more than 59% and 37% of predicted low and high events, respectively. Predictive alerts are a useful technology for users with diabetes to keep SG levels within target range.

		Cohort	Low SG Excursion		High SG Excursion	
			Predictive Alerts Enabled	Alerts Not Enabled	Predictive Alerts Enabled	Alerts Not Enabled
Time to Excursion Resolution		Total Alert Count	301246	9693	134453	115170
	Avoided	Excursion Count	176469	2683	49384	10932
		% of Total Alerts	59%	28%	37%	9%
	≤20 min	Excursion Count	54967	2534	14694	13302
		% of Total Alerts	18%	26%	11%	12%
	20-60 min	Excursion Count	52493	2504	23340	21729

Accuracy assessment of the WaveForm Cascade CGM system versus FreeStyle Libre over 14 days

M. Rebec[1], E. Anderson[1], R. Dutt-Ballerstadt[1], A. Haidar[2], A. Singh[2], A. Janez[3];
[1]WaveForm Technologies, Inc, Wilsonville, USA, [2]BioMedical Engieneering Department, Mc Gill University, Montreal, Canada, [3]Department of Endocrinology, Diabetes and Metabolic Diseases, University of Ljubljana, Ljubljana, Slovenia.

Background and aims: WaveForm is finalizing the development of the Cascade CGM system. The Cascade CGM device features trocar-free insertion and will be launched with 14 day transdermal sensor that is based on a variant of an amperometric GOx-based technology. Completing the algorithm and validating the clinical performance of the device is the final development stage. We are reporting the preliminary analysis of 14-day clinical study that was used to evaluate the accuracy of the Abbott FreeStyle Libre and the Cascade CGM.
Materials and methods: The clinical study that was used to evaluate the two CGM systems included 10 subjects with type 1 and 2 diabetes. There were five in-clinic days (1, 4, 7, 10 and 14) that were used to assess the performance of the CGM's accuracies. Each subject wore two Cascade CGM devices in the abdominal area and one Abbott FreeStyle Libre sensor on the back of the upper arm over 14 days. YSI glucose measurements were performed on plasma from venous blood sampled every 15 minutes during the 12 hour in-clinic days. The overall MARD and MAD calculation for the Cascade CGM and Abbott devices based on a comparison to paired YSI values at the same time points. The Cascade CGM values were obtained by prospectively applying an advanced algorithm to data generated during the study.
Results: Head-to-head MARD comparison between the WaveForm and Abbott FreeStyle Libre sensor over 14 days showed that MARD for the Cascade CGM was11.6 vs 14.0% for the FreeStyle Libre. Consensus error grid analysis for Cascade device showed that 99.7% of data points were in zone A and B, with the remaining 0.3% in zone C.
Conclusion: Overall performance of the Cascade CGM device over 14 days meets the clinical expectations for a potentially non-adjunctive commercial CGM. Direct comparison with the FreeStyle Libre shows that the WaveForm device met and in a number of parameters surpassed the performance of the FreeStyle Libre. The Cascade CGM will be launched as 14-day wear CGM system.

Flash Glucose Monitoring is associated with improved glycaemic control and quality of life in people with type 1 diabetes: a large 'real-world' assessment

F.W. Gibb, R.H. Stimson, N.N. Zammitt, A.R. Dover;
Edinburgh Centre for Endocrinology & Diabetes, Edinburgh, UK.

Background and aims: Flash Glucose Monitoring (FM) has been associated with reduced hypoglycaemia and, in uncontrolled studies, with improvements in HbA1c in type 1 diabetes. NHS (National Health Service) funded FM was recently introduced in our centre. We sought to assess the 'real world' impact of FM in a University hospital diabetes clinic upon HbA1c and patient reported outcomes.
Materials and methods: 2211 people with T1 diabetes were invited to attend an education event leading to NHS-funded FM prescription in February 2018. 646 (29.2%) attended and commenced NHS funded FM. 240 (37.2%) reported previous self-funded use of FM. SCI-Diabetes (national diabetes register) was interrogated to obtain pre- and post-FM HbA1c in previous 'self-funders'. Deprivation was assessed by Scottish Index of Multiple Deprivation 2016 (SIMD). Attendees were invited to complete a questionnaire (36.4% response rate) assessing the impact of FM, including on parameters from the diabetes distress scale (DDS).
Results: Self-funded FM was associated with a median 3 mmol/mol fall in HbA1c, $p < 0.001$ ($n = 204$, median 10 month follow-up [IQR 5–11]). The reduction was greater in those with >75% FM use (−4.5 vs. −2 mmol/mol, $p = 0.01$) and in those above 58 mmol/mol prior to FM use (−4 vs. 0 mmol/mol, $p < 0.001$). Overall, the proportion of people achieving target HbA1c (<58 mmol/mol) rose from 28.9% to 42.6% (figure). 35.3% of our total clinic population in the least deprived quintile commenced NHS-funded FM compared to only 17.5% of those in the most deprived quintile ($p < 0.001$). 37.8% of those with an HbA1c <58 mmol/mol commenced NHS-funded FM compared to only 26.4% of those above target ($p < 0.001$). NHS funded FM use was also greater in women ($p < 0.001$) and younger individuals ($p < 0.001$). User satisfaction was high: the median response (out of 10) was 10 for the question 'How useful has the Libre been in helping control your diabetes?' Emotional burden elements of the DDS were 'unchanged' in 37.4%, 'less of a problem' in 41.9% 'much less of a problem' in 14.6%. Regimen related distress elements were 'unchanged' in 25.2%, 'less of a problem' in 39.5% and 'much less of a problem' in 29.8%.
Conclusion: Self-funded FM was associated with clinically meaningful improvements in HbA1c, particularly in those with higher baseline HbA1c and those using the system regularly. Self-funded and NHS-funded FM is still disproportionately used in more affluent individuals and those with lower HbA1c at baseline. Greater efforts are required to ensure equity of access to diabetes technologies. Patient reported outcomes are overwhelmingly positive - the impact of FM on quality of life should not be underestimated.

Occurrence of severe hypoglycaemic events in the future: analysis of CGM data of the HypoDE study

N. Hermanns[1], D. Ehrmann[1], G. Freckmann[2], D. Waldenmaier[2], S. Pleus[2], G. Faber-Heinemann[3], L. Heinemann[3];
[1]Research Institute of the Diabetes Academy Bad Mergentheim (FIDAM), Bad Mergentheim, [2]IDT-Institut für Diabetes-Technologie, Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Ulm, [3]Science-Consulting in Diabetes GmbH, Düsseldorf, Germany.

Background and aims: Besides many other outcome parameters, rtCGM systems allow an estimation of low glucose events (LGE). In addition to the international consensus statement on CGM data, more empirical evidence is needed to evaluate which rtCGM parameter is the best predictor of the occurrence of severe hypoglycaemic events in the future (SH; defined as events that need third party assistance for recovery). Therefore, we analysed data of the control group of the HypoDE study, a randomised controlled trial that has shown that rtCGM had a beneficial impact on the occurrence of LGE (<55 mg/dl) in patients with type 1 diabetes on multiple daily injections (MDI) and hypoglycaemia problems. We analysed the ability of different rtCGM outcome parameters at baseline to predict the occurrence of SH during therapy- and follow-up-phase (T/F-phase) of the HypoDE-study.
Materials and methods: Participants in the control group wore a masked rtCGM system for 4 weeks in the baseline phase. In the consecutive 26 weeks of the T/F-phase, they continued with blood glucose measurements. The rtCGM data of 66 participants of the control group (age 47 ± 10 years, diabetes duration 21 ± 13 years, HbA1c 7.4 ± 1.0%, 61% with SH during the previous year) were analysed. The area under the Receiver Operating Characteristics (ROC) curves of different rtCGM parameters were used to compare the predictive performance of these parameters.
Results: During the T/F-phase, 39 episodes of SH were observed. At least one episode of SH occurred in 14 of the 66 participants (21.2%). The area under the ROC curve for the percentage of glucose values ≤70 mg/dl was 0.69 (95% CI 0.54–0.85, $p = 0.027$), for ≤55 mg/dl 0.68 (95% CI 0.52–0.85, $p = 0.034$), for ≤45 mg/dl 0.66 (95% CI 0.49–0.84, $p = 0.060$), for time-in-range 0.59 (95% CI 0.44–0.75, $p = 0.293$), for coefficient of variation 0.67 (95% CI 0.49–0.84, $p = 0.056$), for standard deviation 0.51 (95% CI 0.36–0.67, $p = 0.863$), for mean sensor glucose 0.70 (95% CI 0.55–0.86, $p = 0.022$), and for low blood glucose index 0.70 (95% CI 0.55–0.86, $p = 0.022$).
Conclusion: The overall predictive power of rtCGM data for future SH was low. However, the best and significant predictors were percentage ≤70 mg/dl or ≤55 mg/dl, the low glucose index and mean glucose. Lower cut-off values for LGE like ≤45 mg/dl showed a slight deterioration of the predictive performance. Coefficient of variation showed a borderline significance for the prediction of future SH. A systematic analysis of rtCGM while in use and an increase in the number of LGE might be used as a warning signal for people with diabetes to prevent occurrence of SH.

The relationship between HbA_{1c} and hypoglycaemia in the Diamond trial

N. Oliver[1], M. Reddy[1], M. Gimenez[2], V. Moscardo[3];
[1]Endocrinology and Metabolism, Imperial College, London, UK, [2]Endocrinology Department, Hospital Clinic, Barcelona, Spain, [3]Universitat Politecnica de Valencia, Valencia, Spain.

Background and aims: Intensification of insulin therapy and self-monitoring of blood glucose (SMBG) with the aim of reducing glycated hemoglobin (A1C) is classically associated with increased rates of hypoglycemia for patients with type 1 diabetes (T1D). Real-time awareness of sensor glucose (SG) values from continuous glucose monitoring (CGM) systems helps patients with diabetes reduce A1C and avoid hypoglycemia. However, the relationship between A1C and hypoglycemia during CGM use has not been assessed. We retrospectively analyzed data from a large trial, which introduced CGM to subjects with T1D using multiple daily injections (MDI), to determine the relationship between A1C and percent time in hypoglycemia (≤70 mg/dL).
Materials and methods: The DIAMOND clinical trial compared usual care (SMBG) to CGM in subjects with diabetes who were using MDI and who had A1C levels between 7.5% to 10.0%. Data from subjects with T1D completing Phase 1 ($n = 105$ and 53 in the CGM and control groups, respectively) were used for the current analysis. The percentages of sensor glucose (SG) values ≤70 mg/dL (≤3.9 mmol/L) ("%≤70") during the initial and final weeks of the 24-week study were calculated for each subject and compared to corresponding baseline and 24-week A1C values. Logistic regression was performed to determine any potential confounding factor that may have affected differences between the treatment groups. Multivariate regression analysis was performed to adjust for the confounders and assess the treatment effect on %≤70.
Results: Those subjects who had lower baseline A1C spent as much as 8% of the time in hypoglycemia (≤70 mg/dL) (Panels A and B), supporting earlier observations that low A1C is associated with high risk of hypoglycemia. Subjects who were randomized to usual care (SMBG) and those randomized to CGM demonstrated improved A1C after 24 weeks (Panels A and B). At both baseline and week 24, subjects with the lowest A1C values had the highest rates of hypoglycemia (Panels A and B). However, regardless of A1C, subjects randomized to CGM demonstrated lower %≤70 than those randomized to SMBG (Panel B). Moreover, the association between decreasing A1C and increasing exposure to SG values ≤70 mg/dL was attenuated for subjects in the CGM group after 24 weeks of treatment (Panel B). By week 24, some subjects randomized to CGM were able to reach A1C values ~6% while simultaneously reducing their exposure to hypoglycemia (Panel B).
Conclusion: Historically, attempts to achieve near-normal glucose concentrations during aggressive diabetes treatment have come at the expense of increased risk for hypoglycemia. Data shown here demonstrate that CGM allows safe intensification of MDI therapy and achievement of optimal A1C levels while attenuating hypoglycemia. These data also suggest that it is possible that features unique to CGM, such as programmable alerts and alarms, allow patients to take appropriate and timely measures to avoid hypoglycemia.

A new formula to compute eA1c from 3-months average interstitial glucose measured by FreeStyle Libre in patients with type 1 diabetes

P. Oriot[1], M.P. Hermans[2];
[1]Mouscron Hospital Center, Mouscron, [2]Cliniques universitaires St-Luc, Brussels, Belgium.

Background and aims: The FreeStyle Libre sensor automatically captures interstitial glucose levels several times an hour and, provided that the rate of scanned results is sufficient (≥70% of the studied period), it is possible to predict a corresponding value of HbA1c over a similar period of glycaemic exposure (3 months) based on the following equation: eA1c (%) = (mean glucose (mg/dL) + 46.7)/28.7. The actual performance of mean interstitial glucose compared to the measured HbA1c in discriminating patients according to their glycaemic levels is not known. Due to methodological limitations it has become increasingly needed to have a new and validated equation that is not skewed in predicting HbA1c obtained from FreeStyle Libre sensor's recordings.
Materials and methods: The Discriminant Ratio (DR) method was used to compare 3-months average interstitial glucose ($_{3\text{-months}}$AIG; FreeStyle Libre) vs. HbA1c measured in the laboratory during the same period to rank diabetic patients according to their glycaemic exposure. The DR is the ratio of the underlying between-subject standard deviation (SD) to the within-subject SD, and takes into account the variation between subjects, the within-subject biological variation, and the analytical variation. The DRs were calculated over two consecutive 3-months periods in 153 T1DM patients with a sensor scanning frequency ≥70%. The correlation coefficients between the 2 periods were adjusted in order to include an estimate of the underlying correlation, since standard coefficients, due to the presence of within-subject variation, underestimate the true correlation between tests (attenuation). Finally, an unbiased estimation of the linear relationship between $_{3\text{-months}}$AIG and measured HbA1c was established.
Results: Duplicates values of $_{3\text{-months}}$AIG and HbA1c for the 2 consecutive periods of 90 days were 1.84 (0.34) g/L and 1.82 (0.33) g/L for $_{3\text{-months}}$AIG, *vs* 7.76 (0.86)% and 7.84 (0.88)% for HbA1c, respectively. The DR of $_{3\text{-months}}$AIG was 2.34 (2.5%–97.5% CIs: 2.06–2.68), and that of HbA1c was 1.83 (2.5%–97.5% CIs: 1.59–2.12). The difference between DRs was significant (p 0.0137), showing superior intrinsic discriminatory power of $_{3\text{-months}}$AIG. Both interstitial glucose and HbA1c were strictly correlated, with an unadjusted Pearson coefficient between methods of 0.80, rising up to 1.00 following adjustment for the attenuation. The DR method allowed for deriving a novel equation estimate of HbA1c (eA1c) from $_{3\text{-months}}$AIG from the slope and intercept of the unbiased linear relationship between the two measures: **eA1c** *(%)* **= 2.431** x $_{\textbf{3 months}}$ **AIG** *(g/L)* **+ 3.348** or **eA1c** *(%)* **= 0.438** x $_{\textbf{3 months}}$ **AIG** *(mmol/L)* **+ 3.348**
Conclusion: Average interstitial glucose over 3 months ($_{3\text{-months}}$AIG) provides significantly higher discrimination than measured HbA1c over the same period to rank patients with T1DM according to their glycaemic levels. The DR method provides a novel, unbiased equation to calculate HbA1c from $_{3\text{-months}}$AIG values.

Associations between HbA_{1C} and continuous glucose monitoring-derived glycaemic parameters

T.C. Walker, P. Calhoun, T.K. Johnson, J.B. Welsh, D.A. Price;
Dexcom, Inc., San Diego, USA.

Background and aims: Although A_{1C} is strongly associated with the risk of vascular complications in diabetes, a wide range of mean glucose concentrations and glucose profiles can be associated with any given A_{1C} level. Continuous glucose monitoring (CGM) systems can accurately detect and characterize a wider range of glucose characteristics and behaviors; however, consensus goals for many CGM-derived parameters are lacking. We sought to associate several narrow A_{1C} ranges with CGM-derived parameters.
Materials and methods: CGM and A_{1C} data from 4 clinical trials were analyzed: DIAMOND Phase 1 (N = 104), DIAMOND Phase 2 (N = 69 completers of DIAMOND Phase 1), REPLACE-BG (N = 216), and HypoDE (N = 141). Each study lasted ≥24 weeks, used current-generation CGM systems (Dexcom, Inc.), and included comparisons of central-lab end-of-study A_{1C} to CGM data during the preceding 3 months. Data from 530 adults with diabetes (455 with T1D and 75 with T2D; 279 using multiple daily injections and 251 using insulin pumps). Time in range (TIR) was defined as the percentage of sensor glucose (SG) values in the 3.9–10.0 mmol/L (70–180 mg/dL) range, inclusive, and expressed as either a percentage or as minutes/day (assuming 1 SG value = 5 min).
Results: The Figure shows population median and interdecile ranges for mean SG, TIR, time <3.9, <3.0, and >13.9 mmol/L for six A_{1C} bins. Higher A_{1C} bins were associated with higher mean SG and lower TIR values; lower A_{1C} bins were associated with lower mean SG and higher TIR values. For subjects with A_{1C} values <7.0%, median TIR was 72%, with 90% of subjects having TIR >57%. For subjects with A_{1C} ≥8.0%, median TIR was 44%, with 90% of the subjects having TIR <59%. Of the subjects with TIR >60%, 2.7% had an A_{1C} of >8.0% and 55.8% had an A_{1C} of <7.0%. Of the subjects with TIR >70%, 0.7% had an A_{1C} of >8.0% and 75.4% had an A_{1C} of <7.0%. Median time with SG <3.0 mmol/L was <20 min/day for all A_{1C} bins, but median time with SG >13.9 mmol/L increased from 36 min/day for those in the lowest A_{1C} bin to 400 min/day for those in the highest A_{1C} bin.
Conclusion: In CGM users, low A_{1C} values can be achieved with minimal additional exposure to hypoglycaemia. The observed associations between CGM-derived glycaemic parameters and specific A_{1C} ranges may help clinicians and patients establish appropriate TIR goals and guide therapy intensification efforts.

PS 067 Artificial insulin delivery and insulin pump therapy

802

The artificial pancreas ski camp: real-time monitoring and glucose control in youth with type 1 diabetes

D.R. Chernavvsky, M. DeBoer, M. Breton, J. Pinnata, B. Kovatchev; Center for Diabetes Technology, University of Virginia, Charlottesville, USA.

Background and aims: In Type 1 Diabetes (T1D) prolonged moderate/intense physical activity (PA) may result in hypoglycemia and is generally hard to manage. Winter-sport activities add external factors, e.g. cold and altitude, which make them most challenging to patients, health-care providers, and diabetes technologies such as insulin pumps, continuous glucose monitoring (CGM), and the emerging Artificial Pancreas (AP) systems. While AP has been shown to improve glycemic control during and after exercise, AP systems have been tested during structured winter-sport studies only once - in our recently reported 2016 skiing camp trial. Building on this previous experience, we now present the testing of a new system - the Tandem X2 with Control IQ Technology - in a series of ski studies in the winter of 2018. The premise of these studies is that the challenges of skiing provide great environment to test the AP in extreme real-life conditions.

Materials and methods: A sequence of three winter camp trials at ski resorts in Virginia, Colorado and California enrolled $N = 48$ children, ages 6–18, $N = 24$, $N = 12$, and $N = 12$ at each of these sites, respectively. All participants are randomized to the Tandem X2 Insulin Pump with Control IQ Technology (AP group) vs. sensor augmented pump (SAP control group). This new system consists of a G6 CGM (Dexcom, Inc.) and an X2 pump with embedded Control IQ algorithm (Tandem Inc. and Typezero, Inc.), which is identical to the AP algorithm originally developed at the University of Virginia (UVA) and tested in a number of UVA studies. The AP and SAP groups were matched by age and HbA1c. The studies continued for 2 days and on each day the participants had 3 hours of morning and 3 hours of afternoon skiing with instructors. For added safety, all subjects (AP and SAP) were monitored by a physician 24/7 using Dexcom Share G5 CGM. At the time of this writing, the results from the first ski camp in Virginia are ready and presented here; the study in Colorado is completed, and the study in California is scheduled for April 8–10.

Results: The participants in the first camp were teenagers ages 13–18 (14 males). Compared to SAP, glycemic control was significantly better in the AP group, including: percent time between 3.9–10mmol/L of 55.4% (SAP) vs 73.1% (AP), $p = 0.032$; percent above 10 mmol/L and above 13.9 mmol/L of 41%(SAP) vs 21.6% (AP), $p = 0.026$ and 14.8% (SAP) vs 5.6% (AP), $p = 0.02$; mean blood glucose of 9.4 mmol/L (SAP) vs 7.8 mmol/L (AP), $p = 0.03$, and no increase in hypoglycemic events on AP. Hyperglycemia post meals was reduced on AP, thus reducing glucose variability (Figure 1).

Conclusion: During its first winter/ski camp, the new X2 Insulin Pump with embedded Control IQ AP algorithm improved significantly the glycemic control in children with T1D, without adverse events, and with overwhelmingly positive patient feedback.

Figure 1: interquartile plots: Sensor-augmented pump (blue); Tandem X2 with Control IQ (purple)

Real-world use of the MiniMed™ 670G system by patients with type 1 or type 2 diabetes

S.W. Lee, J. Shin, X. Chen, M.-H. Nguyen, T.L. Cordero, F.R. Kaufman; Medtronic, Northridge, USA.

Background and aims: The MiniMed™ 670G system with the SmartGuard™ Auto Mode feature automatically adjusts basal insulin delivery through its hybrid closed-loop algorithm. A retrospective analysis of glycemia in patients self-reported to have type 1 diabetes (T1D) or type 2 diabetes (T2D) during real-world use of the MiniMed™ 670G system (available in the US) was performed.

Materials and methods: Patients with insulin-dependent diabetes using the MiniMed™ 670G system and with ≥3 months of CareLink™ software data (insulin utilization, continuous glucose monitoring [CGM], etc.) were selected. Glycemic control during baseline Manual Mode was compared to that after Auto Mode was enabled and evaluated by diabetes type. All data were de-identified and analyzed in aggregate. Change from baseline data were analyzed using a paired t-test or Wilcoxon signed-rank test. Analyzed endpoints included the mean percentage of time in target glucose range (TIR, 70–180 mg/dL [3.9–10 mmol/L]), hypoglycemic ranges (<50, <54, and <70 mg/dL [<2.8, <3.0, and <3.9 mmol/L]), and hyperglycemic ranges (>180, >250 and >350 mg/dL [>10, >13.9, >19.4 mmol/L]).

Results: For T1D patients ($N = 1833$), the baseline mean ± SD (median, min-max) of age was 45.8 ± 16.5 (49.0, 5.0–84.0) years and that of total daily dose of insulin (TDD) was 45.3 ± 26.1 (38.4, 6–231.3) units. For T2D patients ($N = 58$), the baseline mean ± SD (median, min-max) of age was 54.6 ± 9.0 (55.5, 31.0–72.0) years and that of TDD was 68.7 ± 43.0 (57.6, 28.3–224.7) units. The table shows the mean percentage of glucose values in the different SG ranges for both groups of patients using the MiniMed™ 670G system. A significant increase in TIR and a significant reduction in time >180 mg/dL (10mmol/L) were observed compared to baseline ($p < 0.001$, for both).

Conclusion: An analysis of real-world CGM data demonstrated that use of the MiniMed™ 670G system by patients with T1D and T2D was associated with a significant increase in TIR and a significant reduction in SG values in hyperglycemic ranges. Improved overall glycemia observed with the MiniMed™ 670G system was not associated with increased hypoglycemia. These findings suggest that automated basal insulin delivery with the MiniMed™ 670G system can help manage real-world patients with either T1D or T2D.

Comparing patch vs pen bolus insulin delivery in type 2 diabetes using continuous glucose monitoring metrics and profiles

M.L. Johnson[1], D.M. Dreon[2], B.L. Levy[2], S. Richter[1], D. Mullen[1], R.M. Bergenstal[1];
[1]International Diabetes Center, Park Nicollet, Minneapolis, [2]Calibra Medical, Wayne, USA.

Background and aims: Adults with type 2 diabetes ($n = 97$, HbA_{1c} ≥7.5% [58 mmol/mol] on basal insulin) performed continuous glucose monitoring in a sub-study of a large randomized, controlled trial ($n = 278$) to evaluate initiating mealtime insulin (aspart) with a wearable bolus insulin delivery patch (Patch) vs an insulin pen (Pen) using a self-monitoring blood glucose-based titration algorithm. The patch was applied at least once every 3 days and delivered subcutaneous bolus insulin in 2-U increments per manual click.

Materials and methods: Blinded continuous glucose monitoring was conducted by a sub-set of subjects (50 in each of the treatment arms) for one week during the baseline period and for one week prior to Week 24. Subjects recorded 3 days of 7-point self-monitoring blood glucose and insulin doses during the week that continuous glucose monitoring was conducted.

Results: There was a significant improvement ($p < 0.0001$) in HbA_{1c} and all continuous glucose monitoring metrics at Week 24, but no difference between groups. HbA_{1c}, % ± SD, in patch vs pen arms at baseline was 8.6 ± 0.9 (70 ± 9.8 mmol/mol) vs 8.8 ± 1.0 (73 ± 10.9 mmol/mol) and at Week 24 was 6.8 ± 1.0 (51 ± 10.9 mmol/mol) vs 6.7 ± 0.8 (50 ± 8.7 mmol/mol). Continuous glucose monitoring, mg/dl ± SD, average glucose in patch vs pen at baseline was 188.9 ± 40.9 (10.5 ± 2.3 mmol/l) vs 200.3 ± 41.4 (11.1 ± 2.3 mmol/l) and at Week 24 was 142.4 ± 31.4 (7.9 ± 1.7 mmol/l) vs 140.4 ± 28.3 (7.8 ± 1.6 mmol/l). Continuous glucose monitoring time in range 70–180 mg/dl (4.0–10.0 mmol/l) (% time ± SD) in patch vs pen at baseline was 48.4 ± 25.2 vs 42.4 ± 23.8 and at Week 24 was 74.1 ± 18.7 vs 75.2 ± 16.1. Continuous glucose monitoring >180 mg/dl (>10.0 mmol/l) (% time ± SD) in patch vs pen at baseline was 50.4 ± 26.1 vs 56.7 ± 24.8 and at Week 24 was 21.1 ± 19.9 vs 19.7 ± 17.5. Continuous glucose monitoring >250 mg/dl (13.9 mmol/l) (% time ± SD) in patch vs pen at baseline was 18.3 ± 18.3 vs 23.4 ± 21.8 and at Week 24 was 5.6 ± 9.7 vs 4.6 ± 8.3. Low glucose as measured by continuous glucose monitoring <70 mg/dl (≤3.9 mmol/l) (% time ± SD) in patch vs pen at baseline was 1.2 ± 2.4 vs 0.9 ± 3.2 and at Week 24 was 4.7 ± 5.2 vs 5.1 ± 5.8. Very low glucose as measured by continuous glucose monitoring <54 mg/dl (<3.0 mmol/l) (% time ± SD) in patch vs pen at baseline was 0.2 ± 0.7 vs 0.2 ± 1.1 and at Week 24 was 1.1 ± 2.0 vs 1.2 ± 2.0. Continuous glucose monitoring profiles (Figure) demonstrate it is possible to optimize basal-bolus therapy, dramatically increasing time-in-target range 70–180 mg/dl (4.0–10.0 mmol/l) with minimal significant hypoglycemia <54 mg/dl (<3.0 mmol/l) while achieving a flat bedtime to morning glucose profile.

Conclusion: This is one of the first trials to demonstrate how continuous glucose monitoring in type 2 diabetes can provide a more clinically relevant comparison of different approaches to optimizing glucose management.

Assessment of infusion set survival of the newly developed coated Lantern catheter in type 1 diabetes by glucose clamp technique

J.K. Mader[1], A. Ajsic[1], M.C. Krasser[1], R. Juliussen[2], P.K. Schondorff[2], M. Heschel[2], T. Pöttler[1], D. Schwarzenbacher[1], T. Augustin[3], T.R. Pieber[1], G. Treiber[1];
[1]Department of Internal Medicine/Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria, [2]ConvaTec, Lejre, Denmark, [3]HEALTH, Joanneum Research ForschungsGmbH, Graz, Austria.

Background and aims: The catheter-tissue interface is the bottle neck of insulin pump therapy (CSII). Currently infusion sets shall be changed every 2–3 days to avoid lipohypertrophy, fluctuations in insulin absorption and occlusion. Patients would prefer an extended wear time if stable insulin absorption could be achieved. The novel coated catheter featuring Lantern Technology shall utilize anti-inflammatory effect and allow more stable insulin delivery via slots in the shaft of the soft cannula, even if kinking or clotting occurs. The aim of the present study was to investigate clinical performance of the coated Lantern catheter in 16 patients with type 1 diabetes using CSII over a period of up to 7 days.

Materials and methods: A combined design comprising inpatient (euglycaemic clamps on days 1, 4 and 7) and outpatient phases (insulin pump therapy over 7 days) is chosen to allow assessment of performance and survival time of the coated Lantern catheter. 16 c-peptide negative patients (age 44.2 ± 15.4 years, BMI 24.5 ± 2.3 kg/m^2, HbA1c 55 ± 8 mmol/mol, diabetes duration 20 ± 9 years) completed the 7-day study period.

Results: Geometric means of maximum glucose infusion rates (GIR) were similar for days 1, 4 and 7 (6.1 ± 1.5, 7.2 ± 1.3, 5.8 ± 1.4; $p = 0.14$). Time to reach 50% of the maximum GIR were similar over time (31.5 ± 1.6 min vs. 29.3 ± 1.3 min vs. 27.3 ± 1.3 min for days 1, 4 and 7 respectively; $p = 0.51$). Area under the log-transformed GIR curve did not significantly differ similar for the first 2 hours between days (343.7 ± 1.5 vs. 421.3 ± 1.6 vs. 350.6 ± 1.8; $p = 0.14$; days 1, 4 and 7, respectively); however, there was a trend towards reduced area under the GIR curve over 8 hours over time (874.2 ± 1.4 vs. 744.5 ± 1.7 vs. 509.2 ± 2.0; days 1, 4 and 7, respectively; $p < 0.05$). During outpatient care no severe hypoglycaemic event or ketoacidosis occurred.

Conclusion: The novel coated Lantern catheter could be safely used over an extended wear-time of 7 days. There was a trend towards reduced insulin action over time. The findings need to be confirmed in a larger scale trial under routine conditions.

An assessment on insulin pump precision for artificial pancreas efficiency

S. Girardot[1], F. Mousin[1], S. Hardy[1], J.-P. Riveline[2];
[1]Medico-technical, Explor by Air Liquide Healthcare, Gentilly, [2]Centre Universitaire du diabète et de ses complications, Hôpital Lariboisière, Paris, France.

Background and aims: Insulin pump is nowadays one of the trendiest treatment for type 1 diabetes and is about to become artificial pancreas (AP) major component. However, glycemic control among patients remain unpredictable. Insulin pump accuracy has not been so well studied

so far, especially in a context of a closed-loop system. A leading edge direct flow rate measurement method has been used to compare insulin pump accuracy of 24 h-tests with set basal rate and an AP-like way of delivering.

Materials and methods: Insulin pump tubing is connected to a Bronkhorst BL100: a micro flowmeter based on inertial movement technology. Downstream tubing beyond the instrument is then connected to a micro precision weight scale (XPE 56, Mettler Toledo) which records weight of delivered insulin over the time. This second lecture helps as a measurement control method of the direct flow meter. Instantaneous flow rate recorded by the direct flow is analysed to study performances of insulin pump delivery. Two insulin pump (pump#1: $n = 4$, pump#2: $n = 6$) from the market have been compared regarding their delivering precision while set on two different modes: *Set basal rate mode:* Insulin pump is programmed to deliver at 1UIh basal rate for the whole test. *AP-like mode:* Insulin pump is programmed to get as close as possible to an artificial pancreas way of deliver. Each test last 24-hours and targeted insulin volume has been compared with actual delivered volume for each 30-minutes time intervals. A mean absolute relative difference (MARD) indicator has been used to illustrate overall performances.

Results: Test results suggest differences of performances between pumps and between delivering mode for the same pump. Pump#1 delivering errors are significantly higher for AP-like delivering mode (MARD: 9.64%) rather than for a set 1 UI/h basal rate (MARD: 3.76%) ($p = 3.08.10^{-19}$). Pump#2 accuracy is generally much lower than pump#1. 1 UI/h basal rate set mode for pump#2 remain more accurate (MARD: 14.07%) than AP-like delivering mode (MARD: 36.02%) ($p = 0.01$).

Conclusion: As one of the main artificial pancreas component, insulin pump might drive to unexpected clinical or technical limitation. Beyond obvious clinical consequences, feeding AP control algorithm with inaccurate pump delivering data is likely to be a lack for overall system efficiency.

Fully closed-loop glucose control in haemodialysis patients with type 2 diabetes

L. Bally[1], H. Thabit[2], S. Hartnell[3], E. Andereggen[1], Y. Ruan[4], M.E. Wilinska[4], M.L. Evans[4,3], M. Semmo[1], B. Vogt[1], A.P. Coll[4,3], C. Stettler[1], R. Hovorka[4];
[1]Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland, [2]Manchester University Hospitals NHS Foundation Trust, Manchester, UK, [3]Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK, [4]Wellcome Trust–MRC Institute of Metabolic Science, University of Cambridge, Cambridge, UK.

Background and aims: The management of individuals with diabetes undergoing haemodialysis remains challenging for both patients and healthcare providers.

Materials and methods: Automated fully closed-loop (CL) insulin delivery system without meal-bolusing was evaluated in adult inpatients with insulin-treated type 2 diabetes undergoing haemodialysis. Nineteen participants were randomised to either CL-directed s/c insulin delivery ($n = 10$) or conventional s/c insulin therapy as per local practice with masked continuous glucose monitoring ($n = 9$) for up to 15-days. Participants consumed self-selected hospital meals and were matched for age (72 ± 7 vs. 67 ± 9yrs; CL vs. control), HbA1c (7.4 ± 1.1 vs. 7.2 ± 1.7%) and BMI (31.1 ± 6.1 vs. 33.1 ± 6.5 kg/m^2). During CL, participant's usual insulin and sulphonylurea therapy were withheld.

Results: In an intention to treat analysis, proportion of time when sensor glucose was in target range was 38.6 percentage points (95% confidence interval [CI] 25.9 to 51.2; $p < 0.001$; primary end point; table 1) greater during CL compared to control. CL significantly decreased time spent above target by 40.5 percentage points (95% CI 22.0 to 59.1; $p < 0.001$) without increasing total daily insulin delivered ($p = 0.51$). Mean glucose and standard deviation of sensor glucose were significantly reduced by 3.2 (0.8) mmol/l ($p = 0.001$) and 1.2 (0.4) mmol/l ($p = 0.009$) during CL compared to control, whilst area under the curve below 3.0mmol/l was not different ($p = 0.91$). No episodes of severe hypoglycaemia or hyperglycaemia with ketonaemia occurred during either study period. Study duration was 7.6 and 7.4 days in the closed-loop and control group, respectively ($p = 0.88$). No severe hypoglycaemia or serious adverse events occurred in either group.

Conclusion: Fully CL without meal-bolusing in haemodialysis patients with insulin-treated type 2 diabetes improves glucose control without increasing the risk of hypoglycaemia, and may be a promising treatment modality for this vulnerable population.

	Closed-loop insulin delivery (n=10)	*Conventional insulin therapy (n=9)*	*p*

A comparative effectiveness analysis of real-world use of the MiniMed™640G and MiniMed™ 670G systems

J. Shin, S. Huang, X. Chen, M.-H. Nguyen, T.L. Cordero, S.W. Lee, F.R. Kaufman;
Medtronic, Northridge, USA.

Background and aims: The MiniMed™ 640G system with the SmartGuard™ predictive low glucose management (PLGM) *Suspend before Low* feature suspends insulin delivery in advance of sensor glucose (SG) levels reaching a preset low SG limit, and resumes insulin delivery after SG levels recover. The MiniMed™ 670G system with the SmartGuard™ Auto Mode feature automatically adjusts basal insulin delivery through its hybrid closed-loop algorithm. A retrospective analysis of glycemia during real-world use of the MiniMed™ 640G system

(available outside the US) versus use of the MiniMed™ 670G system (available in the US) was performed.

Materials and methods: Patients with insulin-dependent diabetes using the MiniMed™ 640G system or the MiniMed™ 670G system and with ≥3 months of CareLink™ software data (insulin utilization, continuous glucose monitoring [CGM], etc.), were matched based on a logistic regression model with demographic information that included age, total daily dose of insulin (TDD), and sex. All data were de-identified and analyzed in aggregate. Propensity score of matched patients from each group (MiniMed™ 640G system versus MiniMed™ 670G system) was determined and data were compared using a two-sample t-test or Wilcoxon rank-sum test. Analyzed endpoints included the mean percentage of time in target glucose range (TIR, 70–180 mg/dL [3.9–10 mmol/L]), hypoglycemic ranges (<50, <54, and <70 mg/dL [<2.8, <3.0, and <3.9 mmol/L]), and hyperglycemic ranges (>180, >250, >300 and >350 mg/dL [>10, >13.9, >16.7, >19.4 mmol/L]).

Results: Demographics of patients (N = 1514/group, 45% male/group) were equivalent for both groups. The mean ± SD (median, min-max) of age was 40.7 ± 17.2 (42.0, 4.0–77.0) years, and that of TDD was 41.5 ± 17.3 (38.3, 5.8–152.9) units. The table shows percentage of glucose values in the different SG ranges for both systems. For patients using the MiniMed™ 670G system compared to those using the MiniMed™ 640G system, a significant increase (+9.5%) in TIR and a significant reduction (−9.2%) in time >180 mg/dL (>10 mmol/L) were observed ($p < 0.001$, for both). There was no difference in the mean percentage of time in hypoglycemic ranges.

Conclusion: An analysis of real-world CGM data demonstrated that use of the MiniMed™ 670G system was associated with a significant increase in TIR and a significant reduction in SG values in the hyperglycemic ranges compared to use of the MiniMed™ 640G system. Improved overall glycemia observed with the MiniMed™ 670G system was not associated with an increase in hypoglycemia. These real-world findings indicate that automated basal insulin delivery with the MiniMed™ 670G system provides significant clinical benefit in glucose management.

Table. Percentage of glucose values across sensor glucose ranges for each system.

Glucose Range	MiniMed™ 640G System	MiniMed™ 670G System
<50 mg/dL (<2.8 mmol/L)	0.26 ± 0.43	0.23 ± 0.32
<54 mg/dL (<3 mmol/L)	0.46 ± 0.70	0.42 ± 0.53

Optimising basal-bolus therapy in type 2 diabetes: a randomised, controlled trial comparing bolus insulin delivery using an insulin patch vs an insulin pen

S. Ramtoola[1], V.R. Aroda[2], T.S. Bailey[3], R.L. Brazg[4], D.M. Dreon[5], J.P. Frias[6], D.C. Klonoff[7], D.F. Kruger[8], B.L. Levy[5], M. Peyrot[9], J. Rosenstock[10], P. Serusclat[11], R.S. Weinstock[12], V. Zraick[5], R.M. Bergenstal[13];

[1]East Lancashire Hospitals NHS Trust, Blackburn, UK, [2]Medstar Health Research Institute, Hyattsville, USA, [3]AMCR Institute Inc., Escondido, USA, [4]Rainier Clinical Research Center, Renton, USA, [5]Calibra Medical, Wayne, USA, [6]National Research Institute, Los Angeles, USA, [7]Diabetes Research Institute, San Mateo, USA, [8]Henry Ford Health System, Detroit, USA, [9]Loyola University Maryland, Baltimore, USA, [10]Dallas Diabetes Research Center at Medical City, Dallas, USA, [11]Groupe Hospitalier Mutualiste Les Portes du Sud, Vénissieux, France, [12]SUNY Upstate Medical University, Syracuse, USA, [13]International Diabetes Center, Park Nicollet, Minneapolis, USA.

Background and aims: This multicenter randomized, controlled trial compared efficacy, safety, and subject-reported outcomes for adults with type 2 diabetes on basal insulin (HbA_{1c} 7.5–11% [58–97 mmol/mol]) initiating mealtime insulin (aspart) with a wearable bolus insulin delivery patch (Patch) vs an insulin pen (Pen). The Patch was applied at least every 3 days and delivered subcutaneous bolus insulin in 2-U increments per manual click.

Materials and methods: Subjects (n = 278, mean age: 59 years, mean diabetes duration: 15 years) receiving 0.52 U/kg glargine on average, were randomized to Patch (n = 139) or Pen (n = 139). Baseline glargine dose was divided 1:1 into basal:bolus. Using a pattern-control logbook, subjects adjusted basal and bolus insulin weekly based on fasting and pre-meal glucose targets.

Results: Change in HbA_{1c} from baseline to Week 24 (primary endpoint) for Patch was non-inferior ($p < 0.0001$) to Pen (least squares mean change ± SEM: Patch, −1.7 ± 0.1% [−19 ± 1.0 mmol/mol] vs Pen, −1.6 ± 0.1% [−17 ± 1.0 mmol/mol]); this reduction was significant ($p < 0.0001$) in both groups. HbA_{1c} improvement was maintained at 44 weeks (Figure). At Week 24, 63% of Patch users and 56% of Pen users achieved HbA_{1c} ≤7.0% (≤53 mmol/mol) (OR, 1.3; SEM, 0.25; 95% CI, 0.81, 2.14; p = 0.26). The proportions of Patch and Pen users who achieved HbA1c ≤7.0% (≤53 mmol/mol) at Week 44 rose to 65% and 63%, respectively (OR, 1.2; SEM, 0.28; 95% CI, 0.64, 1.93; p = 0.71). CV of 7-point self-monitoring blood glucose decreased significantly more with Patch compared to Pen; change from baseline to Week 44 was −1.2 ± 0.8% and 1.4 ± 0.8%, respectively (difference, −2.6 ± 1.1%; 95% CI, −4.8, −0.4; p = 0.022). Subjects in Patch and Pen arms, respectively, reported high adherence (mean ± SEM, %) to their insulin regimens at Week 24 (79 ± 18% vs 78 ± 16%; p = 0.70) and Week 44 (81 ± 15% vs 81 ± 17%; p = 0.78). There were no significant differences in adverse events, including hypoglycemia (3 severe episodes/group). There were significantly greater improvements in subject-reported outcomes for Patch vs Pen.

Conclusion: Bolus insulin with Patch or Pen and dosing algorithms improved HbA_{1c} with better experience and preference for Patch.

Insulin pump therapy with simple infusion scheme in insufficiently-controlled patients with type 2 diabetes on intensive injection therapy: a real life study

H.W. de Valk[1], B. Silvius[1], M.J. Kramer[2], BIDON-study group;
[1]Internal Medicine, University Medical Center Utrecht, Utrecht, [2]Internal Medicine, Free University Medical Center, Amsterdam, Netherlands.

Background and aims: A considerable part of patients with type 2 diabetes mellitus on intensive (4 times daily) insulin injection therapy (MDI) do not reach adequate glycemic control. A recent randomized controlled, 26-week clinical trial has shown that continuous subcutaneous insulin infusion (CSII) using a simple infusion scheme, improves glycemic control. This scheme means a single basal infusion rate and a three times daily roughly similar meal-time insulin bolus. The aim of this study was to assess the effectiveness of this simple insulin regime with CSII in obtaining better glycemic control in a real-life setting.
Materials and methods: Patients with type 2 diabetes with HbA1c ≥64 mmol/mol on MDI (at least 4 times daily) with an insulin requirement between 0.7 and 2.2 U/day. were eligible Insulin infusion scheme was calculated as follows: hourly basal insulin rate was 50% of the total daily dose (TDD) divided by 24 and prandial insulin (thrice daily) was calculated by dividing 50% of TDD by 3. Small changes to basal rate and prandial insulin dose were allowed. Trial duration was 6 months. Results at 6 months were compared with those at baseline with (non-)parametric paired tests.
Results: Sixty-seven patients were analyzed. Mean age: 61.3 ± 0.9 years, 42% female; duration of disease: 16.0 ± 7.6 years; weight: 107.4 ± 21.9 kg; BMI: 35.8 ± 6.9 kg/m^2, baseline insulin dose: 135.5 ± 62.3 U/day (large SD due to a few high doses). Macro-angiopathy 28.3%, proliferative retinopathy 13%, renal disease 18%. Mean HbA1c fell from 80.1 ± 15.2 to 62.4 ± 10.0 mmol/mol ($p < 0.001$). Mean change in HbA1c −17.7 ± 2.1 mmol/mol. The main improvement was already visible at three months (mean HbA1c 65.3 ± 1.4 mmol/mol). An improvement in HbA1c at 6 months was seen in 64 patients (96%); in 56 patients, HbA1c fell at least 5 mmol/mol (84%). There were 3 outliers (δHbA1c >−50 mmol/mol (65, 88, 95 mmol/mol)). After explorative exclusion, the change in the remaining 64 patients was 78.0 ± 11.8 to 63.0 ± 9.7 mmol/mol ($p < 0.001$); mean change −15.0 ± 1.5 mmol/mol. The mean change in HbA1c in the randomized trial was 12 mmol/l; the current result of 15 mmol/mol was even slightly better ($p = 0.01$, one sample T-test). In these 64 patients, total cholesterol decreased slightly (4.33 ± 0.13 to 4.21 ± 0.13 mmol/l, $p < 0.05$) with no changes in the other lipid parameters or blood pressure. Body weight increased from 106.2 ± 19.5 to 109.3 ± 20.61 kg ($p < 0.001$), although 20% actually lost weight. Mean weight increase was significantly higher than in the randomized trial (3.3 vs 1.5 kg, $p < 0.001$).
Conclusion: This real-life study shows that introducing CSII in patients with moderately- to poorly-controlled type 2 diabetes on intensive insulin therapy in a real-life setting, leads to a major improvement of glycemic control in most patients. Results are at least comparable to the ones obtained in the prior randomised clinical trial. Glycemic improvement is already visible after 3 months on CSII. Weight increased significantly suggesting that intensified targeted nutritional therapy is crucial with this profound, insulin-driven improvement in glycemic control.

BioChaperone technology enables the development of pramlintide-prandial insulin combinations

R. Soula, G. Meiffren, A. Geissler, Y. Meyer, A. Ranson, C. Fortier, O. Soula, B. Alluis, R. Charvet;
Adocia, Lyon, France.

Background and aims: Pramlintide is currently used on top of mealtime insulin therapy by T1D or T2D patients to achieve a better control of post-prandial glucose excursion. Indeed, pramlintide affects the rate of post-prandial glucose appearance by slowing down gastric emptying, reducing postprandial glucagon secretion and modulating satiety, which affects caloric intake. Nevertheless, the use of pramlintide is currently limited as it cannot be combined in a single formulation with prandial insulin due to pH incompatibility, which results in high burden of additional injections. In this work, BioChaperone technology was used to develop a stable co-formulation of pramlintide and human insulin (BC Pram Ins) at neutral pH.
Materials and methods: BC Pram Ins physical stability was evaluated by visual inspection and micro-flow imaging. For chemical stability, recovery was measured by reversed-phase HPLC while high molecular weight species were measured by size-exclusion HPLC. A preliminary in-use pump stability was performed using a commercially available insulin pump system at 37°C. Pharmacokinetics data were obtained by single subcutaneous administration of the desired formulation at doses of 0.1875 U/kg insulin and 1.125 μg/kg pramlintide to fasted healthy pigs.
Results: BC Pram Ins formulation is physically and chemically stable for at least 6 weeks at 30°C and 9 weeks at 25°C. The physical and chemical stability was similar to that of commercial Humulin® and Symlin®. Under simulated in-use pump conditions at 37°C, BC Pram Ins formulation shows physical and chemical stability for at least 1 week, with insulin and pramlintide recoveries higher than 95% and a formulation free of particles. Following a single subcutaneous administration to fasted healthy pigs, BC Pram Ins results in slower absorption of pramlintide (LSM ratio [95%C|] $\Delta AUC_{Pram0\text{-}30min}$: 0.45 [0.20; 1.05]), while the late exposure to pramlintide is higher ($\Delta AUC_{Pram60\text{-}180min}$: 2.65 [1.44; 4.90]) compared to the separate injections of human insulin and pramlintide.
Conclusion: The *in-vitro* and preclinical pharmacodynamic properties of BC Pram Ins support its clinical development as an improved treatment alternative for postprandial glycemic control in patients with T1D and T2D.

Glycaemic control with fast-acting insulin aspart according to dose adjustment method in type 1 diabetes: a post hoc analysis of onset 8

T.R. Pieber[1], J. Buse[2], L. Rose[3], A. Gorst-Rasmussen[4], T.W. Boesgaard[4], K. Buchholtz[4], O. Mosenzon[5];
[1]Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria, [2]University of North Carolina School of Medicine, Chapel Hill, USA, [3]Institute of Diabetes Research, Münster, Germany, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Diabetes Unit, Hadassah Hebrew University Hospital, Jerusalem, Israel.

Background and aims: Insulin dosing based on carbohydrate counting is the gold standard for improving glycaemic control in type 1 diabetes (T1D). It has previously been suggested that for patients using carbohydrate counting, fast-acting insulin aspart (faster aspart) may offer improved glycaemic control vs insulin aspart (IAsp). This *post hoc* analysis of a large phase 3 trial aimed to further assess the impact of dose adjustment methodology (DAM) in relation to the efficacy and safety of mealtime faster aspart in T1D.

Materials and methods: onset 8 was a 26-week, multicentre, treat-to-target trial in which adults with T1D were randomised to double-blind mealtime faster aspart or IAsp, or open-label post-meal faster aspart, each with insulin degludec. Subjects with previous experience continued carbohydrate counting (baseline characteristics of the mealtime faster aspart [$n = 142$] vs IAsp [$n = 136$] arms: male, 51.4 vs 52.2%; age, 42.3 vs 43.9 years; duration of diabetes, 19.4 vs 18.0 years; HbA_{1c}, 7.5 vs 7.4%), while remaining subjects used a simple bolus algorithm (baseline characteristics of the mealtime faster aspart [$n = 200$] vs IAsp [$n = 206$] arms: male, 55.5 vs 52.4%; age, 40.9 vs 38.7 years; duration of diabetes, 16.3 vs 15.9 years; HbA_{1c}, both 7.4%). In this *post hoc* analysis, endpoints for mealtime faster aspart and IAsp were analysed based on statistical models including a treatment arm-by-DAM interaction term.

Results: HbA_{1c} reduction was similar in both mealtime treatment arms (Table), and non-inferiority of faster aspart was confirmed in the onset 8 population. The estimated treatment difference (95% CI) (faster aspart – IAsp) for change from baseline in HbA_{1c} was −0.14% (−0.28;0.003) in the carbohydrate counting group and 0.06% (−0.06;0.18) in the bolus algorithm group. Rates of severe or blood glucose-confirmed hypoglycaemia (<3.1 mmol/L [56 mg/dL]), and total daily and daily bolus insulin doses were similar between faster aspart and IAsp across DAM groups. No clinically relevant differences were observed in change in body weight between treatments with either DAM. No other safety issues were reported.

Conclusion: Regardless of bolus adjustment method, faster aspart was as effective as IAsp in terms of HbA_{1c} reduction. This analysis is consistent with previous findings and suggests a tendency for improved glycaemic control with faster aspart vs IAsp in patients with T1D using carbohydrate counting, with similar insulin dose and weight gain and without an increased risk of hypoglycaemia.

Table. Endpoints after 26 weeks of mealtime faster aspart vs IAsp for all subjects and by dose adjustment methodology.

		Faster aspart	IAsp	Estimated treatment difference (faster aspart – IAsp), [95% CI]
Change from baseline HbA_{1c} (%)*	All subjects	−0.12	−0.10	−0.02 [−0.11;0.07]
	Carbohydrate counting	−0.16	−0.02	−0.14 [−0.28;0.003]
	Bolus algorithm	−0.09	−0.15	0.06 [−0.06;0.18]
Change from baseline body weight (kg)*	All subjects	1.43	1.24	0.19 [−0.22;0.60]
	Carbohydrate counting	0.76	1.09	−0.33 [−0.97;0.32]
	Bolus algorithm	1.91	1.39	0.51 [−0.02;1.05]
		Faster aspart	**IAsp**	**Estimated treatment ratio (faster aspart/IAsp), [95% CI]**
Total daily insulin dose (U/kg)†	All subjects	0.72	0.74	0.98 [0.92;1.03]
	Carbohydrate counting	0.66	0.66	1.00 [0.91;1.09]
	Bolus algorithm	0.76	0.79	0.96 [0.90;1.04]
Daily insulin bolus dose (U/kg)†	All subjects	0.37	0.39	0.97 [0.90;1.04]
	Carbohydrate counting	0.33	0.34	0.95 [0.85;1.07]
	Bolus algorithm	0.41	0.42	0.98 [0.89;1.07]
Severe or BG-confirmed hypoglycaemic episodes/PYE‡	All subjects	33.72	40.00	0.84 [0.70;1.01]
	Carbohydrate counting	32.96	40.69	0.81 [0.61;1.08]
	Bolus algorithm	34.28	39.56	0.87 [0.68;1.10]

*Change from baseline is analysed using a mixed effects model for repeated measures.
†Doses are analysed on a log-scale using a mixed effects model for repeated measures, with back-transformation to express results as dose ratios.
‡Hypoglycaemia rates are analysed using a negative binomial model for hypoglycaemic episode count with a log link function, and the logarithm of the exposure time as offset.
For all endpoints, estimates by treatment are based on LS mean values.
BG-confirmed: plasma glucose value <3.1 mmol/L (56 mg/dL)
BG, blood glucose; CI, confidence interval; faster aspart, fast-acting insulin aspart; IAsp, insulin aspart; LS, least squares; PYE, patient-year of exposure.

Improved post-prandial blood glucose excursions with Technosphere inhaled insulin compared to aspart in adult patients with type 1 diabetes: STAT study intention to treat analysis

H.K. Akturk[1], J.K. Snell-Bergeon[1], E.A. Beck[1], L.J. Klaff[2], B. Bode[3], A. Peters[4], T.S. Bailey[5], S.K. Garg[1];
[1]University of Colorado, Aurora, [2]Rainier Clinical Research Center, Renton, [3]Atlanta Diabetes Associates, Atlanta, [4]USC Westside Center for Diabetes, Beverly Hills, [5]AMCR Clinic, Escondido, USA.

Background and aims: Post-prandial hyperglycemia remains a significant clinical concern; in great part due to the lack of very rapidly acting prandial insulin therapy. Over the past 2 decades, multiple efforts resulted in the development of faster-acting insulin analogs and inhaled insulin for use in clinical care. In this investigator-led, collaborative open-label randomized pilot clinical trial we evaluated the efficacy of Technosphere Insulin (TI) for lowering post-prandial blood glucose (PPBG) and post-prandial glucose excursion (PPGE) in a 4-week treatment period.

Materials and methods: Sixty patients with T1D on multiple daily injections were randomized in a multi-center study, stratified by A1c values (≤8% or >8%) to the control arm using aspart ($n = 34$) vs TI group ($n = 26$). Two patients in the TI arm discontinued from the study, and 2 had inadequate CGM data for analysis. Patients in the TI arm were instructed per protocol to take insulin doses pre-meal, and at 1 and 2 hours after meals based on observed PPBG values. Compliance with TI use was based on using TI per protocol pre-meal and at 1- and 2-hours post-meal, based on PPBG measures. Patients with at least 80% compliance were included in the TI-compliant per protocol group ($n = 15$), and seven TI patients were evaluated in the per protocol non-compliant group. Baseline characteristics of the study group were compared to the randomization group using a student's t-test, and CGM data from the study group was analyzed using linear regression models. Primary outcomes were CGM glucose percentage time in range (70–180 mg/dL) and PPGE 1–4 hours after meals.

Results: Groups had similar baseline characteristics, including age, sex, HbA1c, bolus insulin dose, and FEV1. Mean CGM glucose, glycemic variability (glucose SD/CV), time in range (70–180 mg/dL), and time in hyper- (>180 mg/dL) or hypoglycemia (<70, <60, or <50 mg/dL) were similar between groups. PPGE was significantly lower in the TI group than in the aspart group (Figure). The PPBG at 1 hour was lower in the TI group (mean ± SE PPBG difference −31.7 ± 6.6 mg/dL, $p < 0.0001$) and was numerically lower at 2 hours (mean ± SE PPBG −13.0 ± 7.1 mg/dL, $p = 0.07$) with no difference at 3 and 4 hours. The TI group increased their bolus insulin dose to mean ± SD of 47.8 ± 23.9 U/day compared to the aspart group (mean ± SD =23.0 ± 9.8 U/day; $p < 0.0001$) during the initial week of the study. There was no difference in HbA1c by study group at either screening or at the study end.

Conclusion: This data demonstrates that Technosphere Insulin when administered at meal time and supplemented (if needed) at appropriate post-meal intervals, significantly improved PPBG at 1- and 2-h after meals and decreased PPGE when compared with insulin aspart in adult patients with T1D using MDI.

Ultra rapid lispro (URLi) reduces postprandial glucose excursions vs lispro in patients with type 2 diabetes at multiple meal-to-dose timing intervals

C. Kapitza[1], J. Leohr[2], R. Liu[2], S.R. Reddy[2], M.A. Dellva[2], M. Matzopoulos[3], M.P. Knadler[2], M.T. Loh[4], T.A. Hardy[2], C. Kazda[2];
[1]Profil Institut fur Stoffwechselforschung GmbH, Nuess, Germany, [2]Eli Lilly and Company, Indianapolis, USA, [3]Eli Lilly and Company, Surrey, UK, [4]Lilly-NUS Centre Clin Pharm Pte Ltd, Singapore, Singapore.

Background and aims: Ultra Rapid Lispro (URLi; LY900014), a novel ultra-rapid mealtime insulin in Phase 3 development, is shown to reduce postprandial glucose after subcutaneous injection.
Materials and methods: This 2-part, randomised, double-blind, Phase 1b study evaluated differences in PK and PD between URLi and lispro (Humalog®) in 30 patients with T2D. Part A used a 6-period crossover design to assess safety and compare PK and postprandial glucose response to solid mixed meal tolerance tests (MMTT) with the same, individualised doses of URLi or lispro at different injection-to-mealtime intervals (-15, 0 & +15 min). Part B evaluated safety, PK and PD during 2 wks of multiple daily dosing (immediately before a meal) in a parallel design. Patients were stabilised overnight to a fasting blood glucose level of 7 mmol/L before the MMTT procedure.
Results: In Part A, URLi reduced glucose excursions (assessed as change in area under the concentration curve vs. time [ΔAUC]) vs. lispro during the first 2 hrs (ΔAUC0-2 h) and entire 5 hrs (ΔAUC0-5 h) of the MMTT regardless of dose timing (Figure). URLi reduced ΔAUC0-2 h by 37% ($p = 0.014$), 47% ($p < 0.0001$), and 4% (p = NS) and ΔAUC0-5 h by 49% ($p = 0.049$), 105% ($p < 0.0001$), and 29% ($p = 0.076$) vs. lispro at −15, 0 and +15 min (significance level = 0.1). The PK and PD profiles for URLi and lispro were sustained after 2 wks of outpatient dosing (Part B). More hypoglycaemic events occurred with URLi during MMTTs but these were mild and mostly asymptomatic. Only a few events occurred in either group during 2 wks of outpatient dosing, with no differences between treatments. Local tolerability was similar between treatments.
Conclusion: These results provide preliminary evidence that URLi may improve postprandial glucose control in T2D.

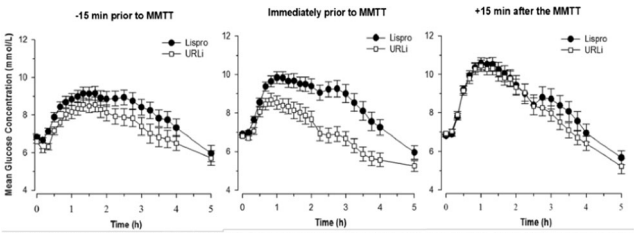

Figure: Mean glucose concentration (±SE) versus time when dosed 15 min before (left), immediately prior (middle), and 15 min post-test meal (right) by treatment following a single dose (Part A).

Pooled analysis of clinical trials investigating the pharmacokinetics (PK) of ultra-rapid insulin BioChaperone Lispro vs lispro in subjects with type 1 and type 2 diabetes

T. Heise[1], A. Ranson[2], M. Gaudier[2], O. Soula[2], B. Alluis[2], E. Zijlstra[1], S. Glezer[2], G. Meiffren[2];
[1]Profil, Neuss, Germany, [2]Adocia, Lyon, France.

Background and aims: BioChaperone Lispro (BCLIS) is an ultra-rapid insulin lispro formulation designed to accelerate the time-action profile versus conventional short-acting insulin analogs.
Materials and methods: PK characteristics of single doses of BCLIS and insulin lispro (LIS) were characterized in four randomized, double-blind, crossover studies in altogether 112 patients with type 1 diabetes and 51 people with type 2 diabetes who received BCLIS and LIS (0.2 U/kg in studies 1 & 2, individualized doses in studies 3 & 4) subcutaneously by syringe.
Results: Insulin absorption was consistently faster with BCLIS than with LIS as indicated by reaching early half-maximum insulin levels (early $t_{50\%max}$) 10.0 (95% confidence interval [−14.3; −5.8]) and time to maximum levels (t_{max}) 8.4 [−9.6; −7.2] min earlier ($p < 0.0001$ for both comparisons). Early insulin exposure was significantly greater for BCLIS for up to 2 hours after administration (figure). BCLIS also showed faster offset of exposure, with a 22.3 [−28.8; −15.7] min earlier time to late half-maximum insulin levels (late $t_{50\%max}$) ($p < 0.0001$) and a 24% lower late exposure ($AUC_{2\text{-}6h}$; figure). Total exposure ($AUC_{0\text{-}6h}$) was similar for both formulations in all studies (treatment ratio in pooled analysis 0.99 [0.95; 1.03], p = NS).
Conclusion: BCLIS consistently shows faster onset and offset of exposure than conventional LIS in both patients with type 1 diabetes and people with type 2 diabetes.

BioChaperone 222, the new excipient enabling the ultra-rapid BioChaperone Lispro formulation, is completely absorbed and rapidly excreted after subcutaneous injection

O. Soula[1], L. Plum-Mörschel[2], E. Anastassiadis[2], G. Andersen[3], S. Glezer[1], A. Ranson[1], B. Alluis[1], J. Correia[1], C. Seroussi[1], M. Gaudier[1], G. Meiffren[1];
[1]Adocia, Lyon, France, [2]Profil, Mainz, Germany, [3]Profil, Neuss, Germany.

Background and aims: BioChaperone 222 (BC222) is an oligosaccharide grafted with anionic charges and amino acid moieties designed to speed up the absorption of insulin lispro in the BioChaperone Lispro (BCLIS) formulation. Non-clinical data indicated that BC222 is rapidly excreted unchanged by the kidney.
Materials and methods: This open label clinical trial conducted in 12 healthy volunteers [mean ± SD age 31.4 ± 9.5 y; weight: 95.3 ± 16.8 kg;

BMI 26.6 ± 4.1 kg/m²] investigated the PK properties and safety and tolerability of a single subcutaneous (s.c.) dose of BC222 (equal to the BC222 content in 1.0 U/kg BCLIS) using validated liquid chromatography mass spectrometry assays for BC222 in plasma and urine samples.
Results: BC222 was rapidly absorbed, with a median plasma Tmax of 1.2 h (figure). BC222 was rapidly cleared from the blood with a mean terminal half-life of 2.07 (±0.52) h reaching baseline levels 10–12 h after administration. Urinary BC222 concentrations reached 95.4 ± 4.7% of the injected dose within 12 h post-dosing and were as high as 97 ± 5% of the total dose after 48 h indicating that BC222 was completely absorbed from the s.c. tissue into the blood and quickly cleared via the urine. BC222 was well tolerated and safe with only two mild adverse events occurring in the whole study.
Conclusion: BC222 is completely absorbed after s.c. injection and rapidly excreted by the kidneys.

Figure: Mean ± SD BC222 plasma concentration over time after subcutaneous administration

Ultra rapid lispro (URLi) shows faster insulin absorption vs lispro during insulin pump (CSII) use in patients with type 1 diabetes

C. Kazda[1], J. Leohr[2], R. Liu[2], T.A. Hardy[2], S. Reddy[2], S.P.C. Chua[3], X. Guo[2], U. Hovelmann[4], C. Kapitza[4];
[1]Lilly France, Neuilly-sur-Seine, France, [2]Eli Lilly and Company, Indianapolis, USA, [3]Lilly-NUS Centre for Clinical Pharmacology Pte Ltd, Singapore, Singapore, [4]Profil Institut für Stoffwechselforschung GmbH, Nuess, Germany.

Background and aims: Ultra Rapid Lispro (URLi; LY900014), a novel ultra-rapid mealtime insulin in Phase 3 development, is shown to reduce postprandial glucose after subcutaneous injection.
Materials and methods: This study evaluated the pharmacokinetics and pharmacodynamics (PD) of URLi via CSII. In a double-blind, randomised cross-over study, 24 adult patients with T1D received URLi or lispro (Humalog®) for 3 days. Mixed meal tolerance tests (MMTT) were conducted on Days 1 and 3 after catheter insertion using a standard (1.5 U/min) single-wave bolus with the same, individualised doses.
Results: URLi showed faster insulin lispro absorption on both days compared to lispro. URLi reduced time to early half-maximal drug concentration by 37% (−8.5 min) and 32% (−5.3 min) compared to lispro on Days 1 and 3 (both $p < 0.0001$). Area under the insulin lispro concentration time curve (AUC) for the first 15 min was >50% higher than lispro after dosing with URLi on Days 1 and 3 ($p < 0.005$). URLi reduced 1-h postprandial glucose excursion of the MMTT by 45% on Day 1 (p = NS) and 47% on Day 3 ($p = 0.059$) compared with lispro (Figure). Accelerated absorption with URLi was associated with trends toward lower postprandial glucose excursion for the entire MMTT (57% and 20% reductions in ΔAUC[0–5 h] on Days 1 and 3; both NS). The study was not powered for PD assessment which may contribute to the lack of statistical significance. No differences were seen in the number or severity of hypoglycaemic events or local tolerability between URLi and lispro.
Conclusion: URLi demonstrated accelerated absorption and a trend toward improved postprandial glucose control in T1D subjects using CSII.

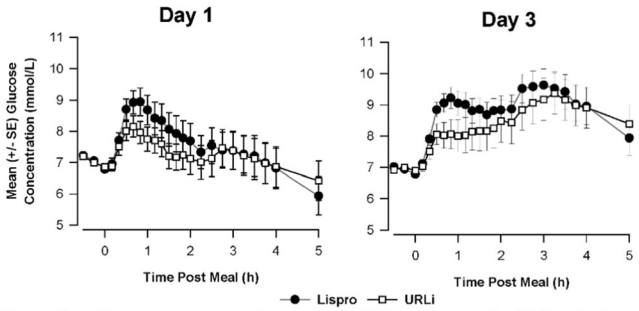

Figure Mean plasma glucose concentration over time for URLi and Lispro on Day 1 (left) vs Day 3 (right).

818

Better postprandial glucose control with BioChaperone Combo than with lispro Mix25 or separate glargine and lispro (G+L) administrations in subjects with type 2 diabetes

T. Herbrand[1], L. Plum-Mörschel[2], C. Mégret[3], T. Heise[1], V. Vacher[3], E. Anastassiadis[2], O. Klein[1], M. Gaudier[3], O. Soula[3], S. Glezer[3], B. Alluis[3], G. Meiffren[3];
[1]Profil, Neuss, Germany, [2]Profil, Mainz, Germany, [3]Adocia, Lyon, France.

Background and aims: BioChaperone Combo (BC Combo) is a co-formulation of prandial insulin lispro (25%) and basal insulin glargine (75%) with a rapid "prandial" insulin component and prolonged flat "basal" component compared to lispro Mix25 (LMx). In this study the effects of BC Combo on postprandial glucose control were investigated vs LMx and G+L.
Materials and methods: Thirty-nine people with type 2 diabetes (mean ± SD age 60.8 ± 7.5 years and HbA1c 7.97 ± 0.6%) were randomised to receive the three insulin combinations immediately before a standardised solid meal test (MMT, 20% protein, 30% fat, 50% carbohydrates) in a double-blind, double-dummy, cross-over design. The individual insulin dose was the same for each visit day (mean 0.62 U/kg).
Results: BC Combo demonstrated improved postprandial glucose control in people with type 2 diabetes compared to LMx (Figure, reduction in the area of postprandial blood glucose excursions ($\Delta AUC_{BG,0\text{-}2h}$) by 18%, $p = 0.0009$) and G+L (reduction in $\Delta AUC_{BG,0\text{-}2h}$ of 10%, $p = 0.0450$). The proportion of subjects experiencing documented symptomatic hypoglycaemic events (plasma glucose <70 mg/mL) over 24 h was numerically lower with BC Combo (15.8%) vs LMx (32.4%) and G+L (21.6%). The total insulin PK profile of BC Combo showed a faster time to insulin peak and a lower exposure in the late prandial phase (2–6 h) than LMx and G+L.
Conclusion: BC Combo demonstrated superior postprandial glucose control with numerically fewer subjects experiencing symptomatic hypoglycaemia compared to both Lispro Mix 25 and separate injections of glargine and lispro.

Efficacy of advanced carbohydrate counting and automated insulin bolus calculators in type 2 diabetes: the BolusCal2 study, an open-label, randomised controlled trial

M.B. Christensen[1], N. Serifovski[1], A.M.H. Herz[1], S. Schmidt[1], P. Gaede[2], E. Hommel[3], L. Raimond[3], A. Gotfredsen[1], K. Nørgaard[1,3]; [1]Dept. of Endocrinology, Hvidovre Hospital, [2]Dept. of Endocrinology, Slagelse Hospital, [3]Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Carbohydrate counting and use of an automated bolus calculator can reduce HbA1C in type 1 diabetes but this approach has never been tested in type 2 diabetes. We aimed to evaluate the efficacy of advanced carbohydrate counting and use of an automated bolus calculator (ABC) compared with mental insulin bolus calculation (MC) in persons with type 2 diabetes on basal-bolus insulin therapy.
Materials and methods: A 24-week open-label, randomized controlled study was conducted in persons with type 2 diabetes treated with basal-bolus insulin. All participants had HbA1C ≥58 mmol/mol, were GAD antibody negative, naïve to carbohydrate counting and bolus calculation and were treated with basal and bolus insulin ≥6 months. 79 participants (mean age 62.5 ± 9.6 yrs, mean HbA1C 72 ± 11 mmol/L, mean diabetes duration 18.7 ± 7.6 yrs, mean BMI 33 ± 6 kg/m^2, mean fasting c-peptide 656 ± 486 pmol/L) were randomized 1:1 into two groups. ABC group received training in advanced carbohydrate counting and use of an automated bolus calculator. MC group received training in advanced carbohydrate counting and mental calculation of insulin bolus (without a bolus calculator). Participants wore blinded continuous glucose monitor (CGM) for 6 days at baseline and at study end. Primary endpoint was change in HbA1C. Secondary endpoints were time spent in glycemic ranges and frequency of severe hypoglycemia. Data is reported for 64 participants having completed the study at present.
Results: Baseline HbA1C was similar in the ABC group and in the MC group (71 ± 11 vs 72 ± 12 mmol/mol). At 24 weeks HbA1C had decreased by 8.1 mmol/mol ($P \leq 0.001$) in the ABC group and by 8.0 mmol/mol ($P \leq 0.001$) in the MC group. There was no difference in change in HbA1C between groups at study end ($P = 0.96$). CGM data showed that time in euglycemic range (sensor glucose (SG) 4.0–10.0 mmol/L) increased significantly from baseline to study end in the ABC group (57.7% to 66.7%, $P = 0.03$) in contrast to the MC group (59.7% to 63.3%, $P = 0.22$), but there was no significant difference in increase between the two groups ($P = 0.52$). Time in hyperglycemia (SG >10 mmol/L) tended to decrease in the ABC group (40.7% to 32.0%, $P = 0.051$) but was unchanged in the MC group (38.3% to 35.6%, $P = 0.29$) with no difference between groups ($P = 0.52$). Time in hypoglycemia (SG ≤3.9 mmol/mol) decreased insignificantly in both groups (ABC: 1.7% to 1.4%, $P = 0.26$; MC: 2.0% to 1.1%, $P = 0.08$) with no difference between groups ($P = 0.67$). Coefficient of variance (CV) decreased in both groups (ABC: 29.1% to 26.7%, $P = 0.03$; MC: 29.4% to 26.1%, $P = 0.004$) without any difference in decrease between groups ($P = 0.87$). There were no episodes of severe hypoglycemia in any of the groups.
Conclusion: Advanced carbohydrate counting and insulin bolus calculation is an efficient, low-cost tool to reduce HbA1C in persons with basal-bolus insulin treated type 2 diabetes. Similar effect was seen with use of an automated bolus calculator and with use of mental bolus calculation. Blinded CGM revealed decreased glycemic variability with both options, whereas only the group using automated bolus calculation increased their time in euglycemic range.

Therapy adjustments of patients with type 1 diabetes on multiple daily injections with an increased risk for hypoglycaemia using real-time continuous glucose monitoring (rtCGM)

D. Waldenmaier[1], G. Freckmann[1], L. Heinemann[2], N. Hermanns[3], S. Pleus[1], C. Haug[1];
[1]Institut für Diabetes-Technologie, Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Ulm, [2]Science-Consulting in Diabetes GmbH, Düsseldorf, [3]Forschungsinstitut der Diabetes-Akademie Bad Mergentheim, Bad Mergentheim, Germany.

Background and aims: There is limited knowledge about how persons with diabetes modify their insulin therapy in daily life based on real-time continuous glucose monitoring (rtCGM) data. The HypoDE study recently demonstrated that the use of an rtCGM system reduces the occurrence of hypoglycaemic events (<55 mg/dl) in patients with type 1 diabetes on multiple daily injections with an increased risk for hypoglycaemia. The present analysis investigated how the patients adjusted their therapeutic decisions.
Materials and methods: Study participants were randomized to rtCGM use (CGM group) or self-monitoring of blood glucose (control group) for 26 weeks. CGM group subjects were trained in interpretation and use of CGM data for therapeutic adjustments. Treating physicians in both groups modified therapies based on available data. During the baseline phase (before randomization) and at the end of the study (follow-up phase), subjects documented every insulin dose and meal intake for 7 days each in a diary. For each subject, changes in daily means of insulin dose and carbohydrate (CHO) intake between the two phases were calculated. Rescue CHO for prevention or treatment of hypoglycaemic events were identified, and based on current glucose values a patient-specific rescue CHO intake threshold was determined.
Results: Diaries for both study phases were available from 96% of the participants (70 CGM group, 65 control group). These subjects were representative for the whole HypoDE population regarding demographic data and occurrence of hypoglycaemic events. CGM group subjects showed a larger reduction of hypoglycaemic events (−1.4 ± 2.3 events per 7 days, $p > 0.001$) from baseline to follow-up phase than subjects in the control group. Based on the subjects' records in their diaries, no changes in insulin doses (total daily dose CGM group: 0.6 ± 0.3 U/kg/day to 0.6 ± 0.4 U/kg/day, control group: 0.6 ± 0.2 U/kg/day to 0.6 ± 0.2 U/kg/day), nor insulin distribution were observed in any of the two study groups. However, CGM subjects, but not control subjects, reported a moderate increase in their blood glucose target value from 120 ± 16 mg/dl to 126 ± 20 mg/dl ($p = 0.015$). In addition, they reported an increased injection meal interval (from 10–11 min to 13–15 min). There was no significant change in daily CHO intake, but CGM group subjects reported more frequent CHO intake during nights of the follow-up phase (from 0.2 ± 0.2 to 0.3 ± 0.3 meals/night, $p = 0.001$). Considering only rescue CHO, a more frequent intake among subjects in the CGM group was observed (from 0.8 ± 0.6 to 1.0 ± 0.8 intakes/day vs. 1.1 ± 0.8 to 0.9 ± 0.8, $p = 0.008$), especially during the night. However, as CGM group subjects reduced the average size of single rescue CHO intakes, only a small difference in total daily rescue CHO amount was observed. The mean rescue CHO intake threshold determined for the CGM group was raised from 71 ± 13 to 79 ± 14 mg/dl ($p < 0.001$) whereas it remained unchanged in the control group.
Conclusion: Participants of the HypoDE study were able to reduce the occurrence of hypoglycaemic events by usage of rtCGM without major changes to their insulin therapy. Instead, they were more active in preventing hypoglycaemia by consuming rescue CHO more often and earlier.

To compare the effectiveness of intravenous variable rate insulin compared to fixed rate weight based insulin infusion on the resolution of diabetic ketoacidosis

Y. Yap, T. Molyneux, C. Gadd, V. Stewart, S. Hammersley;
Department of Endocrine and Diabetes, Leighton Hospital, Crewe, UK.

Background and aims: The latest 2013 Joint British Diabetes Societies Inpatient Care Group guidance (JBDS) has recommended a weight-based fixed rate insulin (FRIII) approach for the treatment of Diabetic ketoacidosis (DKA) as opposed to the variable rate insulin infusion (VRIII) published in 2010. The current evidence for this change is limited. The aim of this study is to review the real world effects on how this change in the rate of insulin delivery affects the time to resolution of DKA and its secondary impact on the length of inpatient stay (LOS).
Materials and methods: A retrospective case note analysis was conducted on patients admitted with DKA treated with a VRIII over 6 months from August 2016 to February 2017. Following implementation of a FRIII protocol a second 6 month period was studied from July 2017 to January 2018. Data gathered included patient demographics, HbA1c, admission blood pH and capillary blood glucose and level of care required. We measured time to resolution of DKA, number of hypoglycaemic episodes on treatment, length of inpatient stay, total time of insulin treatment and time from resolution to insulin cessation.
Results: Baseline demographics for VRIII versus FRIII were: number of patients 21:20 with a male to female ratio of 8:13 and 9:11 respectively. The mean age was 42:45 years old with an average HbA1c of 100:91mmol/mol respectively. The mean pH was 7.14:7.01, mean serum bicarbonate of 11.45:12mmol/L and mean capillary blood glucose 29:28mmol/l respectively. In the VRIII cohort 3 patients required critical care admission versus none in the FRIII group. There were 6 hypoglycaemia episodes on VRIII and 4 episodes on FRIII. There were 3 patients (1 in VRIII and 2 in the FRIII group) that had an extended LOS unrelated to DKA therefore the median value was taken as the measure of LOS. This was 5.5 days in the VRIII group compared with 3 days in the FRIII group.
Conclusion: In conclusion, the FRIII in combination with a treatment protocol achieved a significantly reduced length of time to initiation of treatment (intravenous insulin and intravenous fluids) and improved time to resolution of DKA. Total time on insulin was reduced. Importantly there were less hypoglycaemic episodes and reduced LOS. Our real world data supports the use of FRIII in line with guidelines from JBDS.

Smartphone triggered diabetes self-management education and support in insulin treated type 2 diabetes patients: results of the randomised TRIGGER study

A. Boels[1], R.C. Vos[1], L.-T. Dijkhorst-Oei[2,3], G.E.H. Rutten[1];

[1]University Medical Center Utrecht, Utrecht, [2]Meander Medical Center, Amersfoort, [3]VU University Medical Center, Amsterdam, Netherlands.

Background and aims: Innovative and cost-effective interventions to promote diabetes self-management education and support (DSME/S) are needed. We evaluated the (cost-)effectiveness of DSME/S delivered via a smartphone application in individuals with type 2 diabetes mellitus (T2DM) on insulin therapy.
Materials and methods: We conducted a non-blinded two-arm multicentre randomised clinical superiority trial with parallel-groups and equal randomisation (1:1). In total, 5 hospitals and 66 general practices in the Netherlands included 230 individuals with T2DM aged 40–70 years, on insulin therapy since ≥3 months, with HbA1c >53 mmol/mol (>7%). The intervention group received unidirectional messages with DSME/S on dietary habits, physical activity, hypoglycaemia prevention and glucose variability. Messages were sent at different times of the day, 2 or 6 times per week for 6 to 9 months. Participants could choose their preferred topics, frequency and the duration of the intervention. The control group received usual care. The primary study endpoint was the HbA1c level after 6 months follow-up. Secondary endpoints were body mass index, waist circumference, blood pressure, insulin dose, lipid profile, self-management (assessed with Summary of Diabetes Self-Care Activities), health status (assessed with EQ-5D), diabetes-dependent quality of life (assessed with Audit of Diabetes Dependent Quality of Life), and diabetes treatment satisfaction (assessed with Diabetes Treatment Satisfaction Questionnaire). Here we present the results of the complete case analyses of the first 150 participants who completed the study. At the EASD conference we will be in the position to present the final results of all 230 participants. We used the intention-to-treat principle and general linear models, adjusted for baseline value, baseline insulin dose, age, sex, and duration of diabetes to analyse the data.
Results: There were no differences in baseline characteristics between the control and intervention group: mean age was 58.6 years (intervention group) versus 59.8 years (control group), and the baseline HbA1c was 64.7 mmol/mol (intervention group) versus 66.5 mmol/mol (control group). After 6 months of follow-up, the mean HbA1c in the intervention group was 61.7 mmol/mol (95% CI 58.9–64.5), compared to 65.7 mmol/mol (95% confidence interval (CI) 62.9–68.6) in the control group, $p = 0.051$ ($n = 150$). After adjustment, the mean HbA1c levels became 63.1 mmol/mol (95% CI 61.0–65.2) in the intervention group, versus 64.9 mmol/mol (95% CI 62.8–67.0) in the control group, $p = 0.230$ ($n = 139$). After 6 months, the mean number of days on which participants performed foot care was higher in the control group, adjusted: 1.3 days (95% CI 0.9–1.7) in the intervention group versus 1.9 days (1.5–2.3) in the control group, $p = 0.027$ ($n = 125$). There were no statistically significant effects on other secondary outcomes.
Conclusion: The preliminary results of this trial, which is one of the larger ones in this field worldwide, show modestly promising, yet inconclusive results on the effectiveness of smartphone triggered diabetes self-management education and support in insulin treated T2DM patients. Analyses of all cases will provide final evidence on its effectiveness.

Baseline nocturnal glucose change as a predictor of treatment effect of bolus intensification in insulin-treated type 2 diabetes

K. Salvesen-Sykes[1], A.L. Peters[2], M. Piletic[3], J. Snyder[1], K. Bowering[4]; [1]Novo Nordisk Inc., Plainsboro, USA, [2]Keck School of Medicine of the University of Southern California, Los Angeles, USA, [3]General Hospital, Novo Mesto, Slovenia, [4]Division of Endocrinology and Metabolism, University of Alberta, Edmonton, Canada.

Background and aims: onset 3 (a phase 3, 18-week, randomised controlled trial) demonstrated that fast-acting insulin aspart (faster aspart) in a basal-bolus therapy (BBT) was superior in reducing HbA_{1c} and controlling postprandial glucose (PPG) excursions compared with basal-only therapy (BOT) in type 2 diabetes (T2D). This *post hoc* analysis of onset 3 explored the utility of PPG increments, nocturnal change (NC) and HbA_{1c} for predicting response to bolus insulin intensification.
Materials and methods: Analyses were performed on 236 randomised subjects receiving metformin: 116 received faster aspart BBT; 120 received BOT. Subjects were grouped according to three baseline parameters: HbA_{1c}, PPG increments (calculated as the difference between self-measured plasma glucose 2-h post-meal and pre-meal recorded in a 7-point profile over 3 days), and NC (calculated as the mean of two measurements of the difference between the bedtime glucose measurement and the fasting glucose measurement taken the following morning). Analyses were performed on the end-of-trial treatment differences (BBT versus BOT) between 'high' and 'low' baseline values of each parameter, defined as being above or below the median value at baseline (HbA_{1c}, 7.8% [61.7 mmol/mol]; PPG increment, 2.42 mmol/L [43.6 mg/dL]; NC, 3.11 mmol/L [56 mg/dL]).
Results: At baseline, there was a positive correlation between PPG increment and NC ($r = 0.66$). The changes in mean HbA_{1c} and mean PPG increment at end-of-trial were consistently in favour of faster aspart across all subgroups, and there were significantly larger treatment differences in subjects with high (versus low) baseline NC and PPG increment values (Table). This was not the case for baseline HbA_{1c}, which showed significantly larger treatment differences for change in end-of-trial PPG increments but not for change in end-of-trial HbA_{1c}. There were no significant differences in the treatment rate ratios of severe or blood glucose-confirmed hypoglycaemia between high subgroups or between low subgroups. Those in the high baseline PPG increment and NC subgroups had higher absolute rates of hypoglycaemia.
Conclusion: Within the limitations of a *post hoc* analysis, these data suggest that both mean PPG increment and NC may be useful for identifying subgroups of patients with T2D that would more likely benefit from bolus intensification; NC may perform as well as mean PPG increment while being easier to measure.

Table. Change in HbA_{1c} and mean PPG increment from baseline to end-of-trial stratified by HbA_{1c}, PPG increment, and nocturnal change at baseline.

Baseline value		Δ HbA_{1c}

Achievement of individual HbA_{1c} targets with self- vs physician-led titration of newly or recently initiated basal insulin in type 2 diabetes: DUNE real-world study results

L. Berard[1], D. Mauricio[2], K. Khunti[3], D.R. Franco[4], J. Westerbacka[5], C. Candelas[6], V. Pilorget[6], R. Perfetti[7], L. Meneghini[8];
[1]Winnipeg Regional Health Authority Health Sciences Centre, Winnipeg, Canada, [2]Hospital de la Santa Creu i Sant Pau, Barcelona, Spain, [3]Diabetes Research Centre, University of Leicester, Leicester, UK, [4]CPClin Clinical Research Center, São Paulo, Brazil, [5]Sanofi, Paris, France, [6]Sanofi, Chilly-Mazarin, France, [7]Sanofi, Bridgewater, USA, [8]University of Texas Southwestern Medical Center and Parkland Health & Hospital System, Dallas, USA.

Background and aims: The Diabetes Unmet Need with basal insulin Evaluation (DUNE) study aimed to assess the impact of symptomatic hypoglycaemia on individualised HbA_{1c} target achievement. In this analysis, the achievement of individualised HbA_{1c} targets at 12 weeks with self- vs physician-led insulin titration was evaluated.
Materials and methods: DUNE was a 12-week, prospective, observational study of 3139 adults with type 2 diabetes (T2DM), newly (at enrolment) or recently (<12 months) initiated on basal insulin (BI).
Results: Irrespective of titration method, the proportion of participants who achieved their individualised HbA_{1c} target at week 12 was <30% in both the newly and recently initiated BI groups (**Table**). For both titration groups, there were comparable improvements in fasting plasma glucose from baseline and similar incidence of hypoglycaemia. Increase in mean total daily BI dose for self- vs physician-led titration in the recently initiated BI group was 4.85 vs 4.91 U, respectively, while in newly initiated individuals it was 9.68 vs 7.77 U, respectively. Most participants who were self-titrating did so every 1–3 days, compared with no more frequently than every week for most participants who had physician-led titration. In all groups, the most frequently utilised dose increment was 2 U.
Conclusion: The inability of most participants to achieve their target HbA_{1c} in a real-world scenario, irrespective of the method of titration, warrants further investigation.

Table. Comparison of physician-led and self-titration in participants newly (at enrolment) or recently (<12 months) initiated on basal insulin

	Newly initiated (N=1716)[a]		Recently initiated (N=1423)[b]

Improved efficacy with self- vs physician-led titration of insulin glargine 300 or 100 U/ml in type 2 diabetes: comparison of TAKE CONTROL, AT.LANTUS and ATLAS

M. Davies[1], E. Boelle-Le Corfec[2], M. Bonnemaire[2], M. Odawara[3], L. Popescu[4], J. Sieber[5], D. Russell-Jones[6], K. Strojek[7], N. Tentolouris[8];
[1]Diabetes Research Centre, University of Leicester, University Hospitals of Leicester NHS Trust, Leicester, Leicestershire, UK, [2]Sanofi, Paris, France, [3]Tokyo Medical University, Tokyo, Japan, [4]Global R&D Operations, Sanofi, Bucharest, Romania, [5]Sanofi, Frankfurt, Germany, [6]Department of Diabetes and Endocrinology, Royal Surrey County Hospital, Guildford, UK, [7]Department of Internal Diseases, Diabetology and Cardiometabolic Diseases SMDZ, Zabrze, Silesian Medical University, Katowice, Poland, [8]First Department of Internal Medicine, Medical School, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece.

Background and aims: Empowering individuals to self-titrate their basal insulin may help to reduce rates of sub-optimal titration often observed in clinical practice and help more people achieve HbA_{1c} goals. This analysis examined clinical outcomes with insulin glargine 300 U/mL (Gla-300) or 100 U/mL (Gla-100) following self- or physician-led titration.
Materials and methods: Results from the recently completed TAKE CONTROL study, which evaluated self-titration and physician-led titration of Gla-300 in people with T2DM, were compared with similar studies (AT.LANTUS and ATLAS) of Gla-100. All 3 studies were 24-week, multicentre, randomized, open-label, parallel-group studies.
Results: Fasting blood glucose targets were 4.4–7.2 mmol/L (80–130 mg/dL) in TAKE CONTROL, ≤5.5 mmol/L (≤100 mg/dL) in AT.LANTUS and ≤6.1 mmol/L (≤110 mg/dL) in ATLAS. Mean baseline HbA_{1c} was between 8.4 and 8.9% (**Table**). Self-titration statistically significantly lowered mean HbA_{1c} by 0.97 to 1.40% versus physician-led titration (0.84 to 1.25%; $p < 0.05$ for all 3 studies). The incidence of severe hypoglycaemia and other safety outcomes was similar between titration arms in all 3 studies (**Table**). Both Gla-300 and Gla-100 were effective in improving glycaemic control.
Conclusion: Self-titration with Gla-300 resulted in significantly improved glycaemic control versus physician-led titration, as demonstrated previously with Gla-100, without increased hypoglycaemia.

Table. Comparison of self-titration and physician-led titration with Gla-300 and Gla-100

Daytime and nocturnal glucose checking and hypoglycaemia patterns from real-world flash continuous glucose monitoring use

Y. Xu[1], H. Pryor[2], E. Budiman[1], T. Dunn[1];
[1]Abbott Diabetes Care, Alameda, USA, [2]Abbott Diabetes Care, Witney, UK.

Background and aims: Previous analyses of real-world data have shown that frequent use of flash continuous glucose monitoring (FreeStyle Libre™) is associated with lower average glucose level and shorter time in hypoglycaemia. We studied the patterns of checking glucose during the day and night and time in hypoglycaemia.
Materials and methods: Users scan the sensor with the reader to collect current glucose, glucose trend, and up to 8 hours of glucose readings, which are automatically stored every 15 minutes. When the readers are connected to the desktop software using an internet ready PC, de-identified 90-day reader data is uploaded to a database. De-identified data from September 2014 to September 2017 of all sensors with at least 120 hours of operation were analysed from 202,179 readers and 1.4 million sensors worldwide (84% from Europe). Scan rate per reader was determined and two sets of twenty equally sized rank-ordered groups, categorised by day and night scan frequencies, were evaluated. Time in significant hypoglycaemia (≤3.0 mmol/L [54 mg/dL]) and number of scans during the day (06:00–23:00) and during the night (23:00–06:00) were calculated.
Results: The median (IQR) night time and day time hourly checking rates are 0.22 (0.13, 0.35) and 0.61 (0.40, 0.92), respectively. Higher rates of glucose checking at night time are associated with shorter night time hypoglycaemia duration (15.3 to 9.6 minutes or 3.6% to 2.3% of time per night, p value <0.001) and lower estimated A1c (eA1c) (62 to 54 mmol/mol [7.8% to 7.1%], p value <0.001). Higher rates of glucose checking during the day are associated with lower eA1c (68 to 51 mmol/mol [8.4% to 6.8%], p value <0.001) and shorter daytime hypoglycaemia duration (19.1 to 11.7 minutes or 1.9% to 1.1% of time per day, p value <0.001) when average eA1c level is lower than 62 mmol/mol (7.8%).
Conclusion: Increased glucose testing at night time is associated with decreased eA1c level and lower night time hypoglycaemia duration. Increased glucose testing at daytime is associated with decreased eA1c level. Daytime hypoglycaemia duration reduction does not occur until eA1c level drops below 62 mmol/mol (7.8%), possibly due to glucose reduction being the priority for those with eA1clevel higher than 62 mmol/mol (7.8%).

Use of supportive tools and education enables self-titration with insulin glargine 300 or 100 U/ml in type 2 diabetes: results from TAKE CONTROL, INNOVATE and AUTOMATIX

M. Bonnemaire[1], M. Kvapil[2], H. Goyeau[3], N. Papanas[4], L. Popescu[5], B. Schultes[6], J. Sieber[7], L. Smircic Duvnjak[8];
[1]Global Diabetes Division, Sanofi, Paris, France, [2]Department of Internal Medicine, Second Faculty of Medicine, Charles University, Prague, Czech Republic, [3]Sanofi, Chilly-Mazarin, France, [4]Diabetes Centre, Second Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis, Greece, [5]Global R&D Operations, Sanofi, Bucharest, Romania, [6]eSwiss Medical & Surgical Center, Department of Internal Medicine, Endocrinology, Diabetes, & Metabolism, St. Gallen, Switzerland, [7]Global Diabetes Division, Sanofi, Frankfurt, Germany, [8]University Clinic for Diabetes, Endocrinology and Metabolic Diseases, Vuk Vrhovac, School of Medicine, University of Zagreb, Zagreb, Croatia.

Background and aims: Supporting people with T2DM with education and titration tools may empower them to optimize basal insulin self-titration in order to reach glycaemic targets. This analysis aimed to examine the impact of titration tools and education to support individuals to self-titrate insulin glargine 300 U/mL (Gla-300) or 100 U/mL (Gla-100).
Materials and methods: Three multicentre, randomized, open-label, parallel-group studies have investigated self-titration (supported by either a paper algorithm, web tool or device) vs physician-led titration in people with T2DM, switching to or initiating Gla-300 (TAKE CONTROL and AUTOMATIX) or Gla-100 (INNOVATE). Fasting blood glucose targets for self-titration were 4.4–7.2 mmol/L (80–130 mg/dL) in TAKE CONTROL and 5.0–7.2 mmol/L (90–130 mg/dL) in both INNOVATE and AUTOMATIX.
Results: Self-titration resulted in greater or similar mean HbA_{1c} reductions from baseline vs physician-led titration (**Table**). By using self-titration with Gla-300, more people with T2DM achieved fasting glucose targets without confirmed or severe hypoglycaemia vs physician-led titration (TAKE CONTROL and AUTOMATIX). Severe hypoglycaemia and other safety outcomes were similar between titration arms in all 3 studies.
Conclusion: Self-titration with Gla-300 and Gla-100 using either a paper or device-based algorithm resulted in improved or similar reductions in HbA_{1c}, without an increased risk of hypoglycaemia or safety concerns.

Table. Comparison of self-titration and physician-led titration with Gla-300 and Gla-100

PS 070 Clinical outcomes in insulin treated patients

828

The relationship between urinary albumin excretion, cardiovascular outcomes and total mortality among large cohort of insulin-treated patients with type 2 diabetes

R. Donnelly, U. Anyanwagu, I. Idris;
Royal Derby Hospital Centre, University of Nottingham, Derby, UK.

Background and aims: Albuminuria is a recognised diagnostic and prognostic marker of chronic kidney disease (CKD) and cardiovascular (CV) risk but the precise relationship between increments in urinary albumin-creatinine ratio (ACR) and CV outcomes and mortality among insulin treated patients with Type 2 Diabetes (T2D) in routine clinical care is unclear.

Materials and methods: We investigated data for insulin users with T2D from UK general practices between 2007 and 2014. Urinary ACR at the time of insulin initiation was measured and categorised as: <10 mg/g; 10 to 29 mg/g; 30 to 300 mg/g; and >300 mg/g. Patients were followed up for 5 years or the earliest occurrence of all-cause mortality, non-fatal myocardial infarction (MI) or stroke. Cox proportional hazard models were fitted to estimate the risk of a composite of these events.

Results: A total of 12,725 patients with T2DM (mean age: 58.6 ± 13.8 years, mean HbA1c: 8.7 ± 1.8) initiating insulin therapy between 2007 and 2014 met the inclusion criteria. The adjusted risk of a 3-point composite of all-cause mortality, non-fatal MI and stroke is shown in Figure 1. Compared to patients whose ACR levels at insulin initiation were below 10 mg/g, the adjusted risk of the 3-point composite endpoint was 7%, 30% and 93% higher in those with ACR levels between 10–29 mg/g; 30–300 mg/g and >300 mg/g, respectively, after a follow up period of 5 years. ACR category on its own did not predict risk of all-cause mortality.

Conclusion: This study shows that in patients with T2D on insulin therapy increased urinary ACR is independently associated with an increased risk of major adverse CV events and all-cause mortality.

The association between insulin initiation and adverse outcomes after hospital discharge: a population-based cohort study

L.L. Lipscombe[1,2], Z. Lysy[1,2], H.D. Fischer[3], K. Fung[3], V. Giannakeas[2,3], C.M. Bell[4];
[1]Medicine, University of Toronto, Toronto, [2]Medicine, Women's College Hospital, Toronto, [3]Institute for Clinical Evaluative Sciences, Toronto, [4]Medicine, Sinai Health System, Toronto, Canada.

Background and aims: Transitional care after discharge from a hospitalization may be inadequate for older patients with diabetes, particularly for those started on insulin therapy in hospital. These patients may thus be at increased risk for serious adverse events after discharge. The aims of this study were to quantify the incidence of death and return to hospital after discharge for older hospitalized patients prescribed anti-hyperglycemic agents, and to compare risk of these adverse events between patients prescribed new insulin therapy versus oral hypoglycemic agents (OHAs).

Materials and methods: This retrospective population-based cohort study in Ontario, Canada included persons aged 66 and over discharged from a hospitalization between April 1st 2004 and November 30th 2013, and dispensed a prescription for insulin and/or an OHA within 7 days of discharge.Prescriptions were categorized as new insulin (no insulin before admission), prevalent insulin (prescribed insulin before admission and at discharge), new OHA(s) (no OHA or insulin before admission), and prevalent OHA [prescribed OHA(s) before admission and at discharge] as the referent category. The primary and secondary outcomes were deaths and a return to hospital (emergency visits or hospital admissions) respectively within 30 days of discharge.

Results: Of 104,525 patients, 9.2% were initiated on insulin, 4.1% died and 26.2% had a return to hospital within 30 days. Deaths occurred in 7.14% of new insulin users, 4.86% of prevalent insulin users, 3.25% of new OHA users, and 3.45% of prevalent OHA users. Rates of return to hospital were 28.1% among new insulin users, 29.8% among prevalent insulin users, 25.1% among new OHA users, and 25.0% among prevalent OHA users. After adjustment for covariates, new insulin users had a significantly higher 30-day risk of death (adjusted hazard ratio, aHR 1.52, 95% confidence interval, CI 1.39 to 1.67) and return to hospital (aHR 1.16, 95% CI 1.11 to 1.21) than prevalent OHA users. Findings were similar for hospital visits for hypo/hyperglycemia (see Table).

Conclusion: Older hospitalized patients discharged on new insulin therapy have a high rate of death and return to hospital after discharge, and their risk is significantly higher than prevalent OHA-treated patients. These findings highlight a need for better discharge planning and transitional care for hospitalized patients treated with insulin. Further inquiry should determine appropriate interventions to reduce adverse outcomes after insulin initiation in older hospitalized patients, so that the benefits of effective diabetes management while in hospital are maintained when patients leave the hospital.

Durability of improved patient-reported outcomes in type 2 diabetes patients treated with dapagliflozin plus saxagliptin vs insulin glargine

M.A. Testa[1], J.F. Hayes[2], M. Lind[3], T. Vilsbøll[4], S. Jabbour[5], E. Ekholm[6], E. Johnsson[6], D.C. Simonson[7];
[1]Harvard T. H. Chan School of Public Health, Boston, USA, [2]Phase V Technologies, Wellesley Hills, USA, [3]University of Gothenburg, Gothenburg, Sweden, [4]Steno Diabetes Center, Copenhagen, Denmark, [5]Thomas Jefferson University, Philadelphia, USA, [6]AstraZeneca, Mölndal, Sweden, [7]Endocrinology, Brigham and Women's Hospital, Boston, USA.

Background and aims: Consensus statements on the management of type 2 diabetes (T2D) now recommend personalizing treatment decisions by considering patient-centered behavioral, psychological and emotional factors. We previously reported that T2D patients inadequately controlled on metformin reported more favorable patient-reported outcomes (PRO) with dapagliflozin plus saxagliptin add-on therapy (DAPA+SAXA, $n = 324$) versus insulin glargine add-on therapy (INS, $n = 319$) after 24 weeks during an international, randomized, non-inferiority trial. To evaluate the durability of these effects, we analyzed data through 52 weeks of treatment.
Materials and methods: A1C, weight, and PRO questionnaires were obtained at baseline and weeks 12, 24 and 52. Linear mixed models and correlation analyses were used for testing per protocol 52-week completers not requiring rescue medication (addition of insulin or other glucose-lowering agent) and all completers. Treatment satisfaction included 71 questions measuring overall satisfaction, with subscales of efficacy, flexibility, side effects, convenience, burden, preference, social, general satisfaction, pain, hassle, and interference. Quality-of-life (QOL) measures included 165 items with scales in the physical, mental, social, cognitive, symptoms, weight concern and interference, body image, sexual and functional health domains.
Results: Baseline data were: 54.0% male; 80.4% white; 60.7% working ≥3 days/week; age 55.5 ± 9.6 years; A1C 9.0 ± 1.0%; BMI 32.2 ± 5.3 kg/m^2; diabetes duration 9.4 ± 6.3 years. Satisfaction scales, weight concern and perceived health favored DAPA+SAXA at both weeks 24 and 52 (see Table). Body image and anxiety favored DAPA+SAXA more at week 52 as weight loss and concern continued to improve for DAPA+SAXA. Actual weight loss at 52-weeks was associated with improvements in weight concern ($p < 0.001$) and body image ($p < 0.001$). Greater weight concern and weight-related symptom interference were also associated with decreases in QOL and satisfaction scales ($p < 0.05$ to $p < 0.001$).
Conclusion: At 52 weeks, compared to INS, DAPA+SAXA had better QOL and satisfaction outcomes due to improved perceived health, less weight concern and anxiety, improved body image and greater regimen acceptance. The treatment differences at week 24 were sustained through week 52 providing confirmatory evidence that differential treatment impact on satisfaction and QOL may persist without attenuation due to adaptation or coping. Treatment choices should address both the short and long-term psychological and behavioral effects of diabetes treatment regimens.

Effects of dulaglutide vs glargine in patients with different baseline glycaemic patterns (high/low fasting or high/low postprandial glucose): AWARD-2 post hoc analysis

F. Giorgino[1], M. Yu[2], A. Haupt[2], Z. Milicevic[2], L.-E. García-Pérez[2];
[1]University of Bari Aldo Moro, Bari, Italy, [2]Eli Lilly and Company, Indianapolis, USA.

Background and aims: Insulin glargine exerts its action primarily through a decrease in fasting plasma glucose (FPG), whereas dulaglutide, a once weekly glucagon-like peptide-1 receptor agonist, targets both FPG and postprandial glucose (PPG). This post hoc analysis of the AWARD-2 study assessed the efficacy of dulaglutide vs glargine in patients with type 2 diabetes with different glycaemic patterns at baseline (BL) determined by self-monitoring of blood glucose (fasting glucose [FG] vs PPG).
Materials and methods: Patients were categorized into 4 groups based on combinations of low and high FG and PPG, with median BL values of FG (8.38 mmol/L) and PPG (10.10 mmol/L) used as thresholds for low and high, respectively. Analyses were conducted using analysis of covariance.
Results: Dulaglutide showed a statistically significantly greater reduction in HbA_{1c} vs glargine for all subgroups, except for low FG/high PPG where the numerical difference favoured dulaglutide, but did not reach statistical significance (Table). Total hypoglycaemia was consistently lower for dulaglutide vs glargine in all subgroups.
Conclusion: Dulaglutide showed efficacy on HbA_{1c} reductions across different BL glycaemic patterns vs glargine, indicating a clinical benefit of targeting both FG and PPG, regardless of BL glycaemic phenotype.

Exploring clinical outcomes in diverse populations with uncontrolled type 2 diabetes switching to insulin Gla-300: first-stage analysis of the pooled European Gla-300 studies (REALI)

N. Freemantle[1], P. Gourdy[2], D. Mauricio[3], D. Müller-Wieland[4], R.C. Bonadonna[5], L. Pedrazzini[6], G. Bigot[7], C. Mauquoi[8], M. Bonnemaire[6];
[1]University College London, London, UK, [2]Toulouse University Hospital, Toulouse, France, [3]Hospital de la Santa Creu i Sant Pau, Barcelona, Spain, [4]University Hospital Aachen, Aachen, Germany, [5]University of Parma and AOU of Parma, Parma, Italy, [6]Global

Diabetes, Sanofi, Paris, France, [7]IVIDATA, Paris, France, [8]IDDI, Louvain-la-Neuve, Belgium.

Background and aims: The REALI project is a large database aimed to collect data from over 10,000 people with type 2 and type 1 diabetes mellitus (T2DM, T1DM) uncontrolled with antidiabetic therapy and switched to/initiated on insulin glargine 300 U/ml (Gla-300), providing a pre-defined common core data set from different European Gla-300 studies with diverse objectives and inclusion criteria. We used this platform to perform proof-of-concept analysis on the first three completed, available, interventional and observational studies to evaluate robustness and diversity of Gla-300 efficacy in insulin-naïve and insulin-pre-treated patients.

Materials and methods: The three studies investigated efficacy and safety of Gla-300: Take Control ($N = 631$) was a 24-week interventional, randomised 1:1, 2-arm, controlled study investigating patient- versus physician-managed titration of Gla-300; BOT PLUS Neo ($N = 1523$) and TOP-II ($N = 1216$) were 12-month prospective non-interventional single-arm studies. This first analysis of pooled data examined baseline characteristics, 24-week efficacy endpoints of glucose control, severe hypoglycaemia and body weight in insulin-naïve and insulin-pre-treated T2DM subpopulations using a statistical descriptive and generalised model-based approach.

Results: (Table 1.) Overall, 92.8% of patients across all studies received different insulin regimens before switch to Gla-300 and 7.2% of patients from only Take Control were insulin-naïve. Patient demographics and baseline characteristics are shown. Measurements were performed from baseline to week 24 following Gla-300 initiation. HbA_{1c} LS mean change estimate was −1.5% (95% CI −1.6 to −1.4) in insulin-naïve patients, with 37.3% being at HbA_{1c} target (<7% [53 mmol/mol]). HbA_{1c} LS mean change estimate was −0.5% (95% CI −0.6 to −0.50) in insulin-pre-treated patients, with 20.1% at HbA_{1c} target. Mean (SD) change in basal insulin daily dose was 14.00 (16.2) U/day with mean (SD) body weight gain of 1.2 (2.5) kg for insulin-naïve patients, and 5.7 (14.2) U/day and loss of 0.03 (4.5) kg for insulin-pre-treated patients. Severe hypoglycaemic events were rare.

Conclusion: Switching to/starting on Gla-300 achieved improved glycaemic control and was associated with modest weight change among insulin-naïve patients and prior insulin-treated patients. This first analysis indicates that pooling of diverse populations with uncontrolled T2DM is a powerful approach to investigate the effectiveness of Gla-300 and potentially to predict different clinical outcomes in patient subpopulations.

Table 1. Description of baseline clinical characteristics and outcomes in insulin-naïve and insulin-pre-treated patients over the 24-week treatment with Gla-300 period.

Lower pharmacokinetic and pharmacodynamic within-day variability of individual clinical doses of insulin glargine 300 U/ml vs glargine 100 U/ml in type 1 diabetes

C.G. Fanelli, P. Lucidi, P. Candeloro, P. Cioli, A. Marinelli Andreoli, G.B. Bolli, F. Porcellati;
University of Perugia, Perugia, Italy.

Background and aims: Previous studies have examined variability of pharmacokinetics (PK, plasma insulin concentration) and pharmacodynamics (PD, glucose infusion rate, GIR) of basal insulins at steady-state (SS) and at fixed doses in all subjects studied. To establish within-day PK/PD variability of individual, different, doses of insulin Glargine 300 U/ml (Gla-300) vs Glargine 100 U/ml (Gla-100) that people with T1DM use in real life.

Materials and methods: Eighteen T1DMs [age 40 ± 11 years, diabetes duration 26 ± 12 years, BMI 23.4 ± 2.1 kg/m^2, A1C 7.2 ± 0.5% (55 ± 6 mmol/mol)] were studied after 3 month treatment with Gla-300 and Gla-100 titrated to fasting euglycemia, with a 24 h euglycemic clamp (randomized, crossover). The individual basal insulin doses that subjects used (0.35 ± 0.08 Gla-300, 0.28 ± 0.07 Gla-100, U/kg) were injected s.c. in the clamp study.

Results: Prior to clamp, glycemic control was comparable with Gla-300 and Gla-100. In the clamp, the individual doses of Gla-300 and Gla-100 resulted in 24 h PK/PD bioequivalence, but in lower variability indices of PK/PD with Gla-300 vs Gla-100 (Table).

Conclusion: At clinical, individual doses used by T1DMs in real life, Gla-300 has lower PK/PD within-day variability vs Gla-100. These results may explain the lower glycemic variability and lower risk for hypoglycaemia reported in clinical studies with Gla-300 vs Gla-100.

Pharmacokinetic and pharmacodynamic variables after subcutaneous injection of individual doses of insulin Gla-300 and insulin Gla-100 in subjects with type 1 diabetes in steady state.

Long-acting insulin analogues versus human isophane insulin for type 2 diabetes: update of a Cochrane review

J. Engler[1], K. Horvath[2,2], T. Semlitsch[2], K. Jeitler[3,2], A. Berghold[3], A. Siebenhofer[2,1];
[1]Institute for General Practice, Goethe University, Frankfurt, Germany, [2]Institute of General Practice and Evidence-Based Health Services Research, Medical University of Graz, Graz, Austria, [3]Institute for Medical Informatics, Statistics and Documentation, Medical University of Graz, Graz, Austria.

Background and aims: In persons with type 2 diabetes mellitus (T2DM) insulin treatment is frequently performed by administering basal insulin.

Common adverse effects are hypoglycaemia and weight gain, which can be responsible for difficulties in achieving lower HbA1c. Long-acting insulin-analogues have been developed to minimise side effects and allowing for better blood glucose control. To assess the effects of long-term treatment with long-acting insulin analogues compared to human isophane insulin (NPH insulin) in adult persons with T2DM.

Materials and methods: Systematic review of randomized controlled trials lasting 24 weeks or longer.

Results: We identified 16 studies comparing insulin glargine and 8 studies comparing insulin detemir to NPH insulin. All trials had an unclear or high risk of bias for several Domains. Treatment with insulin glargine compared to NPH insulin treatment showed an OR for severe hypoglycaemia of 0.65 (95% CI 0.48 to 0.87); $p = 0.004$; 14 trials; very low quality evidence. The OR for serious hypoglycaemia (severe event fulfilling at least one criterion for a serious adverse event) was 0.73 (95% CI 0.50 to 1.07); $p = 0.11$; 10 trials; low quality evidence. Treatment with glargine reduced the incidence of confirmed and confirmed nocturnal hypoglycaemia. Differences in the mean change of HbA1c were not statistically significant; very low quality of evidence. Treatment with insulin detemir compared to NPH insulin showed an OR for severe hypoglycaemia of 0.37 (95% CI 0.15 to 0.92); $P = 0.03$; 5 trials; very low-quality evidence. The OR for serious hypoglycaemia was 0.16 (95% CI 0.04 to 0.61); $P = 0.007$; 5 trials; very low-quality evidence. Treatment with detemir also reduced the incidence of confirmed and confirmed nocturnal hypoglycaemia. Differences in the mean change of HbA1c were not statistically significant; very low quality of evidence. Information on diabetes-related complications or health-related quality of life was insufficient in almost all trials. For those outcomes for which some data were available, no meaningful differences were found. The incidence of adverse events was comparable for persons treated with glargine, or detemir, and persons treated with NPH.

Conclusion: Treatment with insulin glargine or insulin detemir resulted in fewer participants experiencing severe, overall and nocturnal hypoglycaemia. The effects on HbA1c were comparable. Low-quality evidence and trial designs that did not conform with current clinical practice meant it remains unclear if the same effects will be observed in daily clinical practice.

Insulin degludec/insulin aspart (IDegAsp) twice daily (BID) vs biphasic insulin aspart 30 (BIAsp 30) BID: a randomised trial in Chinese patients with type 2 diabetes

J. Ma[1], W. Yang[2], T. Hong[3], M. Liu[4], H. Miao[5], Y. Peng[6], C. Wang[7], X. Xu[8], T. Yang[9], W. Liu[10], A. Moeller Nielsen[11], L. Pan[10], Z. Weigang[12]; [1]Nanjing First Hospital, Nanjing, China, [2]China-Japan Friendship Hospital, Beijing, China, [3]Peking University Third Hospital, Beijing, China, [4]Tianjin Medical University General Hospital, Tianjin, China, [5]Nanjing Medical School, 2nd Affiliated Hospital, Nanjing, China, [6]Shanghai First People's Hospital, Shanghai, China, [7]First Affiliated Hospital of Anhui Medical University, Hefei City, China, [8]Fuzhou General Hospital of Nanjing Military Command, Nanjing, China, [9]The First Affiliated Hospital of Nanjing Medical University, Nanjing, China, [10]Novo Nordisk, Beijing, China, [11]Novo Nordisk, Søborg, Denmark, [12]Peking Union Medical College Hospital, Beijing, China.

Background and aims: IDegAsp is the first coformulation of long-acting basal (degludec) and bolus (IAsp) insulin with no need for re-suspension. This 26-week, phase 3, open-label, treat-to-target, 2:1, randomised trial assessed the efficacy and safety of IDegAsp BID vs. BIAsp 30 BID ±metformin in Chinese adults ($N = 541$) with type 2 diabetes inadequately controlled on pre-/self-mix or basal insulin ±metformin.

Materials and methods: Hierarchical testing was used with non-inferiority of HbA_{1c} change from baseline to Week 26 as the primary endpoint and superiority for secondary endpoints.

Results: Non-inferiority of HbA_{1c} change from baseline to Week 26 and statistical superiority of IDegAsp BID vs. BIAsp 30 BID for change in fasting plasma glucose, nocturnal (00:01–05:59 hours inclusive) confirmed hypoglycaemic and confirmed hypoglycaemic episodes (severe or plasma glucose <56 mg/dL with or without symptoms) was confirmed (Table). Significantly more patients reached HbA_{1c} <7% without confirmed hypoglycaemia with IDegAsp BID vs. BIAsp 30 BID by Week 26. Daily insulin dose (U/kg [SD]) was lower in patients receiving IDegAsp BID vs. BIAsp 30 BID at Week 26 (0.78 [0.35] vs. 0.95 [0.35]). No new safety signals were identified.

Conclusion: These results demonstrate the efficacy and safety of IDegAsp in Chinese patients with type 2 diabetes, confirming results from other international trials comparing the two treatment modalities.

Similar glycaemic control and less nocturnal hypoglycaemia with intensification of IDegAsp QD or BID vs glargine U100 QD + IAsp 1-3 in adults with type 2 diabetes

Y. Gupta[1], K. Astamirova[2], E. Fita[3], T. Demir[4], A. Haggag[5], D. Roula[6], B.A. Bak[3], A. Møller Nielsen[3], A. Tsimikas[7];
[1]All India Institute Of Medical Science, Delhi, India, [2]Saint-Petersburg Territorial Diabetic Centre, Saint-Petersburg, Russian Federation, [3]Novo Nordisk A/S, Søborg, Denmark, [4]Dokuz Eylül Üniversity, İzmir, Turkey, [5]Anaheim Clinical Trials, Anaheim, USA, [6]Salah Boubnider University, Constantine, Algeria, [7]Scripps Whittier Diabetes Institute, San Diego, USA.

Background and aims: If intensification of basal insulin is needed, addition of bolus or fixed ratio insulin therapies are recommended treatment options. No head-to-head trials compare IDegAsp once daily (QD) with a "basal plus" insulin regimen, or intensification of IDegAsp QD to twice daily (BID). This study aimed to compare: 1) IDegAsp QD vs insulin glargine 100 units/mL (glargine U100) QD + insulin aspart (IAsp) QD after 26 weeks (w); 2) optional stepwise intensification (26–38 w) of IDegAsp QD/BID vs. glargine U100 + IAsp QD/BD/TID.
Materials and methods: A 38-week, randomised, open-label, treat-to-target trial in adults with type 2 diabetes (T2D), treated with basal insulin ±oral anti-diabetes drugs (OADs) in need of intensification (HbA_{1c} 7–10%). Patients could be intensified (at physician discretion + patient consent) at w 26 + 32 if HbA_{1c} off target (≥7%) in previous week. Randomisation: 1:1 to IDegAsp (w 0–26: IDegAsp QD with largest meal; w 27–38: IDegAsp QD/BID with largest meals), or glargine U100 + IAsp (w 0–26: glargine U100 QD + IAsp QD with largest meal; w 27–38: glargine U100 QD + IAsp QD/BID/TID at main meals). Both groups: ±OADs throughout. Self-measured plasma glucose titration targets: IDegAsp and glargine U100, 4–5 mmol/L; IAsp, 4–6 mmol/L. Hypoglycaemia evaluation included severe (ADA defined) or blood glucose-confirmed (<3.1 mmol/L) symptomatic episodes. Primary endpoint: change HbA_{1c} (%; w 0–26), non-inferiority margin: 0.4%.
Results: Across treatment groups, baseline characteristics and safety profiles 0–38 w were comparable. For w 0–26 + 0–38 data, see Table. Both groups had similar change in HbA_{1c} (%; w 0–26) (mean [SD]: IDegAsp QD, −1.1 [0.9]; glargine U100 QD + IAsp QD, −1.1 [0.8]) and the estimated treatment difference: 0.07% (95% CI −0.06; 0.21) confirmed non-inferiority. After 38 w, changes in HbA_{1c} remained similar. Achievement of HbA_{1c} <7%, mean FPG and mean post-prandial increments were similar across groups at w 26 and 38. At week 38, more patients achieved HbA_{1c} <7% without hypoglycaemic episodes on-treatment with IDegAsp (22.5%) vs glargine U100 + IAsp (21.1%). The hypoglycaemia profile favoured IDegAsp, driven by significantly fewer nocturnal (occurring 00.01–05.59) episodes.
Conclusion: IDegAsp QD and BID are simple, effective treatment intensification options in T2D compared with basal plus or full basal bolus therapy, achieving similar glycaemic control, with fewer nocturnal hypoglycaemia episodes, lower insulin dose and fewer injections.

Effects of IDegLira (insulin degludec/liraglutide) in patients with poorly controlled type 2 diabetes with HbA_{1c} >9%: analyses from the DUAL programme

S. Bain[1], J. Frias[2], D. Gouet[3], R. Takács[4], T. Jia[5], P. Örsy[5], D. Sugimoto[6];
[1]Swansea University, Swansea, UK, [2]National Research Institute, Los Angeles, USA, [3]La Rochelle Hospital, La Rochelle, France, [4]University of Szeged, Szeged, Hungary, [5]Novo Nordisk A/S, Søborg, Denmark, [6]Cedar Crosse Research Center, Chicago, USA.

Background and aims: Despite a variety of treatment options for type 2 diabetes (T2D), more than half of patients do not achieve glycaemic control.
Materials and methods: In a *post hoc* analysis of the DUAL I (oral antidiabetic drugs [OADs]), II, V and VII (basal insulin + OADs) trials, we evaluated patients with an HbA_{1c} >9% at baseline to determine the impact of IDegLira on their glycaemic control. The definition of hypoglycaemia was: unable to self-treat and/or plasma glucose [PG] <3.1 mmol/L (DUAL I, II and V); unable to self-treat or PG <3.1 mmol/L with hypoglycaemia symptoms (DUAL VII).
Results: Within each DUAL trial, baseline characteristics for patients with HbA_{1c} >9% were similar for all treatment groups. In DUAL I, II and V, treatment with IDegLira resulted in greater reductions in HbA_{1c} from baseline, versus comparators of basal insulin or liraglutide, leading to lower HbA_{1c} at end of trial (EOT). In DUAL VII, reduction in HbA_{1c} from baseline and HbA_{1c} at EOT were comparable for IDegLira and

insulin glargine U100 (100 U/mL) + insulin aspart (≤4 times/day). At EOT, the composite endpoint of HbA_{1c} <7% without hypoglycaemia was achieved by a greater proportion of patients treated with IDegLira than with comparators.

Conclusion: Even in patients with T2D with HbA_{1c} >9%, IDegLira treatment achieved glycaemic control with a high proportion of patients achieving HbA_{1c} <7% and clinically important composite endpoints of HbA_{1c} <7% without hypoglycaemia and/or weight gain.

Change in HbA_{1c}, HbA_{1c} at EOT and % patients achieving composite endpoints at EOT for patient group with baseline HbA_{1c} >9% from DUAL I, II, V and VII

Lower day-to-day fasting self-measured plasma glucose (SMPG) variability with insulin degludec/liraglutide (IDegLira) vs insulin glargine 100 units/ml (IGlar U100)

E. Jaeckel[1], A. Doshi[2], P. Garcia-Hernandez[3], J.F. Merino Torres[4], M. Rodacki[5], S. Eggert[6], R. Grøn[6], I. Lingvay[7];
[1]Hannover Medical School, Hannover, Germany, [2]PrimeCare Medical Group, Houston, USA, [3]Hospital Universitario Dr José Eleuterio González, Monterrey, Mexico, [4]University Hospital La Fe, Valencia, Spain, [5]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [6]Novo Nordisk A/S, Søborg, Denmark, [7]UT Southwestern Medical Center, Dallas, USA.

Background and aims: Diabetes therapy aims for stable glycaemic control and minimal hypoglycaemia risk, which has previously been linked to day-to-day variability. In a *post-hoc* analysis, day-to-day fasting glycaemic variability with IDegLira was compared with IGlar U100, in DUAL V (IDegLira vs. IGlar U100) and VII (IDegLira vs IGlar U100 and bolus insulin aspart).

Materials and methods: Daily fasting SMPG values were used to calculate a weekly measure of day-to-day fasting glycaemic variability measurement for each patient by calculating the variance of the daily log-transformed SMPG value. These weekly variances were analysed on log-scale. Based on the weekly variances we calculated an overall variability measure and divided the population into tertiles indicating (high, low, medium) variability. Overall day-to-day variability group (High, Medium, Low) was analysed in multinomial model using a cumulative logit link function. The model included treatment as a fixed factor. Hypoglycaemia was defined as subject unable to treat themselves and/or have a recorded PG <3.1 mmol/L, in DUAL VII the subjects also had to have symptoms consistent with hypoglycaemia. Odds ratios were based on modelling the probability of being in a lower variability group.

Results: Proportional odds were statistically significant favouring IDegLira (Table). More subjects treated with IDegLira had lower overall day-to-day fasting glucose variability vs. IGlar 100 (Table). Hypoglycaemia rates were reduced with lower variability with IDegLira vs. comparators in all tertiles (Table). In DUAL V (IDegLira vs IGlar U100) and DUAL VII (IDegLira vs IGlar U100 plus bolus insulin aspart) respectively, statistical analysis of weekly variances showed a 32% ($p < 0.0001$) and 23% ($p = 0.001$) lower day-to-day fasting glycaemic variability.

Conclusion: Based on fasting SMPG values, there was lower day-to-day variability with IDegLira, possibly contributing to the lower hypoglycaemia rate, compared with IGlar U100 in DUAL V and VII.

Table: Patients grouped according to tertiles of overall day-to-day SMPG variability by treatment

Patient-reported outcomes for insulin degludec/liraglutide vs insulin glargine as add-on to sodium-glucose co-transporter-2 inhibitor in type 2 diabetes: DUAL IX trial

M. Brod[1], L. Billings[2], R. Busch[3], S. Harris[4], C. Morales Portillo[5], R. Sahay[6], A. Busk[7], S. Eggert[7], N. Halladin[7], A. Philis-Tsimikas[8];
[1]The Brod Group, Mill Valley, USA, [2]NorthShore University HealthSystem, Evanston, USA, [3]Albany Medical Center, New York, USA, [4]Western University, London, Canada, [5]Hospital Virgen Macarena, Seville, Spain, [6]Osmania Medical College, Hyderabad, India, [7]Novo Nordisk A/S, Søborg, Denmark, [8]Scripps Whittier Diabetes Institute, San Diego, USA.

Background and aims: In DUAL IX, a 26-week, phase 3b, treat-to-target, open-label trial, patients with uncontrolled type 2 diabetes on sodium-glucose co-transporter-2 inhibitor ± oral antidiabetic drugs (N = 420) were randomised 1:1 to once-daily insulin degludec/liraglutide (IDegLira) or insulin glargine 100 units/mL (IGlar U100) add-on therapy. IDegLira was superior to IGlar U100 for HbA_{1c} (1.9 vs 1.7% reduction), body weight (0.0 vs 2.0 kg gain) and hypoglycaemia rate (58% lower with IDegLira).
Materials and methods: Patient-reported outcomes were measured at baseline and week 26 with the 5-domain Treatment Related Impact Measure - Diabetes (TRIM-D) questionnaire, with higher scores indicating better outcomes.
Results: After 26 weeks, improvements were significantly greater with IDegLira vs IGlar U100 in total TRIM-D, treatment burden domain and especially the diabetes management domain (Table), including 4 of the 5 individual items (estimated treatment ratio [95% CI]): help you control your diabetes: 2.17 [1.47; 3.21], $p < 0.0001$; help you avoid hyperglycaemia: 1.95 [1.32; 2.87], $p = 0.0007$; help you avoid hypoglycaemia: 1.62 [1.12; 2.36], $p = 0.0105$; help you manage your weight: 2.44 [1.69; 3.52], $p < 0.0001$; help you prevent feeling tired/lack of energy: 1.36 [0.95; 1.96], $p = 0.0945$.
Conclusion: Treatment with IDegLira vs IGlar U100 resulted in better clinical and treatment management outcomes.

Table: Change from baseline to week 26 in TRIM-D domain scores – DUAL IX trial

	Baseline score[1] (SD)		Change (SD) from baseline at week 26		ETD [95% CI]	*p*-value

Patients with type 2 diabetes on the maximum dose of insulin degludec/liraglutide (IDegLira) achieve glycaemic target: analyses from the DUAL programme

L. Meneghini[1], S. Linjawi[2], P. Serusclat[3], T. Vilsbøll[4], B.F. Agner[5], T. Hansen[5], L.A. Leiter[6];
[1]UT Southwestern Medical Center, Dallas, USA, [2]Coffs Diabetes and Endocrine Centre, Coffs Harbour, Australia, [3]Clinique Portes du Sud, Vénissieux, France, [4]Gentofte Hospital, Hellerup, Denmark, [5]Novo Nordisk A/S, Søborg, Denmark, [6]University of Toronto, Toronto, Canada.

Background and aims: The efficacy and safety of IDegLira has been established in the DUAL clinical development programme.
Materials and methods: This *post hoc* analysis evaluated glycaemic control in the subgroup of patients titrated to the maximum approved IDegLira dose of 50 dose steps/units (U) (50 U insulin degludec +1.8 mg liraglutide), from trials that evaluated IDegLira versus other comparators (DUAL I-V and VII). For DUAL I-V, missing data were imputed using last observation carried forward.
Results: In all DUAL trials, baseline HbA_{1c} was similar between IDegLira and comparator arms. In DUAL I-V, regardless of end-of-trial (EOT) doses (50 or <50 U), more patients on IDegLira achieved the American Diabetes Association target of HbA_{1c} <7% versus monotherapy of basal insulin, glucagon-like peptide-1 receptor agonist, or placebo comparators (Figure). In DUAL VII, compared with basal-bolus insulin therapy (insulin glargine 100 U/mL + insulin aspart ≤4 times daily [mean total daily insulin dose of 84 U at EOT]), the percentage of patients achieving an HbA_{1c} <7% was greater for patients on <50 U of IDegLira and lower for patients at 50 U of IDegLira at EOT. For patients at 50 U and <50 U of IDegLira, the mean change in HbA_{1c} at EOT was numerically greater than or similar to comparators for all trials.
Conclusion: A high proportion of patients receiving the maximum approved dose of IDegLira are able to achieve good glycaemic control.

IDegLira improves glycaemic control in subjects with type 2 diabetes uncontrolled on basal insulin without deterioration despite discontinuing pre-trial sulphonylurea

A. Janez[1], R. Silver[2], T. Vilsbøll[3], R. Grøn[4], N. Halladin[4], P. Őrsy[4], S. Harris[5];
[1]University Medical Center Ljubljana, Ljubljana, Slovenia, [2]Southern New Hampshire Medical Center, Nashua, USA, [3]Steno Diabetes Center, University of Copenhagen, Copenhagen, Denmark, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Western University, London, Canada.

Background and aims: As combining sulphonylurea (SU) and insulin can elevate the risk of hypoglycaemia, prescribers often reduce SU dose or stop SUs altogether when initiating insulin. This can lead to a deterioration of glycaemic control. The DUAL II trial compared the efficacy and safety of insulin degludec/liraglutide fixed-ratio combination (IDegLira) versus insulin degludec (degludec), (starting doses 16 U, max doses 50 U), both plus metformin (met), in subjects with poor

glycaemic control previously treated with met ± SU/glinides and basal insulin (20–40 U). This sub-group analysis compared clinical findings in subjects discontinuing SU (pre-trial SU users) to those not taking SU pre-trial (non-SU users).

Materials and methods: Change from baseline in HbA_{1c}, fasting plasma glucose (FPG) and body weight, and end of trial (EOT) insulin dose after 26 weeks of treatment were analysed with an analysis of covariance (ANCOVA) model with region, pre-trial use of SU at screening, randomised treatment and interaction between pre-trial use of SU and randomised treatment as fixed factors, and baseline value as covariate (and baseline HbA_{1c} for insulin dose). Treatment-emergent confirmed hypoglycaemia was analysed using a negative binomial regression model with a log link and the logarithm of the time period in which a hypoglycaemic episode is considered treatment emergent as offset and the same fixed effects as the ANCOVA model. Missing data were imputed using last observation carried forward.

Results: IDegLira resulted in greater reductions in HbA_{1c}, FPG and body weight from baseline and lower rates of hypoglycaemia (Table) compared with degludec in both pre-trial SU users and non-SU users. Minor differences were seen in EOT insulin doses. Treatment effect was consistent between the two groups, with no statistically significant interaction between randomised treatment and SU use for all endpoints. As insulin dose was reduced at randomisation from a mean of 27–32 U to 16 U and pre-trial SU stopped, a non-clinically relevant increase in mean self-measured fasting plasma glucose (SMPG) was seen in weeks 0–3 in both arms in the pre-trial SU users. This had returned to baseline by week 4, with a general decrease continuing until the EOT. Mean SMPG decreased from week 0 until EOT with IDegLira in the non-SU users group.

Conclusion: In subjects who reduced their insulin dose and discontinued SU at IDegLira initiation, no clinically relevant deterioration in glycaemic control was seen. For all endpoints analysed, regardless of SU use pre-trial, IDegLira showed better results in all metabolic parameters versus degludec (both with a max dose of 50 U). The clinical findings were consistent between pre-trial SU users and non-SU users.

Simplification of complex insulin regimens with preserving good glycaemic control in type 2 diabetes

Z. Taybani[1], B. Botyik[1], M. Katkó[2];
[1]1. Department of Endocrinology, Békés County Central Hospital, Dr. Rethy Pal Member Hospital, Bekescsaba, [2]Division of Endocrinology, University of Debrecen, Faculty of Internal Medicine, Debrecen, Hungary.

Background and aims: Type 2 diabetic patients presenting with severe hyperglycemia are often put on multiple daily insulin injections (MDI). If glucose toxicity resolves, the regimen may potentially be simplified, but there are no specific guidelines regarding this and a lot of patients are left on MDI. We aimed to examine prospectively the safety and efficacy of switching from MDI to once daily IDegLira, a fixed-ratio combination of insulin degludec and liraglutide, in relatively well controlled (HbA1c <7.5%) subjects with type 2 diabetes using low total daily insulin dose (TDD).

Materials and methods: 48 adults with type 2 diabetes (mean ± SD: age 65 ± 8.6 years, HbA1c 6.48 ± 0.65%, BMI 32.28 ± 6.77 kg/m^2, body weight 90.25 ± 18.83 kg, TDD 40.9 ± 11.1 units, duration of diabetes 12.3 ± 8.1 years) treated with MDI ± metformin were enrolled in our study. Previous insulins were stopped and once daily IDegLira was started. IDegLira was titrated every 3 days with 2 dose steps (each dose steps contains 1 unit of insulin degludec and 0.036 mg of liraglutide) by the patients to achieve a self-measured pre-breakfast plasma glucose contrentration of <6 mmol/l.

Results: After 95.8 days of average follow-up HbA1c, body weight and BMI decreased significantly. Mean HbA1c changed by −0.25% to 6.23 ± 0.61% ($p < 0.001$), body weight changed by −2.63 kg to 87.62 ± 17.78 kg ($p < 0.001$), and BMI changed to 31.34 ± 6.38 kg/m^2 ($p < 0.001$). At the end of the follow-up mean dose of IDegLira was 20.1 dose steps. IDegLira±metformin combination therapy was safe and generally well tolerated. During the month before baseline visit 26 patients (54%), while during the follow-up only 5 (10.4%) patients had at least one documented (self-measured plasma glucose <3.9 mmol/L) or symptomatic hypoglycemia.

Conclusion: In everyday clinical practice switching from low dose MDI to IDegLira in patients with well-controlled type 2 diabetes is safe, may induce weight loss and result in similar or better glycemic control. Simplifying complex treatment regimens may improve adherence and quality of life.

[1]Calibra Medical, Wayne, USA, [2]International Diabetes Center, Park Nicollet, Minneapolis, USA, [3]Medstar Health Research Institute, Hyattsville, USA, [4]AMCR Institute Inc., Escondido, USA, [5]Rainier Clinical Research Center, Renton, USA, [6]National Research Institute, Los Angeles, USA, [7]Diabetes Research Institute, San Mateo, USA, [8]Henry Ford Health System, Detroit, MI, USA, [9]East Lancashire Hospitals NHS Trust, Blackburn, UK, [10]Dallas Diabetes Research Center at Medical City, Dallas, USA, [11]Groupe Hospitalier Mutualiste Les Portes du Sud, Vénissieux, France, [12]SUNY Upstate Medical University, Syracuse, USA, [13]Loyola University Maryland, Baltimore, USA.

Background and aims: This multi-center randomized, controlled trial compared efficacy, safety, and User- /Health Care Provider-reported outcomes for adults with type 2 diabetes (HbA_{1c}: 7.5–11% [58–97 mmol/mol]) on basal insulin initiating mealtime insulin (aspart) with a wearable bolus insulin delivery patch (Patch, $n = 139$) vs an insulin pen (Pen, $n = 139$). Patch was applied at least every 3 days and delivered subcutaneous bolus insulin in 2-U increments per manual click.
Materials and methods: Study duration was 48 weeks with cross-over at Week 44; 88% of Patch Users and 86% of Pen Users completed Week 24 assessments; 77% and 76%, respectively, completed Week 48 assessments. Treating Health Care Providers ($n = 89$) rated their experience with Patch at Week 24.
Results: Change in HbA_{1c} from baseline to Week 24 (primary endpoint) was significant ($p < 0.0001$) in both groups (least squares mean change ± SEM: Patch, $-1.7 \pm 0.1\%$ [-19 ± 1.0 mmol/mol] vs Pen, $-1.6 \pm 0.1\%$ [-17 ± 1.0 mmol/mol]). Change in User satisfaction (measured by the Insulin Delivery System Rating Questionnaire) at Week 24 favored Patch over Pen for all measures; comparisons for convenience and overall satisfaction were significant ($p < 0.01$). Change in User quality of life (measured by the Diabetes-Specific Quality of Life Survey) at Week 24 favored Patch over Pen for 6 of 7 measures; comparisons for daily functions and diet restrictions were significant ($p < 0.05$). Comparisons of User experience ratings at Week 24 favored Patch over Pen for all 11 items; 7 of those showed a significant difference (Table). A User preference survey (Week 48) indicated a significant preference for Patch over Pen in those who used Patch for 44 weeks and those who crossed over to Patch for 4 weeks ($p < 0.0001$); 69% in Patch group wanted to switch from Pen to Patch or had no preference (10%). Health Care Provider questionnaire ratings in favor of Patch at Week 24 ranged from 67% to 85% ($p < 0.0001$). Additionally, 74% rated training for Patch use as "easy" and 89% reported that it took ≤30 minutes; 91% of Health Care Providers preferred Patch over Pen for initiating mealtime insulin ($p < 0.0001$).
Conclusion: The Patch is a viable alternative to Pen for mealtime insulin; both Users and Health Care Providers preferred patch to pen.

User experience survey, week 24 % favorable	Patch (*n*=123) % (95% CI)	Pen (*n*=109) % (95% CI)	Odds Ratio (95% CI)	*p* value (patch vs pen)
Dosed without attracting attention	93.5 (89.8, 97.2)	68.8 (61.5, 76.1)	6.5 (2.9, 14.8)	*p*<0.0001
Taking meal time insulin was painless	90.2 (85.8, 94.6)	70.4 (63.1, 77.6)	3.9 (1.9, 8.0)	*p*=0.0002
Could do things on the spur of the moment	87.0 (82.0, 92.0)	66.7 (59.2, 74.1)	3.3 (1.7, 6.5)	*p*=0.0003
Always had meal time insulin with me	91.2 (86.8, 95.5)	72.5 (65.3, 79.8)	3.9 (1.8, 8.5)	*p*=0.0006
Felt comfortable using it socially	89.3 (84.7, 93.9)	71.0 (63.8, 78.2)	3.4 (1.7, 7.0)	*p*=0.0007
Taking mealtime insulin was easy	92.7 (88.8, 96.5)	78.0 (71.5, 84.5)	3.6 (1.6, 8.1)	*p*=0.002
Recommend for meal time insulin	91.0 (86.7, 95.2)	78.9 (72.5, 85.3)	2.7 (1.2, 5.8)	*p*=0.01
Better relationship with my HCP	74.6 (68.1, 81.1)	66.1 (58.6, 73.5)	1.5 (0.9, 2.7)	*p*=0.16
Confident that dosed correctly	91.9 (87.8, 95.9)	89.9 (85.2, 94.7)	1.3 (0.5, 3.1)	*p*=0.60
Engaged with managing my diabetes	90.1 (85.6, 94.6)	88.9 (83.9, 93.9)	1.1 (0.5, 2.6)	*p*=0.77
Made improvements to my diabetes	87.0 (82.0, 92.0)	86.2 (80.8, 91.7)	1.1 (0.5, 2.3)	*p*=0.87

Fast improvement of glycaemic control during transition of young adults with type 1 diabetes

A. Maurizi, S. Pieralice, R. Del Toro, D. Tuccinardi, A. Lauria Pantano, C. Guglielmi, E. Maddaloni, E. Fioriti, S. Manfrini, P. Pozzilli;
University Campus Bio-Medico, Rome, Italy.

Background and aims: Transition from paediatric to adult diabetes clinics for type 1 diabetes (T1D) patients represents a critical phase often characterized by worsening effects on diabetes outcomes (attendance visit, metabolic control and diabetes related complications). Aim of this study was to evaluate metabolic control of 122 T1D patients [82/40 M/F, mean (SD), age 25.1 ± 5.7 years, disease duration 17.2 ± 8.1 years, HbA1c $7.9\% \pm 1.4$] at time of transition from paediatric clinics to our adult diabetes center.
Materials and methods: At baseline, 102 patients were on multiple daily insulin injections (MDI) and 20 subjects on continuous subcutaneous insulin infusion (CSII). The transition process was performed in a specific "transition clinic" according to the protocol of the Consensus Statement of the American Academy of Paediatrics, American Diabetes Association, Academy of Family Physicians and the American College of Physicians.
Results: Results after 3 and 6 months follow-up showed a significant improvement in metabolic control with reduction of HbA1c in the whole population [Δ HbA1c 0–3 months: −0.3% ($p < 0.05$), Δ HbA1c 0–6 months: −0.5% ($p < 0.02$)] as well as in the different age groups [15–20, 21–30 ($p < 0.05$, $p < 0.001$, respectively)]. At baseline females showed a worst metabolic control compared to male patients (HbA1c: $8.3\% \pm 1.5$ vs. $7.6\% \pm 1.1$, $p = 0.005$) and this result was confirmed at the end of the study period (HbA1c: $7.9\% \pm 1.0$ vs. $7.1\% \pm 0.8$, $p < 0.001$). After 6 months since transition 27% of patients were on CSII compared to 16% of patients in the pre-transfer period, however improvement of metabolic control was independent of CSII use.
Conclusion: In conclusion, our data showed that transition from paediatric to an adult diabetes center promotes a very fast reduction of HbA1c

detectable after 3 months of follow-up only. This unexpected improvement is likely due not only to increased use of technology but to an appropriate clinical setting for emerging adults as recommended by some scientific societies.
Disclosure: **A. Maurizi:** None.

Impairment of cognitive function in newly diagnosed type 2 diabetes, but not in type 1 diabetes

T. van Gemert[1,2], W. Woelwer[3], K.S. Weber[1,4], A. Hoyer[4,5], K. Strassburger[4,5], N.T. Bohnau[1,4], M.A. Brueggen[1,4], K. Ovelgoenne[1,4], E.-M. Goessmann[1,4], V. Burkart[1,4], J. Szendroedi[1,2], M. Roden[1,2], K. Muessig[1,2], GDS Group;
[1]Institute for Clinical Diabetology, German Diabetes Center at Heinrich Heine University, Leibniz Institute for Diabetes Research, Duesseldorf, [2]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Duesseldorf, [3]Department of Psychiatry and Psychotherapy, Medical Faculty, Heinrich Heine University, Duesseldorf, [4]German Center for Diabetes Research (DZD), München-Neuherberg, [5]Institute for Biometrics and Epidemiology, German Diabetes Center at Heinrich Heine University, Leibniz Institute for Diabetes Research, Duesseldorf, Germany.

Background and aims: Diabetes associates with higher risk of cognitive decline and dementia. We hypothesized that cognitive function is already impaired during the early course of diabetes.
Materials and methods: A cross-sectional analysis within the German Diabetes Study included patients within the first year after diagnosis of type 1 (n [%male] = 82[57], age 35 ± 10 years, body mass index (BMI) 25.3 ± 3.8 kg/m²) or type 2 diabetes (n = 119[64], 52 ± 9 years, 32.0 ± 5.7 kg/m²), metabolically healthy persons (n = 42[83], 49 ± 12 years, 29.0 ± 6.1 kg/m²) as well as individuals five years after study inclusion with type 1 (n = 45[60], 41 ± 13 years, 25.1 ± 3.0 kg/m²) or type 2 diabetes (n = 65[63], 59 ± 10 years, 32.1 ± 5.5 kg/m²). They all underwent comprehensive metabolic phenotyping and testing of different domains of cognitive function. Cognition test outcomes were compared between groups using linear regression models with age, sex and crystallized intelligence as independent variables. Furthermore, within the groups, associations between cognitive function and age, sex, BMI, insulin sensitivity, high-sensitivity C-reactive protein, hemoglobin A1c (HbA1c) and crystallized intelligence were analysed using linear regression.
Results: In participants with newly diagnosed diabetes, verbal memory was poorer in patients with type 2 diabetes (ß[mean difference] = −0.49, p = 0.03), but not in patients with type 1 diabetes (β = −0.37, p = 0.16) when compared to healthy persons. Patients with type 2 diabetes examined at five years after diagnosis, also showed lower verbal memory than patients with type 1 diabetes (β = −0.81, p = 0.01). In addition to crystallized intelligence, a higher BMI among individuals with newly diagnosed type 2 and male sex among individuals with newly diagnosed type 1 diabetes were associated with impaired verbal memory (all p < 0.05).
Conclusion: Verbal memory is already impaired within the first year after diagnosis of type 2 diabetes, and associates with higher body mass.

Individuals with stable glucose levels show improved longitudinal glycaemic outcomes: a worldwide observational study

R.A. Ajjan[1], S.R. Jangam[2], Y. Xu[2], G. Hayter[2], T. Dunn[2];
[1]Leeds Institute of Cardiovascular and Metabolic Medicine, University of Leeds, Leeds, UK, [2]Abbott Diabetes Care, Alameda, USA.

Background and aims: Previous analyses of real-world data have shown that testing using flash glucose monitoring (FreeStyle Libre™ system) is associated with improved longitudinal glycemic outcomes amongst individuals at high risk of hyperglycemia or hypoglycemia. Our aim was to understand the relationship between glucose variability (GV) and long-term hypoglycemia using a longitudinal, observational real world study.
Materials and methods: De-identified glucose results were collected from individuals using the Freestyle Libre system and data from 6802 individuals were analyzed. We investigated the effects of testing patterns on GV and analyzed the relationship between hyperglycemia, hypoglycemia and GV in a longitudinal, observational study design. Individuals were divided into groups of high and low GV using coefficient of variation over a period of 6 months (total of 12 sensors). Based on recent consensus, a coefficient of variation of 36% was used as the threshold. Hyperglycemia (time above 240 mg/dL) and hypoglycemia (time at or below 54 mg/dL) were then analyzed during the 6 months of the study. Similar analysis was repeated after including only individuals at high risk of hypoglycemia.
Results: It was observed that increased testing with the system was associated with lower glucose variability. Coefficient of variation decreased from 41.6% to 35.3% (p < 0.001) from the lowest to highest testing frequency groups (4 and 35 scans/day, respectively). It was observed that overall, individuals with low GV spent 81% less time in hypoglycemia across 6 months compared to individuals with high GV (9.37 ± 0.65 and 48.11 ± 1.28 min/day, respectively; p < 0.001). The effect of GV on time spent in hyperglycaemia was also significant, with 38% reduction (1.36 h/day) comparing individuals having low and high GV (2.23 ± 0.09 and 3.59 ± 0.14 h/day, respectively; p < 0.001). Further analysis of individuals at high risk of hypoglycemia showed that those with low GV had, over the study period, more reduction of time spent in hypoglycemia (63%; 69 ± 71 min/day to 26 ± 41 min/day, p < 0.001) compared to those with high GV (23%; 91 ± 65 min/day to 70 ± 72 min/day, p < 0.001).
Conclusion: Increased testing is associated with decreased GV in the real world. High GV shows a strong relationship with hypoglycaemia and hyperglycaemia in a large real world sample population. Low GV is associated with more effective reduction in time spent in hypoglycemia in higher risk individuals.

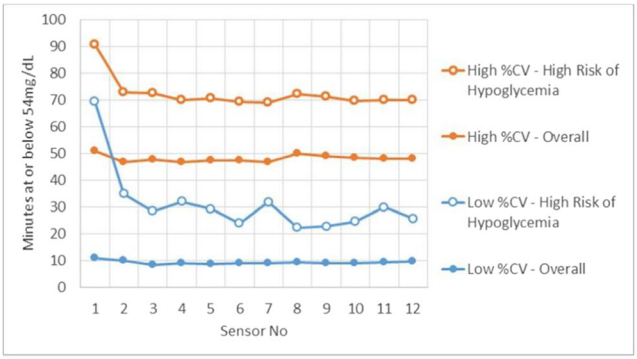

Figure 1. Time spent at or below 54mg/dL over 6 months. The plots show the differences in hypoglycemia outcomes over the long-term in individuals who have high and low variability.

Upper extremity impairments in type 1 diabetes is strongly related to low health related quality of life

K. Gutefeldt[1], C.A. Hedman[1], I.S.M. Thyberg[2], M. Bachrach-Lindström[3], H.J. Arnqvist[4], A. Spångeus[1];

[1]Department of Endocrinology, Department of Medical and Health Sciences, Linköping, [2]Department of Rheumatology, Department of Clinical and Experimental Medicine, Linköping, [3]Division of Nursing Sciences, Department of Medical and Health Sciences, Linköping, [4]Department of Endocrinology, Department of Clinical and Experimental Medicine, Linköping, Sweden.

Background and aims: Upper extremity disability is much more common in patients with diabetes compared to non-diabetic subjects. The aim was to compare health related quality of life (HRQL) in type 1 diabetes (T1DM) with non-diabetic controls and to explore HRQL to presence of upper extremity impairments in T1DM patients.
Materials and methods: In a cross-sectional, population based study patients with T1DM, onset before 35 years of age, duration ≥20 years, <67 years old and matched controls were invited to participate. The participants fulfilled a postal questionnaire including HRQL by the Short Form 36 (SF-36) and study specific questions regarding upper extremity impairments affecting shoulder, hands and fingers. Results are presented as mean ± SD.
Results: A total of 773 patients, age 50 ± 10 years, diabetes duration 35 ± 10 years and 708 controls, age 54 ± 9 years were recruited. Patients reported significantly lower HRQL compared to controls, and the difference was most evident in the subscales general health 59 ± 26 vs 74 ± 22, vitality 55 ± 26 vs 67 ± 24 and bodily pain 64 ± 27 vs 74 ± 25, p value <0.001. Women reported lower HRQL than men in both groups. Patients experiencing shoulder pain and stiffness scored lower in all 8 subscales of SF-36 in comparison with shoulder asymptomatic patients. This was most evident for role physical 55 ± 42 vs 82 ± 31, bodily pain 46 ± 22 vs 75 ± 24, general health 47 ± 24 vs 67 ± 23 and vitality 43 ± 25 vs 63 ± 24, p value <0.001.
Conclusion: T1DM was associated with a lower HRQL compared to non-diabetic controls. Furthermore, in T1DM presence of upper extremity impairments was strongly related to low HRQL. Recognition of upper extremity impairments and their relation to low HRQL are clinically important and early preventive strategies as well as therapeutic and rehabilitative interventions are needed.

Quality of life in diabetes: influence of glycaemic control and other associated psychological variables

M. Carreira[1], M.S. Ruiz de Adana[2,3], M. Domínguez-López[2,3], M.T. Anarte[1];
[1]Department of Personality, Assessment and Psychological Treatment. Instituto de Investigación Biomédica de Málaga (IBIMA), University of Málaga, Malaga, [2]Clinical Management Unit of Endocrinology and Nutrition, Instituto de Investigación Biomédica de Málaga (IBIMA), Regional University Hospital of Málaga, University of Málaga, Malaga, [3]CIBERDEM, Málaga, Spain.

Background and aims: Diabetes has been associated with a poorer quality of life than the general population. In this case, the aim is to evaluate the quality of life in a population with diabetes and its relationship with biomedical and psychological variables depending on the type of diabetes (type 1 and type 2).
Materials and methods: The sample of this study consists of 259 people with type 1 diabetes, 116 people with type 2 diabetes and 182 people from the general population. The biomedical variables were collected in medical consultation (revision). Additionally, a psychological assessment of the following variables was carried out with the indicated instruments: quality of life, evaluated through the Health Questionnaire (SF-12) and the Diabetes Quality of Life (DQOL); depression (Structured Clinical Interview for DSM-IV Axis I Disorders: SCID-1); distress related to diabetes (Diabetic Distress Scale: DDS) and fear of hypoglycemia (Fear of Hypoglycemia Questionnaire: FH-15). To analyze the differences between groups was used the Student's t. Analyzes were performed with the SPSS 15.0 program.
Results: In this study, people with diabetes had worse scores in the Physical SF-12 (PCS) with respect to the general population (p = 0.001). No differences were found in the Mental Scale (MCS) of the SF-12. In addition, people with type 1 diabetes had worse quality of life than people with type 2 diabetes in PCS (p = 0.002) and MCS (p = 0.047) scales. There are also worse results in people with type 1 diabetes on the DQOL scale (p < 0.001). People with diabetes and poor glycemic control (HbA1c >7%) obtained worse scores in the DQOL (type 1: p = 0.026; type 2: p = 0.015). It is observed that the quality of life of people who present complications is worse than in people without complications in both types of diabetes (type 1: p = 0.006, type 2: p = 0.023). Patients with depression and diabetes had worse quality of life (DQOL) than patients without depression and diabetes (type 1: p < 0.001, type 2: p < 0.001). Regarding the fear of hypoglycemia, worse scores were obtained in those people with fear of hypoglycemia (type 1: p < 0.001, type 2: p = 0.007). With respect to distress related to diabetes, people with distress presented worse quality of life (type 1: p < 0.001, type 2: p < 0.001) in both types of diabetes.
Conclusion: In this study, people with diabetes have a poorer quality of life than the general population, with people with type 1 diabetes getting the worst results. On the other hand, it has been found that poor glycemic control and the presence of diabetes complications worsen the quality of life of the person with diabetes in both types, as well as having depression, fear of hypoglycemia or distress related with diabetes. These results highlight the importance of these variables in obtaining an adequate quality of life of the subject with diabetes.

No deterioration in quality of life, treatment satisfaction and wellbeing over 6 years of follow up in people with recently diagnosed type 2 diabetes

H.S. Oldershaw[1], R.A. Oram[1,2], J. Dennis[1], R.C. Andrews[1];
[1]University of Exeter Medical School, Exeter, [2]NIHR Exeter Clinical Research Facility, Exeter, UK.

Background and aims: People living with Type 2 Diabetes (T2DM) report poorer quality of life than those without the disease. It is not clear whether there is a fall in quality of life due to being diagnosed with T2DM or whether this falls over time due to living with the disease. Some studies have shown quality of life declines initially at diagnosis but then returns to its previous level. The American Diabetes Prevention Program (DPP) found quality of life declined over 6 years of follow up. In this study we aimed to assess quality of life, treatment satisfaction and wellbeing in a cohort with recently diagnosed T2DM in the United Kingdom over 6 years.
Materials and methods: The cohort we used were participants enrolled in the Early ACtivity In Diabetes Trial. It was a randomised controlled trial in southwest England in adults aged 30–80 years in whom T2DM had been diagnosed 5–8 months previously. Participants were randomised to a 1 year diet intervention, a 1 year diet and activity intervention, or usual care in a 5:5:2 ratio. At the end of the year participants' care was returned to their general practitioner and they were seen annually for a further 5 years. Patient-reported measures (PRMs) were recorded at 0, 6, 12, 24, 36, 48, 60, 72 months. Health Status was assessed using the EuroQol - 5 Dimensions (EQ-5D) and Brief Illness Perception Questionnaire (BIPQ). Treatment Satisfaction was assessed using the Diabetes Treatment Satisfaction Questionnaire (DTSQ). Self-esteem was assessed using Rosenberg's Self-Esteem Scale (RSES). Life satisfaction was assessed using Diener's Satisfaction with Life Scale (SWLS). We compared scores at baseline and end of follow up and additionally

assessed change in score with a linear mixed effects model with time in years and baseline score as fixed effects and participants as random effects to allow for clustering of results within individuals.

Results: Baseline cohort characteristics were: 64% male, median age 61 years, median time since diagnosis 189 days, mean Hba1c 6.7%, mean BMI 31.7. At baseline 582 of 596 (98%) participants completed all the questionnaires. This fell across the study with 517 (87%) retained at year 1 and 276 (46%) at year 6. Assessing mean (sd) change from baseline score, treatment satisfaction (max score 36) was modestly increased by 0.4 (5.9). Self-esteem (max score 30) and life satisfaction (max score 35) also increased slightly by 0.3 (2.5) and 0.2 (5.5) respectively. Health status declined by −0.05 (0.2) for EQ-5D Index (max score 10) and −1.4 (17.0) for EQ-5D Visual Analogue Scale (VAS) (max score 100). Illness perception (max score 80) was also reduced by −0.4 (7.6). Analysing the change in scores over time there was a very modest decrease in EQ-5D Index (−0.008, $p < 0.001$), EQ-5D VAS (−0.66, $p < 0.001$), BIPQ (−0.23, $p = 0.001$), DTSQ (−0.43, $p < 0.001$), and RSES (0.05, $p = 0.009$). SWLS did not decrease over the study period (−0.03, $p = 0.5$). The trial arm participants were assigned to during the first year did not have an effect on any PRMs.

Conclusion: Quality of life, treatment satisfaction and wellbeing are stable in patients recently diagnosed with T2DM over a 6 year period. Whether people received a diet or diet and activity intervention or usual care made no difference to these measures over the 6 years. Further research is needed to clarify what happens to these measures in the first months after diagnosis.

Patients' and clinicians' preferences on outcomes and medication attributes for type 2 diabetes: a mixed methods study

T. Karagiannis[1], I. Avgerinos[1], M. Toumpalidou[1], G. Dimitriadis[2], A. Bargiota[3], N. Papanas[4], I. Avramidis[1], A. Tentolouris[2], K. Kitsios[1], S. Giannakopoulos[1], S. Alexiadis[1], T. Chatziadamidou[1], A. Liakos[1], K. Malandris[1], A. Tsapas[1,5];
[1]Aristotle University of Thessaloniki, Thessaloniki, Greece, [2]National and Kapodistrian University of Athens, Athens, Greece, [3]University of Thessaly, Larissa, Greece, [4]Democritus University of Thrace, Alexandroupolis, Greece, [5]Harris Manchester College, Oxford, UK.

Background and aims: It is unclear whether clinicians' perceptions are in agreement with patients' preferences regarding outcomes for type 2 diabetes. We conducted a 2-phase mixed methods study to explore both patients' and clinicians' preferences for outcomes and medication attributes for type 2 diabetes.

Materials and methods: We conducted a qualitative study using 6 focus groups (33 patients) and used thematic analysis to identify patient important outcomes. These findings were then used to design a survey, which was administered to 656 patients with type 2 diabetes and 363 clinicians (215 diabetologists, 118 general practitioners and 30 endocrinologists). It included three questions aiming at eliciting preferences about which diabetes-related outcomes and drug attributes are considered most important when choosing among antidiabetic medications. We used descriptive statistics and calculated odds ratios (ORs) to compare patients' preferences with those of clinicians.

Results: When asked to choose 5 among 12 outcomes, the 2 most frequently endorsed outcomes were prevention of diabetic retinopathy (68.6%) and myocardial infarction (66.5%) for patients ($n = 656$), and low incidence of hypoglycaemia (79.9%) and HbA_{1c} reduction (78.5%) for clinicians ($n = 363$). 576 patients and 320 clinicians answered a question about their top choice among the 5 selected outcomes. Patients were significantly more likely than clinicians to rate prevention of diabetic retinopathy (OR 24.17; 95% CI 5.89 to 99.09), amputation (OR 23.8; 95% CI 5.8 to 97.62), stroke, chronic kidney disease and myocardial infarction as the most important outcome, while clinicians were more concerned about prevention of all-cause mortality (OR 0.16; 95% CI 0.11 to 0.22), hypoglycaemic risk (OR 0.38; 95% CI 0.23 to 0.63) and effect on HbA_{1c} (Figure). Regarding specific drug attributes, patients were less concerned than clinicians about drug cost (OR 0.16; 95% CI 0.11 to 0.23) and considered oral (as opposed to injectable) mode of administration (OR 2.56; 95% CI 1.85 to 3.54) and need for less frequent glucose self-monitoring (OR 1.64; 95% CI 1.14 to 2.37) more important.

Conclusion: Patients and clinicians differ in their perceptions of the relative importance of various diabetes-related outcomes, with patients being more concerned on incidence of macrovascular and microvascular endpoints that can directly affect their quality of life. These concerns and preferences should be discussed during the clinical encounter when deciding on an optimal treatment plan for type 2 diabetes.

Figure: Odds Ratios for the most important outcome (patients vs clinicians).

Glycaemia as a risk factor for falls in the hospital population

C. Berra[1], E. Azzolini[1], F. De Fazio[1], M. Mirani[1], G. Favacchio[1], M. Albini[1], F. Folli[2];
[1]Humanitas Research Hospital, Rozzano, [2]Università di Milano, Milano, Italy.

Background and aims: Patient's falls are adverse events in the hospital population, with consequences on worsen prognosis, increased in-patient time and economic costs. Hyperglycemia has been associated with increased morbidity and mortality in hospitalized patients, increased glycemic variability during hospitalization was found to be associated with increased mortality on long-term follow up in non-critically ill patients. Hypoglycemia is associated with increased risk of falls in diabetic patients in outpatients setting. Our aim was to investigate the role of hypoglycemia (glucose <70 mg/dl) or hyperglycemia (glucose >200 mg/dl), or the combination of both, as independent risk factors for falls in a hospitalized population

Materials and methods: A retrospective analysis of patients admitted in Humanitas Research Hospital from January 2015 to December 2016 was performed. All capillary glucose values in fall population and non-fall population were analyzed. Hypoglycemia was defined as value of capillary blood glucose <70 mg/dl during the hospital stay, while hyperglycemia was defined as value of capillary blood glucose more than 200 mg/dl. Fall was defined as an unexpected and unintentional event in which the person came to rest on the ground, floor or lower level. Events were registered in the central network system of the hospital and was available for analysis (EMRS). The obtained data were subjected to multivariate analysis matched for sex, age, admission to hospital (from emergency care or elective) surgical or medical admission and discharge diagnosis

Results: We analyzed medical records of 57411 patients, 759 had a fall during the hospital stay. mean age was 60.7, 52.7% male, 62.4% had medical while 37.6% had surgical discharge diagnosis. 13065 subjects were admitted from emergency room (23.7%). By employing the Charlson index 11.7% had score = 2 while 6.6% scored 1 and 81.7% scored 0. In the group which did not have any capillary glucose measurements ($N = 43627$) there were 374 falls (0.8%). In the group which had at least one capillary glucose measurement ($N = 13410$) there were 385 falls (2.9%) ($p < 0.001$). The presence of one glycemic value out of the range (>200 mg/dl and <70 mg/dl) had an odd ratio for risk of falls of 1.76 (confidence interval 1.42–2.19; $p < 0.001$). Subjects treated with hypoglycemic agents had an odd ratio of 2.97 (confidence interval 2.54–3.49; $p < 0.001$). Insulin treatment (4682 subjects) was more significantly correlated with the risk of falls (odd ratio 3.03; confidence interval 2.53–3.63; $p < 0.001$). After multivariate analysis for sex, age, admission to hospital (from ER/elective) surgical or medical and discharge diagnosis, the presence of at least one glycemic value out of the range confers an odd-ratio for fall of 1.5 (confidence interval between 1.20 and 1.86; $p < 0.001$)

Conclusion: Our data indicate that subjects undergoing capillary blood glucose monitoring falls more than those in which this control is not necessary, independently from diagnosis of diabetes. A strong correlation between hypoglycemia and hyperglycemia with the risk of falling was found. We also found a significant correlation between the number of value lower than 70 mg/dl or over 200 mg/dl in the same subject with the risk for falling, to suggest that also glucose variability could play an important role

Ramachandran's Diabetes Hospitals, Chennai, India, [6]Government of Dubai, Dubai Health Authority, Dubai, United Arab Emirates, [7]Biotechnology Center, Doctoral School of Life Sciences, Health and Environment, and Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon, [8]Endocrinology Research Center, Moscow, Russian Federation, [9]Sanofi, Paris, France, [10]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, The Prince of Wales Hospital, Shatin, Hong Kong SAR, China.

Background and aims: Patient knowledge and self-management are important factors in attaining glycaemic goals. We collected physician-reported data on the achievement of glycaemic control and the challenges that people with diabetes face in achieving glycaemic targets in the developing world.

Materials and methods: The IDMPS is a global observational survey on the management and patterns of care of people with T1D and T2D. Participants were enrolled between 2016 and 2017 in 24 countries across Africa, the Middle East, South Asia and Eurasia.

Results: In people with T1D ($N = 2000$; mean [SD] age 34.0 [12.3] years; 48.8% male), HbA_{1c} levels targeted by physicians were <7% in 45.3% and 7–7.5% in 44.6% of participants. Overall, glycaemic control was poor, with 28.3% of participants attaining their target HbA_{1c} levels and an HbA_{1c}level of <7% (indicative of good control) achieved by only 21.8%. Fear of hypoglycaemia, lack of insulin titration, and cost were the most common reasons given for not attaining glycaemic goals. In people with T2D ($N = 6283$; 57.2 [11.1] years; 47.8% male), 30.1% achieved HbA_{1c} <7%. In those treated with insulin alone or insulin plus oral glucose-lowering drugs (OGLDs), the most common reasons for not attaining glycaemic goals were lack of insulin titration (40.8% and 38.6%, respectively), lack of experience with insulin dosing (40.1% and 34.5%), and lack of education (both 35.0%). The majority (~80%) of insulin users had a glucometer; however, there was a limited number of daily glucose measurements (median 2). In addition, <50% of people with T2D on insulin self-adjusted their dose.

Conclusion: The proportion of people with HbA_{1c} <7% is low. The lack of self-monitoring of blood glucose and of self-adjustment of insulin calls for improved patient education regarding use of glucometers and titration of insulin.

Table. Glycaemic status, insulin management and physician-reported reasons for non-achievement of glycaemic target of people with T1D and T2D

	T1D N=2000*	T2D, OGLD + insulin N=1936	T2D, insulin alone N=660

Socioeconomic inequalities in glycaemic control in people with newly diagnosed type 1 and type 2 diabetes

E. Jacobs[1,2], K. Strassburger[1,2], A. Icks[2,3], O. Kuss[1,2], V. Burkhart[2,4], J. Szendrödi[2,4], K. Müssig[2,4], W. Rathmann[1,2], M. Roden[2,4], and the GDS Group;
[1]Institute for Biometrics and Epidemiology, German Diabetes Center (DDZ), Leibniz Centre for Diabetes Research at Heinrich Heine University Düsseldorf, Düsseldorf, [2]German Center for Diabetes Research (DZD), München-Neuherberg, [3]Institute for Health Service Research and Health Economics, German Diabetes Center (DDZ), Leibniz Centre for Diabetes Research at Heinrich Heine University Düsseldorf, Düsseldorf, [4]Institute for Clinical Diabetology, German Diabetes Center (DDZ), Leibniz Centre for Diabetes Research at Heinrich Heine University Düsseldorf, Düsseldorf, Germany.

Background and aims: There is a lack of studies on the association between socioeconomic status and glycemic control in recently diagnosed diabetes and in people with type 1 diabetes. The aim was to investigate whether low socioeconomic status (SES) is associated with increased HbA1c and fasting blood glucose levels in newly diagnosed type 1 and type 2 diabetes.
Materials and methods: In the prospective German Diabetes Study, people with type 1 ($n = 221$, mean age 36.3 ± 10.6 years) and type 2 diabetes ($n = 469$, mean age 53.0 ± 9.9 years) underwent detailed metabolic characterization within the first year after diagnosis. SES was documented using a standardized German questionnaire (Robert Koch Institute). Associations between SES with HbA1c and fasting blood glucose were assessed using multivariable linear regression analyses. Regression models were fitted using the overall metric SES score (3–21 points) and dichotomized SES Score, in which the SES score was divided in three status groups (low SES: 20%, medium SES: 60% and high SES: 20% of the participants). People in the lowest SES group (<10.8 points) were compared to people in higher SES groups (≥10.8 points). Further independent variables included were age, sex, BMI, smoking status, nationality, diabetes duration, marital status, physical activity, pre-existing conditions (heart, lung, liver), high-sensitivity C-reactive protein, C-peptide secretion (IVGTT), glucose-lowering therapy, antihypertensive and lipid-lowering therapy, process of care indicators (diabetes passport, diabetes education courses, type of health insurance), mental health and diabetes-related emotional distress (SF-36, PAID). All analyses were stratified by diabetes type.
Results: Overall, people with newly diagnosed diabetes had good glycemic control (type 1 diabetes: mean HbA1c 6.7 ± 1.2%, type 2 diabetes: 6.4 ± 0.9%). The multivariate analyses revealed that a higher SES score was inversely associated with lower HbA1c (β-coefficient: −0.113; $p = 0.002$) and with lower fasting blood glucose (β-coefficient: −3.727; $p = 0.011$) in recently diagnosed type 1 diabetes. In the analyses using the dichotomized SES, people with type 1 diabetes and low SES compared to medium and high SES had 1% higher HbA1c (β-coefficient: 0.977; $p = 0.0010$) and 36 mg/dl higher fasting blood glucose (β-coefficient: 35.755; $p = 0.0023$). In type 2 diabetes, no associations of SES with glycemic markers were observed.
Conclusion: The results indicate that socioeconomic inequalities in glycemic control already exist during the first year after manifestation of type 1 diabetes, but not in type 2 diabetes. Whether these inequalities persist after several years and are associated with micro- and macrovascular complications require further investigation in the future.

Global patterns of cardiovascular risk factor control in patients with type 2 diabetes: insights from the global DISCOVER study programme

M.B. Gomes[1], K.K. Patel[2], B. Charbonnel[3], H. Chen[4], J. Cid-Ruzafa[5], P. Fenici[6], N. Hammar[7], L. Ji[8], K.F. Kennedy[2], S. Pocok[9], M.V. Shestakova[10], I. Shimomura[11], H. Watada[12];
[1]State University of Rio de Janeiro, Rio de Janeiro, Brazil, [2]Saint Luke's Mid America Heart Institute, Kansas City, USA, [3]University of Nantes, Nantes, France, [4]AstraZeneca, Gaithersburg, USA, [5]Evidera, Barcelona, Spain, [6]AstraZeneca, Cambridge, UK, [7]AstraZeneca Gothenburg, Mölndal, Sweden, [8]Peking University People's Hospital, Beijing, China, [9]London School of Hygiene and Tropical Medicine, London, UK, [10]Endocrinology Research Center, Diabetes Institute, Moscow, Russian Federation, [11]Osaka University, Osaka, Japan, [12]Juntendo University, Tokyo, Japan.

Background and aims: Guidelines recommend optimal control of cardiovascular (CV) risk factors such as blood pressure (BP), lipids and smoking in addition to glycaemic control to reduce the risk of vascular complications in patients with type 2 diabetes (T2D). However, the extent of CV risk factor control in patients with T2D globally is not well-known. DISCOVER is a 3-year, observational study programme of patients with T2D initiating a second-line glucose-lowering therapy across 38 countries. Here, we assessed the level of CV risk factor control at baseline in patients from 35 countries.
Materials and methods: Optimal CV risk factor management at baseline was defined as control of the following risk factors: 1) Systolic BP <140 mmHg for all patients; 2) statin prescription in patients over 40 years old, high-intensity statin for those with atherosclerotic CV disease (ASCVD); 3) non-smoking status; 4) treatment with angiotensin-converting enzyme inhibitor/angiotensin receptor blocker (ACEi/ARB) in patients with hypertension (HTN)/albuminuria; and 5) secondary ASCVD prevention with low-dose aspirin (ASA) in patients with ASCVD. Global and country specific rates of individual and combined risk factor control were calculated.
Results: For the 15,636 patients included in the analysis, 54.1% were male, mean age was 57.1 (SD = 12.0) years, mean BMI was 29.0 (SD = 5.9) kg/m^2, median duration of T2D was 4.1 (IQR: 1.9–7.9) years. A total of 1779 (11.7%) patients had ASCVD, 7982 (51.1%) had HTN and 582

(4.2%) had albuminuria. Among patients for whom data were available, BP was controlled in 67.9% (10 157/14 968); statin treatment was prescribed in 41.7% (5994/14 370); 83.6% 13 065/14 636) were not smoking; ACEi/ARB treatment was prescribed in 54.0% (5489/10 172), and ASA for secondary prevention was prescribed in 52.8% (940/1179) of patients with ASCVD. Of 14 553 patients with three or more risk factors, 6007 (41.3%) had optimal control of at least three risk factors with variability across countries and regions (Table).

Conclusion: Comprehensive control of CV risk factors was not achieved in most DISCOVER patients, with wide variability across countries. Better strategies are needed to provide consistent and comprehensive CV risk factor control in patients with T2D to improve long-term outcomes.

Table. Proportions of DISCOVER patients with controlled CV risk factors, overall and by WHO region.

	Total (n = 15 636)	Africa (n = 812)	Americas (n = 2002)	South East Asia (n = 3360)	Europe (n = 3123)	Eastern Med. (n = 2182)	Western Pacific (n = 4157)

Cross-sectional study of annual glycaemic control between 2003 and 2015 in primary care: management of type 2 diabetic patients in the Nordic countries

S.T. Knudsen[1], J. Bodegard[2], K.I. Birkeland[3], K. Furuseth[4], M. Thuresson[5], A. Lindh[6], P.M. Nilsson[7], M. Alvarsson[8], M.E. Jørgensen[9], J. Søndergaard[10], F. Persson[9];
[1]MEA, Department of Endocrinology and Diabetes, Aarhus University Hospital, Aarhus, Denmark, [2]AstraZeneca Nordic-Baltic, Oslo, Norway, [3]University of Oslo, Oslo, Norway, [4]Solli Klinikk, Jessheim, Norway, [5]Statisticon AB, Uppsala, Sweden, [6]Åkersberga, Åkersberga, Sweden, [7]Lunds University, Lund, Sweden, [8]Karolinska University Hospital, Stockholm, Sweden, [9]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [10]University of Southern Denmark, Odense, Denmark.

Background and aims: The Nordic countries have nationwide public primary health care systems. Although guidelines argue for treatment intensification at uncontrolled HbA_{1c}, there are country specific differences in T2D treatment guidelines and this might be reflected in differences in glycaemic control. The aim of this study was to describe the annual proportion of patients successfully below HbA_{1c} target levels of 47.5 mmol/mol (DCCT 6.5%), 53 (7.0%) and 58.5 (7.5%) during 12-years using data from Denmark, Norway and Sweden.

Materials and methods: Electronic medical record data were extracted from 60 primary care clinics in Denmark, Norway and Sweden comprising all patients having a diabetes diagnosis and/or prescription of any glucose lowering drug during 2003–2015. Patients with T1D and gestational diabetes were excluded. The study used a cross-sectional method analysing the HbA_{1c} annually from 2003 to 2015.

Results: In 2015, a total of 20,183 T2D patients were identified in Denmark (3909), Norway (3706) and Sweden (12,568). Mean age 66, 65 and 70 years; females 45, 45 and 42%; previous myocardial infarction 8, 8 and 10%; and chronic kidney disease 6, 10 and 7%, respectively. Use of newer GLDs (DPP-4i, GLP-1RA and SGLT-2i) was highest in Norway, followed by Denmark and lastly Sweden. In 2015, the proportion of T2D patients below HbA_{1c} 47.5 mmol/mol was 42%, 29% and 27% in Denmark, Norway and SE respectively (Figure showing for target 53 mmol/mol). Denmark also showed similar beneficial patterns for HbA_{1c} targets below 53.0 and 58.5 mmol/mol compared with the other countries (Figure). Also, the proportion of patients with HbA_{1c} above 70.0 mmol/mol was lower in Denmark, in 2015 9.9% vs 13.4% and 15.0% in Norway and Sweden respectively. From 2003 to 2015, we found that Norway and Sweden had an initial improvement of patients below targets over the first - while remaining unchanged over the next years, whereas Denmark has showed continuous improvement during the whole observation period.

Conclusion: Despite similar demographics and health care systems in three Nordic countries, we have shown marked better glycaemic control in Denmark as compared to Norway and Sweden. This may indicate a more proactive disease management in the general practices included for this observational study, and also point out potential areas of improvement in the management of type 2 diabetes patients particularly in Norway and Sweden.

The influences of ethnicity on the quality of type 2 diabetes care in Norwegian general practice

A.T. Tran[1], B. Gjelsvik[1], T.J. Berg[2], K. Nøkleby[1], J.G. Cooper[3,4], Å. Bakke[3,5], T. Claudi[6], S. Sandberg[4,5], G. Thue[4,5], A.K. Jenum[1];
[1]General Practice Research Unit, Department of General Practice, University of Oslo, Oslo, [2]Institute of Clinical Medicine, Faculty of Medicine, University of Oslo, Oslo, [3]Department of Medicine, Stavanger University Hospital, Stavanger, [4]Norwegian Quality Improvement of Laboratory Examinations, Bergen, [5]Department of Global Public Health and Primary Care, University of Bergen, Bergen, [6]Nordlandssykehuset, Bodø, Norway.

Background and aims: The population in Norway has become multiethnic during the last decades. Ethnic minority groups have a higher prevalence of type 2 diabetes (T2DM), and treatment may be more complicated. We therefore aimed to explore the influence of ethnicity on the quality of type 2 diabetes care in general practice.

Materials and methods: Data on 10 164 patients with T2DM cared for by 282 general practitioners (GP) were extracted from electronic medical records in 2014. Ethnicity was based on country of birth and categorized as follows: Westerners, East Europeans, East Asians, South Asians,

Middle East/North Africa and Horn of Africa. Multilevel regression models with random effects at GP practice level were used to estimate the ethnic differences with Westerners as reference group adjusted for patient factors (age, gender, diabetes duration and education) and GP factors (gender, specialist status, years working as GP in Norway).

Results: Diabetes was diagnosed 6–12 years earlier in patients from ethnic minority groups (Table 1). Only minor differences in processes of care between patient groups were observed. Glucose-lowering agents were prescribed more frequently to all minority groups compared with Westerners (>76% vs. 66%, $p \leq 0.05$). Nevertheless, mean HbA_{1c} was higher in minority groups (East Europeans: 7.60%, South Asians: 7.29%, Middle East/North Africa: 7.21%) than in Westerners (6.98%, $p \leq 0.01$). A significantly lower proportion of East Europeans, South Asians and patients from Middle East/North Africa achieved the treatment target ($HbA_{1c} \leq 7.0\%$) compared with Westerners. Similarly, a larger proportion of these groups had HbA_{1c} >8.5% than Westerners. Anti-hypertensive agents were prescribed less frequently to patients from South Asia, Middle East/North Africa and Horn of Africa compared with Westerners (<51% vs. 71%, $p \leq 0.001$). However, mean blood pressure was lower in these minority groups (South Asians: 131/75 mmHg, Middle East/North Africa: 133/76 mmHg, Horn of Africa: 132/74 mmHg) than in Westerners (136/79 mmHg, $p \leq 0.05$) and a larger proportion of patients achieved the treatment target of ≤135/80 mmHg compared with Westerners (>62% vs. 48%, $p \leq 0.05$).

Conclusion: Age at the time of diagnosis of T2DM was 6–12 years younger in minority groups compared with Westerners. Many minority patients had worse glycaemic control, indicating a need for special attention to compliance, tight follow-up and more shared care between GPs and endocrinologists.

Management and achievement of glycaemic goal in people with diabetes in Africa: results from the International Diabetes Management Practices Study (IDMPS)

J.C. Mbanya[1], P. Aschner[2], J.J. Gagliardino[3], H. Ilkova[4], F. Lavalle[5], A. Ramachandran[6], G. Kaddaha[7], M. Shestakova[8], J.-M. Chantelot[9], J.C.N. Chan[10];

[1]Biotechnology Center, Doctoral School of Life Sciences, Health and Environment, and Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon, [2]Javeriana University School of Medicine and San Ignacio University Hospital, Bogotá, Colombia, [3]CENEXA, Center of Experimental and Applied Endocrinology (La Plata National University – La Plata National Scientific and Technical Research Council), La Plata, Argentina, [4]Istanbul University, Cerrahpasa Medical Faculty, Department of Internal Medicine, Division of Endocrinology, Metabolism and Diabetes, Istanbul, Turkey, [5]Facultad de Medicina de la Universidad Autónoma de Nuevo León, Monterrey, Mexico, [6]India Diabetes Research Foundation, Dr. A. Ramachandran's Diabetes Hospitals, Chennai, India, [7]Government of Dubai, Dubai Health Authority, Dubai, United Arab Emirates, [8]Endocrinology Research Center, Moscow, Russian Federation, [9]Sanofi, Paris, France, [10]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, The Prince of Wales Hospital, Shatin, Hong Kong SAR, China.

Background and aims: By 2045, Africa is predicted to experience a >150% increase in the proportion of people with diabetes; however, there is a lack of data to support clinical practice and healthcare planning. Here we investigate current management practices in people with diabetes in Africa.

Materials and methods: The IDMPS is an observational survey on the management of people with type 1 (T1D) and type 2 (T2D) diabetes in the developing world. Cross-sectional results were generated using data collected in 2015–2016 from 12 African countries. To identify factors related to glycaemic control, a logistic regression model per region was performed, entering factors significant at the 10% level from the univariate analysis. OR with 95% CI were estimated for each significant predictor. A backward selection procedure identified independent predictive factors significant at the 5% level.

Results: Premixed human insulins were the most common formulation (**Table**). Most participants received some diabetes education, but only 14% received a structured course. In people with T1D and T2D, hospitalisations in the past 12 months (OR [95% CI] 2.3 [1.2, 4.2] and 2.7 [1.3, 5.4], respectively), unhealthy diet/lack of exercise (OR 7.1 [4.3, 11.8] and 4.5 [2.7, 7.5]) and lack of self-management (OR 2.5 [1.5, 4.19] and 1.7 [1.0, 2.7]) were significantly associated with an increased risk of not achieving glycaemic control. Only people with T1D were negatively impacted by poor diabetes education (OR 2.7 [1.2, 6.3]) and longer disease duration (OR 1.9 [1.2, 2.9]).

Conclusion: Characteristics of people with diabetes in Africa are similar to those observed in other regions, except for the preferred use of premixed human insulin. Predictors of poor glycaemic control indicate the need for improved patient education.

Improved diabetic outcomes through a new value based commissioned service in England 2014–2017

J. Llewelyn, C. Neely, Y. Kyaw, M. Spring;
Surrey Downs Diabetes Service, Kingston upon Thames, UK.

Background and aims: National Health Service (NHS) diabetes related costs are £10 billion per annum. Compliance with NICE recommended standards of diabetes care including annual care processes and treatment targets for HbA1c, BP and lipids have been shown to be associated with lower morbidity and mortality. Data from the 2012–13 National Diabetes Audit for England and Wales (NDA) showed the Surrey Downs region, (population 300,000) did not meet NICE quality thresholds for diabetes standards with large variability between localities. As part of a major structural NHS reorganisation, a new single integrated diabetes service focused on the regional needs of people with diabetes was commissioned (Surrey Downs Diabetes Service, SDDS) with the aim of improving diabetic outcomes in a cost efficient manner.
Materials and methods: Working with 31 primary care practices a team of consultant diabetologists, primary care specialist physicians, diabetic specialist nurses (DSN), dieticians, podiatrists, clinical psychologists and dedicated administrative staff led by a senior SDN provided the service. A new tier of secondary patient care was introduced with 4 mulit-disciplinary community based 'hospital style' outpatient clinics called hubs. A dedicated SDN was attached to each practice to provide specialist support for complex patients, education of all healthcare professionals (HCPs) involved in diabetes care (including community and nursing home staff), patient education and community based structured education programmes. All consultations were recorded using the same electronic systems already in use by the primary care practices so were instantly available and good communication between all HCPs providing diabetic care was strongly encouraged. A new Hypoglycaemic Pathway was incorporated with the regional ambulance service informing SSDS of every hypoglycaemic event attended. The DSN attached to the practice of the patient would contact them and review their diabetic care.
Results: Between 2013 and 2017 the number of practices in the region participating in the NDA increased from 21 to 30 and the total number of diabetic patients registered who had recorded annual care processes and treatment targets rose from 6919 to 12,360. By 2017 recorded HbA1c (95.3% type 2, 85% type 1), BP(96% type 2, 87.9% type 1) and cholesterol (92.5% type 2,81.6% type1) was increased to align with the national average. In type 2 patients 72.3% had an HbA1c <58 mmol/mol (66% 2013), 71.2% BP <140/80 mmHg (68.3%) and 41,8% cholesterol<4 mmol/L(39.1%). 33.9% type 1 patients had an HbA1c <58 mmol/l (27.1% 2013), 79%BP <140/80 mmHg (75.2%) and 28.1% chol<4(29.5%). Local variability between practices diminished although 4 practices remained below the national average for at least one care process. The number of hospital admissions for diabetes related causes decreased from 681 to 573 with an associated cost reduction of £845,456 per annum. The annual cost of the SDDS was £744,623. The number of notifications of severe hypoglycaemia decreased from 63(2015) to 25.
Conclusion: More patient focused and community based diabetes services designed according to regional needs require large organisational change but are cost efficient and result in higher completion of annual care processes, improved attainment of treatment targets, particularly in type 2 patients and lower diabetes related hospital admissions.
Disclosure: **J. Llewelyn:** None.

Screening patients of type 2 diabetes for probable hypoglycaemia using standford hypoglycaemia questionnaire in outpatient settings in north India

R. Awasthi, K. Chandra, A. Pande, M. Gupta, A. Tewari, V. Agarwal, N. Gupta, S. Chaubey, S. Chowdhary, S. Ansari, Lucknow Diabetes Study Group;
Lucknow Diabetes Study Group, Lucknow, India.

Background and aims: As the current consensus recommends stricter control of glucose levels, hypoglycemia is emerging as major clinical problem in subjects with diabetes on anti diabetic medications. Co-morbidities further complicate this issue. Occurrence of hypoglycemia is known to increase the mortality and morbidity.The present study was aimed to identify the incidence of unreported hypoglycemia in subjects with type 2 diabetes (T2D), on medication, screened using Stanford Hypoglycemia Questionnaire (SHQ). Further analysis was done to see the risk factors associated with high scores.
Materials and methods: This is a multicenter observational study on consecutive subjects attending 10 diabetes care centers across Lucknow, North India. Inclusion criteria were known subjects of T2D, literate, age >18 years, on at least one anti-diabetic agent for >1 month and not doing regular self-monitoring of blood glucose (SMBG). SHQ was translated into Hindi from English for use. Hindi version of SHQ was self-administered to included subjects after written informed consent during routine follow-up visit to their physician. A Score of 1–3 was taken mild, 4–5 moderate and 6–7 severe risk of hypoglycemia.
Results: From August 2017 to April 2018, 1200 patients were included. Of these 47% were males. Mean age was 53.9 (±10.83) years. Among them 46.7% were on sulphonylurea, 16.5% were on pioglitazone, 81.09% on metformin, 7.6% on DPP4i, 2.07% on SGLT2i. Mean SHQ score was 2.04 (±1.59). Incidence of probable hypoglycemia was mild 60.6%, moderate 16.99% and severe 1.82%, with highest proportion among those on sulphonylurea (mean 2.22 (±1.68) $p < 0.004$). On univariate analysis, probable hypoglycemia was statistically significantly higher in older individual ($P < 0.008$), raised Diastolic BP ($P < 0.0001$), and with one or more chronic complications of T2D (retinopathy (mean SHQ score of 2.71, $P < 0.005$), nephropathy (mean SHQ score of 2.40, $P = 0.026$), neuropathy (mean SHQ score of 2.48, $P < 0.001$) or history suggestive of coronary artery disease (mean SHQ score of 2.66, $P = 0.013$). Hypoglycemia was significantly more common in those with previous history of hypoglycemia (mean SHQ score of 2.37 (±1.57), $P < 0.0001$.
Conclusion: Since incidence of probable hypoglycemia is high in T2D not doing SMBG, those at risk must be identified for appropriate management. For this SHQ was found to be simple and cost effective screening tool in resource crunched Indian setup and can be used in outpatient settings.

PS 074 Cost effectiveness in diabetes therapies

860

Population based diabetes screening is associated with less insulin therapy compared to usual care

R.C. Vos[1], H. den Ouden[1], L.A. Daamen[1], H.J.G. Bilo[2], P. Denig[3], G.E.H. Rutten[1];
[1]Julius Center of Health Sciences and Primary Care, Department of General Practice, Univercity Medical Center Utrecht, Utrecht, [2]Department of Internal Medicine, Diabetes Center Isala, Zwolle, [3]Clinical Pharmacy and Pharmacology, University Medical Center Groningen, Groningen, Netherlands.

Background and aims: The number of people with type 2 diabetes (T2DM) in need of insulin might be lower if they were diagnosed by population-based screening, i.e. about three years earlier than during care-as-usual. Dutch care-as-usual implies opportunistic screening in people with a high risk of T2DM during surgery hours in primary care. We compared insulin prescription and glycemic control 10 years after population based screening of T2DM with data from people with known diabetes duration of 7 and 10 years after opportunistic screening.
Materials and methods: People from three cohorts were included, index year 2014: 391 with 10 years screen-detected diabetes duration (ADDITION-NL study), 4473 with 7 years and 2660 with 10 years diabetes diagnosis (GIANTT/ZODIAC primary care databases). Treatment guidelines since 2009 were comparable. Insulin prescription and HbA1c were compared using logistic and linear regression analysis, adjusted for possible confounders (age, sex, BMI, LDL-cholesterol, HbA1c/glucose lowering medication, smoking).
Results: People with screen-detected T2DM were older (71.4 vs 68.4 and 69.7 years, $p < 0.01$) and more often male; 53.8% vs 50.5% in the 7 years and 47.8% in the 10 years diabetes cohorts respectively (Table). Insulin prescription in these groups was: 10.5%, 14.7% and 18.9%. People diagnosed 7 and 10 years before during care-as-usual had 1.5 (95%CI 1.0–2.1) and 1.9 (95%CI 1.3–2.7) higher adjusted odds for insulin prescription than those with screen-detected T2DM. The mean difference in HbA1c levels between people with screen-detected T2DM diagnosis and those diagnosed during care-as-usual 7 and 10 years before was 1.6 mmol/mol (95% CI 0.5–2.7) and 1.8 mmol/mol (95% CI 0.7–2.9) higher for the latter two, after adjustment.
Conclusion: Population based diabetes screening is associated with good glycemic control on the long-term and less need for insulin compared to usual care.

Table: Subject characteristics of the three cohorts ADDITION-NL, 7 and 10 years diabetes diagnosis during care-as-usual

	ADDITION-NL (n=391)	7 years diabetes diagnosis (n= 4473)	10 years diabetes diagnosis (n= 2660)	F-test / Chi-square	P-value

Impact of V-Go versus multiple daily injections on glycaemic control, insulin utilisation and diabetes medication costs among individuals with type 2 diabetes

A. Raval[1], M. Nguyen[2], S. Zhou[1], M. Grabner[1], J. Barron[1], R. Quimbo[1];
[1]Healthcore, Inc., Wilmington, [2]Valeritas, Inc., Bridgewater, USA.

Background and aims: Individuals with type 2 diabetes mellitus (T2DM) requiring multiple daily injections (MDI) of insulin face challenges with compliance, discomfort, and cost. The V-Go® Wearable Insulin Delivery Device may improve the insulin delivery experience and outcomes for such population. A few studies examined the relative effectiveness of V-Go in terms of clinical and economic outcomes in comparison to MDI. This study examined the effectiveness of V-Go in terms of glycemic control, insulin utilization and diabetes medication costs compared to MDI among individuals with T2DM in the United States.
Materials and methods: A retrospective cohort study was performed using a commercial administrative claims-database between 07/01/2011–07/31/2017. Study cohorts included individuals with T2DM aged 21–80 years either newly initiating V-Go or using MDI for basal-bolus insulin with prior exposure to basal ± bolus or premixed insulin. The main sample included individuals with ≥1 glycosylated hemoglobin (HbA1c) laboratory result during the baseline (6 months) and follow-up periods (3–13 months). Insulin utilization and diabetes medication costs were examined during baseline and second-half of 1-year follow-up (months 7–12) among those with continuous health plan coverage. V-Go and MDI users were 1:1 matched on baseline insulin exposure, HbA1c level, and other characteristics. T-test, McNemar test and Chi-square test were used to compare follow-up outcomes. A sensitivity analysis was conducted to examine insulin utilization and diabetes medication costs among a larger sample of individuals with or without HbA1c results.
Results: Matched cohorts included 118 well-balanced pairs for the main analysis (mean age: 56 years; mean baseline HbA1c: 9.2%) and 585 well-balanced pairs for the sensitivity analysis (mean age: 57 years). In the main analysis, both cohorts experienced improvements in glycemic control during follow-up relative to baseline (% with HbA1c ≤9%, pre/post: V-Go 49/69, $p < 0.001$; MDI 50/60, $p = 0.046$). With similar baseline number of insulin Rx fills and diabetes-related medication costs, V-Go users had fewer insulin Rx fills (mean change from baseline: −0.8 vs. +1.8 fills, $p < 0.001$), a 21% decline in insulin total daily dose (TDD) (mean change TDD in IU: −29.2 vs. +5.8, $p < 0.001$), and a lower increase in diabetes-related medication costs (mean change in 2016 USD: $341 vs. $1,628, $p = 0.012$) as compared to MDI users, during the last 6 months of follow-up. Consistent with the main analysis, V-Go users also had fewer insulin Rx fills (mean change from baseline: −0.4 vs. +1.8 fills, $p < 0.001$), a 17.5% decline in TDD (mean change TDD in IU: −23.9 vs. +6.0, $p < 0.001$), and a lower increase in diabetes-related medication costs (mean change in 2016 USD: $506 vs. $1129, $p < 0.001$) in the larger sensitivity analysis sample.
Conclusion: This study is the first to report clinical and economic outcomes associated with V-Go use up to a one-year follow-up period. V-Go therapy was associated with improved glycemic control, and with less total daily insulin requirement and lower diabetes medication costs compared to MDI. V-Go therapy represents an opportunity to improve quality clinical measures more efficiently and less costly among a T2DM population requiring basal-bolus insulin treatment.

Long-term cost-effectiveness of sitagliptin and SGLT2i combination therapy for the management of type 2 diabetes in the UK

M. Pawaskar[1], P. Bilir[2], A. Graber-Naidich[2], C. Gonzalez[1], S. Rajpathak[1], G. Davies[1];
[1]Merck & Co., Inc, Kenilworth, [2]QuintilesIMS, San Francisco, USA.

Background and aims: Clinical benefits of dipeptidyl peptidase-4 inhibitors (DPP-4i) and sodium-glucose co-transporter 2 inhibitors (SGLT2i) combination therapy have been demonstrated through clinical trials; however, there is limited understanding of economic benefits of sequential use of these therapies relative to generic therapies such as NPH insulin. This study evaluated the long-term cost-effectiveness of a treatment strategy involving intensification with SGLT2is (pathway 1) compared to NPH insulin (pathway 2) as a 3rd line therapy in type 2 diabetes (T2D) patients not at goal on metformin (1st line) and sitagliptin (2nd line) therapy in the UK.

Materials and methods: Cost-effectiveness analysis was performed using the validated QuintilesIMS CORE Diabetes Model from a UK payer perspective. Clinical and economic outcomes were modeled over a lifetime for a cohort of T2D patients who fail to achieve glycemic goal on metformin monotherapy. Treatment effect data were obtained from randomized clinical trials and economic data such as direct medical costs (e.g., medications, diabetes management, adverse events, and complications) were obtained from multiple published sources. Several scenario analyses including changes in clinical parameters were performed to assess the robustness of base case results.

Results: Pathway 1 increased total life years (13.49 vs. 13.37, respectively) and quality-adjusted life years (QALY) (9.40 and 9.22, respectively) compared to pathway 2. Although drug costs in pathway 1 were higher than pathway 2, they were offset by decreases in diabetes-related complications and body mass index, leading to lower total direct medical costs for pathway 1 (£25,747 vs £26,095). Thus, pathway 1 dominates pathway 2, as it is both more effective (measured in terms of quality adjusted life years) and less costly. Results from scenario analyses assessing changes in treatment effect, hypoglycemia rate, body mass index, cardiovascular protective effect of SGLT2i (using EMPA-REG, CANVAS, CDV-REAL data) consistently showed that pathway 1 was either dominant (incremental cost effectiveness ratio (ICER) <$0/QALY) or cost-effective per the National Institute for Health and Clinical Excellence's cost-effectiveness threshold of <£30,000/QALY [(ICER <£3,000/QALY for patients with lower baseline HbA1c (7%) or older age (65+ years)].

Conclusion: Among patients not at goal on metformin and sitagliptin therapy, treatment intensification with SGLT2i is likely to be cost effective compared to intensification with NPH insulin as a 3rd line therapy for management of T2D in the UK.

Table: cost effectiveness analysis of two treatment pathways for management of type 2 diabetes

	Pathway 1 (Includes metformin+sitagliptin+SGLT2is)	Pathway 2 (Includes metformin+sitagliptin +NPH insulin)
Life years gained	13.49	13.37
Quality adjusted life years	9.40	9.22
Total medical costs	£ 25,747.38	£ 26,095.18
Incremental cost effectiveness ratio	Pathway 1 dominates Pathway 2

Cost-effectiveness analysis of empagliflozin in comparison to standard of care, sitagliptin and saxagliptin based on cardiovascular outcomes trials

M. Ramos[1], V. Foos[1], A. Ustyugova[2], N. Hau[3], P. Gandhi[4], M. Lamotte[1];
[1]HEOR, IQVIA, Zaventem, Belgium, [2]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [3]Boehringer Ingelheim Ltd, Bracknell, UK, [4]Boehringer Ingelheim Pharmaceuticals Inc, Ridgefield, USA.

Background and aims: Over the recent years, several cardiovascular outcome trials (CVOTs) have been published with the glucose lowering drugs. In the EMPA-REG OUTCOME trial, empagliflozin (SGLT-2) + standard of care (SoC) was compared to SoC (placebo arm in the trial) in patients with type 2 diabetes mellitus (T2DM) and established cardiovascular disease (CVD). The TECOS and SAVOR-TIMI 53 CVOT trials for sitagliptin and saxagliptin (both DPP-4 inhibitors), respectively, were designed similarly. This study assessed the cost-effectiveness of empagliflozin + SoC in comparison to SoC, sitagliptin + SoC and saxagliptin + SoC in patients with T2DM and established CVD based on the data from the respective CVOTs.

Materials and methods: The IQVIA Core Diabetes Model (CDM), a well-established model, was calibrated to reproduce the outcomes from the EMPA-REG OUTCOME trial, both for empagliflozin + SoC and SoC. Baseline characteristics and observed effects on physiological parameters (HbA1c, BMI, blood pressure, lipids) were used as inputs. Network meta-analysis (NMA) provided the relative risks for cardiovascular outcomes with empagliflozin versus sitagliptin and saxagliptin. The CDM was then calibrated to reproduce sitagliptin and saxagliptin trials' outcomes. The effects of the CVOTs were applied for 3 years (the median observation time in the EMPA-REG OUTCOME trial) after which, the UKPDS 82 risk equations predicted events based on HbA1c and other physiological parameters. After the first 3 years, HbA1c progression for all arms was projected based on the progression in the EMPA-REG OUTCOME trial. Given the long diabetes history patients had, basal bolus rescue therapy was assumed whenever modeled individuals exceeded an HbA1c threshold of 8.5%. The analyses were performed from the UK National Health Service (NHS) perspective. UK unit costs of complications and quality of life data were taken from literature. The drug costs were from the British National Formulary and Monthly Index of Medical Specialities. Annual discounting rates of 3.5% were applied.

Results: CDM lifetime projections including CVOT calibration in the initial 3 years demonstrated 9.215, 9.614, 9.235 and 9.169 life years, 5.306, 5.582, 5.342 and 5.297 quality-adjusted life years (QALY), and 44,086 GBP, 45,452 GBP, 44,399 GBP and 44,338 GBP total lifetime costs for SoC, empagliflozin, sitagliptin and saxagliptin, respectively. The incremental cost-effectiveness ratio (ICER) of empagliflozin versus SoC, sitagliptin + SoC and saxagliptin + SoC were 4,952GBP/QALY, 4,389GBP/QALY and 3,911GBP/QALY, respectively. The probabilistic sensitivity analyses demonstrated that empagliflozin is cost-effective at a willingness to pay threshold of 20,000GBP/QALY in 90%, 89% and 64% of cases, when compared to SoC, sitagliptin + SoC and saxagliptin + SoC, respectively. Running these analyses with a time horizon of 5 years showed the same trend.

Conclusion: Based on the results of the EMPA-REG OUTCOME, TECOS and SAVOR-TIMI 53 studies, the cost effectiveness analyses suggest that empagliflozin + SoC is cost-effective treatment alternative to SoC, sitagliptin + SoC and saxagliptin + SoC from the UK NHS perspective.

Impact of exenatide on medical costs and health utilities in type 2 diabetes: experience from EXSCEL

S.D. Reed[1], Y. Li[1], H. Dakin[2], F. Becker[2], J. Leal[2], S.M. Gustavson[3], B. Kartman[4], E. Wittbrodt[3], R.J. Mentz[1], N.J. Pagidipati[1], M.A. Bethel[5], A.M. Gray[2], R.R. Holman[5], A.F. Hernandez[1];
[1]Duke Clinical Research Institute, Durham, USA, [2]Oxford Health Economic Research Centre, Oxford, UK, [3]AstraZeneca, Gaithersburg, USA, [4]AstraZeneca, Molndal, Sweden, [5]Diabetes Trials Unit, Oxford, UK.

Background and aims: The Exenatide Study of Cardiovascular Event Lowering (EXSCEL) demonstrated a numerical, but not statistically significant, reduction in major adverse cardiovascular events and a nominally significant improvement in all-cause mortality in 14,752 patients with type 2 diabetes (T2D), with or without previous cardiovascular disease, randomized 1:1 to exenatide 2 mg once-weekly (EQW) or placebo added to usual care. Those allocated EQW experienced significantly greater reductions in glycated hemoglobin, body weight, LDL-cholesterol and systolic blood pressure compared with placebo. Medical resource use and EQ-5D data were collected throughout the study.
Materials and methods: Medical resources were valued from US and UK perspectives using Medicare payments and wholesale acquisition costs (WAC) for concomitant medications with a 23.1% discount for EQW in the US analysis, and using the English National Schedule of Reference Costs and Prescription Cost Analysis database for the UK analysis. EQ-5D-5L and EQ-5D-3L responses were mapped to 3-level health utilities using both US and UK tariffs. Hierarchical generalized linear models were used to compare medical resource use, costs and health utilities with specific error distributions and link functions.
Results: Mean follow-up was 3.3 years. Mean number of hospitalizations per patient were similar in both groups (EQW 0.83 vs. placebo 0.84; $p = 0.31$), as were annual hospitalization rates, ranging from 0.24–0.29 per person-year from year 1 to year 5. The mean cumulative number of inpatient days over the trial follow-up period was 0.41 days lower in the EQW group than the placebo group (7.05 days vs. 7.46 days respectively; relative rate ratio 0.91; $p = 0.05$). Inpatient and outpatient costs were similar between treatment groups when US or UK costs were assigned. Although EQW-treated patients incurred lower costs for concomitant diabetic and non-diabetic medications, and in overall total costs excluding study medication, inclusion of EQW costs led to higher total mean costs in the EQW arm (Table). There were no significant differences observed in US or UK EQ-5D health utilities between groups throughout the follow-up period.
Conclusion: Similar hospitalization rates and health utilities were reported across time with EQW, compared with placebo. However, mean cumulative inpatient days were significantly reduced with EQW, compared with placebo. Total costs were significantly lower in the EQW group when the cost of study medication was excluded, but were significantly greater when the cost of branded EQW was included in the analysis.

Table: Medical costs over trial period in exenatide and placebo groups, using US and UK unit costs (mean, SD)

	US analysis ($)			UK analysis (£)

No availability, no uptake - exploring the reasons behind low uptake of insulin pump therapy in Irish adults with type 1 diabetes: findings from a national survey

K.A. Gajewska[1], S. Sreenan[2,3], K.E. Bennett[4], J. Gajewski[1], R. Biesma[1];
[1]Department of Epidemiology and Public Health, Royal College of Surgeons in Ireland, Dublin, [2]Department of Diabetes and Endocrinology, Royal College of Surgeons in Ireland, Dublin, [3]3U Diabetes Consortium, 3U Partnership, Dublin, [4]Division of Population Health Sciences, Royal College of Surgeons in Ireland, Dublin, Ireland.

Background and aims: Insulin pump therapy is fully covered for all patients with diabetes in Ireland by the Long-Term Illness Scheme and users are not subject to any out-of-pocket expenses. Despite this, the uptake of insulin pumps in Irish patients with Type 1 diabetes is lower than the European average (9% vs. 15%). It is hypothesised that the low uptake of insulin pumps may be related to availability of clinics offering insulin pumps and the staff trained in insulin pump therapy. The aim of this study is to investigate the availability of insulin pump therapy in adults with Type 1 diabetes in diabetes clinics in Ireland.
Materials and methods: We undertook a cross-sectional, national survey of all diabetes clinics ($n = 50$) offering services to adult patients with Type 1 diabetes in Ireland. The data were collected from private and public clinics through an online questionnaire and by phone, according to participants' preference. One relevant healthcare professional was asked to complete the questionnaire on behalf of the clinic.
Results: Forty-seven diabetes clinics (34 public and 13 private) took part in the study (94% response rate/100% in public clinics). The survey was completed mainly by nurses (49% cases) and endocrinologists (47%). Of all patients with Type 1 diabetes ($n = 22321$), 9.7% were using insulin pumps. One third (32%) of all clinics did not offer any services for patients on pumps. The main reasons for the lack of such services were: absence of a diabetes nurse specialist (60%) or dietician (67%) trained in insulin pump therapy and high current workload (53%). 45% of the clinics in Ireland reported availability of insulin pump therapy and offered training to commence it (37% of public hospitals, 54% of private), but only 12.5% of patients in these clinics were on pumps. Large public clinics ($n >$ median of 315 patients) had higher insulin pump uptake (number of insulin pump users divided by the number of all patients with Type 1 diabetes) then smaller clinics (9% vs. 2%, $p = 0.01$). Less than one percent (0.42%) of patients in clinics offering training to commence insulin pump therapy received such training in the last 12 months ($n = 179$), what gives the average of 9 patients trained per clinic/year. There was no correlation between the number of patients trained to commence an insulin pump therapy and current workload, estimated by the number of patients per healthcare professionals' Whole-Time Equivalent (WTE). The size of the clinic and the number of healthcare professionals' WTE per clinic were the only significant factors associated with frequency of insulin pump training in the last 12 months prior to survey completion.
Conclusion: The low uptake of insulin pump therapy (less than 10% of adults with Type 1 diabetes) may be influenced by the low availability of insulin pump training in diabetes clinics. More studies to explore the determinants of the access to insulin pump therapy and poor availability of insulin pump-related services in Ireland are needed to complement the evidence.

Once-weekly semaglutide provides better health outcomes compared to dulaglutide as dual therapy in the treatment of type 2 diabetes: a cost-effectiveness analysis

C.K. Tikkanen[1], P. Johansen[2], B. Hunt[3], S. Malkin[3], R.F. Pollock[3];

[1]Novo Nordisk Scandinavia AB, Copenhagen, Denmark, [2]Novo Nordisk A/S, Søborg, Denmark, [3]Ossian Health Economics and Communications GmbH, Basel, Switzerland.

Background and aims: Once-weekly semaglutide (semaglutide) is a novel glucagon-like peptide 1 (GLP-1) analogue for the treatment of type 2 diabetes (T2D). The safety and efficacy of semaglutide has been compared with GLP-1 receptor agonist dulaglutide in SUSTAIN 7, a 40-week randomized phase 3b trial in subjects with T2D inadequately controlled with metformin. Semaglutide 0.5 mg and 1 mg lowered HbA_{1c} by 1.5% and 1.8%, respectively, compared to 1.4% for dulaglutide 1.5 mg. Similarly, semaglutide 0.5 mg and 1 mg reduced body weight by 4.6 kg and 6.5 kg, respectively, compared to 3.0 kg for dulaglutide 1.5 mg. The aim of the study was to use computer simulation modelling to project long-term health and economic outcomes with semaglutide 0.5 mg and 1 mg versus dulaglutide 1.5 mg from a Danish healthcare payer perspective.
Materials and methods: Long-term projections of the incidence of complications, costs, and impact on health-related quality of life, were made using the IQVIA CORE Diabetes Model over a 50-year time horizon. Baseline patient characteristics, initial treatment effects, and hypoglycaemic event rates were sourced from the trial. A 3 year treatment period was assumed with semaglutide and dulaglutide after which patients switched to basal insulin rescue therapy. Following switch, a natural HbA_{1c} progression was modelled based on the United Kingdom Prospective Diabetes Study Outcomes Model equation. Treatment and complication costs were captured in 2017 Danish Krone (DKK), and future costs and outcomes were discounted at 3% *per annum*. Extensive one-way and probabilistic sensitivity analyses were conducted around key model assumptions.
Results: Treatment with semaglutide 0.5 mg and 1 mg resulted in increased time to onset of complications relative to dulaglutide 1.5 mg (**Figure**), and reduced incidence of complications over a 50 year time horizon. Mean time to onset of any complication increased by 1.7 and 4.2 months with semaglutide 0.5 mg and 1 mg, respectively. This improved quality-adjusted life expectancy for patients treated with semaglutide 0.5 mg and 1 mg by 0.06 and 0.14 quality-adjusted life years (QALYs), respectively, compared to dulaglutide 1.5 mg. Semaglutide 1 mg was projected to be cost saving relative to dulaglutide 1.5 mg, while the 0.5 mg dose increased total costs by DKK 2,123, resulting in an incremental cost-utility ratio of DKK 37,435 per QALY gained.
Conclusion: This study showed that both doses of semaglutide would result in reductions in cumulative incidence and increased time to onset of complications of T2D relative to dulaglutide 1.5 mg. In patients with T2D inadequately controlled on metformin, treatment with semaglutide 0.5 mg would be cost-effective, while semaglutide 1 mg represented a dominant (i.e. more efficacious and less costly) treatment option relative to dulaglutide 1.5 mg.

The importance of incorporating cardio-protective effects of once-weekly semaglutide in estimates of health benefits for patients with type 2 diabetes

L.M. Evans[1], P. Johansen[2], H. Vrazic[2], A. Pitcher[3], E. Falla[3];
[1]Department of Diabetes, University Hospital Llandough, Cardiff, UK, [2]Novo Nordisk A/S, Søborg, Denmark, [3]IQVIA, London, UK.

Background and aims: Economic modelling of type 2 diabetes (T2D) relies on sets of risk equations (e.g., United Kingdom Prospective Diabetes Study [UKPDS] 68 and 82) to predict cardiovascular (CV) events and mortality as mediated through changes in risk factors (e.g., HbA_{1c}). Recent CV outcomes trials (CVOTs) have shown significant benefits in events over a short time period (between 2–4 years), along with beneficial changes in risk factors such as blood pressure, HbA_{1c}, and weight. The contributions of these changes to the observed outcomes within these CVOTs are unclear. In patients with high CV risk, the SUSTAIN 6 trial of once-weekly semaglutide+standard of care (SoC) reported, amongst other findings, a statistically significant reduction in non-fatal stroke (HR = 0.61; 95% confidence interval 0.38–0.99) after 104 weeks versus placebo+SoC. We sought to establish the contribution of risk factor changes to the observed stroke (non-fatal and fatal) outcome, by evaluating the performance of traditional risk equations in predicting outcome benefits seen with once-weekly semaglutide. As a secondary objective, the impact of incorporating the stroke benefit on estimated long term health benefits was assessed.
Materials and methods: The IQVIA Core Diabetes Model was populated with patient characteristics and risk factor changes (e.g., HbA_{1c}, blood pressure, body-mass index, lipids) for once-weekly semaglutide+SoC and placebo+SoC, as observed in the trial. The model was then run for a two-year time horizon to assess the predictive accuracy of the UKPDS 68 and UKPDS 82 risk equations on the observed stroke (non-fatal and fatal) benefit, as mediated through changes in the risk factors. Secondly, the model was calibrated to preserve the relative risk (RR) ratio of the observed cumulative incidence of stroke between the treatment arms (after taking into account the benefits generated by the risk equations). This was achieved by an iterative process by applying a stroke RR to the once-weekly semaglutide arm only, using the TREND function in Excel® until the predicted RR ratio matched the trial-observed RR ratio. Finally, results were extrapolated over 50 years.
Results: The UKPDS 68 and 82 equations were able to predict 64% and 50%, respectively, of the observed 2-year stroke risk reduction, suggesting a drug-mechanistic effect other than observed through changes in the risk factors. Calibration results indicate that a drug-specific RR of stroke of 0.83 (17% reduction) and 0.75 (25% reduction) applied to once-weekly semaglutide was required to preserve the RR ratio of the observed cumulative incidence, using UKPDS 68 and UKPDS 82, respectively. Results of extrapolation increased quality-adjusted life-years (QALYs) by 0.18 and life-years (LYs) by 0.29 with once-weekly semaglutide+SoC vs placebo+SoC when using UKPDS 68 equations. Using UKPDS 82 equations increased QALYs by 0.11 and LYs by 0.16. QALYs and LYs were slightly increased when the stroke benefit were taken into account, compared to not accounting for it.
Conclusion: Results of this analysis highlight the importance of considering recent evidence on CV benefits for economic modelling, and may have implications to future approaches assessing the long-term economic impact of new therapies in T2D in this era of multiple CVOTs.

Real world practice level data analysis confirms link between variability within blood glucose monitoring strip and glycosylated haemoglobin in type 1 diabetes

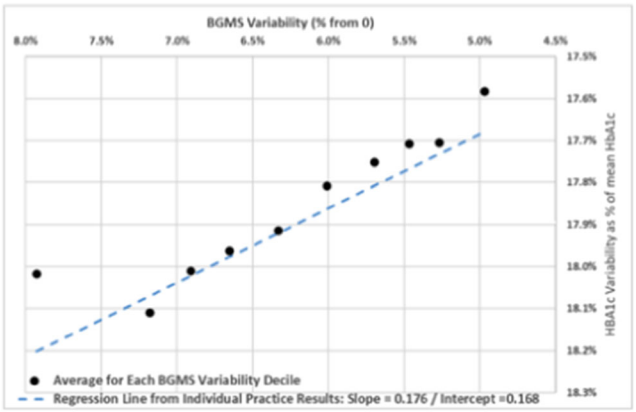
M. Stedman[1], M. Lunt[2], M. Livingston[3], A. Fryer[4], G. Moreno[5], S. Anderson[6], R. Gadsby[7], I. Laing[8], R. Young[9], A. Heald[2,8];
[1]RES Consortium, Andover, UK, [2]University of Manchester, Manchester, UK, [3]Walsall Manor Hospital, Walsall, UK, [4]Keele University, Keele, UK, [5]High Speciality Regional Hospital of Ixtapaluca, Mexico, Mexico, [6]Institute of Cardiovascular Sciences, University of Manchester, Manchester, UK, [7]Warwick Medical School, University of Warwick, Wiltshire, UK, [8]Department of Diabetes and Endocrinology, Salford Royal Hospital, Salford, UK, [9]National Diabetes Audit, Leeds, UK.

Background and aims: Minimising blood glucose variation is key to optimising health outcomes for people with diabetes. Our aim was to see if we could quantify the impact of Blood Glucose Monitoring Strips variability (BGMSV) at GP practice level on the variability of reported glycated haemoglobin (HbA1cV) levels published in the National Diabetes Audit, and from that estimate the impact on Blood Glucose Variability (BGV)

Materials and methods: The overall GP Practice BGMSV was calculated from the quantity of main types of BGMS being prescribed combined with the published accuracy, as % results within ±% bands from reference value for the selected strip type. An estimated HbA1c mean and variability (HbA1cV) was calculated for each practice year from % results within HbA1c bands published in the National Diabetes Audit for Type 1 diabetes (T1DM). The regression coefficient between the BGMSV and HbA1cV was calculated. To allow for the aggregation of estimated 3 tests/day over 13 weeks (i.e. 300 samples) of actual Blood Glucose values up to the HbA1c, we multiplied HbA1cV coefficient by √300 to estimate an empirical value for the impact of BGMSV on BGV.

Results: 4,524 practice years with 159,700 T1DM patient years where accuracy data was available for more than 80% of strips prescribed were included, with overall BGMSV 6.5% and HbA1c mean of 66.9 mmol/mol (8.3%) with variability of 13 mmol/mol equal to 19% of the mean. At a GP practice level, BGMSV and HbA1cV as % of mean HbA1c (in other words the spread of HbA1c) were closely related with a regression coefficient of 0.176, p value <0.001 (see Figure). After correction for aggregation the equivalent BGV correlation factor was calculated at 3. The comparable figure previously found in an in-silico study was 2.7. Applying this factor for BGMS to the national ISO accepted standard where 95% results must be ≤±15% from reference, revealed that for BG, 95% results would ≤±45% from the reference value. So for a patient with BG target @10mmol/l using ISO standard strips, on 1/20 occasions (average 1/week) their actual blood glucose value could be >±4.5 mmol/l from target, compared to the best performing BGMS with BG >±2.2 mmol/l from reference on 1/20 occasions.

Conclusion: Use of more variable/less accurate BGMS is associated both theoretically and in practice with a larger variability in measured BG and HbA1c, with implications for patient confidence in their day to day monitoring experience. Our results suggest clear advantages of best in class accuracy BGMS.



Relation at GP practice Level between BGMS variability and HbA1c variability taken as % of the mean HbA1c for that practice. The points reflect the average within the deciles of practices sorted by BGMS variability. The regression over all practice years gave r^2=0.003 and p value <0.001.

Changed amygdala functional network in type 2 diabetes with major depression disorder

L. Gao;
Southeast University, Nanjing, China.

Background and aims: Patients with type 2 diabetes (T2D) showed significantly increased risk for various psychological disorders, including major depression disorder (MDD), which results from altered connectivity of brain functional network. Previous investigations have suggested the importance of amygdala functional network (AFC) in the pathophysiology process of MDD, however, its neurobiology underlying the diabetes-related mood disorder is poorly understood. The present study aimed to reveal the AFC alteration related to the T2D-MDD interaction via functional MRI approach.
Materials and methods: A total of 163 participants were enrolled, 78 of which were patients with T2D. For the 78 patients with T2D, 37 of them were diagnosed as MDD and the remaining patients had no signs of mood disorder. For the 85 participants without T2D, 37 of them were patients with MDD and the remaining participants had no signs of mood disorder. All the participants went through the clinical evaluations and functional MRI scans. To explore the influence of MDD-T2D interaction on the AFC connectivity, a mixed analysis of covariance (ANCOVA) with T2D status (2 levels: T2D and non-T2D) and MDD status (2 levels: MDD and non-MDD) as fixed factors was performed, followed by post-hoc analyses. Further, the partial correlations analyses were applied to explore the behavior significance of the brain regions with T2D × MDD interactions.
Results: The interactive effects of T2D-MDD on the left AFC connectivity were mainly detected within right middle frontal gyrus (RMFG, $P < 0.01$, corrected by Monte Carlo simulation). Post-hoc analyses suggested T2D patients with MDD showed the significantly decreased connectivity within RMFG compared to the other three groups (all $P < 0.01$). Further, MDD subjects without T2D showed significantly decreased connectivity compared to healthy control ($P = 0.015$). Finally, revealed by the correlations analyses, functional connectivity within AFC showed significantly positive association with HAMD scores for participants with MDD (rho = 0.66, $P = 0.007$).
Conclusion: The functional MRI provided new approach to understand the underlying mechanisms of the MDD for T2D patients, and improving the AFC function may be a promising method to relieve the T2D-related mood disorder.

Depression as an independent predictor for type 2 diabetes incidence in adults: result from Qingdao Diabetes Prevention programme

F. Ning[1], D. Zhang[2], L. Zhang[3], Z. Pang[1], Q. Qiao[4], Standing for Qingdao Diabetes Prevention Program;
[1]Qingdao Centers for Disease Control and Prevention, Qingdao, China, [2]Huangdao Centers for Disease Control and Prevention, Qingdao, China, [3]Qingdao Endocrine and Diabetes Hospital, Qingdao, China, [4]University of Helsinki, Helsinki, Finland.

Background and aims: Cross-sectional studies evidenced the bidirectional associations between depression syndrome and type 2 diabetes in adults. The current study will evaluate depression predicted risk for onset of type 2 diabetes in a longitudinal study in China.
Materials and methods: The 2006 World Health Organization diagnostic criteria and Zung self-assessment score were employed to identify type 2 diabetes and depression syndrome at baseline, respectively. A total of 3581 participants aged 35 to 74 years at baseline randomly sampling from Qingdao Diabetes Prevention Program were collected development of type 2 diabetes followed for 4 years. Multivariate Logistic regression was employed to assess their relationship between depression syndrome and type 2 diabetes, adjusting for age, sex, body mass index, residential area, serum triglycerides, hypertension, family history of diabetes, marital status, education level, income level, physical activity, occupation, smoking and drinking status.
Results: During a 4-year follow up, 305 cases of incident type 2 diabetes was identified, with cumulative incidence of diabetes of 8.52%. At baseline, individuals with depression were positively associated with fasting plasma glucose, women, lower education and lower frequency of metabolic equivalent ($p < 0.01$ for all comparisons). The significant relative risks and 95% confidence interval of depression for onset of type 2 diabetes was 1.52(1.05–2.21) after adjustment for conventional risk factors. Sensitive analysis showed that depression syndrome was significantly associated with type 2 diabetes in women, but moderate in men. The corresponding figures were 1.82(1.14–2.91) and 1.12(0.58–2.17), respectively.
Conclusion: The relationship between depression syndrome and type 2 diabetes incidence is partly explained by health behavior and socioeconomic status. Early identification and lifestyle intervention should prevent residents from risk of depression and type 2 diabetes in China.
Clinical Trial Registration Number: NCT01053195

Depression in type 1 diabetes was associated with high levels of circulating galectin-3

E.O. Melin[1,2], J. Dereke[3], M. Thunander[1,2], M. Hillman[3];
[1]Lund University, Department of Clinical Sciences, Section Endocrinology and Diabetes, Lund, [2]Research and Development, Region Kronoberg, Växjö, [3]Lund University, Department of Clinical Sciences, Diabetes Research Laboratory, Lund, Sweden.

Background and aims: Neuroinflammatory responses are implicated in depression. Galectin-3 is a soluble β-galactoside binding lectin involved in several inflammatory processes, to our knowledge not previously investigated in patients with depression or with type 1 diabetes (T1D). Depression and galectin-3 are both associated with Alzheimer's disease, increased cardiovascular and all-cause mortality. Our hypothesis was that depression is associated with high galectin-3. The aim was to explore whether depression in patients with T1D was associated with high galectin-3, controlling for metabolic variables, s-creatinine, life style factors, medication, and cardiovascular complications.
Materials and methods: Cross-sectional study including 283 T1D patients (56% men, age 18–59 years, diabetes duration ≥1 year), consecutively recruited at regular follow up visits. Depression was assessed by Hospital Anxiety and Depression Scale-depression subscale; blood samples, anthropometrics and blood pressure were collected; data was collected from medical records and the Swedish National Diabetes Registry. Galectin-3 ≥2.562 μg/l, corresponding to the 85th percentile, was defined as high galectin-3.
Results: Median (quartile$_1$, quartile$_3$) galectin-3 (μg/l) was 1.3 (0.8, 2.9) for the 30 depressed patients, and 0.9 (0.5, 1.6) for the 253 non-depressed, $P = 0.009$. Multiple logistic regression analysis (Backward Wald) showed

that depression was associated with high galectin-3 in all the 283 patients (Adjusted odds ratio (AOR) 3.5), in the 161 men (AOR 3.4), and in the 122 women (AOR 3.9). HbA1c, s-lipids, s-creatinine, blood pressure, obesity, smoking, physical inactivity, cardiovascular complications, and drugs (antidepressants, antihypertensive, lipid lowering, and oral antidiabetic drugs) were not associated with high galectin-3.
Conclusion: This is the first study to show an association between depression and galectin-3. Depression was the only explored parameter associated with high circulating galectin-3 levels in the 283 T1D patients. High galectin-3 levels might contribute to the increased risk for Alzheimer's disease, cardiovascular and all-cause mortality observed in persons with depression.

Illness perception moderates the relationship between diabetes distress and depressive symptoms

A.S. Mocan[1,2], A. Nouwen[3], D.E. Dumitraş[4], S.S. Iancu[1], A.S. Baban[2]; [1]Center for Diabetes, Nutrition and Metabolic Diseases, County Emergency Hospital, Cluj-Napoca, Romania, [2]Babes-Bolyai University, Cluj-Napoca, Romania, [3]Middlesex University, London, UK, [4]University of Agricultural Sciences and Veterinary Medicine, Cluj-Napoca, Romania.

Background and aims: Depression is twice as common in type 2 diabetes than in general population. Both diabetes distress and illness perception play a role in the development of depression, but their exact contribution is not clear. The Common Sense Self-Regulation Model of Illness Perception posits that people have different representations and understanding of their illness impacting on self-care behaviors and emotional outcome. The aim of the present study was to assess the role of illness perceptions in the relationship between diabetes distress and depressive symptoms and whether they mediate or moderate this relationship.
Materials and methods: A sample of 431 people with type 2 diabetes were enrolled in the study. Participants completed the Illness Perception Questionnaire- Revised, Diabetes Distress Scale and Beck Depression Inventory-II. Negative events were analyzed as one single variable, life stress. Linear multiple regression analysis was used to determine the association between depressive symptoms and socio-demographic, clinical and illness perception dimensions. Then mediation and moderation equations were established based on the significant associated dimensions of illness perception to depressive symptoms. Last, hierarchical multiple linear regression was used to test the moderation when the following predictors groups were included: socio-demographic (Model 1), clinical characteristics (Model 2), life stress (Model 3), illness perception, diabetes distress and moderation (Model 4), and previous depression (Model 5).
Results: Linear multiple regression showed that of the illness perception dimensions, only perceived illness consequences were significantly associated with depressive symptoms ($\beta = 0.08$, $p = 0.02$) and were further examined. Illness consequences did not significantly mediate the relationship between diabetes distress and depressive symptoms but was a moderator between the two ($\beta = 0.2$, $p = 0.01$). The final model of the hierarchical multiple linear regression showed that illness consequences did not moderate the distress-depressive symptoms relationship ($p = 0.06$) but were independently associated to depressive symptoms ($\beta = 0.2$, $p < 0.001$) along with education ($\beta = -1.4$, $p = 0.002$), diabetes distress ($\beta = 3.1$, $p = 0.001$) and previous depression ($\beta = 5.7$, $p = 0.001$).
Conclusion: The results imply that for people with type 2 diabetes, perceived illness consequences moderated the relationship between diabetes distress and depressive symptoms only in the absence of previous depression. Psychological interventions targeting people's perceptions about the consequences of diabetes might have a positive effect on future depressive symptoms.

Psychological burden and self-reported foot care among participants with or without diabetic foot ulcer

P.T. Murphy[1], B. McGuire[1], S. Conneely[1], J. Bogue[1], M. Pilch[1], A. O'Loughlin[2], S. Dinneen[2], A. Doherty[2], A. Liew[2]; [1]School of Psychology, National University of Ireland, Galway, Galway, [2]School of Medicine, National University of Ireland, Galway, Galway, Ireland.

Background and aims: The role of personality, mood, diabetes-related distress, illness perception and self-reported foot care on the risk of diabetic foot ulcer (DFU) is currently unclear. In this study, we aimed to assess the differences in the personality, mood, diabetes-related distress, illness perception and self-reported foot care between participants with DFU versus those without DFU. We hypothesised that there is a significant difference in these psychological and self-care variables between participants with DFU versus those without DFU.
Materials and methods: Consecutive participants with diabetes mellitus (DM) attending Galway University Hospitals were invited to participate in this study. Following informed consent, structured interviews were conducted using standard questionnaires to simultaneously examine aspects of personality (Type D Scale-14 [DS14] and Standardised Assessment of Personality-Abbreviated Scale [SAPAS]), mood (Patient Health Questionnaire [PHQ-9]), diabetes-related distress (Problem Areas in Diabetes Scale-5 [PAID-5]), illness perceptions (Brief Illness Perceptions Questionnaire [BIPQ]; questions relating to symptoms, perceived control and understanding of diabetes) and self-reported foot care (The Summary of Diabetes Self-Care Activities Measure [SDSCA]). Continuous variables were compared using t-tests with Levene's test for equality of variances. Categorical variables were tested using Chi-squared or Fisher's exact test where appropriate.
Results: One hundred and twenty participants completed the questionnaires. There was no significant difference in gender, occupational history, type of DM, HbA1c among participants with or without DFU. Participants with DFU were significantly older (65.5 ± 9.2 years vs 59.5 ± 16.9 years; $p < 0.05$), had a significantly higher BMI (34.8 ± 7.6 kg/m^2 vs 29.6 ± 7.4 kg/m^2; $p < 0.01$), longer duration of DM (18.6 ± 12.1 years vs 11.9 ± 8.3 years; $p < 0.01$) as well as, more likely to be on insulin therapy (73.7% vs 35.6%; $p < 0.05$) and have concomitant microvascular complications (26.3% vs 14.9%; $p < 0.001$). As expected, participants with DFU perceived more symptoms of diabetes, as compared with those without DFU (4.00 ± 4.44 vs 2.36 ± 2.46; $p = 0.007$). Intriguingly, there was no statistical difference between participants with or without DFU in relation to the other illness perceptions examined, namely, personal control over diabetes or understanding diabetes. Similarly, there was no significant difference in personality, mood, diabetes-related distress, and self-reported foot care between the two groups. Post-hoc analysis of participants who were on insulin therapy showed no significant difference in the results for all questionnaires between those with or without DFU.
Conclusion: Apart from experiencing more symptoms of diabetes and, contrary to expectations, there was no significant difference in personality, mood, diabetes-related distress, other illness perceptions, and self-reported foot care between participants with DFU versus those without DFU.

Mediating role of ventral striatum network in the relationship between the diabetes risk multilocus genetic profile and major depressive disorder

C. He;
Department of Neurology, Affiliated ZhongDa Hospital, School of Medicine, Southeast University, Nanjing, China.

Background and aims: Patients with type 2 diabetes mellitus (T2DM) showed significantly increased risk for major depressive disorder (MDD), which result in injuries of brain structure and function. But how T2DM and MDD are pathologically connected is poorly understood. Substantially, multiple genetic loci of diabetes risk (DR) gene has been suggested to associated with depressive symptom in MDD. However, neural mechanism underlying the polygenic effects involving in DR-pathways on depression remains unclear. We aimed to investigate the neural mechanism underlying the polygenic effects in DR-pathways on the ventral striatum (VS) network in MDD using imaging genetic approach.
Materials and methods: Fifty-nine MDD patients and 37 cognitively normal (CN) subject were recruited and completed the resting-state functional MRI scan. Four loci included in the genetic profile were carefully selected based on previous research. Multivariate linear regression analysis was employed to investigate the effects of disease and multilocus genetic profile scores (MGPS) on the ventral striatum functional connectivity (VSFC) network.
Results: DR-MGPS was widely association within VSFC network, mainly in inferior frontal cortex, occipital cortex, insular, hypothalamus, and superior temporal gyrus. The partial correlation analysis revealed that the DR-MGPS was negatively correlated with depressive symptom ($r = -0.355$, $P = 0.039$). The pattern of DR-MGPS effects in fronto-striatal pathway was opposite in MDD patients compared with CN subjects. More importantly, the VS-mPFC (medial prefrontal cortex) connectivity mediates the association between DR-MGPS and anxious depression traits in MDD patients.
Conclusion: DR multilocus genetic profile makes a considerable contribution to anxious depression in MDD patients. These findings extended our understanding about bidirectional associations between T2DM and depression and give us a new insight into the pathophysiology of polygenic effects underlying the brain network in comorbid T2DM and MDD patient.

Perceptions of diabetes control among physicians and people with type 2 diabetes on basal insulin in Italy

K. Vaccaro[1], S. Frontoni[2], M. Comaschi[3], G. Lastoria[4], A. Nicolucci[5]; [1]CENSIS, Rome, [2]Tor Vergata University, Rome, [3]GVM Care & Research, Rapallo (GE), [4]NovoNordisk SpA, Rome, [5]Center for Outcomes Research and Clinical Epidemiology, Pescara, Italy.

Background and aims: There is limited understanding of how patients perceive diabetes control and whether it differs from physicians' perceptions. The purpose of the study was to investigate how physicians and patients with type 2 diabetes (T2D) using basal insulin perceive diabetes control.
Materials and methods: A web survey of 250 adults with T2D treated with basal insulin and 100 physicians was conducted in Italy.
Results: In defining control, physicians were more likely than patients ($p < 0.05$) to indicate that HbA1c (94% vs. 69%), frequency/severity of hypoglycaemia (93% vs. 52%) and hyperglycemia (79% vs. 61%), adherence to insulin therapy (82% vs. 69%), complications from diabetes (91% vs. 68%), and following a healthy diet (82% vs. 66%) were important. Patients were more likely than physicians to report that other factors were important, including energy levels (58% vs. 38%) and how the patient feels emotionally (56% vs. 43%). Physicians saw more obstacles making control difficult compared to patients ($p < 0.05$), including medicine side effects (63% vs. 32%), complicated schedule for taking insulin (55% vs. 26%), other health issues (60% vs. 36%), alcohol intake (46% vs. 26%), life crises (60% vs. 44%), lack of education from healthcare professionals (47% vs. 31%), diabetes doctor not understanding patient's individual situation (47% vs. 34%), work schedules (47% vs. 34%), and not having a regular daily routine (46% vs. 34%). Patients with uncontrolled diabetes were significantly more likely than those with controlled diabetes to report as barriers to control a wide array of different factors. The largest differences in perceptions of obstacles making diabetes control very/extremely difficult were: people around patient not understanding diabetes (38.0% vs. 12.3%; $p < 0.0001$), other health issues (43.6% vs. 18.8%; $p < 0.0001$), food cravings (64.2% vs. 41.3%; $p = 0.001$), not having a regular daily routine (40.9% vs. 19.4%; $p = 0.001$), skipping insulin doses (35.4% vs. 14.7%; $p = 0.002$) and alcohol intake (31.7% vs. 11.5%; $p = 0.002$). Overall, 14.4% of respondents reported that their diabetes physician had recommended adding bolus insulin therapy to their current basal insulin regimen. The most frequently reported reasons for not taking bolus insulin therapy currently, despite physician recommendation, were not wanting to add more injections (44.4%), being worried it would be too complicated (44.4%), and "doctor agreed I could wait" (44.4%).
Conclusion: Physicians and patients with T2D differ in how they define control and the obstacles they perceive. Raising the awareness of physicians about how patients' perceptions of control may differ from theirs could help improve diabetes management.

A machine learning algorithm can identify clusters of patients with favourable glycaemic outcomes in a pooled European Gla-300 studies (REALI): Novel signposts for clinicians?

M. Rollot[1], M. Bonnemaire[2], C. Brulle-Wohlhueter[2], L. Pedrazzini[2], E. Boëlle-Le Corfec[2], G. Bigot[3], M. Didac[4], R. Bonadonna[5], P. Gourdy[6], D. Müller-Wieland[7], O. Hacman[1], A. Chiorean[1], N. Freemantle[8]; [1]Quinten, Paris, France, [2]Sanofi, Paris, France, [3]IVIDATA, Paris, France, [4]Hospital Universitari Germans Trias i Pujol, Barcelona, Spain, [5]University of Parma School of Medicine and AOU of Parma, Parma, Italy, [6]CHU Toulouse Hospital, Toulouse, France, [7]University Clinic of the RWTH Aachen, Aachen, Germany, [8]University College London, London, UK.

Background and aims: Detecting consistent patterns of interest can be performed using data-driven subgroup discovery algorithms. These may be instrumental in exploiting large healthcare databases and enabling a patient-level and data-driven analysis aiming at identifying patient clusters for clinicians. The REALI project, a pool of a large database collecting data from more than 10,000 people with type 2 and type 1 diabetes mellitus uncontrolled with antidiabetic therapy and initiated on Gla-300 from different European Gla-300 studies, is an appropriate source of data for such an analysis. The objective of the present work was to explore patient-related variables and to identify clusters of patients who: 1. achieved HbA_{1c} drop ≥0.5% from baseline to end of study (EoS); 2. experienced hypoglycemia event during the study (HEOS), and 3. achieved the combined outcome of HbA_{1c} <7% at EoS without HEOS.
Materials and methods: Q-finder, a subgroup discovery algorithm, was first applied to a single study (Take Control) from REALI pooled database. Q-finder is a proprietary non-parametric supervised learning algorithm working with no particular assumption regarding distributions of the outcome or explanatory variables. This algorithm explores the space of explanatory variables to identify areas where the outcome specified for

the exploration shows higher or lower concentration than average. The output is a set of patient clusters, defined as combinations of variables and thresholds which characterize subpopulations with significantly higher/lower probability of experiencing an outcome of interest. All results were tested for their significance in models adjusted for confounding factors and taking into account multiple testing (Bonferroni's correction).
Results: Take Control was a 24-week interventional study of Gla-300 efficacy and safety, including 631 patients. Thousands of queries were performed by the algorithm, and 32 were found statistically significant after Bonferroni's adjustment in models including confounding factors. Among the clusters that were generated, patients with higher probability of having an HbA_{1c} reduction ≥0.5% at EoS were those with no previous insulin exposure (234 patients [pts], RR = 1.6, $p < 10^{-6}$), and those with a baseline HbA_{1c} value ≥7.9% (421 pts, RR = 1.5, $p < 10^{-10}$). Additionally, our findings suggest that patients who received a pre-hypoglycemia average insulin dose ≤33.3 U were at greater risk of HEOS (363 pts, RR = 1.7, $p < 10^{-5}$); moreover, patients with a duration of disease ≤12 years and a baseline alkaline phosphatase value ≤64 U/L were more likely to achieve the combined outcome of HbA_{1c} <7% at EoS without HEOS (127 pts, RR = 2.2, $p < 10^{-6}$).
Conclusion: Our analysis is a new promising and powerful tool, which provides simple and efficient criteria for the clinician to identify clusters of patients in whom the intervention of Gla-300 is most efficacious and safe. This approach will be applied on additional REALI datasets.

PS 076 Education and patient/provider perceptions

877

An interest of people with diabetes and their relatives in diabetes social media communities

L. Chernilova[1], M. Dunicheva[2], E. Patrakeeva[3], J. Zakharchenko[2], E. Shilova[4];
[1]City outpatient clinic 117, St. Petersburg, [2]City center of family planing and reproduction, St. Petersburg, [3]First Pavlov Medical University, St. Petersburg, [4]Almazov National Medical Research Centre, St. Petersburg, Russian Federation.

Background and aims: To study the interest of people with diabetes and their relatives in information about diabetes in social media. To assess the impact of previous diabetes education experience on interest in information about diabetes in social media.
Materials and methods: Participants of the diabetic community Diabet.Connect in social networks Vkontakte and Instagram were asked to fill in a special anonymous questionnaire containing questions about duration and level of diabetes control, their interest in diabetes specialized groups in social media and their previous experience of obtaining knowledge about diabetes. We used ANOVA method and linear regression model for statistical analyses.
Results: 591 people took part in the survey, 37.6% of them were relatives of people with diabetes. The majority of participants (53.5%) were 26–40 years old, 85.5% were women, 71.5% had higher education. According to the received data, the less the relatives of people with diabetes had been satisfied with previous diabetes education experience, the more they tended to devote time to searching for correct information on the Internet ($p = 0.002$). Whereas there was no correlation between these two indices for the actual people with diabetes ($p = 0.234$). For people with diabetes there was no correlation between the value of HbA1c and the interest in diabetic social media resources ($p = 0.97$). While relatives of people with diabetes had a positive feedback between the level of interest in diabetic social media and the level of HbA1c their loved ones ($p = 0.024$).The longer the patient had a duration of diabetes, the less his family and friends tended to seek information about diabetes in social media ($p = 0.000$). Dependence of interest in information in social media on the the diabetes duration for the people with diabetes was not detected ($p = 0.168$). Respondents under the age of 18 were significantly less likely to recommend diabetic communities to other people than respondents over 18 years old. At the same time gender had no influence on the willingness to recommend in any of the age groups.
Conclusion: According to the received data, diabetes communities in social media can be a very important source of information about diabetes, not only for the patients with diabetes themselves, but also for their relatives.

Key components and mechanisms in the integration of self-management education in routine care of people with type 2 diabetes

C. Huber[1], C. Montreuil[2], A. Forbes[1];
[1]Florence Nightingale Faculty of Nursing, Midwifery & Palliative Care, King's College London, London, UK, [2]Department of Cardiovascular Prevention, Outpatient Clinic, University of Lausanne, Lausanne, Switzerland.

Background and aims: National and international guidelines recommend self-management education as a key element of care. However, only a third of people with type 2 diabetes participate in self-management education, suggesting that such programmes are insufficiently integrated in patient care processes. The aim of this study was to

understand how integration at the patient, healthcare professionals (HCPs) and system levels influences the experience of and participation in self-management education. A theoretically and empirically grounded model of integration and its relationship to self-management care delivery helps inform the design of future self-management education programmes.

Materials and methods: A case study research design was used to consider the study aim. Three self-management education programmes were purposively sampled from a quality improvement initiative. The research involved observations, semi-structured in-depth interviews and documentary analysis using NVivo 11 for data management. 20 people with type 2 diabetes and 36 HCPs participated in in-depth interviews; 88 hours of direct programme observations; and 14 programme documents were analysed. The data were triangulated and analysed thematically using a narrative approach; then synthesised across the cases using complex adaptive systems theory to guide the synthesis.

Results: Five main themes were identified representing key components of integration in self-management education: 1. Personalised care - HCPs support individual patient activities but variably implement this in care delivery; 2. Inter-professional work - HCPs may more consistently encourage self-management when they collaboratively consider and develop their understanding supported in interdisciplinary training; 3. Communal resources - self-management education is shaped by the local structures and evident in the supplied resources that direct the programme access and execution; 4. Logical programme guidance - the theoretical programme framework that philosophically guides the self-management delivery but may be differently understood or inconsistently implemented by HCPs; and 5. Programme regulators - the guidelines and recommendations that frame the implementation of the programme in routine practice and permit evaluation in the context. Four key mechanisms were identified to activate the components. These were the extent to which the participants: a) identified with the condition and activity to prioritise self-management, b) experienced social support to learn from sharing practice, c) co-created interactions to build an equal relationship, and d) accepted the paradigm of care to develop a common understanding of self-management. The mechanisms interacted within and across the components of integration. These data were used to develop a model of integrated person-centred self-management education.

Conclusion: This study has identified components and mechanisms that influence the integration of self-management education in routine care at the individual, professional and system level to understand the uptake of such programmes. The findings of the model indicate that multiple strategies are required to enhance programme integration and these strategies may impact on the adoption of individual self-management behaviours.

Comparison of two therapeutic education methods in diabetic patients: a randomised controlled trial

N. Lanasri[1], N.W. Nibouche[1], L. Atif[2], L. Makhlouf[1], F. Zeraoulia[1], F. Hansal[1], L. Benaoua[1], K. Zouai[3], S. Ouadah[3], K. Messous[1], A. Chibane[4], A. Biad[1];
[1]Internal Medicine Service, Ain-taya Hospital, [2]Epidemiology Service, Blida Hospital, [3]Biochemistry Laboratory, Ain-taya Hospital, Algeria.

Background and aims: Because of its effectiveness on glycemic control and quality of life in diabetic patients, a strategy of Therapeutic Education of Patient (TEP) is being settled in Algeria. However, the TEP practices are heterogeneous and disparate. The aim of this study was to compare the impact on the bioclinic and behavioral aspects of 2 TEP methods in diabetic patients.

Materials and methods: A randomized controlled trial was performed to compare the 2 structured methods of TEP. Type 2 diabetic adult patients who had never benefited of therapeutic education were included and randomized in 2 groups: (i) patients who received a TEP program during a 5-day hospitalization and (ii) patients who received an ambulatory TEP program (1 weekly session during 2 weeks). Both programs had the same content, the same educational method, the same overall time, and were delivered by the same team. Outcomes included psycho-social and bioloclinic criteria, were measured at 0, 3 and 12 months, and compared between the 2 diabetic patients groups. HbA1c was used as major biological criteria. The overall quality of life score, evaluated by the ADDQOL questionnaire, was used as major psycho-social criteria.

Results: A total of 200 type 2 diabetic patients were included and randomized: 97 in the outpatient group and 103 in the weekly hospitalization group. Patients' characteristics were not statistically different between the 2 randomized groups. The 2 methods of TEP were effective on almost outcomes criteria. An average reduction (mean ± standard deviation) of HbA1c of 1.6% ± 1.8% was observed at 12 months in the outpatient group versus 1.9% ± 2.0% in the weekly hospitalization group. The difference is not statistically significant. The overall quality of life score increased during 12 month from 3,6/6 to 5,0 /6 in the outpatient group versus 3,5/6 to 4,9 /6 in the weekly hospitalization group. The difference is not statistically significant between the two groups.

Conclusion: The two studied TEP methods have proved effective. Because of its efficiency, the ambulatory TEP program should be recommended for diabetic patients.

Effectiveness evaluation of diabetes Ramadan conversation map intervention for managing type 2 diabetes during Ramadan

E. Srulovici[1,2], M. Leventer-Roberts[2], M. Hoshen[2], A. Bachrach[2], M. Rotem[3], E. Shadmi[1], C. Key[3], B. Feldman[2];
[1]Nursing, University of Haifa, Haifa, [2]Clalit Research Institute, Clalit Healthcare Services, Tel Aviv, [3]Community Nursing Division, Clalit Healthcare Services, Tel Aviv, Israel.

Background and aims: Some individuals with diabetes fast during Ramadan, which has the potential to increase the risk of adverse outcomes, such as hypoglycemia, in high or moderate risk groups. The Diabetes Ramadan Conversation Map (Ramadan Map) is a self-management education group-based intervention for Muslims with type 2 diabetes specifically addressing management during Ramadan. The aim of this study was to evaluate the effectiveness of the Ramadan Map intervention among the participants using short-term clinical outcomes and healthcare utilization.

Materials and methods: This was a retrospective rolling cohort study of members of Clalit Health Services with type 2 diabetes who participated in a Ramadan Map intervention between 2014 and 2017. We used a difference-in-differences (self-comparison) design to examine the association of the Ramadan Map intervention with laboratory test results (HbA1c, glucose, LDL, HDL, and triglycerides) and healthcare utilization outcomes (primary care clinic visits and hospital admissions) comparing changes in outcomes in the six month pre- and post -intervention periods. The differences in the outcomes in the intervention year were compared to the differences in the outcomes the previous year pre- and post-Ramadan. Mixed Model Linear and random effects model with square root transformation regressions were used to estimate adjusted outcomes as appropriate.

Results: There were 1,732 members of Clalit who were included in the study. These cohort members experienced a reduction of 8.61 mg/dL in their glucose levels ($p = 0.005$) and a 0.34% decline in their HbA1c levels ($p < 0.001$) following the Diabetes Ramadan Conversation Map participation. Patient characteristics that were positively associated with this reduction in glucose levels included being 75 years or older, having diabetes for less than 10 years, and having high oral medication adherence. In a sub-group analysis of participants with pre-intervention levels

of HbA1c >7%, participants experienced a reduction of 17.02 mg/dL ($p < 0.001$) in their glucose levels and 0.63% ($p < 0.001$) in their HbA1c levels. They also experienced a reduction of 4.83 mg/dL in their LDL level ($p = 0.007$) and 0.21 fewer primary care visits ($p < 0.001$).

Conclusion: Following participation in the Diabetes Ramadan Conversation Map, Clalit members had lower glucose and HbA1c levels. The effect of participation was more pronounced among those whose baseline HbA1c was considered uncontrolled (>7%). This has important global health impact for the millions of people with type 2 diabetes for whom Ramadan can pose a challenge in disease control.

Table 1: Difference-in-Differences Analysis of Multivariable Mixed Linear Regression Models Comparing Differences Pre-And Post- Ramadan in the Intervention Year to the Year Prior

Treatment of type 2 diabetes: learning from patients' preferences

G. Marchesini, the Italian DCE Study Group;
Metabolic Diseases and Clinical Dietetics, University of Bologna, Italy.

Background and aims: T2DM patients' preferences are not adequately considered by diabetologists, rarely checking patients' adherence. A critical issue is the passage from oral to injectable therapy, perceived as a non-return step, marking disease progression , associated with insulin use, blood glucose monitoring and complications. This is no longer the case with GLP-1 receptor agonists (RA). We aimed to determine patients' preferences whenever treatment intensification is needed to achieve a satisfactory metabolic control.

Materials and methods: We tested preferences using the Delphi method and the procedures of Discrete Choice Experiment (DCE). We considered the following variables, covering the peculiar aspects of most recent antidiabetic drugs: administration route (oral *vs.* injectable), timing (daily *vs.*weekly), type of device (single-dose, disposable *vs.* multidose, to be adjusted), effects on body weight (neutral *vs.* weight loss), possibility of adverse events (AEs): nausea and genito-urinary infections (UTI)(no risk *vs.* high risk for both AEs). According to these 6 variables, 22 possible scenarios were built (excluding impossible, dominant and dominated scenarios), transferred into 192 paired choices. These scenarios were proposed to 491 T2DM patients, naïve to injectable treatment (8 paired choices/patient) and to 171 cases treated by GLP-1RA (12 paired choices/patient). Patients were invited to select their preferences in any paired choice in the event that current treatment might require treatment intensification, independent of their actual metabolic control. The new proposed treatments were supposed to be equally effective.

Results: The two groups were well balanced as to BMI (mean, 29.5 and 29.7 kg/m^2, respectively), and age (66 and 64). In the overall sample, every attribute had a significant effect on patients' choice. While preferences expressed according to dosing frequency, risk of nausea and risk of UTIs were similar across groups (naïve vs. non-naïve), age (>65 vs. ≤65), sex (males *vs.* females) and BMI (>28 *vs.* ≤28), two interactions were highly significant ($p < 0.01$): i) Type of delivery*Group, and ii) Weight change*BMI class, i.e., the preferred type of delivery was different according to previous experience with injectable GLP-1RAs, whereas weight loss was only significant in the presence of obesity (BMI ≥30 kg/m^2). Overall, the route of administration and type of delivery remained the most important attribute accounting for 1/3 of patients' preferences; the risk of UTI, nausea and dose frequency followed, each accounting for approx. 20% of preferences, and a small fraction was left to weight loss (6%). In a random effects logit regression model, patients' preferences were significantly modulated by the combination of different attributes, ranging from above 80% for the most preferred ones to only about 15% for the lowest. However, being naïve or non-naïve significantly affected the ranking of preferences, as indicated by Medications*Group interaction (Wald chi-square, 87.0; df, 22; $p < 0.001$). The first three preferred medications (all injectable) were the same in both groups, but the order markedly differed for other scenarios, with preferences shifted towards injectable medications in non-naïve.

Conclusion: Previous experience with injectable GLP-1RAs favored patients' willingness to accept injectable treatment, particularly when coupled with a ready-to-use device and weekly dosing. However, this treatment was the preferred one also in the total sample, independently of treatment history.

Using structured self-monitoring of blood glucose to improve diabetes knowledge: the SMBG study

S.N. Parsons, S.D. Luzio, D.R. Owens, SMBG Study Group;
Diabetes Research Unit Cymru, Swansea University, Swansea, UK.

Background and aims: The SMBG Study was a 12 month, multi-centre, randomised controlled trial conducted in people with established (>1 year) type 2 diabetes not on insulin therapy, with poor glycaemic control (HbA1c ≥58 to ≤119 mmol/mol or ≥7.5% ≤13%). The primary aim of the study was to determine whether HbA1c was significantly different at 12 months comparing those undertaking SMBG and a control group. The study also assessed patient reported outcomes such as diabetes specific knowledge.

Materials and methods: Participants ($n = 446$) were recruited into one of three groups; Group 1 (G1, $n = 151$), a control group receiving usual diabetes care; Group 2 (G2, $n = 147$), undertook structured SMBG with clinical review every 3 months; Group 3 (G3, $n = 148$), undertook structured SMBG with additional monthly TeleCare support from a trained study nurse. All participants received the same standardised diabetes education before randomisation. Participants in both SMBG groups (G2 & G3) and all healthcare professionals involved in the study received standardised training on SMBG technique, glycaemic pattern recognition and the use of management algorithms. The testing regimen consisted of paired testing pre and 2 hours post breakfast and main meal, 2 days each week plus a 7 point profile for 3 days the week prior to the 3 monthly study visit. In addition to clinical measurements, at each study visit quality of life measures were also administered along with questionnaires to gauge attitudes towards SMBG and measure diabetes knowledge at the beginning and end of the study.

Results: As previously reported there was a statistically significant reduction in mean HbA1c at 12 months in all three groups which was significantly improved in those undertaking SMBG versus the control group with a mean reduction in HbA1c of 0·82%/8·91 mmol/mol (95% CI −1·09 to −0·54/−11·97 to −5·85, $p \leq 0.0001$). The difference between

the two SMBG groups was not significant. At baseline diabetes knowledge, as measured by the ADKnowl questionnaire was similar across the 3 groups with a mean overall score of 65.5%. Knowledge deficits identified included the symptoms and treatments of hypoglycaemia and the effect of alcohol and particular food groups on blood glucose levels. At 12 months, diabetes knowledge had improved overall for those who completed the study (Table 1). Greater improvement in overall knowledge was seen in the SMBG groups and in particular the questions concerning the effects of exercise and food on blood glucose levels. Questions regarding hypoglycaemia and its treatment scored low across all groups at both baseline (47.7%) and at 12 months (56%).

Conclusion: Structured SMBG has been shown to be a valuable tool to improve HbA1c. In this study we have demonstrated that it can also improve overall diabetes knowledge and in particular, significantly improve specific knowledge regarding the effects of food and exercise on blood glucose levels.

Seasonal trends in HbA_{1c} level in adult patients with type 1 diabetes treated with personal insulin pumps

B. Matejko, B. Kieć-Wilk, S. Mrozińska, T. Klupa, M. Malecki;
Jagiellonian University Medical College, Krakow, Poland.

Background and aims: The DCCT and other studies showed that the variability in HbA1c added to mean HbA1c increases the risk of the development of complications of diabetes. There were some earlier reports showing a seasonal variability in the HbA1c level in a pediatric population.

Materials and methods: We evaluated seasonal HbA1c changes over a period of 9 years (2009–2017) in 453 adults with type 1 diabetes (T1DM, 61% women) treated with personal insulin pumps. HbA1c was measured at a tertiary care university hospital on the Bio-Rad D10 hemoglobin testing system. Differences between groups (12 groups for 12 months and six for every consecutive two months) were assessed using the Kruskal-Wallis and post hoc tests.

Results: Patients median age was 24 years [range 18–80 years], median BMI 22.9 kg/m^2 [15.6–43.7 kg/m^2] , median diabetes duration 12 years [1–40 years] and median duration on personal insulin pump 6 years [0–18 years]. A total of 1, 438 HbA1c measurements were analyzed. Median HbA(1c) level for the whole study period was 7.25% [55.7 mmol/mol] (range 4.8–12.8% [29–116.4 mmol/mol]). There were seasonal differences in HbA1c over 12 months ($p = 0.02$): The lowest HbA1c was observed in summer (July, 6.8% [50.8 mmol/mol) and the highest in winter months (from 7.1% [54.1 mmol/mol] in January to 7.3% [56.3 mmol/mol] in February). HbA1c was lower in July than in February ($p = 0.03$). After combining two consecutive months in one group seasonality of HbA1c values was still observed ($p = 0.008$). Median HbA1c in July/August (6.9% [51.9 mmol/mol]) was lower than in January/February (7.2% [55.2 mmol/mol], $p = 0.01$) and in November/December groups (7.3% [56.3 mmol/mol], $p = 0.02$).

Conclusion: To our knowledge this is the first report concerning HbA1c seasonal fluctuations in well controlled cohort of adult T1DM patients treated with insulin pumps. Seasonal changes of HbA1c levels (peak in summer months, drop in winter months) in such a group of patients should be considered in patient education, diabetes management and epidemiological interpretation.

Factors predictive of HbA_{1c} in insulin pump users in Galway University Hospital

C.E.H. Fang[1,2], E. O'Sullivan[1,2];
[1]Centre for Diabetes, Endocrinology and Metabolism, Galway University Hospitals, Galway, [2]School of Medicine National University of Ireland Galway, Galway, Ireland.

Background and aims: Insulin pump therapy in Type 1 Diabetes Mellitus (T1D) patients has been shown to improve glycaemic control, reduce hypoglycaemic episodes and improve quality of life compared to multiple dose injection therapy (MDI). However less improvement in outcomes in adults with T1D using pump therapy compared to those using MDI was shown when both received structured education (SE). It is not always possible for patients to access SE and there are no studies showing whether SE prior to starting insulin pump therapy leads to better outcomes. The purpose of this study was to first, determine if pump therapy was beneficial in reducing HbA1c for adult T1D patients managed in diabetes clinic in Galway University Hospital (GUH). Second, to determine factors predictive of HbA1c such as SE.

Materials and methods: This was a retrospective cohort study on patients with T1D who started insulin pump from January 2014 to December 2017 in UHG. Data was gathered from the DIAMOND database and analysed with Student's t-tests.

Results: 76 patients were started on insulin pump therapy from 2014 to 2017. 4 patients did not have documented pre-pump HbA1c on the DIAMOND system and were excluded. Of the 72 patients, there were 41 females and 31 males, mean age 41.5 ± 12.4 years (range 16–69), average duration of diabetes 22.6 ± 12.0 years (range 10–55). Average age at start of insulin pump was 39 ± 12 years. Average number of clinic visits per year before pump was 1.6 and after pump was 1.4. Baseline HbA1c average 67.1 ± 16.6 mmol/mol (range 59–126). 25 patients were on continuous glucose monitoring pumps. 60 patients underwent a SE programme (DAFNE). Overall, at each time point; from before starting pump therapy, to 3 months, 6 months, 12 months and 24 months, there was a trend toward reduction in HbA1c. There was no significant difference between the HbA1c of patients who had SE and those that did not at baseline or at any of the follow-up time points. Patients who started pump therapy with a high HbA1c (≥75 mmol/mol) had a significant reduction in HbA1c at all time points. However the change in HbA1c for patients who started at a lower HbA1c (≤53 mmol/mol and 54–74 mmol/mol) was not significant.

Conclusion: In the cohort of insulin pump users, there was no difference in HbA1c for those who had SE versus no SE, suggesting that for selected patients who cannot access this, it is reasonable to start insulin pump therapy after one to one educational sessions. For those starting on insulin pump with a high HbA1c (≥75 mmol/mol) there was a significant reduction in HbA1c but not for those staring with a lower HbA1c. Selected

patients who have not attended a SE programme but have had 1:1 education from diabetes educators can benefit from pump therapy, as they may have very elevated HbA1c. Other factors such as sex, age at diagnosis, duration of diabetes and number of clinic visits per year were not shown to be significant.

HbA1c	PrePump	3 months	6 months	12 months	24 months

PS 077 Therapeutic adherence and satisfaction

885

Outpatients' wait times and healthcare professionals' communication behaviours may influence on treatment satisfaction and the intention to drop out

S. Sato[1], T. Tosaki[1], C. Oshiro[1], A. Inagaki[2], M. Kondo[3], S. Tsunekawa[3], Y. Kato[3], H. Kamiya[3], J. Nakamura[3];
[1]Tosaki Clinic for Diabetes and Endocrinology, Nagoya, [2]Diabetes and Endocrinology, Japanese Red Cross Nagoya Daini Hospital, Nagoya, [3]Division of Diabetes, Aichi Medical University School of Medicine, Nagakute, Japan.

Background and aims: We studied influences of perceptions of patients' wait times and communication behaviors of healthcare professionals on treatment satisfaction and the intention to drop out in diabetes outpatients.
Materials and methods: A questionnaire was sent to 888 outpatients with diabetes or impaired glucose tolerance who visited our clinic in April 2016. We also measured time spent in clinics.
Results: Totally, 759 patients responded to the questionnaire; 717 valid responses were obtained for statistical analyses. In the group with the intention to drop out, many replied that they felt that "the wait time from physical examination to accounting" was long; this association was significant ($P = 0.009$, χ^2 test). Communication behaviors of healthcare professionals were also associated with the presence of the intention to drop out. Among patients who intended to drop out, many replied negatively to the following items: "explanation of test results and treatment strategy," "explanation of caution in daily life," "clear and understandable responses to questions," and "communicative atmosphere." Among those who did not intend to drop out, fewer responded negatively to those items. The associations were all significant ($P < 0.001$, $P < 0.005$, $P = 0.001$, and $P = 0.002$, respectively, χ^2 test). Median scores of the first factor of the Diabetes Treatment Satisfaction Questionnaire (DTSQ) were lower in those who intended to drop out than in those who did not (52 vs 632 patients); the DTSQ first factor score was significantly associated with the presence of the intention to drop out ($P < 0.001$, Mann-Whitney U test). Receiver operating characteristic curve analysis revealed the DTSQ score as a significant predictor of the presence of the intention to drop out (area under the curve = 0.746, $P < 0.001$), with an optimal cut-off of 22.5 (sensitivity 70.6%, specificity 67.3%). We compared perceptions about wait times and healthcare professionals' communication behaviors between patients with scores above and below the cut-off. Among less-satisfied patients, many replied that the "wait times (from blood collection to physical examination, from physical examination to accounting, and total)" were long and replied negatively to the items of "explanation about test results and treatment strategy," "caution in daily life," "clear and understandable response to question," and "communicative atmosphere"; here, all associations were significant. Time spent in clinics was also significantly associated with the "perception of wait time (total)."
Conclusion: The DTSQ first factor score cut-off in this study was consistent with the value reported by Saisho et al among 139 patients. However, the findings of this study in a larger sample size suggest that improved treatment satisfaction may reduce incidences of drop out. Thus, improved wait times and better communication behavior from healthcare professions may improve patient satisfaction and reduce the intention to drop out and possibly the dropout rate.

A novel liquid chromatography tandem mass spectrometry method detects high non-adherence rates in people with diabetes

P. Gupta[1], A.A. Mohamed[1], P. Patel[1], A. Burns[1], M. Saeed[1], D. Lane[1], S. Seidu[2], K. Khunti[2];
[1]Chemical Pathology and Metabolic Diseases, University Hospitals of Leicester NHS Trust, Leicester, [2]Diabetes Care Centre, University of Leicester, Leicester, UK.

Background and aims: Type 2 diabetes mellitus (T2DM) is a complex chronic disease associated with life-threatening complications. Poor glycaemic control in people with T2DM is associated with higher morbidity and mortality. It has been shown that up to one-third of people with T2DM fail to derive optimal benefit from therapy because of medication non-adherence. Few practical tools exist to accurately and routinely detect non-adherence to therapy. We have set up a unique and robust biochemical method that can detect 60 most common cardiovascular medications in a spot urine sample.
Aim To determine the prevalence of non-adherence to antidiabetic, antihypertensive and lipid-lowering medications in people with T2DM in the primary care settings.
Materials and methods: 256 patients from six different general practice (GP) surgeries in Leicestershire, UK agreed to aliquots from urine samples collected for routine albumin-creatinine ratio (ACR) analysis to be assessed for adherence to antidiabetic, antihypertensive and lipid-lowering drug intake using liquid chromatography-tandem mass spectrometry (LC-MS/MS). Basic demographic information (age, sex, GP surgery) and biochemical laboratory values for ACR, HbA1c and lipid profile were retrieved retrospectively from laboratory database. Data on the number and doses of prescribed medications were collected from the patients' prescription lists.
Results: The clinical and biochemical characteristics of the patients are shown in table 1. Overall, 27% patients ($N = 69$) were completely or partially non-adherent to antidiabetic, antihypertensive and/or lipid lowering medications (total non-adherence 5.5%, partial non-adherence 21.5%). The highest rate of non-adherence was for statins (21%, $N = 42$ of 198 analysed drugs) while non-adherence to antidiabetic medications was 8% ($N = 27$ of 337 analysed drugs). After adjusting for age and sex using ANCOVA analysis, mean of ACR, HbA1c and lipid profiles were statistically higher for the non-adherent patients compared to adherent patients [Table 1].
Conclusion: Our first of its kind study shows that non-adherence to antidiabetics, anti-hypertensives and lipid-lowering therapy is common in patients with diabetes in primary care settings. Markers of glycaemic and lipid control as well as renal function were significantly worse in non-adherent patients compared to adherent patients. LC-MS/MS urine analysis could be used to objectively detect non-adherence in primary care and could be used to inform clinical decisions of treatment alteration and improve patient outcomes.

Table 1 General demographics, clinical and biochemical characteristics of T2DM patients

	All patients	Adherent	Any non-adherence	Total non-adherent	Difference (P value)*	Difference (P value) †
N (%)	256	187 (73%)	69 (27%)	14 (5.5%)		
Age (years ± SD)	59.93 ± 12.43	60.33 ± 12.38	58.83 ± 12.59	46.07 ± 12.02	1.50 (0.391)

Patient-level predictors of delay in insulin initiation and periods of insulin discontinuation among adults with type 2 diabetes

L. Fisher[1], W. Polonsky[2], D. Hessler[1], J.I. Ivanova[3], U. Desai[4], D. Cao[5], F.J. Snoek[6], M. Perez-Nieves[5];
[1]University of California, San Francisco, San Francisco, USA, [2]Behavioral Diabetes Institute, San Diego, USA, [3]Analysis Group, Inc., New York, USA, [4]Analysis Group, Inc., Boston, MA, USA, [5]Eli Lilly and Company, Indianapolis, USA, [6]VU University Medical Center, Amsterdam, Netherlands.

Background and aims: About 30% of adults with type 2 diabetes (T2D) who are encouraged to initiate basal insulin (BI) by their health care professionals (HCP) initially refuse to do so, and after initiation, many patients use BI only intermittently. This study examined whether key factors, including patient demographics, T2D history and patients' observations of the impact of insulin on family/friends, were associated with delays in BI initiation and problematic BI persistence over time (i.e., having BI discontinuation for $\geq$7 days since BI initiation).

Materials and methods: 594 T2D adults across seven countries (Brazil, Canada, Germany, Japan, Spain, United Kingdom, United States), who indicated initial reluctance to begin BI but eventually agreed to do so, participated (mean age = 53.3 [SD = 11.3], 56.7% male). Two BI use behaviors were assessed: 1) immediate initiation when recommended initially vs. delay; and 2) BI interruption (i.e., discontinuation for ≥7 days) since BI initiation. Examined patient factors included: demographics, T2D history, and patients' perceptions of impact of insulin on overall health and mood in insulin-using family/friends.

Results: In models controlling for patient characteristics and length of time using BI, and adjusting for clustering by country, a delay in beginning BI was significantly ($p < 0.05$) associated with: short duration of T2D (odds ratio [OR] = 0.95), ≥1 severe hypoglycemic episode prior to BI initiation (OR = 1.87) and the belief that insulin use in family/friends had led to their poorer overall health over time. (OR = 1.27). Similarly, interruptions in BI use over time were significantly associated with: younger age (OR = 0.96), higher BMI (OR 25–29.9 kg/m^2 = 0.50; ≥30 kg/m^2 = 0.39), prior use of injectables (OR = 0.38), ≥1 severe hypoglycemic episode prior to BI initiation (OR = 2.55), and the belief that prior insulin use in family/friends had led to poorer overall mood over time (OR = 0.26).

Conclusion: We find that younger age, previous use of injectables, previous severe hypoglycemic episodes, fewer years with T2D, and perceived experiences of family/friends' BI use are significantly associated with delay in BI initiation or problematic BI persistence over time. To enhance a smooth transition to BI and to help maintain BI use over time, HCPs need to consider patients' T2D history and their observations and interpretations of the effects of BI use in others.

On Time: an innovative online discussion tool to overcome barriers to insulin initiation

P. Filteau[1], J. Gilbert[2], G. MacNeill[3], E. Cooke[4], M. Vallis[5], M. Groleau[6], P. Javadi[7], C. Lebovics[6];
[1]Family Doctor, St-Marc-des-carrieres, Canada, [2]Sunnybrook Health Sciences Centre, Toronto, Canada, [3]Mount Sinai Hospital, Toronto, Canada, [4]Elaine Cooke Consulting, Maple Ridge, Canada, [5]Dalhousie University, Halifax, Canada, [6]Sanofi Canada, Laval, Canada, [7]Sanofi, Paris, France.

Background and aims: The On Time education program is an innovative, online point-of-care tool designed to uncover and address barriers to insulin initiation, and to facilitate timely insulin initiation, when appropriate, in insulin-naïve individuals with type 2 diabetes (T2D).

Materials and methods: A total of 195 health care professionals (HCPs) completed online profiles of 1025 insulin-naïve individuals with T2D currently treated with non-insulin antihyperglycemic agents (NIAHAs) and with HbA_{1c} levels above the Diabetes Canada target (for most individuals ≤7%). After having completed the discussion tool and questionnaires, participating HCPs were asked to evaluate the program, tool, and questionnaires.

Results: Mean age of participants was 61.2 years; 55% were male; mean duration of diabetes was 10.5 years. For the majority of participants (70%) the recommended HbA_{1c} target was ≤7.0%. On average, participants were prescribed 2.6 NIAHAs, mainly metformin and dipeptidyl peptidase-4 inhibitors. Prior to using the On Time discussion tool, only 23% of individuals with diabetes were judged as likely (16%) or extremely likely (7%) willing to initiate insulin. The leading barriers to initiating insulin were apprehension toward needles/injections (59%), belief that insulin was complicated (56%), and psychological insulin resistance (45%). After using the On Time discussion tool, participants' perceived willingness to initiate insulin increased (likely: 34%, extremely likely: 28%). Initiation of insulin was planned in 77% of participating individuals. The evaluation questionnaire was completed by 149 HCPs (76.4%), and showed that the discussion tool was perceived to help HCPs address insulin-related barriers (82%), positively impacted their practice (79%), and improved their approach when discussing insulin initiation with individuals with diabetes (76%).

Conclusion: Identifying the barriers to initiating insulin and providing educational interventions to address them may help to improve insulin acceptance.

889

Attitudes among adults with type 2 diabetes affecting insulin initiation and discontinuation

M. Perez-Nieves[1], W. Polonsky[2,3], L. Fisher[3], F. Snoek[4,5], I. Hadjiyianni[6], D. Cao[1], J. Ivanova[7], U. Desai[8], D. Hessler[3];
[1]Eli Lilly and Company, Indianapolis, USA, [2]Behavioral Diabetes Institute, San Diego, USA, [3]University of California, San Francisco, USA, [4]VU University Medical Center, Amsterdam, Netherlands, [5]Academic Medical Center, Amsterdam, Netherlands, [6]Eli Lilly and Company, Bad Homburg, Germany, [7]Analysis Group, Inc, New York, USA, [8]Analysis Group, Inc., Boston, USA.

Background and aims: Approximately 30% of patients with type 2 diabetes (T2D) are reluctant to initiate basal insulin when recommended by their healthcare provider (HCP). Even after initiation, many patients use insulin intermittently. Examining patients' attitudes towards insulin and their links to subsequent use can aid HCPs in improving insulin uptake and adherence.

Materials and methods: 594 T2D adults across seven countries who indicated initial reluctance to begin basal insulin but eventually agreed to do so [mean age = 53.3 (SD = 11.3), 56.7% male], participated in a survey as part of the EMOTION (AccEpting Insulin TreatMent for Reluctant PeOple with Type 2 DIabetes Mellitus - A GlObal Study to IdeNtify Effective Strategies) study. In addition to self-reported insulin behavior (immediate initiation vs. delay, discontinued use for ≥7 days), attitudes towards insulin immediately prior to initiating insulin were captured using a modified version of the Insulin Treatment Appraisal Scale (mITAS).

Results: An exploratory factor analysis of the 21 negatively worded mITAS items (1 = strongly disagree to 5 = strongly agree) yielded four factors: "concerns about injections" ($M = 3.4$, SD = 1.0), "failed diabetes management" ($M = 3.8$, SD = 0.8), "increased disease severity" ($M = 3.0$, SD = 0.9), and "concerns about side effects" (i.e., weight gain, hypoglycemia) ($M = 3.4$, SD = 0.8). In models controlling for patient characteristics and clustering by country, higher scores (more negative appraisal) in all four mITAS factors were linked with greater likelihood of delaying insulin initiation (ORs: 1.34 to 1.73; all $p < 0.05$). Only "concerns about side effects" was associated with discontinuation and inversely related (OR = 0.60, $p < 0.05$). Overall, higher mITAS scores were associated with being female, younger, more recently diagnosed, and without previous experience with injectable medications.

Conclusion: Negative patient appraisals of insulin are linked with delays in their insulin initiation in T2D; while other factors may be more impactful for predicting discontinuation. These patient attitudes should be considered when discussing insulin initiation.

The impact of cardiovascular disease family history on drug adherence in patients with hypertension and type 2 diabetes

B.D. Schaan[1,2], L.G. Bottino[1], G.H. Telo[1];
[1]Universidade Federal do Rio Grande do Sul, Porto Alegre, [2]Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil.

Background and aims: The impact of family history for some diseases such as breast cancer has been associated with better personal health care and treatments adherence. For chronic diseases, however, literature is still not clear. The aim of this study was to investigate the impact of cardiovascular disease (CVD) family history and diabetes family history on the adherence to treatment in patients with hypertension and type 2 diabetes.
Materials and methods: We conducted a cross-sectional study in a tertiary hospital in Southern Brazil. We included patients with type 2 diabetes, hypertension and age <65 years old. Trained researchers collected all clinical and laboratory data. Family history for CVD was defined as having a first-degree relative affected by CVD at age 60 or younger, and family history for diabetes was defined as having a first-degree relative diagnosed with diabetes. The Morisky Questionnaire, which is a 4-item survey designed to evaluate drug adherence, was used in this study. Based on the answers (yes/no), patients were classified as adherent when all the answers were "no", and as non-adherent when one or more "yes" answers were provided. Statistical analyses were performed using SPSS version 18.0; continuous variables were analyzed using the Student t-test; categorical variables were analyzed using the chi-square test. We used 5% as the cutoff of *P* value. This study report followed the STROBE guideline.
Results: The study population was obtained from a consecutive sample of 2342 patients screened, from which 302 were randomly selected. Mean age was 57.2 ± 6.1 years old; 65% were female and 50% were obese (body mass index ≥30.0 kg/m^2). The mean HbA1c was 8.0% (range, 6.9–9.6%), and only 29% of patients had an HbA1c ≤7.0%, which is considered the goal for most adults with diabetes. Mean systolic blood pressure was 142.4 ± 17.8 mmHg, and 27% of patients had a well-controlled blood pressure (systolic <130 mmHg). A hundred and forty-two patients (47%) were classified as non-adherent; 93 (31%) had a family history of CVD and 237 (79%) had a family history of diabetes. Patients with family history for CVD were more frequently classified as adherents than those without CVD family history (63% vs. 49%; p = 0.035). However, this same pattern was not seen in patients with family history for diabetes (50% vs. 64%; p = 0.059). Patients with family history for CVD more likely reported "no" to the Morisky Questionnaire item *"Sometimes, do you neglect to take medication?"* (75% *vs.* 62%; p = 0.041). The other Morisky items reports were not different between patients with and without family history for CVD or diabetes.
Conclusion: Our results showed that patients with family history of CVD had a better drug adherence. This is in agreement with the literature that shows that patients with family history of aggressive and disabling diseases, such as myocardial infarction and stroke, tend to be more adherent to drug therapy. Having diabetes in their family did not change the way in which patients faced their disease, possibly because the relationship between diabetes and complications was not so clear for most patients.

Storage conditions of insulin in domestic refrigerators and carried by patients: insulin is often stored outside recommended temperature range

K. Braune[1], L.A. Kraemer[2], A. Zayani[2], J. Weinstein[2], L. Heinemann[3];
[1]Department of Paediatric Endocrinology and Diabetes, Charité - Universitaetsmedizin Berlin, Berlin, [2]MedAngel BV, Nijmegen, Netherlands, [3]Science & Co, Düsseldorf, Germany.

Background and aims: Not much is known about how patients with diabetes store their insulin in daily life. Objective of our study was to monitor temperature of refrigerated and carried insulin in industrialized countries to investigate how often storage conditions do not meet the manufacturers' recommendations regarding temperature range.
Materials and methods: Patients (n = 338; 46% located in the US, 41% in the EU) put a total number of 400 temperature loggers (MedAngel ONE, Netherlands) next to their insulin into their refrigerator or diabetes bag. Temperature was measured every 3 min (up to 480 times per day). Measurements were automatically sent to an app and stored in a protected online database. Whenever temperature exceeded the recommended range (2–8°C for refrigerated insulin, 2–30°C when opened or carried as a spare), the user was notified by an alarm. Data was collected from Nov 2016 to Feb 2018 with an average protocol length of 49 days.
Results: A total number of 400 temperature logs from individual sensors were analyzed (230 for refrigerated, 170 for carried insulin). Deviations were found in 315 (78.8%) logs (230 (100%) refrigerated, 85 (50%) carried). For refrigerated insulin, temperature recorded by an average sensor was out of the 2–8°C range for 11.31% of the time (10.10%–13.10%; 2h43min per day) with an average deviation of 3.68K (SD 5.02K). For carried insulin, temperatures were out of 2–30°C range 0.54% of the time (0.48%–0.64%; 8min per day) with an average deviation of 1.11K (SD 1.24K). 16.5% of sensors measured temperatures below 0°C (57 for refrigerated, 9 for carried insulin).
Conclusion: Long-term storage conditions of insulin are known to have an impact on its blood-glucose lowering effect. These observational data showed that in a significant number of cases insulin was exposed to temperatures outside the recommended range, especially when refrigerated. Thus, domestic refrigerators may pose an underestimated risk for insulin quality. The extent of how temperature deviations in storage affect insulin efficacy and patient outcomes needs further systematic Investigation.

Do patients with type 1 diabetes and type 2 diabetes understand the medical terms related to their disease?

N. Novoselova[1], A. Mosikian[1], O. Martyanova[2], E. Patrakeeva[3], A. Zalevskaya[3];
[1]Almazov National Medical Research Centre, St. Petersburg, [2]Outpatient clinic № 27, St. Petersburg, [3]Pavlov First Saint Petersburg State Medical University, St. Petersburg, Russian Federation.

Background and aims: 1) To evaluate how patients with diabetes understand the meaning of medical terms related to their disease. 2) To determine social and demographic factors which influence on medical terms understanding. 3) To analyze the impact of medical terms understanding on HbA_{1c}level.
Materials and methods: We asked the group of endocrinologists about frequently used T1D and T2D related terms. Then we created questionnaires based on specialists' answers. The questionnaire for T1D patients included 10 terms: hypoglycemia, glycated hemoglobin, diabetic retinopathy, diabetic nephropathy, diabetic polyneuropathy, diabetic ketoacidosis, bolus insulin, basal insulin, glycemic index, insulin sensitivity factor. The questionnaire for T2D patients included: hyperglycemia, insulin resistance, hypertension, glycated hemoglobin, diabetic polyneuropathy, lipid profile, hypoglycemia, obesity, body mass index, diabetic nephropathy. Then T1D and T2D patients explained the meaning of each term that they understand. The definition accuracy was independently scaled from 0 to 10 by 3 endocrinologists with a «0» is for «completely wrong» and «10» - for «completely correct». Information about gender, age, duration of diabetes, level of education, the last HbA_{1c} was also collected. Patients with a history of mental disorders were excluded. To analyze the results we used Wilcoxon test and linear regression model.

Results: 89 patients with T1D (27% men, HbA_{1c} (mean ± SD) 7.95 ± 1.77%) and 86 patients with T2D (27% men, HbA_{1c} (mean ± SD) 8.11 ± 1.91%) were included in the study. T1D patients received a greater overall score for understanding the terms than T2D patients ($p < 0.0001$) - 57.84 ± 22.66 and 39.33 ± 22.02 from 100, respectively. 38 (42.7%) T1D participants reported that they know all 10 terms, but only 15 (16.8%) respondents understand terms correctly. The greatest frequency of misunderstanding was for insulin sensitivity factor, diabetic polyneuropathy and glycemic index. In T2D group, 9 (10.5%) patients answered yes for all terms, but really know terms only 2 (2.3%) participants. Less than one third patients with T2D knew what means insulin resistance, lipid profile, diabetic polyneuropathy and body mass index. In both groups, the total score of the terms knowledge did not correlate with the HbA_{1c} level ($p = 0.70$ and $p = 0.32$ for T1D and T2D group, respectively). Older women with T1D received a lower overall score in assessing knowledge of medical terms ($p = 0.011$). However, T2D patients of different age received the same score ($p = 0.324$). In T1D group, we revealed tendency to increase an overall score for understanding the terms with increasing duration of diabetes, but it was not statistically significant ($p = 0.18$). The level of education did not influence understanding the terms in both groups.
Conclusion: Our study showed that most patients do not understand the meaning of medical terms, which their doctors use. However, terms understanding does not influence on glycemic control. Medical doctors should use simpler explanations while they consult their patients.

PS 078 Hypoglycaemia rates with basal insulin

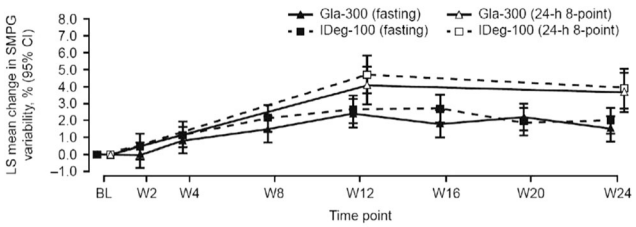
893

Similar variability of fasting and 24-hr self-measured plasma glucose with Gla-300 vs IDeg-100 in insulin-naive adults with type 2 diabetes: the randomised BRIGHT trial

R. Ritzel[1], A. Cheng[2], Z. Bosnyak[3], E. Boëlle-Le Corfec[3], A.M.G. Cali[4], X. Wang[5], J. Frias[6], R. Roussel[7], G.B. Bolli[8];
[1]Klinikum Schwabing and Klinikum Bogenhausen, Städtisches Klinikum München GmbH, Munich, Germany, [2]Department of Medicine, University of Toronto, Toronto, Canada, [3]Sanofi, Paris, France, [4]Sanofi, Tokyo, Japan, [5]Sanofi, Beijing, China, [6]National Research Institute, Los Angeles, USA, [7]INSERM, UMR_S 1138, Centre de Recherche des Cordeliers, Paris, France, [8]Perugia University Medical School, Perugia, Italy.

Background and aims: BRIGHT investigated the efficacy and safety of insulin glargine 300 U/ml (Gla-300) and insulin degludec 100 U/ml (IDeg-100) in insulin-naïve participants with uncontrolled type 2 diabetes (T2DM). The primary objective (non-inferiority of Gla-300 vs IDeg-100 in HbA_{1c}change from baseline to week 24) was met. This analysis examined a secondary endpoint: change in variability of fasting and 24-h self-measured plasma glucose (SMPG).
Materials and methods: BRIGHT was an open-label, randomised, parallel-group, 24-week study. Participants were randomised to Gla-300 or IDeg-100, titrated to a target fasting SMPG of 4.4–5.6 mmol/l.
Results: Eight-point SMPG profiles were similar for both groups at week 24. Mean baseline coefficient of variation (CV) of ≥3 fasting SMPG measurements over 7 days was 13.73% and 14.63% for Gla-300 and IDeg-100, respectively. Change in fasting SMPG variability (standard error [SE]) to week 24 was 1.49% (0.39) and 1.97% (0.39) for Gla-300 and IDeg-100, respectively (least squares [LS] mean difference [95% CI] −0.48 [−1.49 to 0.53]) (**Figure**). Mean baseline CVs for 8-point profiles (24-h SMPG) were 22.60% and 23.41% for Gla-300 and IDeg-100. Mean change in 24-h SMPG variability (SE) was 3.70% (0.59) and 3.95% (0.60) for Gla-300 and IDeg-100 at week 24 (LS mean difference −0.25 [−1.72 to 1.22]).
Conclusion: Gla-300 and IDeg-100 had similar variability of fasting and 24-h SMPG over the 24-week treatment period in BRIGHT.

Figure. LS mean change in the variability of fasting SMPG and 24-h 8-point SMPG



Variability was assessed by the CV calculated over at least 3 SMPG measurements during the 7 days preceding the given visit. For all patients receiving rescue medication during the 24-week period, only the post-baseline fasting SMPG or 24-h SMPG measurements before rescue and during the 24-week on-treatment period are presented. BL, baseline;

Switching to insulin glargine 300 U/ml in patients with type 2 diabetes on basal insulin supported oral therapy (BOT) improves glycaemic control

J. Seufert[1], A. Fritsche[2], H. Anderten[3], K. Pegelow[4], S. Pscherer[5], M. Pfohl[6]; [1]Department of Internal Medicine II, University Hospital, Medical Faculty, University of Freiburg, Freiburg, [2]Department of Medicine IV, University Hospital, Tuebingen, [3]Joint Practice Dres. Anderten-Krok & Partner, Hildesheim, [4]Sanofi-Aventis Deutschland GmbH, Berlin, [5]Department of Internal Medicine III, Sophien- und Hufeland-Klinikum, Weimar, [6]Department of Internal Medicine I, Evang. Bethesda-Krankenhaus, Duisburg, Germany.

Background and aims: The prospective, single-arm, observational TOP-2 study investigated the effects of switching patients (pts) with type 2 diabetes mellitus (T2DM) in Germany (n = 1,662), Austria (n = 103) and Switzerland (n = 100), uncontrolled (HbA_{1c} 7.5–10%) on BOT with other basal insulins (BI), to insulin glargine 300 U/mL (Gla-300) in primary care.

Materials and methods: Primary endpoint was the proportion of pts achieving fasting plasma glucose (FPG) values of ≤110 mg/dL after 6 and 12 months of Gla-300 treatment, respectively. Secondary endpoints included changes over time in HbA_{1c}, FPG, body weight (BW) and insulin dose, hypoglycaemia incidence and safety. Here we report the results of pts recruited at German sites with 12 month results available (n = 679).

Results: At baseline, mean (±SD) age was 64.7 ± 10.3 years, mean BMI 32.0 ± 5.7 kg/m², 56.3% of pts were male, and 54.8% were obese (BMI ≥30 kg/m²). Mean T2DM duration was 11.2 ± 6.8 years. Mean HbA_{1c} was 8.23 ± 0.8%, and mean FPG was 172.7 ± 43.9 mg/dL. The mean pre-specified individual HbA_{1c} target was 7.0 ± 0.4%. Pre-switch BI was predominantly insulin glargine 100 U/mL (Gla-100; 49.2%), and most commonly used oral therapy was metformin ± DPP-4 inhibitors (46.4%). At 12 months, the primary endpoint of an FPG ≤110 mg/dL was achieved by 27.0% of pts, and 43.2% reached their individual HbA_{1c} targets. FPG target achievement was highest in previous Gla-100 pts (29.3%), and HbA_{1c} target achievement was highest in previous insulin detemir pts (55.3%). Hypoglycaemia incidence was low with a trend of >70% reduction of nocturnal hypoglycaemia incidence (Table 1), despite an HbA_{1c} reduction of 0.81 ± 0.99%. BW remained stable. Mean BI doses from baseline slightly increased from 28.1 ± 15.4 U/d (0.30 ± 0.16 U/kg*d) to 33.6 ± 19.6 U/d (0.36 ± 0.19 U/kg*d) at 12 months.

Conclusion: Switching the BI in a BOT regimen to Gla-300 allowed not well controlled pts with T2DM to reduce HbA_{1c} by 0.81% with less nocturnal hypoglycaemia, minor BI dose changes, and weight maintenance in primary care.

Basal insulin initiation on the top of metformin improves glycaemic control and safety in Chinese insulin-naive patients with type 2 diabetes

H. Zhang[1], P. Zhang[1], Y. Luo[2], D. Zhu[1], X. Li[1], J. Ji[1], L. Ji[2]; [1]The George Institute for Global Health at Peking University Health Science Center, Beijing, [2]Department of Endocrinology and Metabolis, Peking University People's Hospital, Beijing, China.

Background and aims: Metformin has been recommended to be combined with basal insulin (BI) when initiating BI treatment by current guidelines. The real-world use as well as the effectiveness and safety of BI initiation on the top of metformin was evaluated in this study.

Materials and methods: For this 6-month, prospective, real-world study, we recruited 16,341 insulin-naïve patients with T2DM uncontrolled (HbA1c ≥7%) on OADs, who initiated BI treatment at physician's discretion and patient's willingness. The effectiveness and safety of metformin-based BI were evaluated by using intent-to-treat (ITT) and per-protocol (PP) analysis separately. The ITT population constituted all patients who successfully completed the 6-month visit, according to whether metformin was prescribed at baseline, irrespective changes of subsequent therapy during follow-up. The PP population constituted patients who kept BI with or without metformin during follow-up as that at baseline. Propensity score adjustment was used to balance covariates of baseline characteristics and process factors during follow-up between two groups.

Results: A total of 7,736 (47.3%) were prescribed metformin in addition to BI, accounting for about half of all patients initiating BI. In ITT analysis, control rates of both HbA1c ≤6.5% and HbA1c <7.0% were significantly higher in metformin-based BI group (26.7% and 40.1%) than those in BI without metformin group (23.6% and 37.2%) ($P < 0.0001$, $P = 0.0009$), whereas the former was associated with lower insulin dose at 6 months (23.0 vs 23.6 IU/day, $P < 0.0001$) and dose increment from baseline to 6 months (−0.3 vs 0.9 IU/day, $P < 0.0001$) compared with the latter; the former showed a lower incidence of the total minor hypoglycemia compared with the latter (24.9 vs 29.6 times/person/year, $P < 0.0001$). These results in PP analysis were concordant with those in ITT analysis. In PP analysis, initiating BI with metformin was significantly associated with greater reduction in HbA1c (−2.4 vs −2.3% $P = 0.0289$) and less weight gain (−0.2 vs 0.1 kg $P = 0.0001$) compared with BI without metformin, whereas these differences between two groups were not significant in ITT analysis.

Conclusion: Metformin-based BI combination therapy in real-world practice was associated with better glycemic control, fewer hypoglycemia events, less weight gain and smaller insulin dose, which corroborates current guidelines that recommend combination regimen of metformin and BI.

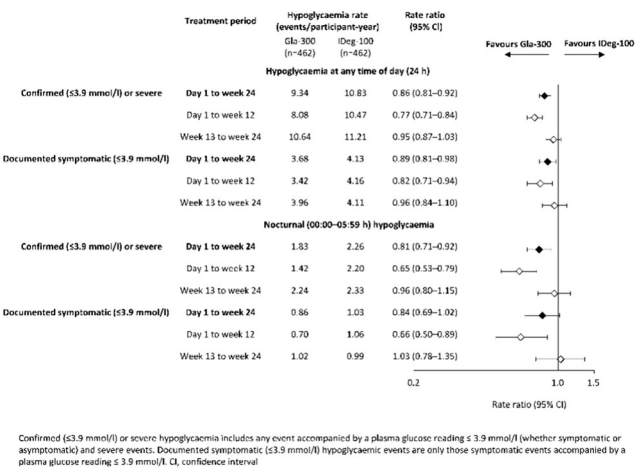
Lower hypoglycaemia rates with insulin glargine 300 U/ml vs insulin degludec 100 U/ml in insulin-naive adults with type 2 diabetes: the BRIGHT randomised trial

G.B. Bolli[1], A. Cheng[2], Z. Bosnyak[3], E. Boëlle-Le Corfec[3], A.M.G. Cali[4], X. Wang[5], J. Frias[6], R. Roussel[7], J. Rosenstock[8];
[1]Perugia University Medical School, Perugia, Italy, [2]Division of Endocrinology and Metabolism, University of Toronto, Toronto, Canada, [3]Sanofi, Paris, France, [4]Sanofi, Tokyo, Japan, [5]Sanofi, Beijing, China, [6]National Research Institute, Los Angeles, USA, [7]INSERM, UMR_S 1138, Centre de Recherche des Cordeliers, Paris, France, [8]Dallas Diabetes Research Center at Medical City, Dallas, USA.

Background and aims: BRIGHT is the first head-to-head trial of insulin glargine 300 U/ml (Gla-300) and insulin degludec 100 U/ml (IDeg-100) in type 2 diabetes (T2DM). Non-inferiority of Gla-300 vs IDeg-100 was demonstrated for the primary endpoint (HbA_{1c} change, baseline to week 24). Here we analysed hypoglycaemia across the full study, and during the titration and maintenance periods.
Materials and methods: BRIGHT was a 24-week open-label, treat-to-target trial that investigated the efficacy and safety of Gla-300 vs IDeg-100 in insulin-naïve people with T2DM, inadequately controlled on oral antihyperglycaemic drugs (OADs) ± glucagon-like peptide-1 receptor agonists (GLP-1 RAs). In this analysis, hypoglycaemia was examined by treatment period; day 1 to week 24 (full study period), day 1 to week 12 (titration period) and week 13 to week 24 (maintenance period).
Results: Incidence of confirmed (≤3.9 mmol/l) or severe hypoglycaemia at any time of day (24 h) was lower with Gla-300 vs IDeg-100 (OR 0.74 [95% CI: 0.57 to 0.97]) during the titration period but was similar at any time of day (24 h) or at night (00:00–05:59 h) during the maintenance and full study periods. Annualised rates of hypoglycaemia (**Figure**) were lower with Gla-300 vs IDeg-100 during the full study period, particularly over the titration period, despite higher final daily doses of Gla-300 vs IDeg-100 (0.54 and 0.43 U/kg from starting doses 0.2 U/kg and 10 U/day [0.12 U/kg], respectively).
Conclusion: Gla-300 resulted in similar incidence but lower rates of hypoglycaemia, particularly during the titration period, with comparable glycaemic control vs IDeg-100 in insulin-naïve people with T2DM on OADs ± GLP-1 RAs.

Figure. Annualised rates of hypoglycaemia with Gla-300 vs IDeg-100, by study period



Confirmed (≤3.9 mmol/l) or severe hypoglycaemia includes any event accompanied by a plasma glucose reading ≤ 3.9 mmol/l (whether symptomatic or asymptomatic) and severe events. Documented symptomatic (≤3.9 mmol/l) hypoglycaemic events are only those symptomatic events accompanied by a plasma glucose reading ≤ 3.9 mmol/l. CI, confidence interval

The risk of total hypoglycaemia in patients with type 2 diabetes self-titrating insulin glargine U-100

J. Kiljanski, E. Spaepen, C. Harris;
Eli Lilly and Company, Indianapolis, USA.

Background and aims: Insulin glargine (IGlar) U-100 has been established as a standard treatment for patients with Type 2 diabetes (T2D) in need of basal insulin. Results of the ELEMENT trials, which compared LY IGlar and Lantus®, showed that patients were able to improve their glycaemic control by self-titrating IGlar U-100 with a simple self-titration algorithm to a fasting blood glucose (BG) target of 5.56 mmol/L. In spite of a very low incidence of severe hypoglycaemia in the ELEMENT trials (<1%), insulin titration can expose patients to potential harm. We aimed to evaluate if level of glycaemic control, age, or being insulin naïve affected the risk of hypoglycaemia (defined by BG <3 mmol/L) during IGlar self-titration.
Materials and methods: We performed exploratory analyses of pooled treatment groups, statistically equivalent according to clinical study results published earlier, in each of 2 Phase 3 studies of LY IGlar vs. Lantus®: ELEMENT-2 (double-blind) and ELEMENT-5 (open label). Hypoglycaemia at Weeks 8 and 12 (titration phase) and at Week 24 (maintenance phase) was analysed by category of HbA1c (<7%, 7–8.5%, >8.5%), and subgroups of age (<65, ≥65 yrs) and previous insulin use (naïve or not). Analyses used were ANOVA for baseline analyses and ANCOVA or MMRM for post-baseline analyses, with a significance level of $\alpha = 0.05$.
Results: In ELEMENT-2 ($N = 756$), 50.0% of patients were male, 28.3% ≥65 yrs of age, 60.4% insulin naïve, and 83.3% on sulfonylureas; baseline HbA1c was 8.33% ± 1.08%. In ELEMENT-5 ($N = 493$), 52.1% were male, 21.3% ≥65 yrs of age, 45.2% insulin naïve, and 84.0% on sulfonylureas; baseline HbA1c was 8.61% ± 1.06%. In ELEMENT-2, there

were no differences in rate or incidence of total hypoglycaemia (BG <3 mmol/L) among HbA1c categories throughout the study. In ELEMENT-5, patients with HbA1c >8.5% had lower rates and incidences of hypoglycaemia throughout the study compared to those in the lower HbA1c category. In both studies, patients ≥65 yrs of age had lower baseline HbA1c, smaller increases in dose with the same frequency of hypoglycaemia compared to patients <65 yrs of age, with no differences in HbA1c post-baseline. The rates and incidences of total hypoglycaemia were similar between naïve patients and patients previously on basal insulin, across all levels of glycaemic control. Hypoglycaemia rates were generally similar during titration phase and maintenance phase for all HbA1c categories and subgroups.

Conclusion: As shown in the ELEMENT trials, patients with T2D can significantly improve glycaemic control by adopting a simple self-titration algorithm. Here we support the safety of this method for most patients. The risk of total hypoglycaemia (BG <3 mmol/L) was similar among new users and prior users of basal insulin who started insulin titration with the algorithm. The risk of hypoglycaemia was not higher among older patients. As with any insulin treatment, hypoglycaemic risk increases as HbA1c approaches 7%; therefore, mitigation of hypoglycaemic risk is prudent as HbA1c improves.

Improved or comparable efficacy without increased hypoglycaemia with self- vs physician-led titration of insulin glargine 300 U/ml in age groups <65 or ≥65 years: TAKE CONTROL

K. Strojek[1], G. Bigot[2], M. Bonnemaire[3], E. Delgado[4,5], V. Donicova[6], M. Kvapil[7], N. Papanas[8], L. Popescu[9], R. Ritzel[10], B. Schultes[11], L. Smircic Duvnjak[12];
[1]Department of Internal Diseases, Diabetology and Cardiometabolic Diseases SMDZ, Zabrze, Silesian Medical University, Zabrze, Poland, [2]IVIDATA, Levallois-Perret, France, [3]Global Diabetes Division, Sanofi, Paris, France, [4]Department of Medicine, University of Oviedo, Oviedo, Spain, [5]Endocrinology and Nutrition Service, Hospital Universitario Central de Asturias, Oviedo, Spain, [6]Outpatient Department for Internal Medicine and Diabetology, Medical Faculty of PJ Safarik University Teaching Affiliate, Kosice, Slovakia, [7]Department of Internal Medicine, Second Faculty of Medicine, Charles University, Prague, Czech Republic, [8]Diabetes Centre, Second Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis, Greece, [9]Global R&D Operations, Sanofi, Bucharest, Romania, [10]Klinikum Schwabing and Klinikum Bogenhausen, Städtisches Klinikum München GmbH, Munich, Germany, [11]eSwiss Medical & Surgical Center, Department of Internal Medicine, Endocrinology, Diabetes, & Metabolism, St. Gallen, Switzerland, [12]University Clinic for Diabetes, Endocrinology and Metabolic Diseases, Vuk Vrhovac, Croatia.

Background and aims: TAKE CONTROL, a 24-week, multicentre, randomized, open-label, parallel-group study, aimed to evaluate self- vs physician-led titration of insulin glargine 300 U/mL (Gla-300) in people with T2DM.
Materials and methods: Efficacy and safety outcomes in people <65 years vs ≥65 years were assessed.
Results: In each age subgroup, baseline HbA_{1c} and fasting SMPG were comparable between self- vs physician-led titration (**Table**); in the older and younger groups, HbA_{1c} ($p = 0.46$ and $p = 0.29$) and fasting SMPG ($p = 0.56$ and $p = 0.15$) reductions were similar between self- vs physician-led titration. Attainment of the fasting SMPG target (4.4–7.2 mmol/L) without confirmed (<3.0 mmol/L) or severe hypoglycaemia was slightly higher in older people; differences in self- vs physician-led titration were not significant in older or younger groups ($p = 0.19$ and $p = 0.05$). Incidences of hypoglycaemia at any time of day (24 h) appeared slightly higher in the ≥65 years, physician-led group. There was no evidence of heterogeneity of effect of self- vs physician-led titration on hypoglycaemia ($p > 0.05$). Adverse events were similar in each group.
Conclusion: Self-titration of Gla-300 resulted in similar glycaemic target achievement to physician-led titration, without an increased risk of hypoglycaemia, irrespective of age. There was a trend for more people to reach fasting SMPG targets without hypoglycaemia with self- vs physician-led titration, including those ≥65 years.

Table. Change in HbA_{1c} and fasting SMPG, and risk ratio for confirmed or severe hypoglycaemia with self- and physician-led insulin titration stratified by age

Parameter	<65 years (N=329)		≥65 years (N=302)	
	Self-titration (N=155)	Physician-led titration (N=174)	Self-titration (N=159)	Physician-led titration (N=143)
Duration of diabetes at baseline, years	10.7 (5.7)	11.5 (5.9)	15.0 (7.8)	14.4 (7.6)
Duration of previous basal insulin treatment at baseline, years	2.9 (2.8)	3.3 (3.7)	3.9 (5.2)	3.9 (4.5)
Baseline HbA_{1c}, %	8.48 (0.93)	8.45 (0.89)	8.32 (0.85)	8.39 (0.95)
HbA_{1c} change from baseline to week 24, %	−1.02 (1.13)	−0.90 (0.97)	−0.89 (0.99)	−0.79 (1.14)
Baseline fasting SMPG[a], mmol/L	8.6 (2.2)	8.4 (2.0)	8.2 (2.0)	8.1 (2.1)
Fasting SMPG[a] change from baseline to week 24, mmol/L	−1.8 (2.2)	−1.5 (2.1)	−1.7 (1.9)	−1.6 (2.2)
Attainment of the fasting SMPG target (4.4–7.2 mmol/L) without confirmed (<3.0 mmol/L) or severe hypoglycaemia, %	67.4	56.4	75.2	68.1
Incidence of confirmed (≤3.9 mmol/L) or severe hypoglycaemia at any time of day (24 h), n (%)	50 (32.5)	51 (29.3)	54 (34.2)	57 (40.1)
Risk ratio self- vs physician-led titration [95% CI]	1.11 [0.81 to 1.53]		65–75 years: 0.85 [0.61 to 1.18] ≥75 years[b]: 0.93 [0.52 to 1.68]	
Incidence of confirmed (3.0 mmol/L) or severe hypoglycaemia at any time of day (24 h), n (%)	11 (7.1)	12 (6.9)	12 (7.6)	13 (9.2)
Risk ratio self- vs physician-led titration [95% CI]	1.05 [0.48 to 2.29]		65–75 years: 0.94 [0.42 to 2.12] ≥75 years[b]: 0.31 [0.03 to 2.85]

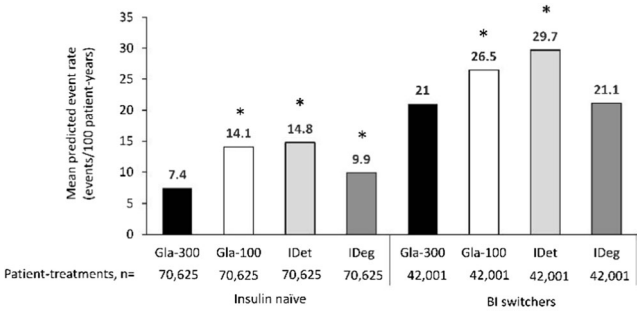
Similar or lower severe hypoglycaemia rates with Gla-300 vs Gla-100, IDet and IDeg in 112,626 people with type 2 diabetes: predictive modelling using real-world data: Lightning

R. Berria[1], J.H. Pettus[2], T. Bailey[3], F.L. Zhou[1], Z. Bosnyak[4], J. Westerbacka[4], J. Jimenez[1], I. Hramiak[5], L. Meneghini[6,7];

[1]Sanofi, Bridgewater, USA, [2]University of California, San Diego, USA, [3]AMCR Institute, Escondido, USA, [4]Sanofi, Paris, France, [5]St Joseph's Health Care, London, Canada, [6]University of Texas Southwestern Medical Center, Dallas, USA, [7]Parkland Health & Hospital System, Dallas, USA.

Background and aims: Using real-world US electronic health record (EHR) data, representative of the general population and real-life practice, the Lightning study aimed to predict hypoglycaemia rates in people with type 2 diabetes (T2DM) prescribed basal insulin (BI) analogues.
Materials and methods: Hypoglycaemic events during BI treatment, as recorded by physicians in EHR, including patients initiating BI ("insulin-naïve") and switching between BIs ("switchers"), were collected between 01 April 2015 and 31 March 2017. Based on real-world data, a predictive model (implementing machine learning and controlling for >160 baseline demographic and clinical variables) was developed and validated for each drug-specific cohort (patients treated with a specific BI).
Results: The models predict significantly lower rates of severe hypoglycaemia in real-world use with insulin glargine 300 U/ml (Gla-300) vs insulin glargine 100 U/ml (Gla-100) or insulin detemir (IDet), irrespective of prior insulin use. In insulin-naïve patients, lower rates of severe hypoglycaemia are predicted with Gla-300 vs insulin degludec (IDeg) ($p < 0.05$), an unexpected finding that warrants further investigation, whereas comparable rates are shown in switchers (**Figure**).
Conclusion: Using real-world data, these predictive modelling results show similar or significantly lower severe hypoglycaemia rates with Gla-300 vs other BIs in people with T2DM.

Figure. Estimated rates of severe hypoglycaemia



Severe hypoglycaemia was defined by: ICD 9/10 codes (either codes specifically for severe hypoglycaemia, or those where hypoglycaemia was the reason for care or occurred on the same day as an emergency department visit/inpatient admission); or blood glucose <3.0 mmol/l; or intramuscular glucagon administration; or mention of hypoglycaemia in patient notes with a descriptor denoting severity or on the same day as an emergency department visit/inpatient admission. BI, basal insulin; ICD, International Classification of Diseases; Patient-treatment, the period during which a patient is using a BI (used as the unit of analysis)
*p<0.05 Gla-300 versus BI comparator

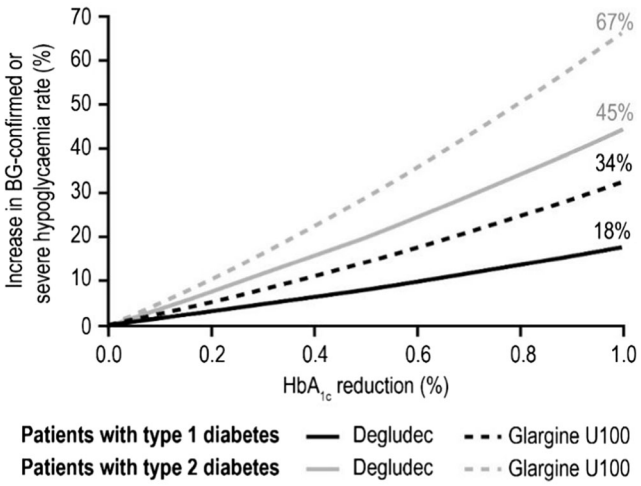
Relationship between HbA_{1c} and hypoglycaemia risk in individual patients comparing insulin degludec with insulin glargine U100

U. Pedersen-Bjergaard[1], A. Philis-Tsimikas[2], W. Lane[3], C. Wysham[4], L. Bardtrum[5], S. Østoft[5], S. Heller[6];
[1]Nordsjællands University Hospital Hillerød, Hillerød, Denmark, [2]Scripps Whittier Diabetes Institute, San Diego, USA, [3]Mountain Diabetes and Endocrine Center, Asheville, USA, [4]Rockwood Clinic, Spokane, USA, [5]Novo Nordisk A/S, Søborg, Denmark, [6]University of Sheffield, Sheffield, UK.

Background and aims: Targeting a lower HbA_{1c} may increase the hypoglycaemia risk in patients with diabetes. We investigated the relationship between HbA_{1c} and hypoglycaemia risk on an individual level.
Materials and methods: This *post hoc* analysis used data from two double-blind, randomised, treat-to-target, two-period (32 weeks each) crossover trials of insulin degludec (degludec) vs. insulin glargine 100 units/mL (glargine U100) in patients with type 1 (T1D; SWITCH 1, $n = 501$) or type 2 diabetes (T2D; SWITCH 2, $n = 721$).
Results: For each patient at each visit, HbA_{1c} was linked with the number of hypoglycaemic events (blood glucose-confirmed [<3.1 mmol/L] with symptoms or severe [third-party assistance]) since last visit. A 1% (10.9 mmol/mol) HbA_{1c} reduction led to an 18% (degludec) and 34% (glargine U100) increased risk of hypoglycaemia in T1D, and 45% (degludec) and 67% (glargine U100) increased risk in T2D (Figure). Assuming an 11% (T1D) and 30% (T2D) reduction in hypoglycaemia risk, as seen in the SWITCH trials, this can be translated into a 0.61% (T1D) and 0.67% (T2D) HbA_{1c} reduction with degludec, with no increase in hypoglycaemia risk vs. glargine U100.
Conclusion: Lowering HbA_{1c} led to a higher hypoglycaemia risk; however, the lower incremental hypoglycaemia risk with degludec vs. glargine U100 may allow for a lower HbA_{1c} target in both T1D and T2D with degludec than with glargine U100 in clinical practice, when hypoglycaemia is a limiting factor for glycaemic control.

Figure. Proportional increase in rate of BG-confirmed or severe hypoglycaemia resulting from a 1% (10.9 mmol/mol) HbA_{1c} reduction with degludec and glargine U100, based on the SWITCH trials



Hypoglycaemia was defined as BG-confirmed (3.1 mmol/L) symptomatic or severe (requiring third party assistance) events.
BG, blood glucose; Glargine U100, insulin glargine 100 units/mL.

Early menopause and primary ovarian failure are associated with increased risk of type 2 diabetes: a systematic review and meta-analysis

P. Anagnostis[1,2], K. Christou[3,2], A.-M. Artzouchaltzi[3,2], S.A. Paschou[4], M. Potoupnis[3,5], E. Tsiridis[3,5], I. Lambrinoudaki[6], D.G. Goulis[1,7];
[1]Unit of Reproductive Endocrinology, First Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, [2]Division of Endocrinology, Police Medical Centre of Thessaloniki, Thessaloniki, [3]Centre of Orthopedic and Regenerative Medicine Research (CORE), Aristotle University of Thessaloniki, Thessaloniki, [4]Division of Endocrinology and Diabetes, "Aghia Sophia" Hospital, Medical School, National and Kapodistrian University of Athens, Athens, [5]Academic Orthopaedic Unit, General Hospital Papageorgiou, Aristotle Univeristy of Thessaloniki, Thessaloniki, [6]Second Department of Obstetrics and Gynecology, National and Kapodistrian University of Athens, Athens, [7]Centre of Orthopedic and Regenerative Medicine Research (CORE), Aristotle Univeristy of Thessaloniki, Thessaloniki, Greece.

Background and aims: Menopausal transition has been associated with a derangement of glucose metabolism. However, it is not known if early menopause (EM, defined as age of menopause <45 years) or primary ovarian failure (POF, defined as age of menopause <40 years) are associated with increased risk of type 2 diabetes mellitus (T2DM). The aim of this study was to systematically investigate and meta-analyze the best evidence regarding the association of menopausal age with the risk of developing T2DM.
Materials and methods: A comprehensive search was conducted in three databases (PubMed, CENTRAL, Scopus) for English papers (up to January 31st, 2018). Random effects model was used for data synthesis. Data were expressed as odds ratio (OR) with 95% confidence intervals (CI) and were combined by the inverse variance method. The I^2 index was employed to indicate heterogeneity; publication bias was inspected by Funnel plots and tested by the Egger's test.
Results: The initial search provided 1,851 studies. After excluding duplicates and after critical appraisal, 13 studies were included in the qualitative and quantitative analysis, providing a total of 191,762 postmenopausal women, with 21,664 cases of T2DM. Both women with EM and POF were at higher risk for developing T2DM compared with those with normal age at menopause (45–55 years) [OR 1.446 (95% CI 1.004–2.084, $p < 0.048$) and 1.134 (95% CI 1.033–1.244, $p < 0.008$), respectively. When women with EM were compared with those of menopausal age >45 years, a greater T2DM risk was detected for the former group (OR 1.121, 95% CI 1.018–1.234, $p < 0.02$).
Conclusion: This is the first meta-analysis showing that both EM and POF are associated with increased risk of T2DM.
Disclosure: **P. Anagnostis:** None.

902

Left ventricular systolic and diastolic function in type 1 diabetic adults with different glucose control

K. Moshenets, N. Pertseva;
Endocrinology, SE "Dnipropetrovsk medical academy of Health Ministry of Ukraine", Dnipro, Ukraine.

Background and aims: To investigate cardiac function in adult patients with type 1 diabetes mellitus (T1DM) depending on glucose control and hypoglycemia
Materials and methods: The study involved 60 patients with T1DM, including 25 men (41%), women - 35 (59%). The average age of patients - 30,1 (22.0; 39.0) yrs., disease duration 11.0 (5.0; 18.0) yrs., BMI 22.01 (20.10; 25.56) kg/m^2. All patients used basic-bolus insulin therapy with daily dose of Units 45 (33; 58). C-peptide, HbA1c, blood creatinine, glomerular filtration rate (GFR) CKD-EPI, first morning urinary albumin excretion (UAE) were determined for verification and evaluation of control. Blood glucose levels were conducted by CGMS (Continuous Glucose Monitoring System). 10 sex- and age-matched healthy controls were included. Systolic and diastolic function were evaluated by standard conventional transthoracic echocardiography and tissue Doppler echocardiography. Patients were divided to groups according to HbA1c and hypoglycemia. Group 1 had HbA1c ≤7.0%, group 2 had HbA1c >7.0%, and subgroups: A-without hypoglycemia, B-with hypoglycemia
Results: The groups were similar according to sex, age, BMI and frequency of hypoglycemia. Calculation of results depending on the duration T1DM showed an increase in left ventricular mass index (LVMI) ($r = 0.31$ $p = 0.02$), and decrease in GFR ($r = -0.40$ $p = 0.01$). Diabetic patients had such significantly higher conventional echocardiography parameters compared to healthy control: left ventricular mass 142.5 (126.5; 168.0) g vs. 121 (115.5; 128.5) g, $p = 0.008$; left ventricular posterior wall thickness (LVPWT) 0.98 (0.94; 1.06) sm vs. 0.91 (0.87; 0.93) sm, $p = 0.02$; interventricular septal excursion (IVSE) 1.24 (1.18; 1.39) sm vs 0.97 (0.86; 1.13) sm, $p < 0.001$; left ventricular posterior wall excursion (LVPWE) 1.34 (1.23; 1.4) sm vs. 1.16 (1.05; 1.25) sm $p = 0.004$. Daily insulin dose correlated with LVMI ($r = 0.31$ $p = 0.02$), IVSE ($r = 0.33$ $p = 0.03$) and LVPWE ($r = 0.36$ $p = 0.04$). In 1 group correlation analyses demonstrated a positive correlation between UAE and LVPWE ($r = 0.59$ $p = 0.03$), IVSE ($r = 0.60$, $p = 0.03$), relative wall thickness (RWT) ($r = 0.58$ $p = 0.02$), and negative correlation with HbA1c ($r = -0.52$ $p = 0.02$). In 2 group UAE correlated with left ventricular end-diastolic volume (EDV) ($r = 0.34$ $p = 0.01$) and stroke volume correlated with GFR ($r = 0.47$ $p = 0.02$) The presence of hypoglycemic episodes affected increasing LVPWE ($r = 0.34$ $p = 0.03$; left ventricular (LV) end-systolic volume ($r = 0.41$ $p = 0.035$) and decreasing ejection fraction ($r = -0.32$ $p = 0.001$). Diastolic dysfunction with impaired relaxation (grade I) had 34.62% diabetic patients: 34.62% in group 1 compared to 36.11% in group 2, $p = 0.04$
Conclusion: Patients with T1DM have increased risk of cardiovascular disease due to early development of left ventricular hypertrophy (LVH). Poor glucose control (HbA1c >7%) is associated with systolic and diastolic dysfunction. Hypoglycemia adversely affects LV myocardial structure and function regardless of HbA1c level with early changes of LV function. LVPWT, IVSE, LVPWE are the independent predictors of cardiovascular events and cardiovascular mortality which progress more rapidly due to hypoglycemia. The low risk of hypoglycemia is the priority task to prevent progression of cardiovascular complications and predict adverse cardiac events in patients with T1DM
Disclosure: **K. Moshenets:** None.

The role of hyperglycaemia in the appearance of tachyarrhythmia in patients with type 2 diabetes, paroxysmal atrial fibrillation (pAfib) and ischaemic stroke

A. Sianni[1], I. Matsoukis[2], T. Athanasopoulou[1], A. Ganotopoulou[3], K. Kanellopoulou[4], X. Triantafillopoulou[1], L. Skorda[5], A. Masgala[1];
[1]Department of Internal Medicine, "Konstantopouleio" - General Hospital of Nea Ionia-Patision, Athens, [2]Department of Cardiology, "Korgialenio-Benakio" - General Hospital of Athens, Athens, [3]Department of Internal Medicine, "Tzaneio" - General Hospital of Pireaus, Athens, [4]Department of Cardiology, "Konstantopouleio" - General Hospital of Nea Ionia-Patision, Athens, [5]Department of Internal Medicine, "Korgialenio-Benakio" - General Hospital of Athens, Athens, Greece.

Background and aims: To study the frequency of hypoglycemia and its correlation with the events of tachyarrhythmia in patients with DMT2 (on

treatment with insulin or oral medication), pAfib (receiving anticoagulation) and ischemic stroke.
Materials and methods: The study duration was 36 months and included 278 patients with DMT2 that had pAfib and ischemic stroke. All patients visited for routine health screening examination or with minor diseases the departments of internal medicine of 3 general hospitals. All participants had ECGs, cerebral computed tomography and a Holter monitoring of rhythm in order to establish the diagnosis of pAfib and previous ischemic stroke. Fasting blood glucose and postprandial glucose (2 hrs after meal) were measured. An ECG was performed to all participants every 3 months and when they visited the collaborating hospitals due to a feeling of high pulses (tachyarrhythmias).
Results: 166 patients (60%) out of 278 suffered from tachyarrhythmias in the context of pAfib. The remaining 112 patients (40%) did not have similar episodes of tachyarrytmia. From blood glucose measurements, there were 133 patients (80%) from the first group that had 10–18 episodes of hypoglycemia (2–4 episodes per month). From the second group that did not show any tachyarrhythmias, only 14 patients had 8–10 episodes of hypoglycemia (0–2 episodes per month). The difference between the two groups was statistically significant ($p = 0.04$)
Conclusion: Hypoglycemia increases the risk of tachyarrhythmia (estimated 20% increase) in the context of pAfib in patients with DMT2 and ischemic stroke. Avoiding hypoglycemia must be a main goal when treating patients with DMT2 especially in those patients with pAfib and ischemic stroke.

Acute hypoglycaemia results in increased activation of responses to an inflammatory challenge induced 48 hours later in human subjects

A. Iqbal[1], L. Prince[1], P. Novodvorsky[1], A. Bernjak[1], M. Thomas[1,2], L. Birch[1], D. Lambert[1], L. Kay[1], F. Wright[1], R. Jacques[1], R. Storey[1], R. McCrimmon[3], S. Francis[1], I. Sabroe[1], S. Heller[1];
[1]University of Sheffield, Sheffield, [2]University of Birmingham, Birmingham, [3]University of Dundee, Dundee, UK.

Background and aims: Hypoglycaemia is emerging as a risk factor for cardiovascular (CV) morbidity and mortality in diabetes but the precise mechanisms are unclear. The innate immune system is critical to the aetiology of CV events. Because CV events do not appear to occur during the hypoglycaemic episode *per se*, we sought to examine the hypothesis that hypoglycaemia may prime the innate immune system, leading to a more marked inflammatory response to a subsequent inflammatory challenge.
Materials and methods: In a novel *in vivo* human experimental model, we combined an established hypoglycaemic stimulus with a classical systemic stimulus of the innate immune system (lipopolysaccharide challenge). Twenty-four healthy volunteers underwent either a hyperinsulinaemic-hypoglycaemic (2.5 mmol/l) ($n = 8$), euglycaemic (6.0 mmol/l) ($n = 8$) or sham-saline clamp ($n = 8$) (normoglycaemic conditions). To determine if hypoglycaemia primed innate immune responses, all participants then received a low-dose (0.3 ng/kg) intravenous endotoxin challenge 48 hours later. Using flow cytometry, we studied total white blood cell and subset kinetics and determined monocyte activation by measuring CD11b expression.
Results: Compared to euglycaemia, both hypoglycaemia and sham-saline were associated with greater leucocyte mobilisation in response to endotoxin ($P < 0.05$, Fig 1). There was a trend towards a higher total monocyte count in the hypoglycaemia group 4 hours post endotoxin compared to euglycaemia (mean ± SEM cells/μL: 0.56 ± 0.11 vs 0.37 ± 0.06; $P = 0.08$). Monocyte CD11b expression at 4 and 6 hours following endotoxin was significantly higher compared to baseline in all groups ($P < 0.001$). The percentage of total monocytes that were positive for CD11b expression was higher in hypoglycaemia versus euglycaemia at 2 hours post endotoxin (mean ± SEM %: 94.10 ± 1.11 vs 86.02 ± 4.64; $P < 0.01$). Adrenaline levels were not significantly different between study groups 6 hours following endotoxin (mean ± SEM nmol/L hypoglycaemia: 0.15 ± 0.04 vs euglycaemia: 0.06 ± 0.01 vs sham-saline 0.09 ± 0.01; $P > 0.05$).
Conclusion: We show that a single episode of hypoglycaemia compared to euglycaemia invokes a stronger proinflammatory response to endotoxin up to 2 days later. Further, the drivers for differential leucocyte mobilisation to endotoxin are not due to between group differences in catecholamines. This suggests hypoglycaemia may prime the innate immune system leading to a more profound inflammatory response to a subsequent inflammatory stimulus, which may in turn explain the increased CV risk associated with hypoglycaemia in diabetes.

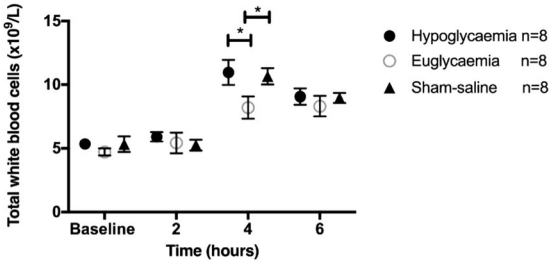

Figure 1: Peripheral total white blood cell (WBC) kinetics post endotoxin challenge. Total number of WBCs 2, 4 and 6 hours following low dose (0.3 ng/kg) intravenous endotoxin challenge in participants that underwent hypoglycaemia, euglycaemia or a sham-saline clamp 48 hours earlier. Data are mean (SEM), *p<0.05, P-values are provided for comparison between study groups.

Peripheral infusion of a hepato-preferential insulin analogue mimics the hypoglycaemia-sparing effect of portal vein human insulin infusion in dogs

G. Kraft[1], M. Scott[1], M. Smith[1], J. Hastings[1], C.L. Brand[2], C. Fledelius[2], P. Madsen[2], T. Kjeldsen[2], S. Hostrup[2], E. Nishimura[2], A.D. Cherrington[1], J.M. Gregory[1];
[1]Vanderbilt University, Nashville, USA, [2]Novo Nordisk, Copenhagen, Denmark.

Background and aims: We previously quantified the hypoglycemia-sparing effect of portal vs peripheral human insulin delivery. As insulin administered via the sub-cutaneous (s.c.) route distributes like peripheral insulin delivery, an acylated insulin analog (INS-406) was engineered to distribute more like portal insulin when delivered s.c. In the present work we hypothesized that a bioequivalent infusion of the hepato-preferential INS-406 into a peripheral vein could achieve a protective effect against hypoglycemia, similar to that of portal human insulin delivery.
Materials and methods: In conscious dogs, human insulin (HI) was infused into either the portal vein (PoHI, $n = 7$) or a peripheral vein (PeHI, $n = 7$) for 180 min at a rate 4.4x basal (6.6 pmol/kg/min). INS-406 (Pe406, $n = 7$) was infused into a peripheral vein at 6.0 pmol/kg/min, a rate determined to bring about the same rate of fall in plasma glucose in the first 60 min as PoHI (before stimulating counter-regulatory hormones). Somatostatin was infused to inhibit glucagon secretion so it could be kept at a basal level, mimicking the diminished α-cell response seen in type 1 diabetes (T1DM). A 120 min recovery period followed the 180 min infusion period. In the PeHI and PoHI groups, insulin was infused portally and reduced to the basal secretion rate and in Pe406 the insulin infusion was reduced by the same proportion and given peripherally.

Results: Glucose fell quickly with PeHI, reaching 41 ± 3 mg/dL at 60 min, but it fell more slowly with PoHI and Pe406 (67 ± 2, $p < 0.01$ vs PeHI and 72.1 ± 4 mg/dL $p < 0.01$ vs PeHI, respectively at 60 min) (see figure). The hypoglycemic nadir occurred at 60 min with PeHI (41 ± 3 mg/dl) vs. 120 min with PoHI (45 ± 1 md/dl) and Pe406 (45 ± 1 mg/dl). IV glucose infusion was needed in four PeHI dogs to prevent severe hypoglycemia but no dogs in the other groups required glucose. ΔAUC (infusion period - basal) for epinephrine in PeHI, PoHI and Pe406 was 204 ± 21, 95 ± 29 ($p < 0.01$ vs PeHI), and 139 ± 21 ng/mL/180 min ($p = 0.04$ vs PeHI), respectively. Glucose production (mg/kg/min) was least suppressed from baseline in PeHI (0.79 ± 0.33) and equivalently but further suppressed in PoHI and Pe406 (1.16 ± 0.21 and 1.18 ± 0.17, respectively). Peak glucose utilization (mg/kg/min) was highest in PeHI (4.94 ± 0.17) and less in PoHI (3.58 ± 0.58, $p = 0.03$ vs PeHI) and Pe406 (3.26 ± 0.08, $p < 0.01$ vs PeHI).

Conclusion: We conclude that peripheral infusion of the hepatopreferential analog, INS-406, can achieve a metabolic profile that closely mimics that seen with portal insulin delivery and would be protective against hypoglycemia compared with peripheral insulin infusion. It is therefore hypothesized that hypoglycemia-sparing effects may be apparent with eventual s.c. treatment with INS-406 compared to conventional insulin therapy.

Improved skeletal muscle energy metabolism relates to the recovery of beta cell function by early insulin intensive therapy in drug naive type 2 diabetes

W. Tang[1], Y. Bi[1], H. Wang[2], B. Zhang[2], D. Zhu[1];
[1]Department of Endocrinology, Drum Tower Hospital Affiliated to Nanjing University Medical School, Nanjing, [2]Department of Radiology, Drum Tower Hospital Affiliated to Nanjing University Medical School, Nanjing, China.

Background and aims: Early insulin intensive therapy protracts glycaemic remission in patients with newly diagnosed type 2 diabetes (T2DM), while the underlying mechanism remains to be elucidated. Recent studies have shown that an impaired skeletal muscle mitochondrial function is associated with the development of insulin resistance and type 2 diabetes mellitus. Thus, we aimed to characterize the contribution of mitochondrial activity to insulin-induced glycaemic control.

Materials and methods: Drug-naïve T2DM patients were recruited to receive continuous subcutaneous insulin infusion with an insulin pump. Treatment was stopped after normoglycaemia was maintained for 7 days. Muscular phosphocreatine (PCr) flux was acquired by ^{31}P magnetic resonance spectroscopy before and after insulin therapy. The total acquisition time consisted of 2 min of rest, 10 min of plantar flexion exercise and 10 min of recovery. The rates of adenosine triphosphate (ATP) synthesis in gastrocnemius were calculated as ΔPCr/Δtime during the first 10s after cessation of exercise. The study protocol was carried out in compliance with the principles of the Declaration of Helsinki and was approved by the Ethics Committee of Dum Tower Hospital affiliated to Nanjing University.

Results: A total of 20 patients enrolled in the study, with mean age of 40.0 years, mean body mass index (BMI) of 24.3 kg/m^2 and mean HbA1c of 11.2%. β-cell function (represented by HOMA2-B) and systematic insulin sensitivity (represented by HOMA2-IR) improved significantly after intensive insulin intervention. In addition, the relative changes of postprandial C peptide increased along with the improvement of muscular ATP synthesis efficacy after adjustments of age and BMI ($r = 0.620$, $p = 0.006$). Participants who achieved higher relative changes of postprandial C peptide had approximately 2-fold increase in the rates of ATP synthesis and performed lower HbA1c (6.3 ± 0.4 versus 7.6 ± 0.4, $p = 0.044$) after 3-months follow-up.

Conclusion: These data firstly suggested that improved muscular mitochondrial ATP synthesis might play a role in the promising effects of insulin on glycaemic control in newly diagnosed type 2 diabetes.

Circulating dipeptidyl peptidase-4 activity is decreased by short-term intensive insulin therapy in patients with newly diagnosed type 2 diabetes

L. Liehua, W. Ke, H. Li, J. Liu, X. He, J. Chen, Y. Li;
Endocrinology, The First Affiliated Hospital of Sun Yat-sen University, Guangzhou, China.

Background and aims: Short-term intensive insulin therapy is shown to induce recovery of β cell function and subsequent glycemic remission in patients with newly diagnosed type 2 diabetes, but the detailed mechanism is not fully understood. Activity of dipeptidyl peptidase-4 (DPP-4) is an important regulatory factors of β cell function as it cleaves incretin hormones. Whether DPP-4 plays a role in the mechanism of restoration of β cell function remains to be clarified. This study analyzed the changed of DPP-4 activity during short-term intensive insulin therapy and its association with metabolic parameters.

Materials and methods: In this study we enrolled 51 patients with newly diagnosed type 2 diabetes who had never accepted any anti-hyperglycemic agents. Baseline blood samples were collected for measurements of lipid profiles, alanine transaminase (ALT) , aspartate transaminase (AST), γ-glutamyltransferase (GGT), free fatty acid (FFA), HbA1c and fasting and post-prandial plasma glucose. Fasting DPP-4 activity was determined using Gly-Pro-p-nitroanilineas substrate with the release of p-nitroaniline monitored at 405 nm. An intravenous tolerance test is performed for assessing acute insulin response (AIR). Afterwards, short-term intensive insulin therapy using insulin pump was given to all patients with near-normoglycemia (fasting blood glucose 4.4–6.1 mmol/L, 2 h post-prandial blood glucose 4.4–7.8 mmol/L) achieved and maintained for 2 weeks. Then insulin infusion was stopped and baseline measurements were repeated in the next morning.

Results: After the therapy, fasting plasma glucose (11.5 ± 3.3 mmol/L vs 6.6 ± 1.2 mmol/L, $P < 0.001$), post-prandial plasma glucose (17.7 ± 6.8 mmol/L vs 9.4 ± 2.4 mmol/L, $P < 0.001$) ALT(37.0 ± 30.3 U/L vs 29.1 ± 20.8 U/L), GGT (49.2 ± 40.3 U/L vs 30.1 ± 24.5 U/L) , FFA (672.4 ± 230.2 μmol/L vs 571.8 ± 209.6 μmol/L, $P < 0.02$) and HOMA IR (3.5 ± 2.4 vs 2.4 ± 1.4, $P = 0.001$) were all significantly decreased, while AIR (−61.5 ± 26.4 pmol/L min vs 388.0 ± 72.3 pmol/L min, $P < 0.001$) and HOMA B (22.1 ± 20.0 vs 54.7 ± 33.8 , $P < 0.001$) were elevated. Serum DPP-4 significantly decreased from 36.1 ± 8.4 nmol/min/ml to 31.0 ± 7.2 nmol/min/ml ($P < 0.001$). At baseline, Circulating DPP-4 activity was associated with ALT ($r = 0.30$, $P = 0.03$), AST ($r = 0.32$, $P = 0.02$), GGT ($r = 0.36$, $P = 0.01$) and FFA ($r = 0.41$, $P = 0.01$); similar association of DPP-4 with liver enzymes was found after the therapy (for ALT, $r = 0.34$, $P = 0.02$; for AST, $r = 0.29$, $P = 0.04$; for GGT, $r = 0.42$, $P = 0.003$). Decrement of DPP-4 was only associated with reduction of FFA ($r = 0.50$, $P < 0.001$). No significant association was found between DPP-4 and blood glucose, HbA1c, lipid profiles, HOMA IR, HOMA B, AIR and body-weight at baseline or after the therapy.
Conclusion: Circulating DPP-4 activity is significantly decreased after short-term intensive insulin therapy. Moreover, circulating DPP-4 activity was only associated with liver enzymes and FFA other than blood glucose, HOMA IR or β-cell function indices. This fact implied that circulating DPP-4 activity is a potential indicator of metabolic dysfunction in liver and adipose tissue, instead of glucose homeostasis.

Intraperitoneal insulin does not result in less systemic oxidative stress

H. van Goor[1], A. Pasch[2], N. Kleefstra[3], S.J.J. Logtenberg[4], K.H. Groenier[5], T.M. Vriesendorp[5], F. Waanders[6], H.J.G. Bilo[5,7], P.R. van Dijk[5,7];
[1]Department of Pathology and Medical Biology, Division of Pathology, University of Groningen, Groningen, Netherlands, [2]Department of Biomedical Research, University of Bern, Bern, Switzerland, [3]Langerhans Medical Research Group, Ommen, Netherlands, [4]Internal Medicine, Diakonessenhuis, Utrecht, Netherlands, [5]Diabetes Centre, Isala, Zwolle, Netherlands, [6]Internal Medicine, Isala, Zwolle, Netherlands, [7]Internal Medicine, University of Groningen, Groningen, Netherlands.

Background and aims: Continuous intraperitoneal insulin infusion (CIPII) is a last-resort treatment option for patients with type 1 diabetes mellitus (T1DM) who fail to achieve glycemic control with subcutaneous (SC) insulin administration. In animal experiments CIPII was accompanied by less oxidative stress as compared to SC insulin administration. Data concerning humans are lacking. As thiols (R-SH; compounds with free sulfhydryl groups) are readily oxidized by reactive oxygen and sulfur species, their circulating concentrations directly reflect systemic redox status. We hypothesized that in patients with T1DM CIPII lead to higher R-SH concentrations as compared to SC insulin administration.
Materials and methods: This study is a post-hoc analysis of a prospective, observational case-control multicentre study. Age and gender matched patients were treated with either CIPII or SC insulin using multiple daily injections (MDI) or continuous subcutaneous insulin infusion (CSII). Measurements were performed at the start and end of a 26-week interval. Differences between IP and SC groups averaged over the study period and in time were estimated using a general linear model. Multivariate regression analysis was performed with the mean score over the study period. A total of 180 patients with a mean age of 50 (12) years, BMI of 26 (5) kg/m^2, diabetes duration of 24 [17, 35] years and HbA1c of 64 (10) mmol/mol were analysed. Of these patients 39 were treated with IP and 141 with SC insulin (67 MDI and 74 CSII).
Results: For all patients, the estimated geometric mean R-SH concentrations increased with 21 μM (95%CI 13 to 28) from 250 μM (95%CI 245 to 256) at visit 1 to 271 μM (95%CI 266 to 276) at visit 2. Among patients treated with CIPII this increase was 18 μM (95%CI 5 to 32), from 254 μM (95%CI 244 to 264) at visit 1 to 272 μM (95%CI 263 to 282) at visit 2. And it was 23 μM (95%CI 15 to 30), 246 (95%CI 240 to 251) to 269 μM (95%CI 264 to 274), among SC treated patients. R-SH concentrations among patients treated with CIPII were similar as compared to patients treated with SC insulin: 263 μM (95%CI 256 to 270) versus 257 μM (95%CI 254 to 261), difference: 6 μM (95%CI −1 to 13). In multivariate regression analysis, R-SH concentrations were significantly associated with BMI and total insulin dose while gender, HbA1c, LDL cholesterol and route of insulin administration were not.
Conclusion: This in the fist study in human T1DM patients to demonstrate that the route of insulin administration (CIPII or SC) does not significantly influence the systemic redox status.

PS 080 Causes and consequences of hypoglycaemia

909

Moderate to vigorous physical activity is not associated with increased hypoglycaemia or glycaemic variability in individuals with type 1 diabetes

G.S. Taylor[1], R.J. Stefanetti[2], S. Cassidy[1], A.J. Flatt[1], A.S. Bashir[1], M.D. Campbell[3], E.J. Stevenson[1], J.A. Shaw[1], D.J. West[1];
[1]Institute of Cellular Medicine, Newcastle University, Newcastle Upon Tyne, [2]Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, [3]Institute for Sport, Physical Activity & Leisure, Leeds Beckett University, Leeds, UK.

Background and aims: Regular physical activity (PA) is recommended for individuals with Type 1 diabetes (T1D) as it can improve a range of cardiovascular risk factors. PA levels are generally lower in T1D compared to the wider population, with disrupted glucose control, particularly hypoglycaemia, suggested to be a barrier to people achieving the recommended 150 minutes of moderate to vigorous activity (MVPA) per week. At present there is limited data that has objectively measured PA levels alongside free-living glucose control. The aim of this study was to explore PA in individuals with T1D, and determine if the amount of MVPA is associated with measures of glycaemic control.
Materials and methods: 47 participants with T1D (M/F 27/20, age 40 ± 11 years, HbA1c 57.2 ± 9.1 mmol/mol^{-1}, BMI 25.3 ± 3.4 kg/m^2 and diabetes duration 21 ± 11 years) attended the laboratory for fitting of a blinded interstitial Continuous Glucose Monitor (CGM) and physical activity accelerometer. The devices were worn for 7 days. ≥3 valid daily blood glucose calibrations with a correlation >0.79 were required for the day's CGM data to be accepted. Time spent in range was calculated as a percentage of total time. Accelerometer data were processed in R using R-package GGIR with the threshold for moderate activity or greater set as ≥100 mg. 18 hours of daily wear time was considered an acceptable threshold for data inclusion and only moderate and vigorous activity bouts of ≥10 minutes duration were analysed. Data were reported as mean ± SD and analysed by an independent sample t-test and Pearson's correlation with significance accepted at $p \leq 0.05$.
Results: Participants achieved 26.8 ± 20.7 minutes of MVPA a day with no difference between genders ($p = 0.872$). 24 (51%) of the participants completed >150 minutes of MVPA across 7 days, with 4 participants completing 0 minutes. No correlations were found between amount of MVPA and mean glucose ($r = -0.210$ $p = 0.166$), HbA1c ($r = 0.045$, $p = 0.770$), or any CGM glycaemic parameters: time <3 mmol/l $r = -0.038$, $p = 0.805$; >13.9 mmol/l $r = -0.154$, $p = 0.313$; time in range 3.9–10 mmol/l $r = 0.207$, $p = 0.172$; outside range <3.9 and >10 mmol/l $r = -0.207$, $p = 0.172$. There was no association between MVPA and various measures of glycaemic variability (SD $r = -0.045$, $p = 0.771$; CV $r = 0.122$, $p = 0.426$). No differences were found between individuals completing over ($n = 24$, daily MVPA 42.74 ± 14.57 minutes) and under ($n = 21$, daily MVPA 8.78 ± 7.03 minutes, $p < 0.01$) 150 minutes of MVPA for age ($p = 0.833$), duration of diabetes ($p = 0.482$), HbA1c ($p = 0.708$) or BMI ($p = 0.147$). Additionally, there were no differences in any CGM parameters ($p > 0.05$).
Conclusion: This is the first observational study to compare objectively measured physical activity with glycaemic control under free-living conditions in T1D. We show that greater time spent doing MVPA is not associated with increased glycaemic variation, hypoglycaemia or time out of range. Moreover, there were no clinical or glycaemic differences between those individuals achieving over 150 minutes of physical activity compared to those below. Future research is needed to explore how accumulative PA bouts impact upon glycaemic variability and time in range.

Relationship between severe hypoglycaemia, impaired awareness of hypoglycaemia, psychological distress, quality of life and cognition in type 1 diabetes

E. Sepulveda[1], D. Carvalho[2], D. Seixas[3], S.A. Amiel[4], S.G. Vicente[1];
[1]Centre for Psychology at University of Porto, Faculty of Psychology and Educational Sciences, University of Porto, Porto, Portugal, [2]Department of Endocrinology, Diabetes and Metabolism, Centro Hospitalar São João, Porto, Portugal, [3]Institute for Biomedical Imaging and Life Sciences, University of Coimbra, Coimbra, Portugal, [4]Diabetes Research Group, King's College London, London, UK.

Background and aims: Impaired awareness of hypoglycaemia (IAH) in type 1 diabetes increases risk of severe hypoglycaemia (SH) six-fold. SH is associated with impaired cognitive function acutely, with reports of an association with long-term cognitive dysfunction. This study examined age, diabetes duration, psychological distress, quality of life (QoL), and cognition in adults with type 1 diabetes with intact hypoglycaemia awareness (HA) and IAH, according to the Gold score (GS) or Guy's and St Thomas' Minimally Modified Clarke Hypoglycaemia Survey (MMCHS), and also in those reporting presence or absence of ≥1 SH in the past 6 months; and sought predictors of moderate or severe cognitive impairment in global cognition and executive functions.
Materials and methods: We recruited 137 adults with type 1 diabetes. Hypoglycaemia awareness status was determined using the GS (one-item) and MMCHS (eight-item), with ≥4 = IAH. SH was evaluated by one question (question 3) in the MMCHS. Participants also completed the Montreal Cognitive Assessment (MoCA; global cognition: visuospatial abilities, executive functions, language, delayed recall, and orientation); the INECO Frontal Screening (IFS; executive functions: inhibition and set shifting, abstraction, and working memory); the Diabetes Health Profile (DHP; QoL: barriers to activity [BA], psychological distress [PD], and disinhibited eating [DE]); and the Hospital Anxiety and Depression Scale (HADS).
Results: Participants' mean age, diabetes duration and HbA1c were 38.1 years, 19.7 years, and 8.0%, respectively; 51.8% were women. Patients with IAH, according to the MMCHS, had a longer diabetes duration ($U = 947.0$, $p = 0.012$) and higher scores on HADS depression scale ($U = 910.5$, $p = 0.012$) than HA ones. Patients with SH in the past 6 months had higher scores on HADS total ($U = 1572.5$, $p = 0.022$) and DHP total ($U = 1498.5$, $p = 0.035$), higher depression on HADS ($U = 1594.5$, $p = 0.027$), and lower performance on z-score MoCA executive functions domain ($U = 1012.5$, $p = 0.032$) than patients with no SH. No diferences were found in age, QoL, and cognition between HA and IAH assessed by GS or MMCHS, or in age and diabetes duration between patients with and without SH. Being female (Exp (B) = 4.327, $p = 0.005$), having peripheral neuropathy (PN) (Exp (B) = 6.656, $p = 0.018$), and lower education (Exp (B) = 0.878, $p = 0.034$) were independent predictors of worse performance in IFS total.
Conclusion: While SH has sometimes controversially been associated with impaired cognitive function, the impact of IAH alone has not been studied. Our findings suggest that IAH was related with depression but not with cognitive impairment, while SH was related with both. The different relationships of IAH and SH with executive dysfunction suggest that SH may be a necessary event for cognitive dysfunction, although the direction of the link cannot be established from this study. In addition to SH, PN, female gender, and lower education may impact executive functioning.

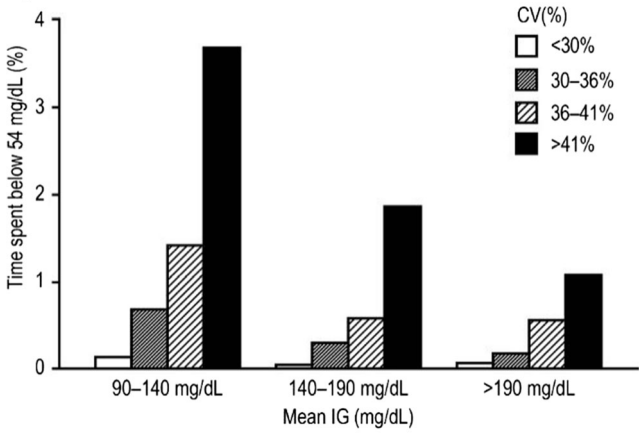
Reducing glycaemic variability decreases time in hypoglycaemia independent of mean glucose: data from real-world continuous glucose monitoring in type 1 diabetes patients

R. Bergenstal[1], E. Hachmann-Nielsen[2], A. Kaas[2], K. Kvist[2];
[1]International Diabetes Center, Minneapolis, USA, [2]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: The increasing amount of continuous glucose monitoring (CGM) data reveals insights to better understand glucose control in diabetes and opens up for valuable indicator metrics like time in range, time in hypoglycaemia and time in hyperglycaemia. Previous studies have related lower HbA_{1c} with higher risk of hypoglycaemia, but less strict HbA_{1c} control does not protect against hypoglycaemia. CGM data can assist in answering the question: what is the role of glycaemic variability in diabetes management? The objective was to explore the association between glucose variability (coefficient of variation [CV%]), mean interstitial glucose (IG) and time spent in hypoglycaemia (TIHypo; % time with IG <54 mg/dL [3.0 mmol/L]). In addition, the link between CV and time spent in hyperglycaemia (TIHyper; % time with IG >250 mg/dL [13.9 mmol/L]) and time in range (TIR; % time with IG between 70 and 180 mg/dL [3.9 and 10.0 mmol/L]) was explored for different levels of mean IG.
Materials and methods: Patients volunteered to upload their data via Cornerstone4Care (C4C), a freely available digital patient management programme (app) for diabetes mellitus. The app supports diabetes self-management and captures self-reported patient data and real-world, real-time CGM data. A total of 112 type 1 diabetes (T1D) patients uploaded their CGM data via the C4C app for analysis. The CV was calculated based on non-overlapping 2-week intervals of CGM data. For each 2-week period, a CV index, mean IG, proportion of TIHypo, TIR and TIHyper was determined. The impact of glycaemic variability (CV) on TIHypo, TIR and TIHyper was analysed across a range of IG values (Figure). Definitions and data analysis was done in accordance with directions from the International Consensus on Use of Continuous Glucose Monitoring: a minimum of 14 consecutive days of data with approximately 70% of possible CGM readings over those 14 days. Stable glucose levels were defined as a CV <36%.
Results: A total of 369 non-overlapping 2-week periods with a high rate of available data (>70%) was available for analysis. There was a significant association between CV and TIHypo ($p = 0.0007$), linking higher glucose variability (CV) to more TIHypo. However, there was no significant association between CGM-derived mean IG and TIHypo ($p = 0.051$), indicating that, in these data, a lower mean IG does not significantly result in more TIHypo. When adjusting for the levels of CV, the association with mean IG becomes significant for TIHypo ($p = 0.0019$); likewise, CV significantly increased the TIHypo for all levels of mean IG (Figure, $p = 0.0006$). Both TIHyper and TIR showed significant associations to mean IG and CV in a multivariate setting ($p < 0.01$).
Conclusion: Hypoglycaemia can be a problem across all levels of CGM-derived mean IG. Independent of mean IG, there is a significant value of reducing variability to minimise time spent in hypoglycaemia.

Figure: The association between glycaemic variability (CV%) and TIHypo by CGM-derived mean IG



CGM, continuous glucose monitoring; CV, coefficient of variation; IG, interstitial glucose; TIHypo, time spent in hypoglycaemia.

Common yet overlooked: non-severe hypoglycaemia and its risk indicators in type 2 diabetes (InHypo-DM Study)

N.H. Au, A. Ratzki-Leewing, B.L. Ryan, S. Mequanint, J.E. Black, S. Reichert, J.B. Brown, S. Harris;
Western University, London, Canada.

Background and aims: Non-severe hypoglycemia (NSH) is a common adverse event among people with type 2 diabetes mellitus (T2DM) using insulin and/or secretagogues. Its reoccurrence induces fear and other patient behaviors, which can lead to changes in glycemic therapies thereby impeding optimization of glycemic control. In addition, NSH can increase the risk of severe hypoglycemia (SH) and associated clinical sequelae. Much attention has focused on the importance of SH with less understanding of the risk indicators and impact of NSH. As NSH is self-treated and frequently under-reported, its clinical relevance has often been overlooked and its occurrence is too commonly not captured in electronic medical records/claims databases. Our current understanding of NSH has mainly come from clinical trials, which may not be reflective of the real-world incidence of NSH due to the stringent sampling frames used. Drawing on the strength of self-reported NSH, the population-based InHypo-DM study explored the association between relevant risk indicators and the rate of NSH among individuals with T2DM.
Materials and methods: Adults with diabetes (≥18 years of age) treated with insulin and/or secretagogues were recruited from a nationally-representative online panel in Canada. A validated questionnaire elicited self-reported frequencies of NSH, socio-demographic and clinical characteristics. Multivariable negative binomial regression, informed by univariable analyses ($p \leq 0.2$) and subsequent backward selection ($p < 0.05$), identified pertinent risk indicators of NSH frequency among complete cases.
Results: This analysis is based on 432 individuals with T2DM (male: 56.3%, mean age: 53.0 years (SD: 14.7), mean duration of diabetes: 11.7 years (SD: 7.8)). Over half (54.2%, 95% CI: 49.5% to 58.9%) of the respondents self-reported at least one NSH event in the past 30 days. The annualized incidence rate of NSH was 28.7 (95% CI: 26.9 to 30.5) events/person-year. Multivariable analysis suggested that being employed (versus other) and presence (versus absence) of comorbidities that interfere with hypoglycemia management increased the expected rate of NSH by a factor of 1.46 (95% CI: 1.01 to 2.10; $p = 0.0444$) and 2.08 (95% CI: 1.52 to 2.84; $p < 0.0001$), respectively. Lower annual household income brackets ($p < 0.0001$) and higher levels of HbA_{1c} ($p = 0.0067$) were independently associated with increased rates of NSH. Longer duration of diabetes ($p = 0.0005$) and younger age ($p < 0.0001$) were also identified as risk indicators of increased rates for NSH.
Conclusion: Our study identified relevant socio-demographic and clinical risk indicators for NSH in a real-world setting. Most notably, lower annual household income, being employed, and presence of comorbidities were associated with higher rates of NSH. Results suggest the influence of determinants beyond traditional clinical factors on hypoglycemia frequency, such as socio-economic and situational context. The InHypo-DM study presents compelling real-world evidence of the frequent burden imposed by NSH on adults with T2DM. These findings may identify patients at risk of higher rates of NSH, creating clinically relevant opportunities to improve glycemic management and initiate upstream prevention of NSH and SH in T2DM.

Hypoglycaemia and risk of all-cause mortality in people with dementia and diabetes: a cohort study

K. Mattishent[1], K. Richardson[2], G. Savva[3], K. Dhatariya[4], C. Fox[1], Y. Loke[1];
[1]Norwich Medical School, Norwich, [2]School of Health Sciences, Norwich, [3]Quadram Institute Bioscience, Norwich, [4]Norfolk and Norwich University Hospital Foundation Trust, Norwich, UK.

Background and aims: A recent meta-analysis has found that hypoglycaemia may be associated with increased risk of mortality, cardiovascular events, falls and fractures. However, the included studies have not addressed serious consequences in specific patient groups at particularly high risk of hypoglycaemia, such as those with co-morbid dementia and diabetes. We aimed to determine the risk of all-cause mortality associated with hypoglycemia in older patients with diabetes and dementia.
Materials and methods: Retrospective cohort study of patients with diabetes (± dementia) in England aged >65 years based on the Clinical Practice Research Datalink with linkage to Hospital Episode Statistics and mortality data from Office of National Statistics (April 1997 to March 2016). We constructed three cohorts:Cohort 1: patients with dementia and diabetes and no hypoglycemic episodes;Cohort 2: patients with comorbid dementia and diabetes at first hypoglycemic episode;Cohort 3: patients with diabetes and first hypoglycemic episode (no dementia). The exposure/index date was defined as the first hypoglycemic episode captured on healthcare database after 1 April 1997. We evaluated mortality data for up to 5 years after index hypoglycemia, or end of available HES linkage. First, we compared whether the presence or absence of hypoglycemic episodes was associated with mortality in patients with dementia and diabetes (cohort 2 compared with cohort 1). Secondly, we compared whether hypoglycemic episodes have a different association with mortality in patients with dementia and diabetes compared to those with diabetes but no dementia (cohort 2 compared with cohort 3). We estimated Hazard Ratios (HR) and 95% confidence intervals (CI) for the association between hypoglycemia and subsequent mortality using Cox proportional hazard regression models with adjustment for age, sex, sociodemographics, co-morbidities and medications.
Results: We enrolled 19995 participants and found that hypoglycemia was associated with greater subsequent mortality in patients with diabetes and dementia (cohort 2). See Table 1 for number of deaths during follow-up and adjusted HR for association between hypoglycemic episodes and mortality.
Conclusion: Hypoglycemia has serious consequences in older people with diabetes and dementia. The consequences of hypoglycemia are worse in patients with comorbid dementia compared to those with diabetes alone. Prevention and reduction of hypoglycemia in older people with dementia and diabetes should be a top priority.

Table 1: Number of deaths and adjusted HR for association between hypoglycemic episodes and mortality

Cohort	Deaths during follow-up	Adjusted HR (95% CI)	
1 (n=6134)	3853 (63%)	Effect of hypoglycemia on mortality in patients with dementia (cohort 2 vs cohort 1)	Effect of dementia on mortality in patients with hypoglycemia (cohort 2 vs cohort 3)
2 (n= 1679)	1369 (82%)		
3 (n=12182)	6494 (53%)		
		1.66 (1.51-1.81)	1.67 (1.54-1.80)

Alexithymia, perfectionism, and attachment insecurities in type 1 diabetes patients with impaired awareness of hypoglycaemia: a pilot study

A. Naito[1,2], M. Nwokolo[2], E. Smith[1], N. De Zoysa[1], C. Garrett[3], P. Choudhary[1,2], S.A. Amiel[1,2];
[1]Diabetes Department, King's College Hospital NHS Foundation Trust, London, [2]Diabetes Research Group, Faculty of Life Sciences and Medicine, King's College London, London, [3]Diabetes and Psychiatry Research Group, Department of Psychological Medicine, King's College London, London, UK.

Background and aims: Up to a third of people with type 1 diabetes (T1D) have Impaired Awareness of Hypoglycaemia (IAH), increasing their risk of severe hypoglycaemia (SH) six-fold. Qualitative studies have identified cognitive barriers to behaviour change around hypoglycaemia avoidance and management in individuals with IAH that may diminish potential benefit from interventions to reduce SH such as structured education and technology. This study explores the hypothesis that IAH may be associated with specific personality traits of alexithymia (difficulty in identifying and expressing one's own emotions) and clinical perfectionism (striving for excessively high personal standards despite adverse consequences, combined with overly critical self-evaluation) and examines emotional dysregulation and attachment insecurities as possible factors distinguishing people with the condition.
Materials and methods: Five validated self-reported questionnaires, the Total Alexithymia Scale (TAS-20); the Frost Multidimensional Perfectionism Score (FMPS) exploring specific aspects of personality; the Reflective Functioning Questionnaire (RFQ); the Difficulties in Emotion Regulation Scale (DERS) and the Experiences in Close Relationships-Revised Scale (ECR-R) exploring attachment types; plus Attitudes to Awareness Questionnaire (A2A) exploring attitudes and beliefs about hypoglycaemia were distributed to 19 people with IAH [Gold score >4; age 40.7 ± 11.0 (mean ± SD) years, diabetes duration 26.5 ± 10.3 years, HbA1c 7.8 ± 0.8% (61.5 ± 8.8 mmol/mol)] and 15 with intact hypoglycaemia awareness (HA) [Gold score <3; age 39.5 ± 12.2 years, diabetes duration 26.7 ± 12.3 years, HbA1c 7.7 ± 1.0% (60.7 ± 11.3 mmol/mol), all $p > 0.05$ except Gold scores, $p < 0.001$] in a pilot study.
Results: Compared to those with HA, participants with IAH were more likely to have alexithymia on TAS-20 with a trend to significance (21% vs. 0%, χ^2 (1) = 3.58, $p = 0.059$) and had significantly greater variations in the Difficulty Identifying Feelings subscale ($p = 0.042$). There was a large variation in the Concerns over Mistakes (CM) subscale of the FMPS ($p = 0.014$). There were trends towards higher Impulse subscale score on the DERS: ($p = 0.126$) and the dismissing attachment type on ECR-R (29% vs. 7%, χ^2 (1) = 2.44, $p = 0.118$). Scores on the Prioritising Hyperglycaemia Avoidance subscale on the A2A correlated strongly with the Concerns over Mistakes scores in the FMPS ($r = 0.736$, $n = 26$, $p < 0.001$).
Conclusion: This pilot study demonstrates the feasibility of assessing aspects of personality, emotion regulation, and attachment type in people with T1D with IAH. Early evidence suggests that specific psychological traits are associated with higher risk of IAH and SH, which may characterise the psychological processes underlying this presentation. Alexithymia may be a good candidate as a predictor for development of IAH. Confirmation of these findings in a larger cohort may help clinicians in assessing which patients are at higher risk of IAH and help structure the psychological support offered in addition to structured education and technology in order to prevent SH and retain or regain hypoglycaemia awareness.

Risk factors for severe hypoglycaemia in community-based patients with type 2 diabetes: the Fremantle Diabetes Study Phase II

T.M.E. Davis, W.A. Davis;
Medical School, University of Western Australia, Fremantle, Australia.

Background and aims: Data from the Fremantle Diabetes Study Phase I (FDS1) collected between 1998 and 2006 showed that the risk factors for incident severe hypoglycaemia (that requiring ambulance/hospital attendance) in type 2 diabetes were duration of insulin treatment, renal impairment, peripheral neuropathy, education beyond primary level and past severe hypoglycaemia. Given subsequent changes in clinical management and outcome, the aim of this study was to perform a parallel analysis in FDS Phase II (FDS2) >10 years later to determine whether the predictors of severe hypoglycaemia had also changed.
Materials and methods: The FDS2 is community-based observational cohort study that enrolled representative patients from an urban population of 150,000 people between 2008 and 2011. Severe hypoglycaemia was ascertained to end-2013 from: i) public/private hospitalisations, ii) Emergency Department presentations, and iii) ambulance attendances. For i) and ii), relevant International Classification of Diseases codes were required. For i), episodes were identified from a validated data linkage system and the case-notes accessed where possible to validate coding and provide detailed concomitant data. Cox proportional hazards modeling with imputation of missing data was used to identify clinically plausible independent predictors of the first episode of severe hypoglycaemia during follow-up.
Results: The 1,551 FDS2 patients with type 2 diabetes were of mean age 65.7 years, 51.9% were male, and their median diabetes duration was 9.0 years. Sixty-three (4.1%) experienced 83 episodes of severe hypoglycaemia during 6,195 patient-years (mean 4.0 ± 1.2 years) of follow-up with an incidence of 1.34 (95% CI 1.07–1.66)/100 patient-years. In the Cox model, age, current smoking, sulfonylurea and/or insulin treatment, prior severe hypoglycaemia, renal dysfunction, retinopathy, and the plasma N-terminal pro-B-type natriuretic peptide concentration (ln(NT-proBNP)) were positive independent predictors of time to first episode, while Southern European ethnicity was protective (see Table for hazard ratios (95% CIs) and *P* values).
Conclusion: These data confirm that older age, insulin/secretagogues, progressively worsening renal function, and prior severe hypoglycaemia are potent risk factors for severe hypoglycaemia complicating type 2 diabetes. The association with smoking may reflect reduced insulin clearance. Microangiopathy is a recognised risk factor but the present data show that retinopathy is predictive independently of nephropathy. The relatively low severe hypoglycaemia risk in Southern Europeans parallels evidence of geographic variation in other observational studies that reflects differences in anthropometric, lifestyle and clinical management between populations. The link with NT-proBNP suggests that patients with heart failure, an increasingly recognised chronic complication, may require intensive glycaemic monitoring and use of therapies with a low risk of hypoglycaemia.

Age (increase of 1 year)	1.04 (1.01-1.07)	0.005
Southern European ethnicity	0.28 (0.09-0.91)	0.035
Current smoker	2.64 (1.31-5.35)	0.007
Diabetes pharmacotherapy: Sulfonylurea (±other glucose-lowering drug)	2.15 (1.23-3.77)	0.007

Maternal and foetal complications in women with gestational and pre-gestational diabetes: a population study

G. Di Cianni[1], E. Gualdani[2], C. Lencioni[1], E. Lacaria[1], P. Francesconi[2], G. Seghieri[2];
[1]Diabetes and Metabolic Diseases Unit, Health Local Unit Nord-West Tuscany, Livorno and Lucca Hospital, [2]Epidemiology Unit, Agenzia Regionale Sanità, Florence, Italy.

Background and aims: Both gestational (GDM) and pre-gestational diabetes (PGDM) are associated with an increased risk of maternal and fetal complications. Less known is the situation in the real world where pregnant women are monitored for metabolic conditions as well as for main risk factors throughout pregnancy. By means of available data concerning pregnant women who have performed an OGTT in Tuscany, a region of central Italy, we conducted a study to evaluate the risk of macrosomia, as well as that of neonatal or delivery outcomes (such as Apgar index or emergency cesarean section), comparing women with GDM and PGDM with a population of women without diabetes.
Materials and methods: We studied all women aged >15 aa living in Tuscany who delivered in the years 2012–2016. Women were identified by means of their childbirth certificate (CeDAP) and performed an OGTT after the 16th week of gestation. The diagnosis of GDM was performed using a validated algorithm including as parameters: having received a first prescription of insulin during pregnancy later interrupted after delivery, having at least a prescription for a visit by a diabetologist, having received an educational program or having performed an OGTT after 6 months of delivery. PGDM was diagnosed from the regional database of people with diabetes prior to index pregnancy. Women with normal glucose tolerance (NGT), were compared with those with GDM and PGDM, as for the risk of macrosomia (neonatal weight >4 Kg), of elective or urgent Caesarean section and of neonatal suffering (Apgar index <7).
Results: On a total of 85075 deliveries, as compared to NGT women, the relative risk of macrosomia was twice as high in women with pre-gestational diabetes: IRR: 2.00 (95% CI: 1.54–2.58); $p < 0.0001$, but on the contrary it was significantly reduced in women with GDM: IRR: 0.89 (0.81–0.98); $p = 0.02$. The risk of caesarean section both in urgency and in election was increased in women with GDM: IRR: 1.11 (1.05–1.17); $p = 0.0002$ and IRR: 1.38 (1.31–1.45), respectively; $p = 0.0001$) and was also significantly higher in PGDM: 1.28 (1.05–1.57) and 2.02 (1.72–2.37) respectively; $p = 0.0001$. These results did not change after adjustement for neonatal sex and for gestational age. In GDM and PGDM there was a trend of non-significant increase in neonatal distress (Apgar Index <7): IRR:1.12 (0.92–1.39) and 1.59 (0.80–3.16), p = NS for both.
Conclusion: Women with GDM had a reduced risk of macrosomia, suggesting an effective prevention of this complication in our population.The risk of macrosomia was instead significantly increased in women with PGDM. The risk of caesarean section was increased in both GDM and PGDM, without any evidence of increased risk of neonatal distress at delivery.

Gestational diabetes (GDM <24 weeks) is associated with worse pregnancy outcomes despite early treatment, when compared with GDM diagnosed at 24–28 weeks gestation

M. Mustafa, A. Khattak, D. Bogdanet, L. Mcknenna, L.A. Carmody, B. Kirwan, G. Gaffney, P. O'Shea, F. Dunne;
Galway Diabetes Research Centre, National University of Ireland Galway, Galway, Ireland.

Background and aims: Gestational Diabetes Mellitus is associated with more adverse pregnancy outcomes compared to women with normal glucose tolerance in pregnancy. WHO recommends screening at 24–28 weeks gestation. However some women are screened earlier due to symptoms or because of prior GDM. Those screened and diagnosed earlier in pregnancy have a longer period of intervention which may have an impact on pregnancy outcome. Information on the outcomes of women with GDM diagnosed <24 weeks gestation is limited. we aimed to examine pregnancy outcomes of women with GDM diagnosed <24 weeks gestation compared to those diagnosed at 24–28 weeks in a large treated European cohort.
Materials and methods: A retrospective cohort study was carried out of 1471 pregnancies from women with GDM diagnosed using IADPSG criteria. Women were classified as early GDM diagnosed (<24 weeks) (n = 275), or standard GDM diagnosed (24–28 weeks) gestation (n = 1,196).
Results: Women with early GDM had higher BMI at diagnosis than women diagnosed between 24–28 weeks [34.522 ± 7.33 versus 31.88 ± 5.96 (P value <0.001, mean difference 95%CI (1.63, 3.64)]. Although there was no significant differences between the 2 groups in Antenatal OGTT, Post partum OGTT was significantly higher in early GDM group [32% vs. 15.6% (P value <0.001, mean difference 95%CI (0.09, 0.24)], fasting glucose (5.253 ± 0.726 vs. 4.994 ± 0.723 P value <0.001, 95%CI (0.13, 0.38), 2 hour Glucose 5.69 ± 1.90 vs. 5.30 1.69 P value 0.012, 95%CI (0.07, 0.70). Table 1 below shows pregnancy outcomes.
Conclusion: Women with early GDM are more likely to develop hypertensive disorders and have an operative delivery. Stillbirths, preterm delivery and requirement for NNU care are more common in offspring of mothers with early GDM. Although birth weights are similar, a greater number of babies from mothers with early GDM are born LGA. In view of the greater number of early GDM women displaying abnormal OGTT post-partum, this may reflect a more advanced state along the pathway to diabetes.

Maternal outcome	<24 week (n=279,18.9%)	24-28 week (n=1197,80.1%)	P-value	95% CI for difference
Total C-Section	47 %	41.5 %	0.08	(0.008, 0.13)
Pregnancy induced Hypertension	12.4%	5.3%	<0.01	(0.03, 0.12)
Preeclampsia	3.8%	0.9%	<0.05	(0.004, 0.05)
Post-Partum Hemorrhage	8.7%	2.4%	<0.05	(0.01, 0.084)
Neonatal outcome Stillbirth	1.4%	0.5 %	<0.01	(0.11, -0.04)

The effect of baseline maternal weight and weight gain on pregnancy outcome in women with untreated, mild gestational diabetes

Z. Szili-Janicsek[1], T. Tänczer[1], E. Szabó[2], B. Domján[1], V. Ferencz[1], Z. Kerényi[3], A. Péterfalvi[3], Á.G. Tabák[1,4];
[1]1st Department of Medicine, Semmelweis University, Budapest, Hungary, [2]Szent Imre Hospital, Budapest, Hungary, [3]Diabetes Outpatient Clinic Tóth Ilona Health Service, Budapest, Hungary, [4]Department of Epidemiology and Public Health, University College London, London, UK.

Background and aims: Both obesity and GDM are associated with an increased fetal and maternal risk during and after pregnancy. However, knowledge is limited on the combined effect of these risk factors on pregnancy outcomes. We aimed to clarify the extent by which adverse pregnancy outcomes of women with "mild GDM" are explained by maternal body weight. Mild GDM was diagnosed if glucose tolerance test was normal according to WHO-1999 but GDM was proved by WHO-2014 diagnostic criteria (fasting blood glucose between 5.1 and 6.9 mmol/l and 2-h post load blood glucose <7.8 mmol/l).
Materials and methods: Between 2002–2005 n = 5335 pregnant women participated in a population-based screening program using 75 g OGTT. After excluding pregestational diabetes, twin pregnancies, and GDM according to WHO-1999, data on n = 4362 pregnancies were analyzed. We assessed adverse fetal (large for gestational age, LGA ≥90 percentage, 1-minute Apgar ≤7), maternal (pregnancy induced hypertension, preeclampsia), and delivery (preterm delivery <37 weeks of gestation, Caesarean delivery) outcomes. Associations of these adverse outcomes with mild GDM were analyzed by logistic regression. Models then were further adjusted for maternal weight at delivery, weight gain during pregnancy and other known risk factors of adverse outcomes.
Results: Mean maternal age was 29.5 ± 0.7 (mean ± SD) years, body mass index (BMI) 22.6 ± 0.4 kg/m^2, fasting glucose 4.5 ± 0.4 mmol/l, 2-h glucose was 5.2 ± 1.7 mmol/l. Mild GDM was diagnosed in n = 510 women. Mild GDM was associated with an increased risk of LGA (OR: 1.57 95%CI: 1.25–1.98), pregnancy induced hypertension (OR: 2.27 95%CI: 1.50–3.45), preeclampsia (OR: 1.88 95%CI: 0.90–3.92), preterm delivery (OR: 1.70 95%CI: 1.04–2.78), and Caesarean section (OR: 1.3 95%CI: 1.02–1.65). No association between mild GDM and the 1-min Apgar score was found. Odds ratios almost halved after adjustment for maternal BMI at delivery, all (except for preterm delivery where the risk remained the same) became non-significant after further adjustment in multivariate models.
Conclusion: Our results suggest that mild GDM based solely on fasting glucose had little effect on pregnancy outcomes when maternal body weight and other known pregnancy risk factors are taken into account. Randomized controlled trials are required to determine whether lifestyle recommendations focusing on optimizing weight gain are sufficient to treat GDM cases diagnosed based solely on elevated fasting glucose.

Foetal abdominal overgrowth already affected at diagnosis of gestational diabetes (GDM) in elderly and obese women persists until delivery despite of treatment

Y. Kim[1], W. Kim[1], W. Park[1], J. Kim[1], S. Park[2];
[1]Kangnam CHA Medical Center, CHA University, Seoul, Republic of Korea, [2]Department of Epidemiology, The Johns Hopkins Bloomberg School of Public Health, Baltimore, USA.

Background and aims: We previously observed that altered glucose metabolism already existed, and affected fetal growth at the time of GDM diagnosis in elderly and obese women. The aims of this study was to determine whether fetal abdominal overgrowth already affected

at the time of diagnosis of GDM in the elderly with/without obese women persist until delivery despite appropriate GDM treatment.

Materials and methods: Medical records of 1419 singleton pregnancy including 384 GDM and 1035 NGT (normal glucose tolerance) subjects were reviewed. GDM was diagnosed by 100-g OGTT after 50-g glucose screening tests according to ADA criteria. We collected serial HbA1C and fetal biometry data measured both at diagnosisof GDM and near term. Fetal ultrasonographic measurements of biparietal diameter(BPD), abdominal circumference(AC), and femur length(FL) were converted to each estimated gestational ages(GA-BPD, GA-AC, GA-FL) and estimated fetal weight (EFW) was calculated by Shinozukafomula. Ratio of GA-AC/GA-LMP(gestational age by LMP), GA-AC/GA-BPD, and GA-AC/GA-FL were calculated as indices for fetal abdominal obesity. GDM subjects were divided into 4 groups: group1 (age <35 and prepregnant BMI <25, $n = 147$), group 2 (<35 & ≥25, $n = 23$), group 3 (≥35 & <25, $n = 163$), and group 4 (≥35 & ≥25, $n = 51$). NGT subjects were compared with 4 subgroups of GDM subjects.

Results: 1) Frequency of insulin treatment in group2 and 4 GDM subjects were significantly higher than in group 1 and 3 GDM subjects (17.4% and 15.7% vs. 8.2% and 9.8%, $p < 0.05$). **2)** HbA1C of group 2 and 4 GDM subjects were significantly higher than group 1 and 3 GDM subjectsmeasured at diagnosis of GDM (5.6 ± 0.6 and5.6 ± 1.0% vs. 5.2 ± 0.3 and 5.2 ± 0.3%, $p < 0.0001$) and near term (5.9 ± 0.5 and 5.8 ± 0.7% vs. 5.5 ± 0.4 and 5.5 ± 0.4%, $p < 0.005$). **3)** GA-ACof group3 GDM were significantly higher than that of NGT at diagnosisof GDM (27.5 ± 1.4 vs. 27.1 ± 1.4, $p < 0.01$) and near term (38.7 ± 2.3 vs. 37.9 ± 2.4, $p < 0.0005$) but GA-BPD, GA-FL, and EFWof other subgroups were not different from NGT subjectsboth at diagnosisof GDM and near term.**4)** Only group3 and 4 GDM subjectsshowed fetal abdominal obesity with significantly higherratio of GA-AC/GA-LMP (1.05 ± 0.04 and1.05 ± 0.04 vs. 1.03 ± 0.04, $p < 0.001$), GA-AC/GA-BPD(1.03 ± 0.04 and 1.03 ± 0.04 vs. 1.01 ± 0.05, $p < 0.05$), and GA-AC/GA-FL (1.02 ± 0.05 and 1.03 ± 0.04 vs.1.01 ± 0.04, $p < 0.001$)compared with NGT subjects at diagnosis of GDM. **5)** Also near term, group 3 and 4 GDM subjects showed significantly higher ratio of GA-AC/GA-LMP (1.08 ± 0.05and1.09 ± 0.05 vs. 1.06 ± 0.05, $p < 0.0001$), GA-AC/GA-BPD(1.04 ± 0.05 and 1.06 ± 0.07 vs. 1.02 ± 0.06, $p < 0.0005$), and GA-AC/GA-FL (1.05 ± 0.05 and 1.05 ± 0.05 vs. 1.03 ± 0.05, $p < 0.005$) compared with NGT subjects. **6)** But fetal abdominal obesity indices of group 1 and 2 GDM subjects were not different from those of NGT subjects both at diagnosis of GDM and near term.

Conclusion: Fetal abdominal overgrowth already affected in the elderly with/without obeseGDM mothersat the time of GDM diagnosis at 24–28 weeks' gestation persisted until delivery despite appropriate GDM treatment. These findings suggest that active interventions before or early in pregnancy to normalize metabolic derangement and more strict glucose control during pregnancy would be necessary in the elderly with/without obese women.

What is the impact of weight gain less than that recommended by IOM on pregnancy outcome for women with GDM and BMI ≥30

D. Bogdanet[1], A. Khattak[1], M. Mustafa[1], L. Carmody[1], B. Kirwan[1], P. O'Shea[1], G. Gaffney[1], F. Dunne[2];
[1]Galway University Hospital, Galway, [2]National University of Ireland Galway, Galway, Ireland.

Background and aims: The Institute of Medicine (IOM) recommends gestational weight gain (GWG) of 5–9 kg in women with a body mass index of ≥30. Debate continues as to whether GWG less than that recommended is safe. Concern relates to whether this would result in an increase in small for gestational age (SGA) infants, or an increase in rates of prematurity.

Materials and methods: We examined pregnancy outcomes for mothers with GDM and a BMI ≥30 and their offspring ($n = 752$) of whom 473 were treated with insulin. Women were categorised into 3 groups (1) those with weight loss or weight gain 0–5 kg, (2) weight gain 5–9 kg (3) weight gain >9 kg, from the first antenatal visit to delivery. We examined pregnancy outcomes for groups 1 and 2 in women treated by diet only (GDM-D) and in those treated with insulin (GDM-I). Rates of maternal outcomes (pregnancy induced hypertension (PIH), pre-eclampsia (PET), antepartum (APH) and postpartum haemorrhage (PPH), week of delivery, caesarean section (CS) delivery) and neonatal outcomes (birth weight, large for gestational age (LGA), small for gestational age (SGA), macrosomia, prematurity <37 weeks, neonatal morbidities) were compared between groups.

Results: Maternal age BMI and week of GDM diagnosis were similar between groups. In the GDM-D group ($n = 120$) the baseline systolic (123 vs 117 mmHg; $p = 0.03$) and diastolic (73 vs 68 mmHg; $p = 0.01$) pressure was higher in group 1 vs 2. Women in Group 1 ($n = 91$) were more likely to deliver earlier (38.9 vs 39.8 weeks, $p < 0.01$), to develop PIH (15.4% v 0%; $p = 0.02$) or have a PPH (13.2% vs 0, $p = 0.03$) compared to GDM-D women in Group 2 ($n = 29$). Rates of prematurity were higher in group 1 vs 2 (14.3% vs 0%, $p = 0.03$). All other neonatal outcomes were similar with no excess of LGA, macrosomia, SGA, neonatal morbidities or need for NNU care. In the GDM-I group ($n = 192$), women in Group 1 ($n = 144$) had similar delivery time, rates of PIH, PET and CS as women in Group 2 ($n = 48$) but rates of PPH were higher (7.9% vs 0, $p = 0.05$). Rates of LGA, macrosomia, SGA, prematurity, neonatal morbidities and need for NNU care were similar between groups.

Conclusion: Weight gain less than IOM recommendations appears safe for infants of women with GDM. Reasons for an excess of maternal PPH or PIH are not apparent and require further investigation in other cohorts.

Heterogeneity in insulin sensitivity and insulin secretion in gestational diabetes relates to differences in pregnancy outcomes

L.R. Madsen[1,2], K. Gibbons[3], D. McIntyre[3,2];
[1]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, Denmark, [2]Danish Diabetes Academy, Odense, Denmark, [3]Mater Research Institute, South Brisbane, Australia.

Background and aims: Varying clinical phenotypes exist within the overarching "diagnosis" of Gestational Diabetes Mellitus (GDM), encompassing women with predominant defects in insulin sensitivity, insulin secretion or a combination of both. We aimed to determine if GDM phenotypes as defined by estimates of insulin sensitivity and secretion were independently associated with birthweight, LGA (large for gestational age), preterm delivery, caesarean delivery (CS), and a composite of GDM-related adverse pregnancy outcomes (LGA, neonatal hypoglycemia, or caesarean delivery), when adjusted for potential confounders.

Materials and methods: Using data from OGTTs at mean gestational week 28 in the Brisbane HAPO study cohort, we estimated insulin sensitivity (Matsuda index) and secretion (HOMA β) in 1245 women. In women with GDM (10.5%, when using IADPSG criteria), defects in insulin sensitivity and/or insulin secretion were defined as <25th percentile in non-GDM women. This approach yielded four subgroups named by the predominant defect; low insulin sensitivity (GDMsens), low insulin secretion (GDMsec), both defects (GDMmixed), or no detectable defects (ND). We created linear and logistic regression models adjusted for maternal age, maternal height, BMI, smoking, gravidity, parity, family history of diabetes, mean arterial BP, and HbA_{1c}. No women received GDM treatment during pregnancy.

Results: Relative to non-GDM women, women in the GDMsens group (52.7% of all GDM) had higher BMI (33.8 vs 28.6 kg/m^2, $p < 0.001$), higher mean arterial BP (87 [SD 7] vs 83 [SD 7] mmHg, $p < 0.001$), gave birth to heavier infants (birth weight z scores 0.67 [SD 1.12] vs 0.19 [SD 0.98], $p < 0.001$) with a higher odds of LGA (OR 2.34; 95% CI 1.33,

4.12; $p = 0.003$); had higher odds of preterm delivery (OR 2.62; 95% CI 1.14, 6.04; $p = 0.024$), and higher odds of delivering by CS (OR 1.89; 95% CI 1.15;3.10, $p = 0.012$). Relative to non-GDM women, women with GDMsec defects (17.6%) were older (33.6 [SD 4.5] vs 29.2 [SD 5.2] years, $p < 0.001$), but pregnancy outcomes were similar. Relative to non-GDM women, women in the GDMmixed (14.5%) group had higher BMI (32.8 [SD 6.5] vs 28.6 [SD 5.5] kg/m^2, $p = 0.003$) and showed similar trends in outcomes to the GDMsens group, though none achieved significance. The ND women (15.3%) did not differ from non-GDM women. When adjusting for confounders including BMI, only the GDMsens group were still at increased odds for adverse outcomes; preterm delivery (OR 2.56; 95% CI 1.02, 6.46; $p = 0.046$), and birth weight z score of +0.30 (95% CI 0.060, 0.55; $p = 0.015$) in comparison to non-GDM women. After adjusting for BMI, the odds of CS and LGA babies were no longer higher in the GDMsens group. We found no increased risk of the composite GDM-related adverse pregnancy outcome (LGA, neonatal hypoglycemia, or caesarean delivery) in any subgroup.

Conclusion: Different clinical phenotypes in GDM are associated with differing risks of LGA infants, preterm delivery, and caesarean delivery. Women with GDM, predominantly due to a defect in insulin sensitivity have higher risks of adverse outcomes; only partly explained by BMI and other confounders.

Preconceptional care in diabetes: results from a single reference centre

A. González Lleó[1], B. Vega-Guedes[2], A. López-Alonso[2], M. Alberiche[1], A. Arencibia[2], O. Ramírez[2], L. Maya[2], A. Wägner[1,3];
[1]Endocrinology and Nutrition Department, Complejo Hospitalario Universitario Insular Materno-Infantil de Gran Canaria, Las Palmas de Gran Canaria, [2]Obstetrics and Gynaecology Department, Complejo Hospitalario Universitario Insular Materno-Infantil de Gran Canaria, Las Palmas de Gran Canaria, [3]Instituto Universitario de Investigaciones Biomédicas y Sanitarias (IUIBS), Las Palmas de Gran Canaria, Spain.

Background and aims: Preconceptional care (PC) is associated with improved pregnancy outcomes in previous studies in women with pregestational diabetes. The aim of this study was to assess the frequency of preconceptional planning in our population and compare the features and outcomes of women with and without PC.

Materials and methods: All women with pregestational diabetes who were followed at our centre during pregnancy and delivered between 1st January 2011 and 31st December 2017 were included in the analysis. PC was defined as attending our preconceptional clinic at least once before pregnancy, regardless of whether green light for pregnancy had been given or not. Comparisons were made between women with and without PC (Student's *t* and chi-squared, $p < 0.05$).

Results: Of the 401 women with pregestational diabetes (48% type 1) who delivered during the study period, 60 (15%) had attended PC (18.8% of those with type 1 vs 11.6% of those with type 2 diabetes, $p = 0.046$). There were no significant differences in the distribution according to Priscilla White classification of diabetes. Women with PC were more frequently nulliparous (87.8 vs 52.7%, $p < 0.0005$), but there were no differences in age or body mass index. PC was associated with lower HbA1c before pregnancy (6.3 ± 1.7 vs 7.8 ± 1.7%, $p < 0.0005$) and in the 1st trimestre (6.1 ± 0.7 vs 7.0 ± 1.3% $p < 0.0005$), although these differences were attenuated in the 2nd (5.9 ± 0.7 vs 6.0 ± 0.8% $p = 0.091$) and 3rd trimestres (6.1 ± 0.7 vs 6.2 ± 0.8%, $p > 0.1$). Women with PC had less often large for gestational age (LGA, $p >$ p90) babies (36.7% vs 51.5%, $p = 0.03$). There were no significant differences in the frequencies of caesarean section, shoulder dystocia, preterm delivery, intrauterine growth restriction, preeclampsia or admission to intensive care of the newborns.

Conclusion: The frequency of PC in our population with pregestational diabetes is low, especially among women with type 2 diabetes. PC is associated with lower pregestational and 1st trimestre HbA1c and with a lower frequency of LGA babies.

Disclosure: **A. González Lleó:** None.

When is HbA_{1c} during pregnancy correlated with macrosomia of the newborn in women with type 1 diabetes?

P. Kazakou[1], P. Antsaklis[2], P. Kontou[1], M. Mitropoulou[1], V. Sarantopoulou[1], G. Daskalakis[2], E. Anastasiou[1];
[1]Department of Endocrinology-Diabetes Center, General Hospital of Alexandra, Athens, [2]1st Department of Obstetrics and Gynecology, General Hospital of Alexandra, Athens, Greece.

Background and aims: It is well documented in the literature that poor glycemic control in pregnant women with type 1 diabetes is related with increased risk of adverse fetal and maternal outcomes, including macrosomia of the newborn. However, there are limited data regarding the time window during pregnancy that glycemic control can affect fetal growth and determine the development of macrosomia. The aim of this study was to investigate the correlation of A1C during pregnancy with macrosomia and birth weight of newborn in women with type 1 diabetes.

Materials and methods: This is a retrospective study which included a total of 184 pregnant women with type 1 diabetes followed in our department since 2010. Data regarding medical history, parameters of glycemic control, fetal ultrasounds and neonatal outcomes were recorded.

Results: Mean age was 30.3 ± 6.4 years and average duration of diabetes was 11.5 ± 8.7 years. 45.2% of the women were nulliparous and 54.8% multiparous. Mean gestational age at delivery was 37.0 ± 2.3 weeks and mean birthweight was 3163 ± 720 g. The rate of cesarean section was 87.1%. Of the newborns 46.7% were male and 53.3% were female. Mean daily insulin dose/weight kg was 0.63 U/kg (±0.27) during 1st trimester, 0.73 U/kg (±0.29) during 2nd trimester and 0.90 U/kg (±0.37) during 3^{d} trimester. The increase rate of daily insulin/kg dose throughout gestation was 42.4%. Mean A1C was 7% ± 1.38 for the 1st trimester, 5.6% ± 1.1 for the 2nd trimester, and 5.5% ± 0.8 for the 3^{d} trimester. For the fetuses with abdominal circumference (AC) >75th percentile during 3^{d} trimester, the levels of A1C of the 1st trimester were statistically higher (7.06% ± 1.77 vs 5.94% ± 0.86) ($p = 0.012$). The prognostic value of A1C of the 1st trimester remained statistically significant when the maternal weight gain was also taken into account. Linear regression analysis showed that A1C of the 1st trimester correlated with birthweight ($p = 0.011$) independently of the week of gestation, the fetal sex or maternal weight gain.

Conclusion: These findings suggest that macrosomia of the fetus/newborn, as documented by fetal ultrasound and birthweight, correlates with poor maternal glycemic control during the 1st trimester of gestation. The improvement of glycemic control subsequently doesn't seem to slow the accelerated fetal growth. This observation might be due to nonreversible pancreatic disorder of the fetus.

Sensitivity and specificity of the glucose challenge test for gestational diabetes using the 2013 World Health Organization criteria

K. Benhalima[1], P. Van Crombrugge[2], C. Moyson[1], J. Verhaeghe[1], S. Vandeginste[2], H. Verlaenen[2], C. Vercammen[3], T. Maes[3], E. Dufraimont[3], C. Deblock[4], Y. Jacquemyn[4], K. De Clippel[5], A. Loccufier[6], R. Devlieger[1], C. Mathieu[1];
[1]UZ Gasthuisberg, Leuven, [2]OLV ziekenhuis Aalst-Asse-Ninove, Aalst, [3]Imelda ziekenhuis, Bonheiden, [4]Antwerp University Hospital, Antwerp, [5]Kliniek St-Jan, Brussel, Belgium, [6]AZ St Jan, Brugge, Belgium.

Background and aims: A two-step screening strategy with a 50 g glucose challenge test (GCT) and the 2013 World Health Organization (WHO) criteria for gestational diabetes (GDM), might be a valuable alternative to the one-step approach with the 75 g oral glucose tolerance test (OGTT) with the advantage of limiting the number of OGTT's. The aim was to determine the sensitivity and specificity of the GCT in a universal two-step screening strategy for GDM using the 2013 WHO criteria.
Materials and methods: We performed a multi-centric prospective cohort study enrolling 2006 women before 14 weeks of pregnancy. Women without (pre)diabetes in early pregnancy, received both a GCT and 75 g OGTT between 24–28 weeks of pregnancy. Participants and health care providers were blinded for result of the GCT. The diagnosis of GDM was based on the 2013 WHO criteria. The performance of the GCT was assessed by a receiver-operating characteristic (ROC) curve and area under the curve (AUC). Sensitivity and specificity were analyzed across a wide range of GCT thresholds, with or without the addition of clinical risk factors. Women's preferences for the different screening strategies were also evaluated.
Results: Of all participants, 1811 (90.3%) received both a GCT and OGTT. Based on the OGTT, GDM prevalence was 12.5% (231). Using a two-step strategy with a GCT, GDM prevalence increased from 7.5% (136) to 9.1% (165) and 10.3% (187) when the threshold for consequent OGTT was lowered from 140 mg/dl to 130 mg/dl and 120 mg/dl. The ROC curve showed a AUC of 0.77 (95% CI 0.74–0.81) for the GCT. Sensitivity increased with decreasing GCT threshold [59.6% (95% CI 53.0–66.1), 72.4% (95% CI 66.1–78.1) and 82.0% (95% CI 76.4–86.8) for 140 mg/dl, 130 mg/dl and 120 mg/dl], at the expense of specificity [81.0% (95% CI 79.0–82.9), 70.2% (95% CI 67.9–72.4) and 56.0% (95% CI 53.5–58.4)]. Using a GCT threshold of 130 mg/dl, 65% of all OGTT's could be avoided compared to a one-step approach, with little added value of clinical risk factors. 20.6% (377) of women had complaints of the GCT and 43.4% (784) of the OGTT. More women preferred a two-step strategy or had no clear preference.
Conclusion: The GCT has a moderate diagnostic accuracy in a universal two-step screening strategy for GDM using the 2013 WHO criteria. A GCT threshold of 140 mg/dl had only a sensitivity of 59.6% and can therefore not be recommended in a two-step approach for GDM using the 2013 WHO criteria. To achieve sensitivity rates ≥70%, the threshold of the GCT would need to be reduced to at least 130 mg/dl.
Clinical Trial Registration Number: NCT02036619

When timely gestational diabetes screening should occur in in vitro fertilisation pregnancies and how important is intensive glucose management?

P. Thomakos[1], O. Kepaptsoglou[1], A. Trouva[1], A. Sklavounos[2], E. Kapetanakis[3], A. Korantzis[4], D. Trouvas[2], P. Karantzis[5], C. Barreto[1], I. Taraoune[1], I. Sklavounos[5], C.S. Zoupas[1];
[1]Diabetes Center & Clinic, Hygeia General Hospital, Athens, [2]Mitera Maternity Hospital, Athens, [3]IVF center Chalandri, Athens, [4]IASO Maternity Hospital, Athens, [5]IVF department, Mitera Maternity Hospital, Athens, Greece.

Background and aims: In Vitro Fertilization (IVF) is a popular method of assisted reproduction. Gestational Diabetes Mellitus (GDM) is increased in IVF pregnancies. We aimed to investigate the effect of GDM in IVF pregnancies and its impact on maternal and fetal outcomes.
Materials and methods: Our study included a total of 408 singleton pregnancies [102 IVF with GDM (a) vs 102 spontaneous conception with GDM (b) vs 102 IVF without GDM (c) vs 102 normal pregnancies (d)]. The clinical characteristics of the study groups are (Mean ± SD): [age: 38.2 ± 4 vs 34.1 ± 3 vs 37.4 ± 4 vs 37.4 ± 5 years, $p < 0.001$ (a vs b) (b vs c) (b vs d); BMI: 25.8 ± 5 vs 23 ± 4 vs 24.8 ± 3 vs 22.7 ± 4 kg/m^2, $p <$ 0.001 (a vs b) (a vs d); HbA1c: 5.2 ± 0.5 vs 5.2 ± 0.7 vs 4.9 ± 0.3 vs 4.7 ± 0.3% , $p < 0.001$ (a vs c) (a vs d) (b vs c) (b vs d); Fasting Blood Glucose: 84.1 ± 8 vs 84.2 ± 7 vs 79.2 ± 8 vs 78.2 ± 5 mg/dl, $p < 0.001$ (a vs c) (a vs d) (b vs c) (b vs d), 1-h postprandial BG: 103.6 ± 11 vs 106.5 ± 10 mg/dl, p = NS (a vs b); week of diagnosis GDM: 21.8 ± 5.2 vs 23.8 ± 6.2, $p =$ 0.03 (a vs b); week of starting insulin: 22.8 ± 5 vs 24.8 ± 5, $p = 0.03$ (a vs b); insulin dose: 34.7 ± 10 vs 29.5 ± 16 iu/day, $p = 0.03$ (a vs b); smoking history: 30.5 vs 31.2 vs 31.3 vs 28.4%.
Results: The summary of obstetric and neonatal history between the 4 groups are: Maternal weight gain: 10.4 ± 4 vs 11.9 ± 3 vs 11.8 ± 3 vs 10.5 ± 2 kg, $p = 0.03$ (a vs b) (a vs c) (b vs d) (c vs d); week of delivery: 36.9 ± 2 vs 37.4 ± 1 vs 37.8 ± 1 vs 38.1, $p = 0.04$ (a vs b) $p < 0.001$ (a vs c) (a vs d) (b vs c) $p = 0.01$ (b vs d); neonatal birth weight: 2857 ± 517 vs 2891 ± 341 vs 3049 ± 379 vs 3117 ± 347 g, $p < 0.001$ (a vs c) (a vs d) (b vs c) (b vs d); women experienced hypoglycemia episodes: 24.5 vs 26.5%, $p =$ NS, pre-eclampsia rate: 4.9 vs 3.9 vs 2.4 vs 1.9%; Respiratory Distress Syndrome: 14.7 vs 12 vs 10.5 vs 5.8%, $p = 0.03$ (a vs d); Neonatal hypoglycemia: 17.6 vs 14.7%, p = NS, Neonatal Intensive Care Unit admittance: 14.7 vs 15.6 vs 10.5 vs 5.8% $p = 0.03$ (a vs d) $p = 0.02$ (b vs d), Caesarean Section: 86.3 vs 56.9 vs 74.4 vs 41.1%. There were 2 cases of perinatal mortality in each IVF groups. 1-hour Postprandial BG was associated with maternal-fetal complications ($r = 0.504$, $p < 0.001$). Maternal hypoglycemia did not affect fetal outcome. Age and BMI were not correlated with the week of GDM diagnosis.
Conclusion: GDM screening in IVF pregnancies should be much earlier than 24–28 weeks. Strict postprandial metabolic control with early insulin therapy limits adverse pregnancy outcomes, while maternal hypoglycemia does not seem to have an effect. Further studies are necessary to clarify the role of GDM in increased fetal complications, especially in IVF pregnancies.
Disclosure: **P. Thomakos:** None.

Screening for early gestational diabetes is not associated with a better pregnancy prognosis than no early screening: an observational study including 9975 women

E. Cosson[1], D. Sandre-Banon[1], F. Gary[1], I. Pharisien[2], J.-J. Portal[3], I. Banu[1], L. Bianchi[1], C. Cussac-Pillegand[1], S. Chiheb[1], E. Vicaut[3], P. Valensi[1], L. Carbillon[2];
[1]Department of Endocrinology Diabetology Nutrition, Bondy, [2]Department of Gynecology-Obstetrics, Bondy, [3]Clinical Research Unit, Fernand Vidal Hospital, Paris, France.

Background and aims: In addition to screening for gestational diabetes mellitus (GDM) after 24 gestational weeks (GW), the IADPSG proposed to screen in early pregnancy and to refer women with early GDM (eGDM) for immediate care. The usefulness of such a strategy is still unknown.
Materials and methods: We included women with a singleton pregnancy, without personal history of diabetes or bariatric surgery, who delivered

in our University hospital between 2012 and 2016. We compared the incidence of preeclampsia or large for gestational age infant or shoulder dystocia (predefined composite criterion) whether an early screening (before 22 WG) -leading to care for eGDM (FPG 92–125 mg/dL) or diabetes in pregnancy (DIP: FPG ≥126 mg/dL)- was performed (screened group) or not (unscreened group).

Results: Compared with women in the unscreened group ($n = 5190$, 53.0%), those in the screened group ($n = 4605$) had different ethnicities ($p < 0.0001$) and more risk factors for GDM including overweight (unscreened 45.9 *vs* screened 48.7%, $p < 0.01$), family history of diabetes (25.3 *vs* 27.9%, $p < 0.01$), personal history of GDM (4.3 *vs* 6.2%, $p < 0.01$) and macrosomic infant (2.7 *vs* 3.4%, $p < 0.05$). Early screening increased from 2012 to 2016 ($p < 0.0001$) and was associated with less maternal smoking during pregnancy (7.5 *vs* 6.2%, $p = 0.027$). Glycaemic status was different ($p < 0.001$) in the unscreened group (GDM 16.8% and DIP 1.2%) and the screened group (eGDM 8.5%, GDM 12.1% and DIP 0.9%), with a lower rate of insulin therapy (6.0% *vs* 8.9%, $p < 0.001$) and a higher gestational weight gain (11.4 ± 5.5 *vs* 11.1 ± 5.4 kg, $p = 0.013$) in the unscreened group. Composite criterion rate was similar in the unscreened and the screened groups (11.6 *vs* 12.0% respectively, odds ratio 1.040 (95% confidence interval 0.920–1.176) $p = 0.53$), also after adjusting for a propensity score considering factors associated with early screening (OR 1.034 (0.911–1.175), $p = 0.6036$) alone or in addition to predictors of pregnancy outcomes that were forced in the model (OR 1.057 (0.928–1.205), $p = 0.4022$). The incidence of other outcomes was similar in both groups. The results were similar considering only the 6656 women with risk factors for GDM (composite criterion 11.6 *vs* 12.0% respectively, OR 1.051 (0.915–1.207) $p = 0.4822$).

Conclusion: Our observational results show that a strategy including early measurement of FPG during pregnancy increases the number of GDM cases and care with more insulin therapy and lower gestational weight gain, but suggest that it may not improve pregnancy prognosis.

Effect of probiotics on glucose and lipid metabolism in pregnant women: a systematic review and meta-analysis

M.M. Han[1], J.F. Sun[2], C.H. Wu[1], X.Y. Zhu[1], L. Li[1];
[1]Department of Endocrinology, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, [2]Key Laboratory of Environmental Medicine Engineering, Ministry of Education, School of Public Health, Southeast University, Nanjing, China.

Background and aims: Gut microbiome are altered in pregnancy. These alterations may influence the maternal glucose and lipid metabolism and contribute to gestational diabetes mellitus (GDM). Probiotics could be a method to alter the gut microbiome, however, little is known about their use in influencing the metabolic environment of pregnancy. The aim of this meta-analysis was to assess the effects of probiotics supplementation in pregnancy on relevant maternal metabolic control and rate of GDM.

Materials and methods: We searched PubMed, Web of Science and the Cochrane Library for reports published up to October 2017. We performed a meta-analysis of randomized controlled trials (RCTs) on the relationship between probiotics supplementation and glucose and lipid metabolism in pregnant women. After study selection, two authors performed quality assessment and data extraction independently, and mean differences (MD) or standard mean differences (SMD) or relative risk (RR) with 95% confidence intervals (CIs) were calculated with the random-effects model in this meta-analysis.

Results: From 648 citations, a total of 13 articles (10-RCTs) with 1139 participants met the inclusion criteria; it was at a low risk of bias. We found that there were no significant differences on quantitative insulin sensitivity check index (QUICKI) (MD 0.01, $p = 0.06$) or maternal weight change (MD −0.27 kg, $p = 0.13$). However, the meta-analysis showed that probiotics supplement significantly reduced the fasting blood glucose level (MD −0.11 mmol/L, $p = 0.0003$), serum insulin level (MD −2.06 μU/mL, $p < 0.00001$), homeostasis mode assessment of insulin resistance (HOMA-IR) (MD −0.38, $p < 0.00001$). And the Meta-analyses showed that a reduction in the rate of GDM (risk ratio (RR) 0.52, $p = 0.003$) when women are randomized to probiotics early in pregnancy. Additionally, there was statistically significant reduction in total cholesterol following probiotic supplementation (SMD −0.56, $p = 0.03$). However, there was no significant reduction in other lipid profiles following probiotic supplementation.

Conclusion: Probiotics supplementation is associated with improved glucose and lipid metabolism in pregnant women, and may contribute to reduce the risk of GDM. The use of probiotics supplementation is promising as a potential prevention and therapy to assist in the metabolic management of GDM.

The prevalence of microvascular complications during the third trimester in women with gestational diabetes

B.R. Shah, D.Z. Cherney, D.S. Feig, E. Herer, M.A. Hladunewich, A. Kiss, R.P. Kohly, L.L. Lipscombe;
University of Toronto, Toronto, Canada.

Background and aims: Chronic exposure to hyperglycemia is a key factor that promotes the development of microvascular complications of diabetes. However, women with gestational diabetes mellitus (GDM) with only short-term hyperglycemia may nonetheless be at risk for these complications. Our aim was to determine the prevalence of retinopathy and microalbuminuria in women in the third trimester of pregnancy with and without gestational diabetes.

Materials and methods: We recruited women between 32 and 40 weeks' gestational age. Women who developed hypertensive disorders of pregnancy including preeclampsia, and those with a positive postpartum oral glucose tolerance test, were retrospectively excluded. Blood pressure (BP), body-mass index, fundus photographs, urine albumin-creatinine ratio and A1c were obtained. Photographs were graded by an ophthalmologist, and those with ETDRS step ≥14 were considered to have retinopathy. Microalbuminuria was defined as an albumin-creatinine ratio ≥2.0 mg/mmol. The prevalence of retinopathy and microalbuminuria were determined among women with and without GDM, and bivariate analysis was performed to determine what baseline factors were associated with each outcome. Logistic regression was used to determine the independent predictors.

Results: We studied 213 women with GDM and 178 without. Their baseline characteristics are presented in the Table. Retinopathy was present in 10% of women with GDM and 11% without ($p = 0.7$), whereas microalbuminuria was found in 15% and 6%, respectively ($p = 0.007$). In additional bivariate analysis, systolic BP, diastolic BP, body-mass index, 1 hr glucose challenge test and A1c were all significantly associated with microalbuminuria. Age, gestational age, gravidity, parity and ethnicity were not. In multivariable modeling, after adjusting for A1c and diastolic BP, GDM was no longer significantly associated with microalbuminuria. Each 5 mmHg increase in diastolic BP increased the odds of microalbuminuria by 50%, while each 0.1% increase in HbA1c increased the odds by 11%. No baseline factors were associated with retinopathy in bivariate or multivariate analysis.

Conclusion: GDM increases the risk of microalbuminuria, but not retinopathy, after only a brief exposure to hyperglycemia. The risk for microalbuminuria was driven by differences in A1c and diastolic BP, potentially highlighting the importance of controlling these risk factors in patients with GDM.

Table. Baseline characteristics of study subjects

Characteristic	With GDM	Without GDM	p
Age (years)	34.6 ± 4.5	33.7 ± 3.5	0.03

Gestational diabetes is associated with increased risk of non-alcoholic fatty liver disease: a population-based cohort study

A. Lavrentaki[1,2], A. Subramanian[3], N. Thomas[3], G. Valsamakis[2], K. Toulis[3,4], B. Daly[5], G. Mastorakos[2], A.A. Tahrani[1,6], K. Nirantharakumar[3];
[1]Institute of Metabolism and System Research, University of Birmingham, Birmingham, UK, [2]Endocrine Unit, Aretaieion University Hospital, Athens Medical School, Athens, Greece, [3]Institute of Applied Health Research, University of Birmingham, Birmingham, UK, [4]Department of Endocrinology, 424 General Military Hospital, Thessaloniki, Greece, [5]School of Nursing, University of Auckland, Auckland, New Zealand, [6]Centre for Endocrinology, Birmingham Health Partners, Birmingham, UK.

Background and aims: Gestational diabetes mellitus (GDM) is associated with adverse perinatal outcomes, and increased risk of postnatal type 2 diabetes and cardiovascular disease. However, whether GDM increases the risk of developing incident Non-alcoholic Fatty Liver Disease (NAFLD) is unclear and has not been well examined in previous studies. This is important considering the significant health burden of NAFLD and the opportunity to interfere in high risk population in order to reduce the risk of developing end-stage liver disease.
Materials and methods: We conducted a retrospective cohort study after extracting data from a large primary care database in the United Kingdom. The cohort consisted of 9,640 women with GDM diagnosis and 31,296 control women, matched for age, body mass index (BMI) and time of pregnancy. All study participants were free from NAFLD diagnosis at study entry.
Results: Mean (standard deviation) age of the whole cohort was 32.62 (SD:5.34) years and BMI 28.62 (SD:6.10) kg/m^2. There were 44 (0.46%) and 41 (0.13%) NAFLD incident diagnosis in the GDM and control population respectively over a median follow-up of 2.87 (IQR 1.16–5.81) years. Unadjusted incidence rate ratio (IRR) for NAFLD development was 3.28 (95% CI 2.14–5.02). After adjusting for age, Townsend (deprivation) quintile, smoking, BMI and Metformin usage; women with GDM remained at increased risk of developing NAFLD compared to women without GDM (IRR 2.95; 95%CI 1.91–4.55). Further adjustment for the diagnosis of polycystic ovarian syndrome, hypertension, hypothyroidism, and lipids lowering treatment did not change our findings (IRR 2.83; 95%CI 1.83–4.38).
Conclusion: Women diagnosed with GDM were at significantly increased risk of NAFLD development in their post-delivery life compared to women without GDM. Clinicians should have a low threshold to investigate women with history of GDM for the presence of NAFLD. Future studies need to examine whether lifestyle or pharmacological interventions could reduce the risk of developing NAFLD in women with history of GDM.

Comparison of diagnostic value and cost-effectiveness in screening approaches for postpartum pre-diabetes and diabetes among women with history of gestational diabetes

L.-J. Li[1,2], I.M. Aris[3], Y. Chong[4], P. Gluckman[3], S. Ang[5,6], K. Tan[1,2];
[1]Division of O&G, KK Women's and Children's Hospital, Singapore, [2]O&g acp, Duke-NUS Medical School, Singapore, [3]Singapore Institute for Clinical Sciences, Agency for Science Technology and Research, Singapore, [4]Department of O&G, Yong Loo Lin School of Medicine, Singapore, [5]Division of Family Medicine, KK Women's and Children's Hospital, Singapore, [6]Duke-NUS Medical School, Singapore, Singapore.

Background and aims: Women with a history of gestational diabetes mellitus (GDM) are at high risk for developing pre-diabetes and type 2 diabetes (T2D) after delivery. However, current guidelines regarding the methods of postpartum routine screening on GDM mothers are inconsistent and not directive. We aimed to compare different screening methods [fasting HbA1c, fasting glucose level and 2-hour glucose level] for diagnosing pre-diabetes and T2D in women with GDM.
Materials and methods: Of participants from a Singapore birth cohort, 142 mothers attended both baseline (26–28 gestation weeks) and follow-up (5-year postpartum) visits. At baseline, we diagnosed GDM using a 75 g OGTT according to World Health Organization (WHO) guidelines. At follow-up, we assessed glucose tolerance using fasting HbA1c, fasting glucose level, and a 75 g oral glucose tolerance test (OGTT). We defined pre-diabetes when either of the following was present: a) fasting plasma glucose ranged between 6.1 mmol/Land 6.9 mmol/L; b) fasting plasma glucose <7.0 mmol/L and 2-h plasma glucose ranged between 7.9 and 11.0 mmol/L. We defined T2D if: a) fasting plasma glucose ≥7.0 mmol/L or 2-h plasma glucose ≥11.0 mmol/L, or b) has been diagnosed T2D during the 5 years' interval. We estimated area under the curve (AUC) to compare the diagnostic values, and conducted cost-effectiveness analysis for each of the three screening approaches.
Results: Of 142 mothers with GDM diagnosed at baseline, 57 (40.1%) developed pre-diabetes or T2D at the 5-year postpartum visit. AUC was 74.0, 73.5 and 76.5 for fasting HbA1c alone, fasting glucose alone, and the combination of fasting HBA1c and fasting glucose respectively. AUC predicted pre-diabetes and T2D perfectly (98.8%) if using 2-h glucose >7.7 mmol/L. Cost-effectiveness analysis showed that 2-h glucose level is a better postpartum screening tool for GDM mothers than fasting HbA1c and/or fasting glucose test.
Conclusion: Our study showed that either fasting HbA1c and fasting glucose level screening approach missed around a quarter of the pre-diabetes or T2D cases, among mothers with a history of GDM. Two-h glucose level and even OGTT may be the most optimal screening tool in terms of its accuracy in diagnostic value and economic cost-effectiveness.

Breastfeeding at night is rarely followed by hypoglycaemia in women with type 1 diabetes using carbohydrate counting and modern insulin therapy

L. Ringholm[1,2], A.B. Roskjær[1], S. Engberg[2], H.U. Andersen[2], A.L. Secher[1], P. Damm[1], E.R. Mathiesen[1];
[1]Center for Pregnant Women with Diabetes, Rigshospitalet, Copenhagen, [2]Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Hypoglycaemia in association with breastfeeding is a feared condition in mothers with type 1 diabetes.

Thus, routine carbohydrate intake at each night-time breastfeeding is often recommended despite lack of evidence. We evaluated glucose levels during breastfeeding with focus on whether night-time breastfeeding induced hypoglycaemia in mothers with type 1 diabetes.

Materials and methods: Out of 43 consecutive mothers with type 1 diabetes, 33 (77%) were included prospectively one month after singleton delivery. Thereof 26 mothers (mean age 30.7 (SD ±5.8) years, 64% nulliparous, duration of diabetes 18.6 (10.3) years) were breastfeeding and 7 mothers (31.7 (5.6) years, 57% nulliparous, duration of diabetes 20.4 (6.2) years) were formula feeding. Thirty-two women with type 1 diabetes, who had not given birth or breastfed in the previous year, served as age and BMI matched controls. All 33 mothers were experienced in carbohydrate counting with 45% on insulin pump and 55% on multiple daily injections. Blinded continuous glucose monitoring (CGM) for six days was applied at one, two and six months postpartum in the breastfeeding mothers and they recorded breastfeedings and carbohydrate intake. CGM data were evaluated once in the control women and at one month postpartum in the formula feeding mothers.

Results: One month postpartum the percentage of night-time (11 pm to 7 am) spent with CGM <4.0 mmol/l in the breastfeeding mothers was comparable with the control women (median 4.6% (range 0–20.8) and 1.6% (0–39.1), $p = 0.68$). The figure for formula feeding mothers was 8.2% (0–14.8). Mean glucose level at night-time was lower in breastfeeding mothers than in control women (8.3 (1.7) and 9.7 (2.4) mmol/l, $p = 0.02$) and formula feeding mothers (9.4 (1.6) mmol/l). In the breastfeeding mothers the mean glucose levels at night were similar at one, two and six months postpartum (8.3 (1.7) mmol/l, 8.6 (2.5) mmol/l and 7.9 (1.6) mmol/l, $p = 0.55$). Symptomatic hypoglycaemia occurred 2–3 times per week in the breastfeeding mothers at one, two and six months postpartum and in the control women with no significant differences between the breastfeeding mothers and the control women. Severe hypoglycaemia was reported by one (3%) mother during the 6-month post-partum period and by one (3%) control woman in the previous year (0.74). In breastfeeding mothers the insulin dose at one month postpartum was 18% lower than before pregnancy ($p = 0.04$). At one, two and six months postpartum carbohydrate was not ingested at a total of 438 (93%) night-time breastfeedings, whereof 20 (4.6%) breastfeedings were followed by CGM <4.0 mmol/l within 3 hours.

Conclusion: The percentage of night-time spent with hypoglycaemia in the breastfeeding mothers with type 1 diabetes was at the level of that in the non-pregnant control women with type 1 diabetes. Among >400 documented night-time breastfeedings without carbohydrate intake, hypoglycaemia within 3 hours was rare. The recommendation of routine carbohydrate intake at night-time breastfeeding may be obsolete in mothers with type 1 diabetes on modern insulin therapy who count carbohydrate.

Diagnosis of gestational diabetes in fasting serum samples - biomarkers detected by GC-MS based metabolomics

B.A. Raczkowska[1], D. Rojo[2], B. Telejko[1], M. Paczkowska-Abdulsalam[3], J. Hryniewicka[1], A. Zielinska[1], M. Szelachowska[1], M. Gorska[1], M. Ciborowski[3], C. Barbas[2], A. Kretowski[1,3];

Background and aims: Gestational diabetes mellitus (GDM) is one of the most common metabolic disorders in pregnancy which increases the risk of complications for mother and foetus, in particular the risk of developing diabetes type 2 later in life. Despite the fact that the criteria proposed by IADPSG were approved by WHO, the diagnosis of GDM varies considerably between individual countries and therefore it is still controversial, particularly with respect to the short and long term complications for mother and offspring. The aim of this study was to investigate the differences between fasting serum metabolites of GDM women with isolated impaired glucose tolerance (iIGT) or isolated impaired fasting glucose (iIFG) in comparison to normal glucose tolerance (NGT) pregnant women and to propose the potential biomarkers of GDM that can facilitate its diagnosis.

Materials and methods: Fasting serum samples were collected during 75 g oral glucose tolerance test (OGTT) between 24–28 weeks of gestation (gwk). Patients were diagnosed with GDM based on IADPSG criteria and divided into 2 subgroups: i) iIGT and ii) iIFG. Although there are no established criteria to identify prediabetes states i.e., iIGT and iIFG in pregnancy, for the aim of this research, we used these terms to clearly demonstrate the differences between GDM patients characterized by different glycemic status. Control group comprised of NGT pregnant individuals. Serum samples (discovery cohort, $n = 79$) were fingerprinted using gas-chromatography-mass spectrometry (GC-MS). Selected metabolites significantly discriminating iIGT from NGT group were quantified in a larger cohort (validation cohort, $n = 163$) by a targeted GC-MS. The statistical analysis was performed using the Student's t-test for normally distributed data and Mann-Whitney U test for the data without the normal distribution, followed by Benjamini-Hochberg post hoc correction. ROC curve analysis was performed to evaluate the clinical usefulness of proposed biomarkers.

Results: We identified a set of metabolites discriminating iIGT, iIFG and NGT groups. α-Hydroxybutyric acid (α-HB), β-hydroxybutyric acid (β-HB) and several fatty acids were found to be associated with iIGT. A combination of α-HB, β-HB and myristic acid was found highly specific and sensitive for diagnosis of GDM manifested by iIGT (AUC = 0.828).

Conclusion: Measurement of α-HB, β-HB and myristic acid in the fasting serum sample may allow for diagnosis of GDM manifested by iIGT without the need to perform OGTT.

Effect of gestational diabetic blood soluble factors on beta cell function: in vitro physiological analysis combined with proteomics approach

H. Kenar[1], C.Y. Ozdogan[1], H. Keskin[1], E.E. Islek[2], E. Doger[3], A. Nalla[4], I. Tarkun[5], J.H. Nielsen[4], M. Kasap[2];

[1]Diabetes and Obesity Research Laboratory, Kocaeli University, Kocaeli, Turkey, [2]DEKART Proteomics Laboratory, Kocaeli University, Kocaeli, Turkey, [3]Department of Gynecology and Obstetrics, Faculty of Medicine, Kocaeli University, Kocaeli, Turkey, [4]Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark, [5]Department of Endocrinology and Metabolism, Faculty of Medicine, Kocaeli University, Kocaeli, Turkey.

Background and aims: Pancreatic beta cell mass increases in pregnancy, but Gestational diabetes mellitus (GDM) may develop when adaptation of beta cells to compensate for the increased peripheral insulin resistance fails. The aim of this study was to investigate the effect of blood soluble factors from GDM and healthy glucose- tolerant (NGT) pregnants on beta cell function through *in vitro* physiological tests and proteomics approach.
Materials and methods: Blood plasma from 3rd-trimester GDM ($n = 8$) and NGT ($n = 10$) pregnant women was used in culture of INS-1E (rat insulinoma cell line) cells at 5% (v/v) concentration. After 24 h-culturing in RPMI 1640 supplemented with 5% (v/v) NGT/GDM blood plasma, glucose stimulated insulin secretion (GSIS) was performed under static conditions for 1 h in presence of 5% (v/v) NGT/GDM blood plasma and both secreted and intracellular insulin concentrations were determined by ELISA. Data were normalized to total DNA amount. Samples were studied in triplicate and data were statistically analyzed using Student's t-test; differences were considered significant when $p < 0.05$. Time dependent membrane depolarization and calcium influx into the cells upon glucose stimulation were determined in an automated spectrofluorometer. At the end of 1h - stimulation with 16.7 mM glucose, the cells were lysed and the proteins analyzed by 2D gel electrophoresis coupled with MALDI TOF-TOF MS/MS. Interactome analysis of the differentially regulated proteins was performed by using the STRING program.
Results: GDM blood plasma was associated with elevated insulin secretion ($p < 0.05$) from INS-1E upon exposure to 16.7 mM glucose, while caused no difference in intracellular insulin when compared with NGT group. Time dependent membrane depolarization of INS-1E and calcium influx into the cells occurred earlier and to a higher extent in the GDM group. Interactome analysis of the differentially regulated proteins in the GDM group revealed 4 glycolytic pathway proteins (Pkm, Aldoa, Eno 1, Gapdh), the mitochondrial glutamate dehydrogenase 1 (Glud1) and 2 proteins (HspA5 and HspA8) responsible for protein folding. In the NGT group, 7 of the proteins residing in the same interactome were related to energy metabolism - 3 Krebs cycle proteins (Atp5a1, Aco2, Cs) and 4 glycolytic pathway proteins (Gapdh, Pkm, Pgk1, TPI) - and still others were HspA8 and Hadh, an enzyme having essential role in mitochondrial beta-oxidation of short chain fatty acids.
Conclusion: These results demonstrated that glucose stimulated insulin secretion was elevated by GDM blood soluble factors and that under high glucose concentration the differentially regulated proteins in the beta cells mostly took role in the glycolytic pathway. On the contrary, NGT blood soluble factors caused differential regulation of both the glycolytic pathway and the Krebs cycle proteins.

The long-term maternal impact of impaired glucose tolerance during pregnancy: a role for placental kisspeptin signalling

L.I.F. Smith, T.G. Hill, S.J.S. Simpson, J.E. Bowe, P.M. Jones;
Department of Diabetes, School of Life Course Sciences, King's College London, London, UK.

Background and aims: During pregnancy increased maternal insulin resistance requires compensatory islet adaptation to maintain normoglycemia. Kisspeptin, released in high levels from the placenta, has previously been shown to potentiate glucose-induced insulin secretion through direct action on its receptor, GPR54, on the beta-cells. Beta-cell specific knockout of GPR54 (βGPR54ko) leads to impaired glucose tolerance in mice during pregnancy, but not in non-pregnant controls, whilst in pregnant women gestational diabetes (GDM) correlates with reduced plasma kisspeptin levels. GDM is also associated with an increased risk of T2DM in later life, though whether GDM is causative for T2DM development has not been fully determined. We monitored the glucose homeostasis of βGPR54ko mothers compared to age matched virgin controls to determine whether impaired glucose tolerance during pregnancy is causative for impaired glucose tolerance in later life.
Materials and methods: MIP-CreERT^{1Lphi}xGPR54*loxP* mice were administered tamoxifen (TMX) at 8 weeks to induce GPR54 knockout. Mice not administered TMX (Cre con) and TMX-injected mice lacking the Cre transgene (TMX con) were used as two separate control groups. Mice were maintained on either a standard chow diet (CD) or a high-fat high-sugar diet (HFHSD) from 12 weeks. At 18 weeks glucose tolerance was assessed through an intraperitoneal glucose tolerance test (IPGTT) and intraperitoneal insulin tolerance test (IPITT). Females were then either left as virgin controls or mated with males. IPGTT and IPITT were repeated at 4 weeks postpartum and every subsequent 4 weeks.
Results: Prior to mating, all female HFHSD groups had significantly worse glucose tolerance than their CD counterparts (CD vs HFHSD AUC: Cre con 1304 ± 115 vs 2903 ± 170, $P = 0.0002$; TMX con 1257 ± 50 vs 2196 ± 538, $P = 0.0567$; βGPR54ko 1390 ± 52 vs 2538 ± 383, $P = 0.0018$). However, there were no significant differences between control and knockout groups ($P = 0.2299$). At 4 weeks post-partum, CD mothers had similar glucose tolerance to age-matched virgins ($P = 0.8815$) suggesting a successful recovery of normal glucose homeostasis. However, βGPR54ko mothers on HFHSD had impaired glucose tolerance compared to virgins at 30 min after i.p. glucose (HFHSD βGPR54ko mothers vs βGPR54ko virgins 30 min glucose: 29.47 ± 2.02 mM vs 13.75 ± 0.65 mM, $P = 0.076$), a trend which is not observed in other groups (HFHSD Cre con mothers vs Cre con virgins 30 min glucose: 26.55 ± 4.75 mM vs 20.75 ± 5.65 mM, $P > 0.999$). In age-matched males, HFHSD caused an overall significant impairment of glucose tolerance ($P = 0.0002$), whilst there were no differences between control and knockout groups at 18 weeks ($P = 0.9728$), nor at any subsequent age.
Conclusion: Beta-cell specific GPR54 knockout does not impair glucose tolerance in males, nor in non-pregnant females on either a CD or HFHSD. This suggests that kisspeptin is likely to be a pregnancy-specific regulator of beta-cell function. On CD, females recover from the impaired glucose tolerance during pregnancy caused by GPR54 knockout and have similar long-term glucose homeostasis as virgin females. However, on HFHSD, females do not recover from the impaired pregnant glucose tolerance caused by GPR54 knockout. This suggests that the combined effects of HFHSD and a lack of islet kisspeptin signalling are causative for prolonged post-partum maternal glucose intolerance.

Association of gestational diabetes with low-grade inflammation and lymphocyte populations in subcutaneous and visceral adipose tissue

A. Cinkajzlova[1,2], K. Anderlova[3,4], P. Simjak[4], Z. Lacinova[1,2], J. Klouckova[1,2], H. Kratochvilova[1,2], H. Krejci[3,4], A. Parizek[4], M. Mraz[5,2], M. Krsek[3,6], M. Haluzik[1,2];
[1]Centre for Experimental Medicine, Institute for Clinical and Experimental Medicine, Prague, [2]Institute of Medical Biochemistry and Laboratory Diagnostics, First Faculty of Medicine, Charles University and General University Hospital, Prague, [3]3rd Department of Medicine, First Faculty of Medicine, Charles University and General University Hospital, Prague, [4]Gynaecology and Obstetrics Department, First

Faculty of Medicine, Charles University and General University Hospital, Prague, [5]Department of Diabetes, Institute for Clinical and Experimental Medicine, Prague, [6]2nd Department of Internal Medicine, Third Faculty of Medicine, Charles University and University Hospital Královské Vinohrady, Prague, Czech Republic.

Background and aims: Low-grade inflammation accompanying obesity and metabolic syndrome is associated with changed immune cell composition and phenotype in adipose tissue. Nevertheless, little is known about subclinical inflammation in gestational diabetes mellitus (GDM). The aim of this study was to analyze lymphocyte populations in subcutaneous (SAT) and visceral adipose tissue (VAT) together with systemic levels and mRNA expression of selected cytokines in these depots and placenta in the context of GDM and normal pregnancy.
Materials and methods: Thirty-seven pregnant females - 21 with GDM (GDM group) and 16 without GDM (P group) - were included into the study. Blood samples were taken in 28^{th}–32^{th} and 36^{th}–38^{th} gestational week and 6 months after delivery and SAT, VAT and placental samples were obtained during delivery. Lymphocytes were assessed as % of CD45+ cells measured by flow cytometry.
Results: In both groups CD45+ lymphocytes were higher in VAT compared to SAT (19.2 ± 2.2 vs. $6.5 \pm 0.7\%$, $p < 0.001$ for GDM and 18.3 ± 3.4 vs.7.8 ± 1.6, $p = 0.008$ for *P*, respectively). In GDM group T helper (CD4+) cells were higher in SAT compared to VAT (37.6 ± 2.4 vs. $28.6 \pm 2.6\%$, $p = 0.019$), resulting in a higher ratio of CD4+/CD8+ cells. Similarly, the amount of B (CD19+) and NKT (CD16/56+CD3+) cells was higher in SAT relative to VAT in GDM subjects, but not in P group. NK (CD15/56+CD3-) cells were increased in VAT only in GDM group (17.9 ± 3.1 vs. $9.1 \pm 1.3\%$, $p = 0.015$). CRP levels did not differ between GDM and P group, while circulatory TNF-α levels were higher in GDM females throughout the study (7.92 ± 0.69 vs. 4.59 ± 0.61 pg/ml, $p = 0.001$). Placental mRNA expression of IL-10 and IL-8 was higher in GDM versus P group with no difference between adipose tissue depots.
Conclusion: GDM is associated with increased systemic TNF-α levels and changed lymphocyte content in subcutaneous and visceral adipose tissue. These changes could be partly responsible for increased risk of complications for both mother and child during and after pregnancy.

Polyphenols as preventatives for gestational diabetes

C. Nguyen-Ngo, S. Liong, R. Lim, M. Lappas;
University of Melbourne, Melbourne, Australia.

Background and aims: Low-grade maternal inflammation, oxidative stress and peripheral insulin resistance are key features of GDM, and can lead to multiple short- and long-term complications for both mother and offspring. Recent epidemiological data suggest diets high in fruits, vegetables and plant-based foods confer potent health benefits. Polyphenols are the active compounds of these foods, and they possess potent anti-inflammatory, anti-oxidant and anti-diabetic properties. However, the effects of polyphenols on inflammation, oxidative stress and insulin resistance associated with GDM has not yet been studied. Therefore, the aims of this study were to examine the effects of the polyphenols naringenin, nobiletin and curcumin on the expression of pro-inflammatory mediators, oxidative stress, and insulin resistance associated with GDM.
Materials and methods: An *in vitro* explant model was used to determine the effects of naringenin, nobiletin and curcumin on TNF-α-induced expression of pro-inflammatory mediators and anti-oxidants in human placenta and adipose tissue, and glucose uptake in skeletal muscle ($n = 6$ patients/treatment/tissue). For these studies, a repeated measures ANOVA was used, with Fisher's Least Significant Difference (LSD) post hoc testing to discriminate among the means. A mouse model of GDM was used to assess the effects of polyphenols on glucose metabolism and inflammation ($n = 6$–7 mice/treatment group). GDM mice were injected intraperitoneally with or without polyphenols from gestational day (gd) 10 to gd 18. An oral glucose tolerance test was performed to assess glucose tolerance, and placenta and adipose tissues collected to assess gene expression of pro-inflammatory markers. Unpaired Student's t-test was used to assess statistical significance between normally distributed data; otherwise, the nonparametric Mann-Whitney *U* (unpaired) test was used for comparisons between groups. For all data, statistical significance was assigned to *P* value <0.05.
Results: *In vitro*, naringenin, nobiletin and curcumin significantly reduced TNF-α-induced mRNA expression and protein secretion of pro-inflammatory cytokines and chemokines including IL-6, IL-8, growth-regulated oncogene (GRO)-α and monocyte chemotactic protein (MCP)-1 from human placenta and adipose tissue. Naringenin and curcumin significantly increased mRNA expression of the antioxidants thioredoxin reductase (TrxR), Glutathione reductase (GR) and catalase in placenta and adipose tissue. Naringenin, nobiletin and curcumin significantly attenuated the decrease in glucose uptake induced by TNF-α in skeletal muscle. *In vivo*, GDM mice treated with naringenin and nobiletin had significantly reduced fasting glucose levels. Additionally, when compared to control treated mice, naringenin and nobiletin significantly decreased mRNA expression of IL-1α, IL-1β, TNF-α, IL-6, GRO-α and or MCP-1 in placenta, visceral and subcutaneous adipose of GDM mice.
Conclusion: Naringenin, nobiletin and curcumin possess potent anti-inflammatory, anti-oxidant and anti-diabetic properties in both *in vitro* and *in vivo* models of GDM. These polyphenols may act as novel therapeutics for the prevention of GDM.

Inflammation markers and insulin like growth factor binding protein 1 in women with gestational diabetes treated with metformin or insulin

M. Huhtala[1], K. Tertti[2], T. Rönnemaa[3];
[1]Department of Obstetrics and Gynecology, University of Turku, Turku, [2]Department of Obstetrics and Gynecology, Turku University Hospital, Turku, [3]Department of Medicine, University of Turku, Turku, Finland.

Background and aims: The prevalence of gestational diabetes (GDM) is increasing worldwide. Pregnancy as such influences inflammation markers. Modulation of inflammatory mediators such as high sensitivity C-reactive protein (hsCRP) and interleukine-6 (IL6) occurs in GDM. Insulin like growth factor binding protein 1 (IGFBP1) has been associated to obesity in pregnancy and GDM. Our aim was to characterise the inflammatory profile of GDM, its changes during pregnancy and the possible effects of metformin compared to insulin. Moreover, we examined the associations of birth weight with inflammation markers and IGFBP1.
Materials and methods: 217 pregnant women diagnosed with GDM were randomized to receive either metformin (n 110) or insulin (n 107). Fasting serum samples were collected at mean 30 gestational weeks (gw) and at 36 gw. In addition, baseline serum samples of 126 women with GDM achieving sufficient glycemic control with lifestyle modifications only were included in the study. Concentrations of hsCRP, IL6, matrix metalloproteinase-8 (MMP8), glycoprotein acetylation (GlycA), IGFBP1 and its entirely and partly phosphorylated isoforms, were measured using ELISA and nuclear magnetic resonance spectroscopy in the case of GlycA. Statistical analyses were done using Mann-Whitney *U*, t-test or Wilcoxon signed-rank test and Spearman's rank correlation.
Results: At baseline none of the variables differed significantly between diet and medically treated groups. In medically treated groups combined, hsCRP decreased ($p = 0.01$), whereas IL6 ($p = 0.002$) and GlycA ($p <$

0.001) increased from baseline to 36 gw. MMP8 was unchanged. All IGFBP1 isoforms increased ($p < 0.001$). GlycA (8.3% vs 5.6%, $p = 0.02$) and non-phosphorylated IGFBP1 (29% vs 18%, $p = 0.008$) increased more in the metformin than in the insulin group. At baseline BMI and fasting C-peptide correlated positively with hsCRP, IL6 and GlycA. On the contrary, IGFBP1s correlated inversely with BMI and C-peptide. Baseline, but not 36 gw, GlycA correlated positively and IGFBP1 inversely with birth weight, while MMP8 measured at 36 gw correlated inversely with birth weight. In regression analysis one SD change in MMP8 was associated to 72 g lower birth weight independent of BMI and smoking (95%CI: 8.1–150).

Conclusion: Serum concentrations of inflammation markers change significantly during the last trimester of pregnancy in GDM patients. The changes were parallel between medically treated groups. However, metformin associated with a higher increase in GlycA and a simultaneous decrease in hsCRP, thus not explicitly indicating either a pro- or anti-inflammatory environment. High IGFBP1, which has been associated to a healthier metabolic profile, rose more in metformin group. Most of the markers measured relate to BMI and C-peptide but respond differently to progression of pregnancy, thus together providing more detailed insight of inflammation in GDM. High MMP8, previously associated to cardiovascular risk and insulin resistance, did not correlate with BMI or fasting C-peptide in our data, unlike the other inflammation markers at baseline. Yet it was the only marker measured at 36 gw relating to birth weight. Our results suggest that compared to insulin, metformin does not have unfavourable effects on GDM pregnancy in terms of inflammation markers.

Association of nuclear-mitochondrial epistasis with BMI in type 1 diabetic patients

A.H. Ludwig-Slomczynska[1], M.T. Seweryn[1], P. Kapusta[1], E. Pitera[1], K. Cyganek[2], U. Mantaj[3], L. Dobrucka[2], E. Wender-Ożegowska[3], M.T. Malecki[2], P. Wolkow[1];

[1]Center for Medical Genomics OMICRON, Jagiellonian University Medical College , Krakow, Poland, Krakow, [2]Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland, Krakow, [3]Poznan University of Medical Sciences, Department of Obstetrics and Women's Diseases, Poznan, Poland, Poznan, Poland.

Background and aims: Obesity results from an imbalance between energy intake and its expenditure. GWAS analyses have led to discovery of only about 100 variants influencing BMI, which explain only a small portion of genetic variability. Analysis of gene epistasis gives a chance to discover another part. Since it was shown that interaction and communication between nuclear and mitochondrial genome is indispensable for normal cell function we have looked for epistatic interactions between the two genomes to find their correlation with BMI.

Materials and methods: The analysis was performed on 366 T1DM female pregnant patients using Illumina Infinium OmniExpressExome-8 chip. Only genes which influence mitochondrial functioning were included in the analysis - variants of nuclear origin (MAF >5%) in 1158 genes and 42 mitochondrial variants (MAF >1%). Gene expression analysis was performed on GTex data. Association analysis between genetic variants and prepregnancy BMI was performed with the use of Linear Mixed Models as implemented in the package 'GENESIS' in R. Analysis of association between mRNA expression and BMI was performed with the use of linear models and standard significance tests in R.

Results: Among genes involved in epistasis between mitochondria and nucleus we have identified mitochondrial transcription factor TFB2M. It interacted with few mitochondrial variants localized to MT-RNR1 ($p = 0.0004$, MAF = 15%), MT-ND2 ($p = 0.07$, MAF = 5%) and MT-ND4 ($p = 0.01$, MAF = 1.1%). Analysis of the interaction between nuclear variant rs6701836 localized to TFB2M and rs3021088 localized to MT-ND2 mitochondrial gene has shown that the combination of the two led to BMI decrease ($p = 0.02411025$). Each of the variants on its own does not correlate with higher BMI (p(nuc) = 0.8566547, p(mito) = 0.1160552). Although rs6701836 is intronic it influences gene expression in thyroid ($p = 0.000037$). rs3021088 is a missense variant that leads to Alanine to Threonine substitution in the MT-ND2 gene which belongs to complex I of the electron transport chain. The analysis of the influence of genetic variant on gene expression has confirmed the trend explained above - each of the mRNAs on its own is associated with higher BMI (p-(mito) = 0.0244 and p(nuc) = 0.0269), however, their interaction leads to BMI decrease ($p = 0.0308$).

Conclusion: Our results show that nuclear-mitochondrial epistasis can influence BMI in T1DM patients. The correlation between transcription factor expression and existence of genetic variants will be subject of further analysis.

PS 084 Neuropathy: prevalence and clinical impact

939

Prevalence of and risk factors associated with distal symmetric diabetic polyneuropathy in the SDRNT1BIO cohort

A. Jeyam[1], A. Ochs[1], S.J. McGurnaghan[1], L.A.K. Blackbourn[1], P.M. McKeigue[2], H.M. Colhoun[1,3], on behalf of the SDRNT1BIO Investigators;
[1]Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, [2]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, [3]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: Distal symmetric diabetic polyneuropathy (DSPN) is a major complication of diabetes, but its presence is difficult to assess before the pathology reaches an advanced stage with several clinical signs (e.g. foot sensation loss, ulcerations etc). We used the validated Michigan Screening Instrument Patient Questionnaire score threshold of ≥4 as a measure of DSPN to evaluate the contemporary prevalence of and cross sectional risk factor associations with DSPN in a large population representative cohort with type 1 diabetes (T1DM): the Scottish Diabetes Research Network Type 1 Bioresource (SDRNT1BIO).
Materials and methods: SDRNT1BIO is a large cohort ($N = 6127$) of adults with Type 1 diabetes recruited between 2010 and 2013 across primary and secondary care in Scotland. The characteristics of this cohort and their representativeness of the total adult T1DM population have been previously described in the literature. Patients completed the MSI at recruitment. Clinical risk factor data at time of recruitment was obtained by linkage to the comprehensive electronic health care record (SCI-Diabetes). The clinical factors examined for association with a MSI patient score of 4 or more were: HbA1c (mmol/mol), age at study date (years), duration of diabetes at study date (years), systolic blood pressure (mmHg), diastolic blood pressure (mmHg), height (cm), weight (kg), eGFR (ml/min/1.73 m^2), total cholesterol (mmol/L) triglycerides level (mmol/L), smoking status, gender. These variables were entered simultaneously into the model and logistic regression was used for the analysis.
Results: Overall the prevalence of DSPN was 13.4% (based on the $N = 5486$ available MSI binary scores), ranging from 5.9% in those aged 16–25 ($N = 577$ available binary scores out of 646 patients in this age group) to 19.4% in those aged 75 and above ($N = 103$ available binary scores out of 126 patients). A significant independent positive association was found between duration of diabetes and the prevalence of DSPN: the odds of having diabetic neuropathy for individuals with a diabetes duration of 20 to 30 years was 1.55 (95% CI: 1.7–2.24) times higher than those with a diabetes duration lower than 5 years while the odds were 2.25 (95% CI: 1.55–3.27) higher for those with diabetes duration higher than 30 years. The odds of having diabetic neuropathy also increased significantly with age (OR = 1.06 per 5 years, 95%CI: 1.02–1.10), HbA1C levels (OR = 1.17 per 5 mmol/mol, 95%CI: 1.14–1.20), weight (OR = 1.06 per 5 kg, 95%CI: 1.03–1.09). Smoking increased the odds of presenting diabetic neuropathy by 1.55 (95%CI: 1.27–1.90) and an increase of one unit in triglyceride levels mmol/L was significantly associated with higher odds of diabetic neuropathy (1.25, 95%CI: 1.16–1.34). Height was inversely associated with DSPN (OR per 5 cm 0.91, 95%CI = 0.85–0.97), higher eGFR was also significantly associated with lower odds of diabetic neuropathy (OR: 0.99 per ml/min/1.73 m^2, 95%CI = 0.98–0.99).
Conclusion: These data indicate a substantial burden of DSPN still remains in those with T1DM. Factors other than glycaemic control are associated with DSPN and these factors are modifiable, including lipids and smoking.

Contemporary prevalence of diabetic neuropathy in type 1 diabetes: findings from the T1D Exchange

R. Pop-Busui[1], C. Boyle[2], V. Shah[3], G. Aleppo[4], J. McGill[5], R. Pratley[6], E. Toshchi[7], L. Ang[1], K. Mizokami-Stout[1];
[1]University of Michigan, Ann Arbor, [2]Jaeb Center for Health Research, Tampa, [3]Barbara Davis Center for Diabetes, Aurora, [4]Northwestern University, Chicago, [5]Washington University School of Medicine, St Louis, [6]Florida Hospital Diabetes Institute, Orlanda, [7]Joslin Diabetes Center, Boston, USA.

Background and aims: Diabetic peripheral neuropathy (DPN) is a major cause of disability, mortality and poor quality of life in patients with T1D, with prior reported prevalence rates of up to 35%. The contemporary prevalence of DPN in T1D patients was evaluated in T1D Exchange Registry centers throughout the United States.
Materials and methods: The Michigan Neuropathy Screening Instrument (MNSI), a validated 15-item self-administered questionnaire, was used to assess DPN in adults ≥18 years with ≥5 years of T1D duration. A score of ≥4 was used to define DPN. Diabetes-related characteristics and laboratory data were obtained through the most recent clinic update. Chi-square and t-tests were used to compare demographic and diabetes-related characteristics between those with and without DPN. Linear regression was used to determine the effect of DPN on HbA1c, adjusted for possible confounders.
Results: In preliminary analyses of 5,058 participants across 62 sites (mean age 39 ± 18 years, T1D duration 22 ± 14 years, 56% female, 88% non-Hispanic White, mean HbA1c 8.1 ± 1.6%), the prevalence of DPN was 10%. Those with DPN were older (52 ± 17 vs 37 ± 18 years), more likely to be female (61% vs 55%), had longer T1D duration (32 ± 16 vs 21 ± 13 years), lower annual household income (37% vs. 59% earning ≥$75K), and lower education level (55% vs. 69% with college degree) than those without DPN (all $p < 0.001$). They also had higher systolic blood pressure (126 ± 17 vs 123 ± 14 mmHg), triglycerides (117 ± 89 vs 95 ± 62 mg/dL), tobacco use (9% vs 4%) and prevalence of established CVD (26% vs 6%), despite higher use of CVD-modifying agents such as statins (64% vs 31%) and ACE-inhibitors/ARBs (45% vs 23%) (all $p < 0.001$). Participants with DPN had higher HbA1c (8.4 ± 1.7% vs 8.1 ± 1.6%), even after adjusting for multiple confounders ($p < 0.01$).
Conclusion: The prevalence of DPN in this national T1D cohort is lower than prior published reports, reflecting current clinical care practices, and highlighting other non-glycemic risk factors for DPN including CVD risk factors and socioeconomic status.

Sex differences in neuropathy and neuropathic pain in longstanding diabetes: results from the Canadian study of Longevity in type 1 diabetes

N. Cardinez[1], L.E. Lovblom[1], J.-W. Bai[1], A. Abraham[2], E. Lewis[1], J.A. Lovshin[1], A. Orszag[1], A. Weisman[1], H. Keenan[3], M. Brent[4], N. Paul[5], V. Bril[6], D. Cherney[7], B. Perkins[1];
[1]Division of Endocrinology and Metabolism, Department of Medicine, University of Toronto, Sinai Health System, Toronto, Canada, [2]Neuromuscular Diseases Unit of the Department of Neurology, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, [3]Division of Endocrinology and Metabolism, Department of Medicine, Joslin Diabetes Center, Cambridge, USA, [4]Department of Ophthalmology and Vision Sciences, Department of Medicine, University of Toronto, Toronto, Canada, [5]Joint Department of Medical Imaging, Division of Cardiothoracic Radiology, University Health Network, Toronto, Canada, [6]Department of Medicine, University Health Network, University of Toronto, The Ellen and Martin Prosserman Centre for Neuromuscular Diseases, Krembil Neuroscience Centre, Division of

Neurology,, Toronto, Canada, [7]Division of Nephrology, Department of Medicine, University of Toronto, Toronto, Canada.

Background and aims: Neuropathy and neuropathic pain are common complications in T1D. We aimed to determine if sex-specific differences in the prevalence of neuropathic pain and neuropathy exist in patients with longstanding T1D.
Materials and methods: In Phase 1 of the study, 361 Canadians with ≥50 years of T1D completed questionnaires which included subjective assessment for neuropathy defined by Michigan Neuropathy Screening Instrument Questionnaire score ≥3, termed $NEUROPATHY_{MNSI-Q}$. In Phase 2 of the study, we studied a sub-cohort of 75 diabetes participants and 75 age- and sex-matched non-diabetic controls who completed objective neurological examinations which included assessment of abnormal nerve conduction studies (NCS) for neuropathy, termed $NEUROPATHY_{NCS}$.
Results: In the Phase 1 cohort, more females than males reported neuropathic pain [87(42%) vs 41(27%); $p = 0.003$)], but the presence of neuropathy ($NEUROPATHY_{MNSI-Q}$) did not differ by sex [87(42%) females vs. 66(43%) males, $p = 0.82$], and thus neuropathic pain was independent of the presence of neuropathy [adjusted OR for neuropathic pain in females compared to males, 2.7 (1.4–5.0; $p = 0.002$)]. In the Phase 2 participants, neuropathic pain was similar between the sexes (29% females vs 21% males, $p = 0.43$) while $NEUROPATHY_{NCS}$ was less prevalent among females (83% females vs 97% males, $p = 0.05$). Though not statistically significant, in a combined analysis of Phase 2 participants adjusted for $NEUROPATHY_{NCS}$, females had a tendency to a higher adjusted OR for neuropathic pain compared to males [OR 2.0 (95% CI 0.8–4.7), $p = 0.11$].
Conclusion: In conclusion, in patients with longstanding TID, neuropathic pain appears to be greater among females compared to males independent of the presence of neuropathy. Further research using larger datasets with objective neuropathy measures are required to further confirm and address these sex-specific differences.

Clinical and genetic factors contributing to protection from neuropathy in extreme duration patients with type 1 diabetes

S. Azmi[1], M. Ferdousi[1], R. Donn[1], J. O'Sullivan[1], I. Petropoulos[2], G. Ponirakis[2], U. Alam[3], A. Marshall[1], A. Sankar[1], O. Asghar[1], A.J.M. Boulton[1], H. Soran[1], N. Efron[4], R.A. Malik[1,2];
[1]University of Manchester, Manchester, UK, [2]Weill Cornell Medical College Qatar, Doha, Qatar, [3]University of Liverpool, Liverpool, UK, [4]Queensland University of Technology, Queensland, Australia.

Background and aims: Individuals with Type 1 Diabetes Mellitus (T1DM) for more than 50 years (medallists) represent a unique cohort, to study factors, which protect individuals from developing complications. We aim to identify factors that may protect this cohort from complications, in particular neuropathy.
Materials and methods: Thirty-three medallists age (63.7 ± 1.4 years), duration of diabetes (58.5 ± 0.8 years) and HbA1c (65.9 ± 2.1 mmol/mmol) underwent detailed assessment of neuropathy and eight individuals with minimal/no evidence of neuropathy underwent exome sequencing.
Results: Medallists without neuropathy had a shorter duration of diabetes ($p = 0.006$), lower alcohol consumption ($p = 0.04$), lower cholesterol ($p = 0.04$) and LDL ($p = 0.02$), but no difference in smoking, BMI, HbA1c, HDL or triglycerides, compared to medallists with complications. They also had a significantly lower ACR ($p < 0.001$) and higher eGFR ($p = 0.001$), lower neuropathy symptom profile ($p = 0.002$), vibration perception threshold ($p = 0.02$), warm threshold ($p = 0.05$) and higher peroneal amplitude ($p = 0.005$) and velocity ($p = 0.03$), heart rate variability ($p = 0.001$), corneal nerve fibre density ($p = 0.001$), branch density ($p < 0.001$) and length ($p = 0.001$), compared to medallists with complications. Targeted enrichment and sequencing was performed on 200 ng of DNA extracted from peripheral blood and sequence data was mapped with BWA software with the hg19 human genome as a reference. Variants were called using GATK v2.4.7 software and filtered out if they were non-functional in dbSNP138 (unless seen in HGMD) and in our in-house variant database. Exome sequencing, replicated by Sanger sequencing failed to identify any unique variant in medallists without neuropathy.
Conclusion: Medallists with minimal complications have a lower cholesterol, LDL and alcohol consumption, but no evidence of any unique genetic variant contributing to this protection.

Looking for an early marker of diabetic neuropathy in type 1 diabetes

S. Frontoni[1], F. Picconi[1], M. Parravano[2], D. Schiano Lomoriello[2], L. Ziccardi[2], G. Mataluni[3], P. Pasqualetti[4], D. Ylli[5], L. Chioma[1], I. Malandrucco[1], G. Marfia[3];
[1]Department of Systems Medicine, University of Rome Tor Vergata, Rome, Italy, [2]IRCCS-G.B. Bietti Foundation, Rome, Italy, [3]Unit of Disimmune Neuropathies, University of Rome Tor Vergata, Rome, Italy, [4]AFaR Division, Fatebenefratelli Foundation for Health Research and Education, Rome, Italy, [5]Department of Clinical Semiotics and Imaging, University of Medicine Tirana, Tirana, Albania.

Background and aims: A painless, non-invasive, reproducible, cost-effective and clinically available tool is necessary for the early detection and diagnosis of diabetic neuropathy. Retinal neurodegeneration has been considered so far a predictive sign for the development of microvascular alterations in diabetic retinopathy (DR). However, few data are available on the association between neuroretinal damage and diabetic neuropathy. Our study, therefore, was aimed to investigate the possible role of retinal neurodegeneration, as an early marker of diabetic peripheral neuropathy (DPN).
Materials and methods: 15 type 1 diabetes mellitus (DM1) patients with no symptoms/signs of peripheral polyneuropathy, without DR or with very mild non-proliferative DR, and 14 healthy controls (C), matched for age and gender, were enrolled. All patients underwent corneal confocal microscopy, including the number of fibers, the number of fiber beadings, the degree of fiber branching, and the degree of fiber tortuosity of corneal sub-basal nerve plexus. Cardiovascular autonomic function was evaluated by cardiovascular autonomic reflex tests (CARTs). The following electrophysiological tests were also performed: standard nerve conduction studies (NCS), incremental motor unit number estimation (MUNE) from abductor hallucis (AH) and abductor digiti minimi (ADM) with assessment of AH and ADM average single motor unit potential (SMUP) size. Neuroretinal function was analyzed by multifocal electroretinogram measuring amplitude density (Amp) and implicit time (IT) of nasal (N)/ temporal (T)/superior (S)/ inferior (I) macular quadrants.
Results: Amp of all macular quadrants was significantly reduced in DM1 ($p < 0.001$) vs C. ADM MUNE and AH MUNE were significantly decreased in DM1 (p 0.039; $p < 0.0001$, respectively), and AH-SMUP significantly increased (p 0.002) vs. C. A positive correlation between Amp in N and I quadrant and AH MUNE (r 0.368, p 0.01; r 0.288, p 0.03, respectively) was observed in DM1 patients. A negative correlation between degree of corneal sub-basal nerve plexus fiber tortuosity and Amp in N, I, T quadrants (r −0.780, p 0.002; r −0.583, p 0.036; r −0.571, p 0.041 respectively) and between degree of fiber tortuosity and AH

MUNE (r −0.547, p 0.043) were observed in DM1. No abnormalities of NCS were found in any subject. A positive correlation between lying-to-standing (LTS) values and Amp S, I, T, N (r 0.826, p 0.002; r 0.749, p 0.008; r 0.797 p 0.003; r 0.694, p 0.018 respectively) were observed in DM1.

Conclusion: Neuroretinal dysfunction and motor unit loss are already present in DM1 patients without DPN. The association between neuroretinal changes and motor unit decline, corneal confocal microscopy parameters and autonomic function supports the hypothesis that neuroretina could represent a new "point of view" to detect the early overall neurogenic process in diabetes.

Disclosure: **S. Frontoni:** None.

Independent correlations between the presence of retinopathy and kidney disease in diabetes and measures of both metabolic control and neuropathy

D. Tesic[1], M. Mitrovic[1], J. Ljikar[2], D. Popovic[1], D. Tesic[3], M. Tomic[1], B. Vukovic[1];
[1]Clinic of Endocrinology, Diabetes and Metabolic Disorders, Clinical Center of Vojvodina, Novi Sad, [2]Clinic of Ophthalmology, Clinical Center of Vojvodina, Novi Sad, [3]Clinic of Cardiology, Institut for Cardiovascular Diseases, Sremska Kamenica, Serbia.

Background and aims: The aim of this study was to examine associations between measures of neuropathy, nephropathy and lower-extremity artery disease (LEAD) in people with diabetes complicated by nonproliferative retinopathy (NPDR), maculopathy and proliferative retinopathy (PDR).

Materials and methods: People were included who attended a specialist service for review between September 2012 and September 2017. Clinical examination of the eyes was performed through dilated pupils using a slit lamp. VPT was measured using a semiquantitative tuning fork C128 and ankle reflexes (AR) were recorded. Sudomotor function was determined as the time until total colour change using Neuropad®. LEAD was defined with ABPI >1.4 or <0.8 or Continous wave Doppler monophasic curve. In a fasting blood sample serum creatinine, lipids and lipoproteins were measured. Urinary protein excretion (mg/24 h) and the presence of coronary and cerebrovascular disease, neuropathy symptom score (NSS) of Veves et al (1994) were documented. Hypertension was defined as ≥140/90 mmHg or by antihypertensive therapy. All tests were undertaken as part of routine clinical care.

Results: Of 469 people, 46.1% were male and 68.4% had T2DM. 30 had PDR, 98 had maculopathy, 89 had NPDR and 252 had no evidence of retinopathy. Compared with people without retinopathy, those with retinopathy were older (58 ± 12.5 vs. 52.3 ± 15.1 years), with lower VPT (5.1 ± 2.8 vs. 6.6 ± 2), more often with missing ankle reflexes (2.9 ± 1.3 vs. 2.0 ± 1.6), higher prevalence of LEAD (18.4% vs. 7.9%) and arterial hypertension (52.9% vs. 36.5%), lower height (175.4 ± 8.5 vs. 177 ± 5.9 cm), higher waist circumference (96.3 ± 12.6 vs. 91 ± 13.6 cm) and longer diabetes duration (18.2 ± 8.7 vs. 12.2 ± 8.6 years); all $p < 0.01$. After multivariable logistic regression analysis (MVLR), the differences in VPT, AR and diabetes duration all persisted ($p < 0.01$). People with PDR compared with controls had worse VPT (3.8 ± 3.3 vs. 6.6 ± 2; $p < 0.001$). In a univariate model PDR was related to creatinine (OR 1.014 [95% CI: 1.005–1.023]), triglycerides (1.022 [1.02–1.46]), duration of insulin therapy (1.057 [1.015–1.101]); all $p < 0.01$. After MVLR the differences remained significant ($p < 0.01$) for creatinine and duration on insulin therapy. People with maculopathy had worse sudomotor neuropathy (10 ± 7.3 vs. 7 ± 5.7 min; $p < 0.001$). In a univariate model maculopathy was related to NSS (OR 2.19 [1.35–3.04]), Neuropad® time (1.07 [1.033–1.109]); T2DM (77.6 vs. 62.3%), HbA1c 1.083 [1.058–1.108]); all $p < 0.01$, and to fasting cholesterol (1.035 [1.05–1.71]; $p = 0.02$). After MVLG the significance remained: for NSS, Neuropad® time, HbA1c (all $p < 0.05$). Both PDR and maculopathy in univariate analyses was related to proteinuria (OR 1.000 [1.0–1.001]) and after MVLR with creatinine clearance (0.976 [0.98–0.99]) and highest life BMI (1.067 [1.029–1.106]); all $p = 0.000$.

Conclusion: Our data showed associations between the presence of different clinical measures and peripheral neuropathy with both retinopathy and kidney disease, complications associated with severe insulin deficient diabetes and severe insulin resistant diabetes. Diabetic neuropathy reinforce the need to strive to optimise metabolic control.

Assessment of diabetic peripheral neuropathy in patients with prediabetes, type 1 and type 2 diabetes using corneal confocal microscopy

M. Ferdousi[1], S. Azmi[1], A. Kalteniece[1], I.N. Petropoulos[2], G. Ponirakis[2], U. Alam[3], O. Asghar[1], A. Marshall[1], W. Jones[1], M. Jeziorska[1], H. Soran[1], N. Efron[4], A.J. Boulton[3], R.A. Malik[2];
[1]Institute of Human Development, Manchester, UK, [2]Weill Cornell Medicine-Qatar, Doha, Qatar, [3]Division of Endocrinology, Diabetes and Gastroenterology, Manchester, UK, [4]Faculty of Health, School - Optometry and Vision Science, Sydney, Australia.

Background and aims: Over the past decade corneal confocal microscopy (CCM) has been introduced as a surrogate end point for the assessment of diabetic neuropathy. We aimed to utilise CCM for the assessment of diabetic neuropathy and associated risk factors.

Materials and methods: 597 participants including 98 controls (age = 42.11 ± 15.06), 171 patients with T1DM (age = 49.02 ± 16.14, Duration: 27.69 ± 17.96), 271 with T2DM (age = 62.73 ± 9.56, Duration: 12.40 ± 13.5) and 57 with IGT (age: 59.55 ± 10.85, Duration: 6.96 ± 9.30) underwent the detailed assessment of neuropathy.

Results: Patients with T1DM had evidence of neuropathy with significant impairment of all neuropathy markers compared to controls. Corneal nerve fibre length (CNFL) was significantly associated with duration of diabetes ($r = -0.3$, $P < 0.0001$). Patients with T2DM also had neuropathy with all markers being significantly impaired ($P < 0.05$) apart from vibration perception threshold (VPT) and cold perception threshold (CPT) compared to the controls. In this cohort CNFL was significantly associated with HDL ($r = 0.2$, $P = 0.04$), Triglyceride ($r = -0.2$, $P = 0.004$), VPT ($r = -0.2$, $P < 0.0001$), CPT ($r = 0.24$, $P < 0.0001$). Patients with IGT had small fibre neuropathy with impaired corneal nerve fibre density (CNFD), branch density (CNBD), CNFL, WPT, CIP and HIP compared to controls. There was no association between CNFL, HbA1c, lipid profiles and other clinical measure of neuropathy in patients with IGT. The area under the curve for CNFD were 0.72 in T1DM, 0.55 in T2DM and 0.65 in patients with IGT.

Conclusion: CCM detects neuropathy in patients with IGT, T1DM and T2DM. CNFL was associated with other measurements of neuropathy only in patients with T2DM. CNFL was associated with duration of diabetes only in patients with T1DM and with lipid profile in T2DM highlighting the difference in aetiology between these 2 groups.

Parameters	Control (n=98)	T1D M(n=171)	T2DM (N=271)	IGT(N=57)

Physical and psychological determinants of fall risk in patients with diabetic neuropathy: a prospective investigation

S.J. Brown[1], L. Vileikyte[2], A.J.M. Boulton[2], N.D. Reeves[1];
[1]Manchester Metropolitan University, Manchester, [2]University of Manchester, Manchester, UK.

Background and aims: People with diabetic peripheral neuropathy (DPN) are more likely to fall and report diminished levels of physical activity (PA). However, determinants of DPN-related falls and PA are not well described. This prospective study examined the physical (DPN severity and unsteadiness) and psychological factors (fear of falling (FoF) and generalized distress) in their relationship to falling and PA levels.

Materials and methods: Twenty-two type 2 diabetes patients (18 males; age: 70 ± 9 years, Vibration Perception Threshold, VPT: 23 ± 11 V, Neuropathy disability score: 6 ± 3 score/10) wore hip mounted activity monitors for 4 weeks (adherence: 17 ± 6 days). Daily activity levels were separated into minutes of: sedentary, light, moderate and vigorous. Unsteadiness at baseline was measured objectively- by Berg balance test (48 ± 6 score/56) and subjectively - by patient self-report (2-item NeuroQoL; 3.7 ± 1 score/5). Diaries were used to self-record falls during the study (8/22 individuals fell at least once, median: 2 [range: 1–12] falls per faller). FoF at baseline was assessed with Falls Self-Efficacy-International Scale (FES-I; 29 ± 12 score/64); generalized distress-with Hospital Anxiety and Depression Scale (HADS; 18 ± 3 score/21). Associations between variables were assessed by Pearson's correlations.

Results: More severe DPN was associated similarly with self-reported unsteadiness ($r = 0.41$, $p = 0.03$) and with objective, Berg balance test ($r = 0.43$, $p < 0.02$). Berg and self-reported measures of unsteadiness were significantly correlated ($r = 0.49$, $p = 0.02$, Fig. 1), however, whilst self-reported unsteadiness was associated with greater FoF ($r = 0.64$, $p < 0.01$) and with fall incidence ($r = 0.68$, $p < 0.01$), objectively measured unsteadiness was associated with FoF only ($r = 0.68$, $p < 0.01$), and not reported fall incidence. Higher levels of FoF were strongly associated with increased fall incidence ($r = 0.81$, $p < 0.01$), while increased generalized distress was associated higher fall incidence ($r = 0.47$, $p = 0.04$). Higher levels of light activity were associated with more falls ($r = 0.73$, $p < 0.01$).

Conclusion: These findings suggest that subjective measures such as self-reported DPN-unsteadiness and fear of falling may be valuable indicators of fall risk and of at least similar value compared to simple laboratory measures of balance such as the Berg Balance test. This makes the case for incorporating psychological components in carefully designed multifactorial interventions. Moreover, as increments even in light activity levels are associated with more falls, potentially due to increased opportunities to fall, balance should be taken into consideration when designing interventions to improve physical activity.

A systemic inflammatory signature reflecting crosstalk between innate and adaptive immunity is associated with polyneuropathy: KORA F4/FF4 Study

C. Herder[1,2], J.M. Kannenberg[1,2], M. Carstensen-Kirberg[1,2], A. Strom[1,2], G.J. Bönhof[1], W. Rathmann[1,2], C. Huth[3,2], W. Koenig[4,5], M. Heier[3], J. Krumsiek[3,2], A. Peters[3,2], C. Meisinger[3,6], M. Roden[1,7], B. Thorand[3,2], D. Ziegler[1,7];
[1]German Diabetes Center, Duesseldorf, [2]German Center for Diabetes Research (DZD), Muenchen-Neuherberg, [3]Helmholtz Zentrum München, Neuherberg, [4]Technische Universität München, Munich, [5]German Center for Cardiovascular Research (DZHK), Munich, [6]Ludwig-Maximilians-Universität München am UNIKA-T Augsburg, Augsburg, [7]Medical Faculty, Heinrich Heine University Duesseldorf, Duesseldorf, Germany.

Background and aims: Data on the association between biomarkers of inflammation and distal sensorimotor polyneuropathy (DSPN) from large cohorts are scarce and limited to biomarkers of innate immunity. Therefore, we aimed to assess associations between biomarkers reflecting multiple aspects of immune activation and DSPN in a population-based cohort.
Materials and methods: This cross-sectional analysis included 1048 participants of the population-based Cooperative Health Research in the Region of Augsburg (KORA) F4 study. Serum levels of biomarkers of inflammation were measured at baseline using proximity extension assay technology. The 92-biomarker panel covers a range of proteins including pro- and anti-inflammatory cytokines, chemokines, growth factors and factors involved in acute inflammatory and immune responses, angiogenesis, fibrosis and endothelial activation. Associations between biomarkers and the Michigan Neuropathy Screening Instrument (MNSI) score were estimated and followed-up by pathway analysis.
Results: Linear regression analysis showed that 27 out of 71 biomarkers of inflammation that passed quality control were positively associated with the MNSI score after adjustment for a range of anthropometric, metabolic, clinical and lifestyle factors ($P < 0.05$). Correction for multiple testing reduced the number of biomarkers that remained associated with the MNSI score to 20 (false-discovery rate/FDR <0.05). Ingenuity Pathway Analysis revealed an enrichment of the 27 biomarkers that were associated with incident DSPN in 22 canonical pathways (FDR <0.001). These results indicated that multiple cell types from innate and adaptive immunity may be involved in the development of DSPN and pointed towards hepatic fibrosis and autoimmunity as additional pathomechanisms. Potential upstream regulators for this set of differentially expressed biomarkers were the proinflammatory cytokines TNFalpha ($P = 2 \times 10^{-15}$) and IL-1beta ($P = 1 \times 10^{-14}$).
Conclusion: We identified multiple novel associations between biomarkers of inflammation and DSPN pointing to a complex cross-talk between innate and adaptive immunity in the pathogenesis of neuropathy.

Acute hyperoxia deteriorates nerve conduction velocity in type 1 diabetes: A possible effect on oxidative stress?

J.C. Laursen[1], C. Stevns Hansen[1], M. Bordino[2], E. Hein Zobel[1], S. Abitz Winther[1], P.-H. Groop[2], M. Frimodt-Møller[1], L. Bernardi[2], P. Rossing[1];
[1]Steno Diabetes Center Copenhagen, Copenhagen, Denmark, [2]Folkhälsen Research Center, Folkhälsen Institute of Genetics, Helsinki, Finland.

Background and aims: Cardiovascular autonomic dysfunction (CAD) and distal symmetric polyneuropathy (DSPN) are prevalent diabetic complications, associated with increased morbidity and mortality. In previous studies, acute hyperoxia and slow deep breathing (SDB) improved measures of CAD in patients with both type 1 diabetes (T1D) and type 2 diabetes (T2D). However, acute oxygen inhalation has been shown to deteriorate arterial function and increase blood pressure due to acute oxidative stress, while SDB improves both. Such effects have not been addressed in respect to DSPN. The aim of this study is to examine the effects of acute hyperoxia on measures of DSPN and blood pressure and whether these could be modified by albuminuria or existing autonomic dysfunction.
Materials and methods: Fifty-four patients with T1D (57% male) were enrolled in a cross-sectional study stratified by normoalbuminuria (n = 29) and presence of/or historical macroalbuminuria (n = 25). Mean age and diabetes duration were 59.8 (SD 9.5) and 37.5 (SD 14.4) years respectively. CAD was diagnosed when a minimum of two out of three standard cardiovascular autonomic reflex tests (CARTs) were abnormal. Patients were exposed to acute oxygen inhalation and SDB respectively, while obtaining continuous systolic blood pressure (SBP), diastolic blood pressure (DBP) and blood oxygen saturation (SAT). Patients were exposed to acute oxygen inhalation while obtaining measures of DSPN. DSPN was assessed by sural nerve conduction velocity (SNCV), action potential (SNAP) and electrochemical skin conduction (ESC). Effects were evaluated by linear regression analyses adjusted for baseline values of outcome variables.
Results: Acute oxygen inhalation was associated with an increase of 2.1% (95CI 1.7; 2.6), 3.9 mmHg (95%CI 1.3; 6.5) and 2.5% (95%CI 0.1; 5.0) in SAT, DBP and hands-ESC (μS) respectively. Conversely, acute oxygen inhalation was associated with a decrease of −1.7 ms (95%CI −3.22; −0.12) and −2.1% (−4.1;−0.01) in SNCV and feet-ESC (μS) respectively. SDB was associated with an increase of 1.2% (95%CI 1.0; 1.5) in SAT, compared to spontaneous breathing. SDB was associated with a decrease of −8.4 mmHg (95%CI −14.4; −2.4) and −3.6 mmHg (95%CI −5.8; −1.4) in SBP and DBP respectively. Interventions had no effect on SNAP. Oxygen inhalation induced a 6mmHg higher (95%CI 0.45; 11.55) response in DBP and a 4.8 ms higher (95%CI 1.4; 8.1) response in SNCV (ms) in patients with CAD compared with those without. Albuminuria or existing autonomic dysfunction did not modify any other associations.
Conclusion: Acute hyperoxia deteriorates blood pressure and nerve conduction velocity in T1D and SDB improves blood pressure. The effect of acute hyperoxia is stronger on blood pressure and diminished on nerve conduction velocity in patients with CAD. Similarly to the demonstrated effect of oxidative stress on blood pressure, we hypothesise that the acute worsening in SNCV, is a direct effect of oxidative stress (present in both hypoxia and hyperoxia) on nerve function. This novel finding indicates that peripheral neuropathy has a functional component that could be acutely modified by manipulation of oxygen. Further studies exploring the pathological pathways causing tissue hypoxia may improve the understanding and treatment of diabetic neuropathy.

Associations between vitamin D and diabetic neuropathy in adolescents with type 1 diabetes

A. Heinesen[1,2], M.M.B. Christensen[1,2], J. Fleisher[3], M.E. Jørgensen[1,4], E.E. Hommel[5], C.S. Hansen[1];
[1]Department of clinical epidemiolgy, Steno Diabetes Center Copenhagen, Gentofte, [2]University of Copenhagen, Copenhagen, [3]Medical Research Laboratories, Clinical Institute of Medicine, Aarhus University, Aarhus, [4]University of Southern Denmark, Odense, [5]Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Diabetic peripheral- and cardiovascular autonomic neuropathy (DPN, CAN) are severe and prevalent complications to diabetes, associated with increased morbidity and mortality. Manifest diabetic neuropathy is not reversible why early detection and prevention is essential e.g. in early diabetes. Vitamin D has been independently associated with diabetic neuropathy. Our aim is to investigate this association in a population of adolescent type 1 diabetes patients.
Materials and methods: 151 patients with type 1 diabetes (42% male, mean age 22 years (IQR 21; 23), mean diabetes duration 11.2 years (SD 5.1)) were screened for CAN and DPN. CAN was measured by 5 minute resting heart rate variability and three standard cardiovascular autonomic reflex tests (CARTs): lying to standing (30:15), deep breathing (E:I) and Valsalva Maneuver (VM). DPN was measured by light touch perception, pain perception, vibration perception threshold, electrochemical skin conductance, Sural nerve conductance velocity (SNCV) and Sural nerve action potentials. Models were adjusted for age, sex, diabetes duration, HbA1c, cholesterol, triglycerides, systolic BP, smoking, beta blockers and seasonal variation for vitamin D.
Results: Twenty patients (13.6%) had vitamin D deficiency (<25 nmol/l). The mean level of serum vitamin D was 62.6 nmol/l (IQR 35; 86), 32 patients (21.2%) used vitamin D supplements. Vitamin D was significantly associated with the VM (0.16% (95%CI: 0.019; 0.30) $p = 0.027$) and SNCV (2.9% (95%CI: 0.93; 4.8) $p = 0.004$), in a non-linear manner as an inverse U-shaped association for both outcomes (figure 1). No associations were established between vitamin D and other outcomes.
Conclusion: High and low serum vitamin D levels are associated with both CAN and DPN in young adults with type 1 diabetes. The associations were found despite a low prevalence of vitamin D deficiency. Our findings indicate that high and low levels of vitamin D may be a risk factor for diabetic neuropathy in young diabetes patients. Future studies could elucidate if vitamin D monitoring and management could have beneficial effects on diabetic neuropathy.

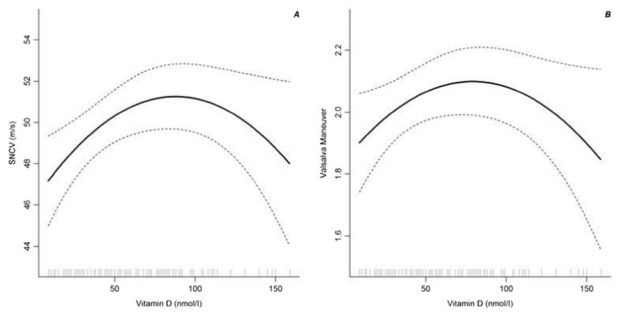

Figure 1
Complete lines show the predicted values of the SNCV (A) and VM (B) as a function of vitamin D. Dashed lines show 95% CI. Both models are estimates for a 22 year old, non-smoking, male with a diabetes duration of 11 years, a HbA1c at 69 mmol/mol, with serum cholesterol at 4.5 mmol/l, triglyceride at 1.3 mmol/l and a systolic BP of 125 who does not use beta blockers.

Glycaemic variability and diabetic neuropathy in adolescents with type 1 diabetes

M.M.B. Christensen[1], E.E. Hommel[1], M.E. Jørgensen[1,2], J. Fleischer[3], C.S. Hansen[1];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]National Insitute of Public Health, University of Southern Denmark, Odense, [3]Clinical Institute of Medicine, Aarhus University, Aarhus, Denmark.

Background and aims: Glycemic control assessed by HbA1c is a risk factor for diabetic neuropathy. However averaged long-term glucose measurement does not necessarily reflect the daily glycemic variability (GV). Hypo- or hyperglycemic events may attribute to the pathogenesis of diabetic neuropathy. Early stages of diabetic peripheral neuropathy (DPN) and cardiovascular autonomic neuropathy (CAN) may be reversible, thus early detection and prevention is crucial. The aim of the study was to investigate the association between GV and DPN and CAN in a Danish population of adolescent patients with type 1 diabetes.
Materials and methods: Adolescent type 1 diabetes patients were enrolled in a single-center study. CAN was assessed by cardiovascular autonomic reflex tests (CARTs) and measures of 5 min. resting heart rate variability (HRV). CAN was diagnosed if two or three out of three tests were abnormal. HRV indices were analysed in time- and frequency-domain. Time-domain analyses included the root mean square of the sum of the squares of differences between consecutive R-R intervals (RMSSD) and standard deviation of normal-to-normal intervals (SDNN). Frequency-domain analyses included low-frequency power band (LF) (0.04–0.15 Hz), high-frequency power band (HF) (0.15–0.4 Hz) and the LH/HF-ratio. DPN was assessed by light touch perception, pain perception, vibration perception threshold (VPT), electrochemical skin conductance (ESC), sural nerve conduction velocity (SNCV) and sural nerve action potential (SNAP). Data on five-day continuous glucose monitoring was obtained. Coefficient of variation (CV), SD, mean amplitude of glucose excursions (MAGE), continuous overall net glycemic action (CONGA) and time spent in hypo- (<3.9 mmol/l), eu- (≥3.9; ≤10.0 mmol/l) and hyperglycemia (>10.0 mmol/l) were calculated. The associations between GV and neuropathy measures were assessed by logistic and linear regression analyses adjusting for age and gender (model 1) and subsequently BMI, exercise and HbA1c (model 2).
Results: The study comprised 133 adolescents (44% were males) with a mean age of 22 years (SD 1.6), a mean diabetes duration of 11 years (SD 5.2) and a median HbA_{1c} of 65.5 mmol/mol (IQR 57; 74). Mean CV and CONGA were 40% (SD 10) and 9.1 mmol/l (SD 2.2), respectively; median SD and MAGE were 3.9 mmol/l (IQR 3.2; 4.7) and 7.7 mmol/l (IQR 5.9; 9.9). Median percentage of time spent in hypo-, eu- and hyperglycemia was 4% (IQR 1.0; 10), 47.9% (SD 18.7) and 44.7% (SD 20.6), respectively. Higher CONGA was associated with increasing incidents of the composite measure of symmetric peripheral neuropathy, abnormal SNAP and SNCV and incidents of CAN, however significance was lost in model 2. Higher MAGE was associated with increasing SDNN (1.0(95%CI: 1.0; 1.0) $p = 0.037$), RMSSD (1.0(95%CI: 1.0; 1.0) $p = 0.041$) and HF (1.0(95%CI: 1.0; 1.0) $p = 0.0095$) in fully adjusted models. No other significant associations were found.
Conclusion: Modest associations between GV and measures of autonomic and peripheral neuropathy were found. Findings were confounded by relevant risk factors for diabetic neuropathy. This suggests that GV is not a risk factor for diabetic neuropathy in adolescents with type 1 diabetes. However long-term effects of GV excursions may still play a role in the pathogenic mechanisms leading to neuropathy in later life.

Relation of oxidative stress and glycaemic variability with in vivo corneal confocal microscopy parameters in type 1 diabetes

F. Picconi[1], R. Squitti[2], M. Siotto[3], D. Schiano Lomoriello[4], M. Parravano[4], P. Pasqualetti[5], D. Ylli[6], L. Chioma[1], I. Malandrucco[1], S. Frontoni[1];
[1]Department of Systems Medicine, University of Rome Tor Vergata, Rome, Italy, [2]Molecular marker laboratory, IRCCS Istituto centro San Giovanni di Dio-Fatebenefratelli, Brescia, Italy, [3]Don Carlo Gnocchi ONLUS Foundation, Milan, Italy, [4]IRCCS-G.B. Bietti Foundation, Rome, Italy, [5]AFaR Division, Fatebenefratelli Foundation for Health Research and Education, Rome, Italy, [6]Department of Clinical Semiotics and Imaging, University of Medicine Tirana, Tirana, Albania.

Background and aims: In vivo corneal confocal microscopy (CCM), measuring corneal sub-basal nerve plexus, is a validated screening tool, diagnosis method, and biomarker of diabetic sensorimotor polyneuropathy (DSP) in type 1 diabetes mellitus (DM1). Both copper and iron homeostasis and glucose variability have been implicated in the activation of oxidative stress pathways, and subsequent onset of diabetes and neurodegeneration. The aim of the present study is to evaluate the impact of metabolic and oxidative markers on corneal sub-basal nerve plexus parameters.
Materials and methods: 15 DM1 patients with no symptoms/signs of peripheral polyneuropathy and 15 healthy controls (C), matched for age and gender, were studied. All patients underwent CCM, including the number of fibers, the number and density of fiber beadings, the degree of fiber branching, and the degree of fiber tortuosity of corneal sub-basal nerve plexus. Oxidative stress was evaluated by the measurement of systemic variation of markers of iron and copper metabolism, such as serum iron, ceruloplasmin (Cp), transferrin (Tf), non-ceruloplasmin bound copper (nonCp-Cu), Cp specific activity (eCp/iCp) and ceruloplasmin to transferrin ratio (Cp/Tf). All DM1 persons underwent a 72-h continuous glucose monitoring (CGM), with the calculation of glycemic variability GV indexes
Results: Cp/Tf, nonCp-Cu and eCp/iCp were significantly increased and Tf decresed in DM1 group vs C group. A positive correlation between density of beadings of corneal sub-basal nerve plexus and Tf (r 0.760, p 0.003) and a negative with Continuous Overall Net Glycemic Action (CONGA) 1–2 −4 h indexes (r −0.755, p 0.005; r −0,790 p 0.002; r −0.818, p 0.001) were observed in DM1 group. No correlation was found between glycated hemoglobin and CCM parameters. After mutivariate analysis, only Cp/Tf ratio was an independent predictor of density of fiber beadings.
Conclusion: Oxidative stress, correlated to metal dysregulation and GV is associated with density of beadings, in DM1. Nerve beadings density is a parameter of metabolic activity of small nerve fibers, and represents the accumulation of mitochondria along the nerve. Mitochondria play a critical role in controlling nerve function and their morphological and functional anomalies are involved in development of diabetic neuropathy

A novel method for measuring vibration perception thresholds (VPTs) shows an improvement in VPTs in type 1 diabetic patients with improved metabolic control

E. Lindholm[1], T. Elgzyri[1], M. Löndahl[2], L.B. Dahlin[1];
[1]Lund University, Malmo, [2]Lund University, Lund, Sweden.

Background and aims: Whilst improvement of metabolic control has been shown to result in improvement in tests evaluating functional and structural measures of small diameter nerve fibres, no such improvement has been presented for large diameter (i.e. myelinated) nerve fibres detected by vibration perception tests or electrophysiology. A novel method for measurement of vibration perception thresholds (VPTs) was used to study if better metabolic control can improve VPTs in adults with type 1 diabetes.
Materials and methods: VPTs were investigated at six frequencies (4, 8, 16, 32, 64 and 125 Hz) using VibroSense Meter (VibroSense Dynamics AB) in the sole of the foot - at the first metatarsal head (MTH1) and at fifth metatarsal head (MTH5) - at two different occasions (mean follow up time 1.6 ± 0.3 years) in patients with type 1 diabetes (n = 122; 55 males, 67 females). VPTs at the right foot at baseline and at follow up were compared separately in the patients with lower HbA_{1c} (n = 70) and with the same or higher HbA_{1c} at follow up (n = 52). The significant p value after multiple comparisons (n = 24) was less than 0.002.
Results: In patients with lower HbA_{1c} at follow up, the VPTs improved at 64 Hz at the MTH1 and at 4 Hz, 64 Hz and 125 Hz at MTH5 (Table). No significant difference was seen in VPTs when the patients' HbA_{1c} was similar or higher at the follow up compared to the baseline.
Conclusion: Improving metabolic control measured by HbA_{1c} in patients with type 1 diabetes can improve VPTs, suggesting a reversible effect on nerve function by improved metabolic control. The use of the non-invasive method VibroSense Meter to assess early changes in nerve function can further motivate patients with diabetes to adhere to a strict treatment strategy.

Table. Difference in VPTs in patients according to changes in metabolic control when HbA_{1c} was lower at the follow up.

	baseline	follow up	P[a]
HbA_{1c}(mmol/mol)	65.8±11.5	56.7±11.0	**<0.00001**
MTH1 4 Hz (Db)	95.8[91.6-108.8]	95.1[90.1-102.2]	0.02
MTH1 64 Hz (Db)	128.5[117.2-138.4]	122.1[111.5-135.1]	**0.00006**
MTH1 125 Hz (Db)	136.0[121.3-147.3]	131.6[113.4-147.2]	0.011
MTH5 4 Hz (Db)	99.3[93.7-108.3]	94.5[89.3-101.9]	**0.00002**
MTH5 8 Hz (Db)	104.8[100.5-116.0]	103.2[94.9-111.1]	0.003
MTH5 16 Hz (Db)	112.2[105.9-122.9]	109.2[103.1-120.1]	0.003
MTH5 32 Hz (Db)	120.2[112.0-133.5]	117.7[111.3-125.9]	0.006
MTH5 64 Hz (Db)	127.7[118.9-139.2]	123.8[111.8-133.6]	**0.00006**
MTH5 125 Hz (Db)	133.0[119.6-143.5]	130.0[114.6-141.8]	**0.001**

[a]Significant after multiple comparisons (n=24) if p <0.002; Db=decibel. Numbers are mean ± standard deviation for the HbA_{1c} and median [25th-75th percentile] for the VPTs. For the VPTs at MTH1 8 Hz,16 Hz and 32 Hz p> 0.05 (data not shown).

Impact of normoglycaemia in reducing microvascular complications in patients with type 2 diabetes

M. Tavakoli[1], F. Ishibashi[2];
[1]University of Exeter Medical School, Exeter, UK, [2]Ishibashi Medical Centre, Hiroshima, Japan.

Background and aims: Hyperglycemia is associated with increased risk of microvascular complications in patients with type 2 diabetes (T2DM). The strict glycemic control is the only strategy for slowing DPN progression in T2DM. Thus, identifying potentially modifiable risk factors for neuropathy is crucial. The aim of present study was to investigate whether reduction of the level of HbA1c by tight glycemic control (GC) decreases the rate of microvascular complications and improves the neurological functions in patients with T2DM over 4 years period.
Materials and methods: Detailed clinical and neurological examinations including corneal confocal microscopy (CCM) were performed in 141 patients with type 2 diabetes and 60 age-matched control subjects at baseline and follow-up with GC for 4 years. Patients were stratified according to mean HbA1c level during follow-up into good (HbA1c <53.0 mmol/mol, mean; 47.5 mmol/mol), fair (53.0 mmol/mol ≤HbA1c <58.5 mmol/mol, mean; 55.6 mmol/mol), and poor (HbA1c ≥58.5 mmol/mol, mean; 68.9 mmol/mol) GC groups with similar HbA1c levels at baseline (84.5–88.2 mmol/mol).The patients assigned to the insulin-sensitizing or insulin providing strategy were treated with biguanides or pioglitazone, or with sulfonylureas or insulin, respectively. The HbA1c for patients was measured monthly during the follow-up period. And hence the mean HbA1c levels during follow-up are representative, and the linear regression provided changes in neuropathy outcomes by a reduction in mean HbA1c level per year of follow-up.
Results: At baseline, CCM revealed significant nerve damage in all patients compared to controls. The interval changes in most CNF parameters and neurophysiological functions were significantly related to mean HbA1c levels during follow-up. Interestingly the baseline HbA1c level did not impact on neurological functions at follow-up. Interval changes in neuropathy outcomes were associated with mean clinical factors during follow-up and hypoglycemic strategies. Good GC improved all nerve functions, including CNF branch density and bead, but not length and

main fibre density. Fair GC deteriorated some nerve functions. Poor GC compromised all neuropathy outcomes. Irrespective of GC levels retinopathy increased after follow-up period, while nephropathy decreased.After follow-up among the patient subgroups, despite strict glycemic control and improvement in mean HbA1c by around 30.6 mmol/mol, the cumulative incidence of neuropathy increased from 17.7% at baseline to 21.3% ($p = 0.383$) and retinopathy increased from 21.3% to 35.5% ($p < 0.001$), however the cumulative incidence of nephropathy reduced from 37.6% to 22.0% ($p < 0.001$) (Table 1). Neuropathy decreased insignificantly in subgroup-3 (those with the poorest glycemic control at baseline which suffered from severe neuropathy).

Conclusion: Despite strict GC, the retinopathy progressed in T2DM. The near normoglycemia improved most neuropathy outcomes. The HbA1c level close to 47.5 mmol/mol achieved mainly with insulin-sensitizing agents and lifestyle modification would be a safe glycemic goal for improving the outcome measures of DPN in patients with poorly controlled type 2 diabetes with mild to moderate neuropathy. The near-normoglycemia is effective for preventing the development of neuropathy and nephropathy, but not retinopathy.

Effects of methylcobalamin on diabetic peripheral neuropathy: a meta-analysis of randomised controlled trial

Q. Li[1], H. Wu[2];
[1]PLA Rocket Force General Hospital, Beijing, [2]Eisai China Inc., Shanghai, China.

Background and aims: Methylcobalamin has long been used for treatment of peripheral neuropathy. This study aimed to examine the effect of Methylcobalamin in the treatment of diabetic mellitus peripheral neuropathy (DPN) by performing a meta-analysis of all available relevant randomized controlled trials (RCTs).

Materials and methods: PubMed, Cochrane Library, Web of Science, Embase, and other databases were searched to retrieve articles published in English and Chinese up to February 28, 2018. RCTs evaluating effects of methylcobalamin on the treatment of DPN were included. Excluded from the analysis were studies without any type of control. Pooled relative risks (RRs) and 95% confidence intervals (CIs), and, standard mean difference (SMD) and 95% confidence intervals (CIs) were calculated with a random effect model to estimate the effect of methylcobalaminon on the treatment of DPN. Its effect on clinical signs and symptoms of DPN, conduction velocities of sensory and motor nerves were assessed where appropriate.

Results: 43 relevant RCTs with 3 619 patients with DPN were included in the meta-analyses. 1) In the pooled analysis with 19 RCTs wherein the control group receiving general treatment only, methylcobalamin showed significantly positive effects on the improvement of the signs and symptoms of DPN (RR: 1.43, 95%CI: 1.31–1.56, $P < 0.0001$). Compared to patients who were not treated with methycobalamin, patients treated with methylcobalamin showed greater increase of conduction velocities of Peroneal Nerve (sensory: SMD: 1.71, 95%CI: 1.28–2.15, $P < 0.0001$; motor: SMD: 1.09, 95%CI: 0.78–1.40, $P < 0.0001$) and Median Nerve (sensory: SMD: 1.01, 95%CI: 0.65–1.38, $P < 0.0001$; motor: SMD:1.13, 95%CI: 0.28–1.97, $P = 0.0090$). 2) In the pooled analysis with 24 RCTs wherein the control group receiving general treatment plus vitamin B agents, methylcobalamin showed significantly positive effects on the improvement of the signs and symptoms of DPN (RR: 1.87, 95%CI: 1.58–2.21, $P < 0.0001$). Compared to patients who were treated with vitamin B agents, patients treated with methylcobalamin showed greater increase of conduction velocities of Peroneal Nerve (sensory: SMD: 0.73, 95%CI: 0.42–1.04, $P < 0.0001$; motor: SMD: 0.64, 95%CI: 0.35–0.93, $P < 0.0001$) and Median Nerve (sensory: SMD: 0.73, 95%CI: 0.42–1.04, $P < 0.0001$; motor: SMD:0.75, 95%CI: 0.39–1.12, $P < 0.0001$).

Conclusion: Methylcobalamin appeared to be effective and better than vitamin B agents in treating DPN, and more rigorously designed, randomized, double-blinded, placebo controlled trials for DPN are needed.

Effect of slow breathing and apnoea on arterial stiffness in type 2 diabetic and obese patients

P. Valensi[1], S. Chiheb[1], I. Banu[1], A. Rezki[1], E. Cosson[1], L. Bernardi[2], L. Bianchi[1];
[1]Jean Verdier Hospital, Bondy, France, [2]Folkhälsan Research Centre, Helsinki, Finland.

Background and aims: Several studies have shown that slow breathing (SLB) improves oxygen saturation (SaO_2) and the baro-chemoreflex interaction through the stimulation of parasympathetic nervous system. We recently reported that a short period of SLB can trigger the onset of apneas in patients with alterations of cardiorespiratory reflexes, particularly OSAS patients. The activation of sympathetic nervous system is a physiological response to apnea. The aim of this study was to evaluate the effects of SLB and apneas on arterial stiffness mediated by the autonomic nervous system.
Materials and methods: We included 66 patients (42 type 2 diabetic and 24 obese patients) who underwent the following protocol: spontaneous breathing (5 min), slow breathing at 6 cycles/min (5 min) and finally 10 minutes of spontaneous breathing (POST-SLB). Among them, 40 patients (26 diabetics, 53 ± 12 years, 14 men, BMI 36.6 ± 6.2 kg/m^2, HbA1c 6.9 ± 1.7%) developed apneas or hypopneas during the POST-SLB; 26 patients (16 diabetics, 53 ± 14 years, 11 men, BMI 33.8 ± 8.3 kg/m^2, HbA1c 7.3 ± 1.8%) did not develop respiratory abnormalities after SLB. We recorded heart rate (HR) and blood pressure (by Finapres®) continuously during the whole protocol. We calculated arterial stiffness (augmentation index, AIx and pulse wave velocity, PWV) with a software that reproduce the central aortic pressure waveform from the periphery (measured on finger) through a transfer function (validated from Sphygmocor ®).
Results: At baseline arterial stiffness was similar in both groups of patients: with apneas (APN+) and without apneas (APN-) (AIx 16.9 ± 9.2% *vs* 15.9 ± 7.4%, p = ns; PWV 8.3 ± 1.7 *vs* 7.9 ± 1.0 m/s, p = ns), as well as systolic (SBP 131 ± 22 *vs* 124 ± 19 mmHg, p = ns) and diastolic blood pressure (DBP 72 ± 15 *vs* 73 ± 12 mmHg). During SLB, all patients improved AIx (average −2.3% in APN+ and −2.0% in APN-, $p < 0.001$ *vs* baseline), PWV did not change (−0.2 m/s in APN+ and −0.1 m/s in APN-, p = ns *vs* baseline), SBP decreased (−8.8 mmHg in APN+ and −6.8 mmHg in APN-, $p < 0.001$ *vs* baseline) as well as DBP (−4.1 mmHg in APN+ and −3.2 mmHg in APN-, $p < 0.001$ *vs* baseline). During the POST-SLB, AIx increased in APN+ and became even higher than baseline values (+1.1%, $p < 0.05$) while in APN- AIx returned to baseline values (−0.1%, p = ns), PWV did not change in the two groups, SBP returned to baseline values in APN+ while it remained low in APN- (−6.7 mmHg, $p < 0.01$), DBP showed the same trend (in APN+, p = ns *vs* baseline; in APN- −2.6 mmHg, $p < 0.01$ *vs* baseline).
Conclusion: Slow breathing has shown the capacity to reduce blood pressure through the stimulation of parasympathetic nervous system and to influence the arterial stiffness favorably (AIx proner to acute changes than PWV). Conversely apneas induce sympathetic activation that increases blood pressure and worsens arterial stiffness. These important changes highlight the central role of the autonomic nervous system in the cardiovascular risk related to OSAS and suggest an acute benefit of slow breathing. The long-term outcomes of repeated sessions of SLB remain to be explored.

The impact of the interaction between obstructive sleep apnoea and cardiac autonomic neuropathy on eGFR decline in patients with type 2 diabetes: a longitudinal study

A. Tahrani[1], Q.-A. Altaf[2];
[1]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, [2]Department of Diabetes and Endocrinology, University Hospital NHS Foundation Trust, Birmingham, UK.

Background and aims: Diabetes-related chronic kidney disease (CKD) is a leading cause of end-stage renal disease (ESRD). We have previously shown that both obstructive sleep apnoea (OSA) and cardiac autonomic neuropathy (CAN) are independently associated with renal function decline in patients with Type 2 diabetes (T2DM). We have also shown that OSA is associated with CAN in patients with T2DM. Hence, in this study we aimed to assess the impact of the interaction between OSA and CAN on renal function longitudinally.
Materials and methods: Patients with T2DM and no ESRD were recruited from a single tertiary diabetes centre in the UK 2009–2011. Renal function was assessed using MDRD-calculated estimated glomerular filtration rate (eGFR). Rapid eGFR decline was defined as 4% decline of eGFR/year. OSA was diagnosed if the apnoea hypopnea index (AHI) was ≥5 events/hour using overnight cardiorespiratory portable monitoring. CAN was assessed based on heart rate variability using ANSAR^{TM} technology. CAN was present if at least 2 of the standardized tests were abnormal. Patients were divided into 4 groups; Group 1: no OSA and no CAN (n = 45); Group 2: CAN with no OSA (n = 27); Group 3: OSA with no CAN (n = 67); and Group 4: OSA and CAN (n = 54).
Results: A total of 200 patients were included [mean age (57.4 (12) years, gender (male 57.5% (n = 115), diabetes duration 12.6 (7.7) years]. The mean follow-up duration was 2.5 (0.7) years. The OSA and CAN prevalence was 63% (n = 126) and 39.5% (n = 79) respectively. The mean baseline eGFR was lowest in patients with CAN and OSA (mean (SD); ml/min/1.73 m^2) [Group 1: 98.5 (22.2); Group 2: 87.7 (28.9); Group 3: 88.6 (25.9); Group 4: 76.7 (27); p = 0.001]. The eGFR decline (defined as % of baseline eGFR) was greater in patients with OSA and CAN [−1.9 (6.5) %; vs. −1.4 (11.7) %; vs. −3.2 (10.6) %; vs. −9.4 (13.2) % for group 1 to 4 respectively; p = 0.002). Rapid eGFR decline was more common in patients with OSA and CAN as compared with other groups [21.4% (n = 9) vs. 25% (n = 15) vs. 24% (n = 6) vs. 51% (n = 26) for groups 1 to 4 respectively, p = 0.005]. After adjusting for baseline eGFR, age, sex, ethnicity, diabetes duration, body mass index, mean arterial pressure, HbA1c, total cholesterol, triglycerides, insulin use, lipid lowering treatment, anti-hypertensive use, anti-platelets, oral anti diabetic agents, and smoking, having OSA and CAN predicted lower study-end eGFR (R^2 = 0.9; B = −7.2, p = 0.006), and greater drop in eGFR (R^2 = 0.13; B = −6.7, p = 0.01). After similar adjustments, OSA and CAN predicted rapid eGFR decline (OR = 3.38; 95% CI 1.08, 9.9; p = 0.04).
Conclusion: Detecting OSA and CAN in patients with T2DM identifies a high risk population for eGFR decline. Patients with T2DM and OSA and CAN are at increased risk of greater eGFR decline compared to those with either OSA only or CAN only or neither OSA nor CAN. Studies assessing the impact of OSA treatment on eGFR decline are ongoing.

The effect of autonomic and sensory neuropathy on all-cause mortality: a retrospective cohort study

M.M. Svebis[1], V.J. Horváth[1], A.E. Körei[1], P. Fadgyas-Freyler[2], G. Korponai[2], T. Tänczer[1], B.A. Domján[1], P. Kempler[1], A.G. Tabák[1,3];
[1]1st Department of Internal Medicine, Semmelweis University, Budapest, Hungary, [2]Strategic Analysis Department, National Health Insurance Fund of Hungary, Budapest, Hungary, [3]Department of Epidemiology and Public Health, University College London, London, UK.

Background and aims: It is well-accepted that people with autonomic neuropathy have an increased risk of cardiovascular mortality. Much less is known in this respect about sensory neuropathy. Furthermore, there is a lack of information on the association between any neuropathy and all-

cause mortality. Thus our aim was to examine the effect of both autonomic and sensory neuropathy on all-cause mortality in a well-phenotyped cohort.

Materials and methods: Participants: patients living in the service area of the 1st Department of Medicine, Semmelweis University with detailed autonomic and sensory neuropathy assessments between 1997 and 2016 ($n = 1940$). Predictors: autonomic neuropathy (≥2 positive Ewing-tests), sensory neuropathy (≥1 abnormal result of one type of nerve fibre on both sides using Neurometer). Covariants: age, sex, type and duration of diabetes, comorbidities, medications, lifestyle factors. Outcome: all-cause mortality based on data from the National Health Insurance Fund of Hungary. Statistical analysis: Kaplan-Meier survival curves and Cox-regression models.

Results: Altogether $n = 1940$ patients had any neuropathy examinations. Full sensory assessment was available for $n = 1873$ cases (96.5%), autonomic neuropathy in $n = 1692$ cases (87.2%). Participants were 61.8 ± 12.0 years old at baseline, $n = 1311$ had diabetes (type 1 diabetes $n = 126$), 43.4% were male ($n = 813$). Autonomic neuropathy was found in $n = 492$ cases (29.0%), sensory neuropathy in $n = 673$ cases (35.9%), combination of both neuropathies in $n = 196$ cases (12.0%). During the 1–17-year follow-up, 788 participants died (40,6%). According to models adjusted for baseline age, sex, type and duration of diabetes, and comorbidities, patients with either autonomic or sensory neuropathy had an approximately 50% increased risk of mortality (hazard ratio [HR] 1.47, 95%CI: 1.25–1.74 and HR 1.55, 95%CI: 1.32–1.83, respectively). When both types of neuropathy were present together the risk more than doubled (HR 2.19, 95%CI: 1.74–2.77).

Conclusion: Our results confirm the association between autonomic neuropathy and all-cause mortality. Furthermore, they suggest that the presence of sensory neuropathy is at least as strongly related to all-cause mortality as autonomic neuropathy, and it is not only an important determinant of quality of life.

Effects of ivabradine, a selective I_{funny} channels blocker, on erectile function in streptozotocin-induced diabetic rats

S. Gur[1], D. Yilmaz-Oral[2], G. Koroglu[1], A. Onder[3], A. Gulpinar[3];
[1]Pharmacology, Ankara Universty Pharmacy Faculty, Ankara, [2]Pharmacology, Cukurova Universty Pharmacy Faculty, Adana, [3]Pharmacognosy, Ankara Universty Pharmacy Faculty, Ankara, Turkey.

Background and aims: High heart rate independent risk factor for the worsening of erectile dysfunction (ED), which is a major health issue in diabetic patients. The I_{funny} (I_f) or hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are involved in synaptic transmission and neuronal excitability under physiological conditions. Corlanor (ivabradine) is selective HCN-gated channel blocker in the sinoatrial node. This study is focused on the possible beneficial effect of intracavernosal injection of ivabradine, on ED in streptozotocin-induced diabetic rats.

Materials and methods: Adult Sprague-Dawley ($n = 20$) rats were equally divided into two groups: Control and diabetes, which was induced by single intraperitoneal injection of 45 mg/kg of streptozotocin. *In vivo* erectile responses were also repeated after intracavernosal injection of ivabradine (dose of 0.45 mg/kg) in anesthetized rats. Ivabradine relaxant responses were assessed in control rat corpus cavernosum (CC) strips after several inhibitors. The relaxant responses of CC strips were evaluated in the presence or absence of ivabradine (10 μM).

Results: Diabetic rats demonstrated significantly decreased ratio of intracavernosal pressure to mean arterial pressure (0.18 ± 0.02; $p < 0.001$) and total intracavernosal pressure (2058 ± 199 mmHg; $p < 0.01$) after were restored by intracavernosal administration of ivabradine (0.68 ± 0.05; 3691 ± 116 mmHg). Ivabradine causes a relaxant effect on rat CC tissues independent on the nitric oxide-cyclic guanosine monophosphate system, which may affect L-type Ca^{+2}, Ca^{+2}-activated K^+ and ATP-sensitive K^+ channels. No difference in the ivabradine-related relaxation response was observed between groups. In *in vitro* studies, the maximum nitrergic relaxation response to electrical field stimulation in diabetic CC (34.4 ± 2.8, $p < 0.001$) was enhanced after the presence of ivabradine (66.6 ± 3.4). Ivabradine increased acetylcholine (100 μM), sodium nitroprusside(10 nM) and sildenafil (1 μM)-induced relaxation in diabetic CC.

Conclusion: Our results firstly indicated that the beneficial effect of intracavernosal administration of ivabradine in the full recovery of erectile function and completely improved CC endothelial and neurogenic relaxation in diabetic rats. These data may support further clinical and preclinical studies using combinations of ivabradine with phosphodiesterase type 5 inhibitors for ED.

Carotid baroreceptor magnetic activation increases heart rate variability in human, implications to treat type 2 diabetes

J. Gmitrov;
Krompachy Hospital, Agel SK inc., Krompachy, Slovakia.

Background and aims: Increasing evidence suggests that positive feedback loop relationship exists between impaired autonomic function evidenced by reduced heart rate variability (HRV) and type 2 diabetes (T2DM). Lower HRV was found to increase risk of new onset T2DM which generates further decrease in HRV coupled with glucometabolic abnormalities, coronary heart disease and sudden cardiac death. This evokes emergent need to find a tool how to increase HRV, a marker of autonomic capacity to stabilize hemodynamic fluctuations and tissue perfusion finely adjusted to actual metabolic demands, severely impaired in T2DM. To test hypothesis that carotid baroreceptor (CB) magnetic stimulation has a modulatory effect on autonomic cardiovascular regulation, HRV was measured before and after CB exposure to static magnetic field (SMF).

Materials and methods: Spontaneous short-term HRV was measured in 16 supine healthy volunteers (mean age, 26 y) before and after CB local exposure to 120 mT intensity SMF generated by iron bar magnets, positioned with opposite poles over right and left carotid sinus area. For each patient three consecutive 300 cardiac intervals (5 min) were analyzed in blank control (BLANK), sham magnet (SHAM) and SMF exposure runs, using fast Fourier transform. HRV total power spectrum was divided into low (Lo) 0–150 mHz and high (Hi) 150–500 mHz frequency bands. The amplitude of the total power (ms^2), frequency-bounded area ($Hz \times ms^2$) and frequency corresponding to the peak of the power spectrum (mHz) were recorded. In addition, low and high frequency power spectrum ratio (Lo/Hi ratio) was calculated.

Results: In low frequency band, SMF induced increase of the power spectrum amplitude by 15.2%, area by 28.0% and Lo/Hi ratio by 20.6% accompanied by shift of the power spectrum peak to lower frequency region compared with SHAM magnet exposure: 102.1 ± 23.7 *vs.* 88.4 ± 14.7 mHz, $p < 0.05$. There were no significant changes of the power spectrum in high-frequency band. **Fig. 1. The frequency domain analysis of the HRV in healthy volunteer after CB magnetic activation.** SMF induced remarkable increase of the power spectrum area (Area) and amplitude (Amp) in low frequency band with maximal rise in 0.1-Hz frequency region which is strongly coupled with arterial baroreflex activation. The increase of the Lo/Hi ratio and the move of the power spectrum amplitude to lower frequency band suggests shift of the sympathovagal balance toward vagal predominance.

Conclusion: The important, novel finding demonstrated in this study is that SMF exerts stimulatory effect on CB in human reflected by increase in HRV. Each of SMF-enhanced HRV spectral components (Fig. 1) are depleted in T2DM even before clinical manifestation of the disease,

generating significant cardiovascular risk and a therapeutic opportunity to use CB stimulation techniques in T2DM where sympathetic overactivity, coupled with insulin resistance and endothelial nitric oxide deficit, triggers profound cardio-metabolic regulatory and structural damage, worsening cardiovascular outcomes substantially.

Saliva-derived extracellular vesicles carry distinct miRNAs in type 1 diabetic patients with altered cardiovascular tests

E. Favaro, T. Lopatina, C. Deregibus, C. Gai, M. Pomatto, S. Valerio, P. Passera, M. Porta, G. Camussi, M. Zanone;
University of Turin, Turin, Italy.

Background and aims: MicroRNAs (miRNAs), detected in body fluids, are becoming increasingly recognized as crucial regulators in gene expression both in physiological and pathologic processes, including diabetes and diabetic complications. Extracellular vesicles (EVs) released from healthy and diseased cells are potential biomarkers for ongoing pathological processes; they are recognised as an integral component of the cellular network, expressing surface receptors and carrying biologically active proteins, lipids, mRNAs, long non-coding RNAs and miRNAs, thus protected from plasma endogenous Rnases. miRNAs and miRNA gene polymorphisms have been recently described to be potentially associated with presence of, or susceptibility to, diabetic somatic and autonomic neuropathy. We aimed to characterize EVs and miRNA in the saliva obtained from type 1 diabetic patients and their correlation with neurological characteristics.
Materials and methods: Approximately 5–10 ml of saliva was obtained from 8 patients with type 1 diabetes of long duration (mean age 37.5 ± 2 , mean duration 29.4 ± 3, mean 1 year HbA1c 62.5 ± 7.6 mol/mol); neurological examination, autonomic CV tests and vibration perception threshold were assessed. EV were purified from saliva by charge-based precipitation. Briefly, the saliva samples were incubated with the protamine/polyethylene glycon precipitation solution (1 volume precipitation solution: 4 volume sample) overnight at 4°C. After centrifugation, the supernatant was discarded and the pellet was treated with different lysis buffer to study miRNA or protein expressions. miRNA expression levels were analysed using the Applied Biosystems TaqMan® Array Human MicroRNA A/B Cards (Applied Biosystems, Foster City, CA) to profile 754 mature miRNAs by qRT-PCR. The kit used gene-specific stem-loop reverse transcription primers and TaqMan probes to detect mature miRNA transcripts in a 2-step real-time reverse-transcription PCR assay. Western Blot analysis for neuronal markers was also performed.
Results: EVs were isolated and characterized by Nanosight instrument with a mean concentration of 5×10^8 particles/ml and with a mean size of 150 nm. Enolase and beta 3 tubulin, as as neuronal markers, were detected by Western blot analyses. In 2 patients with one altered CV test and in 1 patient with two altered CV tests, increased levels of miRNA146a, 146b, 29, 203 and 210 were detected.
Conclusion: EVs can be efficiently isolated from the saliva and may be exploited for the search of new biomarkers or pathogenetic mechanisms in diabetic complications. The miRNAs conveyed, with their involvement in inflammation and oxidative stress, suggest a role in diabetic autonomic dysfunction to be investigated.

The influence of clinically diagnosed neuropathy on respiratory muscle strength in type 2 diabetes

B.L.M. Van Eetvelde, D. Cambier, B. Celie, P. Calders;
Rehabilitation Sciences and Physiotherapy, University of Ghent, Ghent, Belgium.

Background and aims: Among all chronic disorders, Type 2 Diabetes Mellitus is the most common cause of peripheral and autonomic neuropathy (NP). The influence of NP on functional (dis)abilities is determined by the assessment of skeletal muscle strength and has been described extensively. This study investigated the influence of diabetes and diabetic neuropathy on respiratory muscle function.
Materials and methods: One hundred and ten diabetic patients and eighty controls, aged 60 years or more, were enrolled and allocated into 4 groups, depending on the presence or absence of neuropathy: patients with type 2 diabetes mellitus (T2DM) without NP (D-; $n = 28$), T2DM with NP (D+; $n = 82$), non-diabetic controls without NP (C-; $n = 35$), and non-diabetic controls with NP (C+; $n = 45$). Diabetes was diagnosed according to the Type 2 Diabetes ADA Diagnosis Criteria either by the specialist on the Department of Endocrinology or by the generalist of the participant. Neuropathy was examined based on clinical neurological examination, which consisted of Vibration Perception Threshold (VPT) and the Diabetic Neuropathy Symptom score (DNS). Respiratory muscle strength was registered by maximal static Inspiratory and Expiratory Pressure (PImax and PEmax), and Peak Expiratory Flow (PEF) measurements. Isometric handgrip strength and the Short Physical Performance Battery (SPPB) were used to capture peripheral skeletal muscle strength and physical performance. Univariate analysis of covariance (ANCOVA) was used with age, level of physical activity and BMI as covariates, to compare between groups and across the muscle strength conditions.
Results: Overall respiratory muscle strength (PI_{max}, PE_{max} and PEF; Table 1 - A) was higher in the controls without neuropathy (C-) compared to the other groups (C+, D- and D+). The presence of NP seemed to strongly affect the respiratory muscle strength (C+ versus C-) as well as the presence of T2DM (D- versus C-). The respiratory parameters in the diabetic patient group were less impacted when neuropathy was present (D+ versus D-). Significant differences were observed for SPPB total ($F = 4.588$; $p = 0.004$), Timed Chair Stands and gait (both subdomains of SPPB; respectively $F = 3.147$; $p = 0.027$ and $F = 7.505$; $p < 0.001$). For hand grip strength ($F = 2.396$; $p = 0.071$) and balance total (subdomain of SPPB, $F = 2.280$; $p = 0.083$) only a tendency was noticed between the four groups. SPPB total, and the subtests Timed Chair Stands and gait were affected by both presence of NP, T2DM and T2DM with NP in a similar way (Table 1 - B).

Conclusion: The presence of NP has an impact on respiratory muscle strength in T2DM patients as well as in non-diabetic controls. Therefore, it should be taken into consideration to integrate PI_{max}, PE_{max} and PEF measurements in the screening for respiratory muscle weakness as an indication for the presence of neuropathy.

Table 1: Univariate analysis of covariance (ANCOVA, corrected for age, BMI and physical activity) on respiratory muscle strength, and on peripheral muscle strength, balance and gait.

Panel A: Respiratory muscle strength

	F-value p-value	C-	C+	D-	D+

PS 087 Foot ulcers: morbidity and mortality

962

Developing a foot ulcer risk algorithm: the reality of doing this in a real world primary care setting

G. Dunn[1], M. Lunt[2], M. Rutter[2], G. Moreno[3], M. Edmonds[4], E. Jude[5], A. Heald[2], A. Boulton[2];
[1]Department of Podiatry, East Cheshire Trust, Macclesfield, UK, [2]Academic Health Sciences Centre, University of Manchester, Manchester, UK, [3]Head of Medical Department, High Speciality Regional Hospital of Ixtapaluca, Mexico, Mexico, [4]Department of Diabetes, Kings College Hospital, London, London, UK, [5]Department of Diabetes, Tameside Hospital NHS Foundation Trust, Manchester, UK.

Background and aims: Foot ulceration is a major complication of type 1 and type 2 diabetes. The lifetime risk of foot ulceration in patients with diabetes is 25%. Foot ulceration is associated with significant morbidity and increased mortality. Our aim was to determine how data collected in the course of diabetes reviews of patients in UK primary care, can inform a risk algorithm to predict de novo foot ulcer presentation.
Materials and methods: We examined pseudo-anonymised electronic health records in a retrospective cohort of all men and women aged 16–89 years, attending 42 general practices (GPs) in Central and Eastern Cheshire, UK. The total population of the geographical area studied is 475,000 people. Data was available on 15,727 individuals without foot ulcers and 1,125 individuals with new foot ulcers over 12 year follow-up. Data search was performed through EMIS®. We examined all known risk factors (RFs) and added putative RFs in our model.
Results: People who developed foot ulcers were significantly older at baseline (mean age 77.9 ± (sd) 14.1 vs 73.8 ± 16.9) than those without, and had higher HbA1c% (mean 7.9 ± 1.9 vs 7.5 ± 1.7)/ HbA1C mmol/mol (62.8 ± 20.8/58.5 ± 18.5), creatinine (μmol/L) (99.9 ± 45.5 vs 93.0 ± 39.3) and social disadvantage a measured by Townsend Score (a higher score relates to greater social disadvantage) (−0.72 ± 2.84 vs −1.14 ± 2.70) ($p < 0.0001$ in all cases). Absence of monofilament was more common in cases (Left foot 21.5%; Right Foot 26.2% vs non-cases Left Foot 16.5%; Left Foot 18.8%) ($p < 0.0001$) as was absence of foot pulses ($p = 0.02$) (Table 1). There was no difference between cases and non-cases in smoking status, gender, history of stroke or foot deformity, although foot deformity was extremely rare (0.4% in cases, 0.6% in non-cases) (Table 1). Combining the 6 risk factors in a single logistic regression model gave modest predictive power, with an area under the ROC curve of 0.65. The absolute risk of ulceration in the bottom decile of risk was 1.8% and in the top decile 13.4% Thus the presence of all 6 risk factors gave a relative risk of 7.4 for development of a foot ulcer over time.
Conclusion: We have made progress in defining a usable algorithm for foot ulcer prediction. However more accurate determination of foot deformity and pedal circulation in the UK GP setting may improve the positive predictive value of the algorithm. It is clear that vascular dysfunction must be severe - much reduced in order to affect ulcer formation. However diminished sensation appears to be implicit in ulcer formation. Additional risk parameters will need to be identified to improve prediction to clinically useful levels to predict foot ulcers. We have made steps in the right direction.

Uncensored incidence of diabetic foot ulcers to patients in remission

L. Lavery[1], J. Bloom[2], B. Petersen[2], G. Rothenberg[3];
[1]University of Texas Southwestern Medical Center; Department of Plastic Surgery, Dallas, [2]Podimetrics, Somerville, [3]University of Michigan School of Medicine, Ann Arbor, USA.

Background and aims: Diabetic foot ulcers (DFU) are known to be associated with increased morbidity, mortality, and resource utilization. Patients with history of DFU are among those at highest risk, with several prospective studies reporting annual incidence between 20% and 40% for those in remission. However, nearly all of these studies report DFU-free survival ("censored incidence") and right-censor outcomes by (1) disenrolling patients upon initial observation of DFU occurrence, and (2) characterizing multiple distinct DFU observed on the same date as a single occurrence. Reporting uncensored incidence, which includes all observed outcomes over the entire followup period, may more accurately reflect the true burden of DFU in high-risk populations. We hypothesized that the uncensored incidence is meaningfully larger than the censored incidence.
Materials and methods: A recent multi-center investigation recorded all DFU occurring in a cohort of 129 participants in remission from a DFU healing prior to enrollment. Participants were followed for 34 weeks or until withdrawing consent. We modeled DFU occurrences as a nonhomogeneous Poisson point process over time indexed from the participants becoming DFU-free prior to enrollment. From this, we estimated the instantaneous incidence through Savitzky-Golay smoothing of the counting process and numerical differentiation. We compared the time-dependent censored and uncensored incidence curves qualitatively, and assessed the aggregate difference qualitatively by testing censored and uncensored ratios of DFU/participant over the 34 week followup for significance.
Results: At least one DFU occurred to 37 participants, resulting in a censored ratio of 0.29 DFU/participant (37/129). The uncensored ratio was found to be 0.41 DFU/participant (53/129) given a total of 53 DFU during the study. The 16 additional DFU in the uncensored ratio occurred to eleven participants. Six of these participants presented with multiple DFU on the same date. Although the observed difference of 0.12 DFU/participant is not statistically-significant at the alpha = 0.05 level (p = 0.06), this study was not a priori powered to detect this difference. Both the censored and uncensored instantaneous incidence curves are unimodal with annualized peak rates of 0.42 DFU/participant/year and 0.71 DFU/participant/year during month four of remission. The censored and uncensored instantaneous incidences asymptote to the same baseline value of approximately 0.03 DFU/participant/year after month 18 of remission.
Conclusion: These data suggest a clinically-meaningful component of incidence that is underreported in the literature and potentially underappreciated by researchers and practitioners. Furthermore, it may be misleading to annualize DFU incidence by extrapolating the results from studies with followup shorter than one year because this approach may understate the true burden of DFU due to the strong temporal dependence of incidence during remission. Better characterizing DFU incidence for those in remission may enable improved allocation of resources, organization of care, and communication of prognosis, possibly resulting in reduced DFU-related morbidity, mortality, and resource utilization.

A risk prediction score for early-onset lower extremity arterial disease in Chinese type 2 diabetes

X. Zhang[1], X. Ran[2], Z. Xu[3], L. Ji[1,4];
[1]Endocrinology, Peking University International Hospital, Beijing, [2]Endocrinology, West China Hospital, Sichuan University, Chengdu, [3]Endocrinology, The 306th Hospital of PLA, Beijing, [4]Endocrinology and Metabolism, Peking University People's Hospital, Beijing, China.

Background and aims: Lower extremity arterial disease (LEAD) is highly prevalent in Chinese type 2 diabetes mellitus patients, but half of cases are underdiagnosed at incipient stage of onset because of diversified clinical presentations. Patients with early-onset LEAD are at increased risk of further cardiovascular comorbidities and mortality, but early initiation of secondary prevention is proved to improve prognosis. The present study was designed to develop a risk score for early-onset LEAD in diabetes patients, facilitating patient screening.
Materials and methods: 10,681 diabetes patients from the China DIA-LEAD Study, a multicenters, cross-sectional epidemiological investigation during June 2016 and January 2017, were selected as the training set to develop a weighted risk score associated with early-onset LEAD by multivariate regression. The risk score was confirmed by a validation dataset of 486 patients consecutively enrolled from a teaching hospital between Jul 2017 and Nov 2017. Receiver operator curves (ROC) with 95% CI were calculated to evaluate the discrimination capacity of the risk score. All patients were assessed for LEAD by ABI and/or lower limb ultrasonography according to 2013 Chinese guidelines on LEAD screening and management. The early-onset LEAD was defined as the ages at the date of first diagnosis <60 years.
Results: A total of 450 (4.2%) patients were diagnosed as early-onset LEAD in the training set. Of the candidate variables analyzed, factors (gender, body mass index, smoking, family history of premature cardiovascular disease, established coronary heart disease and skin test abnormality) correlated with early-onset LEAD in multivariate model resulted in weighted risk score of 0–20. The risk score discriminated patients with low risk (0–4, 0.8%), moderate risk (5–8, 3.0%), high risk (9–12, 7.4%) and very high risk (≥13, 12.2%) of early-onset LEAD, respectively. The prevalence of early-onset LEAD in different risk groups were 0.9%, 3.1%, 7.4% and 14.5% in the validation set. When the risk scores were analyzed by ROCs, a score of ≥13 was found to be optimal cut-off for

discriminating very high risk patients with the area under curve (aROC) of 0.82 (95%CI: 0.77–0.89), sensitivity of 0.79 (95%CI: 0.77–0.90) and specificity of 0.74 (95%CI: 0.69–0.88). Similar performance of aROC, sensitivity and specificity for different risk score cut-points (4, 8 and 12) were observed in the validation set.

Conclusion: The present study was the first attempt to develop an early-onset LEAD risk score system specific for type 2 diabetes mellitus patients based on a large population. The objective, weighted risk score for early-onset LEAD could reliably discriminate the occurrence of LEAD in patients younger than 60 years old, which may be helpful in a precise risk assessment, early diagnosis and treatment of LEAD. The continued refinement and multicenter validation of early-onset LEAD risk score with well-defined diagnostic procedure prospectively is required.

Incidence and clinical features of new onset diabetic foot ulcer post simultaneous pancreas-kidney transplantation

A. Sharma[1], S. Cohen[2], S. Thomas[3], T. Patel[4], J. Karalliedde[5], P. Vas[6];
[1]King's College London, London, [2]Renal unit, Guy's and St Thomas' NHS Trust, London, [3]Diabetes and Endocrinology, Guy's and St Thomas' NHS Trust, London, [4]Foot health team, Guy's and St Thomas' NHS Trust, London, [5]Cardiovascular Division, Faculty of Life Science & Medicine, King's College London, London, [6]Diabetes and Diabetes Foot Medicine, King's College Hospital, London, UK.

Background and aims: Patients with diabetes and renal dysfunction are at high risk of diabetic foot ulcers (DFU). Whether this risk is modified post simultaneous pancreas-kidney (SPK) transplantation is unknown with limited data on the incidence and predictors of new onset DFU in this population. We evaluated the incidence of new onset DFU post SPK in a single centre retrospective study. Patients who underwent SPK transplantation between 2004–2014 were evaluated.

Materials and methods: In total, 90 (51% male) patients were evaluated. Median (range) follow up was 6 (3 to 13) years. Median age was 49 (28 to 69) years and duration of diabetes was 32 (10 to 56) years. Electronic patient investigation records and podiatry medical notes were reviewed.

Results: Over the follow-up period, 16 (17%) patients developed a new DFU. Patients with a DFU were of similar age, duration of diabetes, and had similar pre-transplantation haemoglobin, HbA1c and estimated glomerular filtration rate as compared to those without a DFU. Patients who developed a DFU were more likely to have history of peripheral vascular disease (PVD) [37.5% vs. 4%, $p < 0.05$]. Of the cohort, 8 patients had a history of DFU pre-transplantation and all 8 developed a new onset DFU post SPK transplantation. Median (range) duration of healing was 7 (2–27) weeks. Site, Ischaemia, Neuropathy, Bacterial Infection, and Depth (SINBAD) classification score was <3 in 10 of the 16 DFU cases. Nearly 60% of DFU occurred within 500 days post-transplantation (Figure 1). Only 1 out of 16 needed a minor amputation. There was no significant difference in transplant failure between those with and without DFU (31% vs. 23.3%). When compared with UK national data - healing time, rates and severity of ulcer at presentation are significantly better in this cohort.

Conclusion: Nearly 1 in 6 patients developed a new DFU post SPK transplantation with greater than 50% of cases occurring within the first 500 days post-transplantation. A pre-transplantation history of PVD and DFU is associated with increased risk of new onset post-transplantation DFU. Our results highlight the need for greater awareness of regular foot evaluation post-transplantation and the burden and risks of DFU in this high-risk patient population.

966

Years of life lost due to diabetic foot complications during a 20-year follow-up

K. Ogurtsova[1], S. Morbach[2], G. Rümenapf[3], D. Ziegler[4], A. Icks[1,5];
[1]Institute for Health Services Research and Health Economics, German Diabetes Center, Düsseldorf, [2]Department of Diabetes and Angiology, Marienkrankenhaus, Soest, [3]Klinik für Gefäßchirurgie, Diakonissen-Stiftungs-Krankenhaus Speyer, Speyer, [4]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, [5]Institute for Health Services Research and Health Economics, Faculty of Medicine, Heinrich-Heine-University, Düsseldorf, Germany.

Background and aims: Diabetic foot ulcers (DFUs) and consequent amputations, shorten patients' life. There is a lack of knowledge to which extent these conditions affect life expectancy (LE). The objection of this study is to estimate years of life lost (YLL) from DFUs and LE of patients with DFUs in a long-term follow-up study.

Materials and methods: 260 patients with new DFUs consecutively presenting to a single diabetes centre in Germany between June 1998 and December 1999 were included in this study and followed up until December 31st 2017 (mean age at baseline and death: 69.1 (SD: 10.8) 76.1 (SD 10.4) years, respectively), 59.2% male, 88.1% type 2 diabetes (T2DM). 13 (5.0%) patients had a first unilateral major amputation before study inclusion, 16 (10.0%) during the study period and 15 patients (5.8%) experienced bilateral major amputation. There are observations on 637 recurring ulcer episodes. The follow-ups were analysed by the Kaplan-Meier method to derive a cumulative hazard function. LE was estimated in the Cox-regression model with age, sex, smoking status (have ever smoked), type and duration of diabetes, as well as the presence of ischemic heart disease (IHD), peripheral arterial disease (PAD) and Charcot neuroosteoarthropathy at inclusion as covariates. Only death was considered as a final event; patients who dropped out due to other reasons were censored. YLL are calculated from the number of deaths multiplied by a standard LE at the age of death. The standard life tables were obtained from the Human Mortality Database (HMD) and matched with the sample by sex, age at deaths and calendar year when death occurred.

Results: 228 patients died and 19 were lost to follow-up. Of the 241 patients who were followed to death or are still under observation, 241, 233 and 229 have completed 18, 19 and 20 years of follow-up, respectively. At present 13 patients are alive and under observation. The Cox-

regression showed that the following baseline variables adjusted to other covariates are significantly associated with a probability of death: having any PAD (RR = 1.48, p value = 0.008), age (RR = 0.85 per year, p value <0.001). LE in a general German population over the follow-up period for men and women at age 65 was 80.2 and 84.0 years, accordingly. At the same time, the estimated LE for a counterpart at age 65 with DFUs and T2DM of 20 years' duration (a mean duration in the sample) ranges from 72.1 (CI = 70.76–77.62) years to 74.2 (CI = 73.60–77.62) years with all and without any complications included in the analysis for non-smokers while LE of smokers ranged from 70.5 (CI = 69.54 75.97) to 72.6 (CI = 71.89–74.82) years respectively, irrespective of sex. The YLL from DFUs and its complications was 10.0 (SD 6.3) years compared with the general population in Germany, 8.9 (SD 6.3) for female and 10.8 (SD 6.2) for male (t-test = −2.29, df = 212.82, p value = 0.023).

Conclusion: Our results confirm that diabetes in conjunction with DFUs and its related complications lie a great burden on patients by lessening their LE and long-term survival.

Disclosure: **K. Ogurtsova:** None.

Perioperative and long term mortality after lower limb amputation in patients with diabetes

M. López Valverde[1], J. Aragón Sánchez[2], V. Guerrero Cedeño[3], R. Tejedor Méndez[4], G. Víquez Molina[5];
[1]Endocrinology and Nutrition, Hospital San Pedro, Logroño, Spain, [2]General Surgery, Diabeti Foot Unit, Hospital La Paloma, Las Palmas de Gran Canaria, Spain, [3]Geriatry, Hospital San Jorge, Huesca, Spain, [4]General Medicine, Hospital San Jorge, Huesca, Spain, [5]Hospital San Juan de Dios, San José de Costa Rica, Costa Rica.

Background and aims: Long-term mortality of patients with diabetes who underwent a lower extremity amputation (LEA) has not been reported in Spain. The aim of the present research is to study in-hospital and long-term mortality in a retrospective cohort of patients with diabetes who underwent LEAs

Materials and methods: The retrospective cohort included all subjects who underwent LEA from January 1, 2005 to December 31, 2015 in San Jorge Hospital, Huesca, Spain. Perioperative mortality was defined as death within 30 days after the index procedure. Live status of every patient up to September 2017 and the date of the death were retrieved using the national death index from the civil registry of Huesca.

Results: The series included 203 patients who underwent LEA. One hundred sixteen patients (57.1%) underwent a minor amputation and 87 patients (42.9%) underwent a major amputation. Twenty-five patients (12.3%) died in the perioperative period. Significant risk factors of perioperative mortality were: undergoing an above-the-knee amputation (p = 0.04, OR 2.6, 95% CI 1.0–6.9), postoperative cardiac complications (p = 0.02, OR = 3.3, 95% CI 1.1–9.8), age >74 years old (p = 0.002OR 6.5, 95% CI1.9–22.1) and acute renal failure (p = 0.004, OR 17.8, 95% CI 2.5–124.1). Survival rates in patients who underwent a minor amputation at 1, 3 and 5 years were 90.6%, 72.8% and 55.5% compared with 70.8%, 41.3% and 34.4% in patients who underwent a major amputation. Log-rank test between the two groups was $\chi^2 = 12.7$ ($P < 0.01$). The Cox's proportional hazards model performed to analyse the association between the covariables and the mortality showed a significant hazard with: PAD (p = 0.04, Hazard ratio [HR] 1.6, 95% CI 1.0–2.7), major amputation (p = 0.01, HR 1.9, 95% CI 1.3–2.8), age >74 years (p < 0.01, HR 2.0, 95% CI 1.3–3.0) and previous amputation before the index amputation (p < 0.01, HR 4.1, 95% CI 2.4–6.9).

Conclusion: Long-term survival is worse in patients who underwent a major amputation with a five-years mortality of 65.6%. This mortality is worse than what has been reported for some types of common malignancies. Prevention and aggressive treatment of comorbidities should be implemented in order to reduce these poor outcomes.

Disclosure: **M. López Valverde:** None.

968

Presence, characterisation and clinical impact of anaemia in diabetic foot ulceration: a cross sectional study with longitudinal follow up of ulcer outcomes

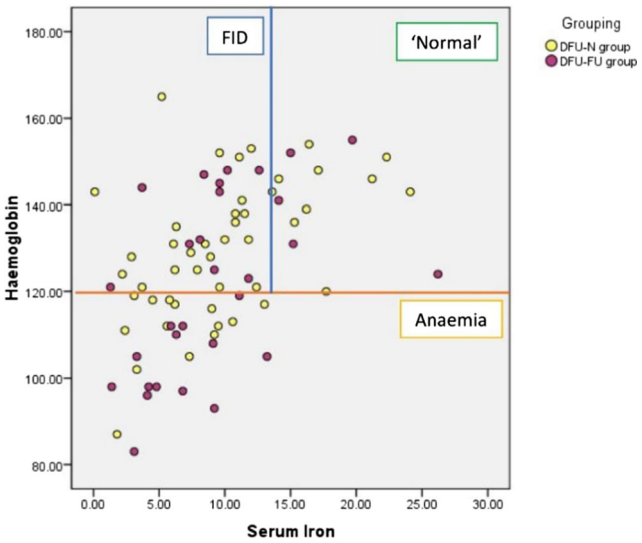
M. Anson[1], J. Karalliedde[1], I. Alejandro[2], M. Bates[2], C. Manu[2], M. Edmonds[2], I. Macdougall[2], P. Vas[2];
[1]King's College London, London, [2]King's College Hospital, London, UK.

Background and aims: Anaemia is a commonly understood to be associated with diabetic foot ulceration (DFU). However, the prevalence and the influence on DFU outcomes, is poorly understood and seldom researched. The aims of this study are to assess the prevalence of anaemia and functional iron deficiency (FID, low iron indices but normal haemoglobin) in patients attending a tertiary diabetic foot clinic, and to determine whether they are predictive of a poor DFU outcome.

Materials and methods: A cross sectional study with a prospective, observational intent was undertaken between November 2017 and February 2018. Patients were stratified into how they were assessed on visitation, into New (DFU-N, n = 48) or Follow up (DFU-FU, n = 31) groups. They were then subsequently classified into an anaemia, FID or normal subgroups. DFU was characterised using the SINBAD score. Those on iron/folate/vitamin B12 replacement and those receiving dialysis were excluded. The DFU-N cohort was followed up for a period of 6 weeks, and prognosis classified as favourable (healing or improvement in DFU size) or unfavourable (static, worsening DFU, amputation or death).

Results: There was no significant difference in age (66 ± 15 v 63 ± 12 years), gender (males 73% v 84%) HbA1C (8.3 ± 2.2 v 9.5 ± 2.9, p = 0.11) or DFU severity (p = 0.73) between the two groups. EGFR was lower in the DFU-FU group (72 ± 20 v 57 ± 21 ml/min, p = 0.007) and there was a trend for the DFU-FU to have a longer duration of diabetes (16 ± 11 v 22 ± 15 years, p = 0.053). Prevalence of anaemia and FID in the DFU-N group was 40% and 40% respectively; in the DFU-FU it was 55% and 32% respectively. For the whole cohort, haemoglobin value correlated with CRP (rho −0.282, p = 0.13), eGFR (0.282, p = 0.01) and serum albumin (0.393, p < 0.0001). Serum iron correlated with CRP (−0.591, p < 0.0001), White cell count (WCC) (−0.359, p = 0.001), albumin (0.233, p = 0.02). There was no correlation between serum iron and ferritin (0.31, p = 0.13), nor did it differ between the 2 groups (Z score −1.63, p = 0.1). None of the patients had low vitamin B12 or folate. In the follow up cohort, presence of anaemia and FID were both predictors of an unfavourable ulcer prognosis at 6 weeks with an unfavourable outcome in 82% of those with anaemia and 67% of FID compared to only 14% in those with normal haematinics (p < 0.05).

Conclusion: A very high prevalence of Anaemia and FID was noted in patients with DFU and to our surprise, there was little difference between DFU-N and DFU-FU groups. This was associated with poor DFU outcome, even at 6 weeks. Taken together, along with the association with CRP, WCC and albumin, our findings are suggestive that inflammation of any degree may initiate the pathway to anaemia development. Studies looking at larger, more diverse cohorts and settings with assessment of DFU outcomes over 12, 24 and 52-weeks are required to confirm our early findings.



Disclosure: **M. Anson:** None.

Non-neuronal control of proliferation and migration of keratinocytes on site of ulceration

E. Artemova[1], Z. Abdulvapova[1], E. Ivanov[2], A. Gorbacheva[1], S. Gavrilova[2], A. Tokmakova[1], G. Galstyan[1];
[1]Endocrinology Research Center, Moscow, [2]Lomonosov Moscow State University, Moscow, Russian Federation.

Background and aims: to assess proliferation and migration of keratinocytes at the nonhealing edges of neuropathic wounds, identify key enzymes for the synthesis of catecholamines in keratinocytes
Materials and methods: 25 patients (DM2 - 87.5%), with neuropathic ulcers (duration about 12 months) and 5 patients without diabetes with decubitus were enrolled. DF patients were underwent to standard treatment including debridement, atraumatic dressing, offloading with removable total contact cast, antibacterial therapy if it needs. Severity of peripheral neuropathy was assessed according to the NDS scales; was evaluated. Histological (hematoxylin and eosin) and immunohistochemical (Ki 67, α7nAChR, keratin K10, tyrosine hydroxylase) examination of wound edge were done during treatment (0, 10, 24 days).
Results: All patients have severe neuropathy according to NDSm (>8). The average size of DF ulcers before and on 10th day of treatment was of 5.56 cm^2 and 4.29 cm^2, respectively ($p < 0.004$). Neuropathic ulcers were characterized by hyperproliferative epidermis. Mitotically active keratinocytes reside throughout the suprabasal layers. Ki-67 expressed all layers of the epidermis, but a greater staining density was detected in the basal layer. The density of a7nAChR-positive cells increased from 0 to 24 days. Skin samples taken from patients on the 0th and 10th day of therapy were characterized by a low density for tyrosine hydroxylase, in contrast to samples taken on the 24th day. There was a low expression of K10 keratin differentiation markers before the beginning of therapy. There was formed a hyperproliferative epidermis, the cells of which lost the ability for terminal differentiation, the process of cornification was disturbed.
Conclusion: All layers of the epidermis of wound edge actively proliferated at conditionally separated stages of the wound process, which led to a pathological thickening of the epidermis, despite regular debridement. An increase in the expression of receptors for α7nAChR indicates a low migration potential of keratinocytes of the edge of neuropathic wounds. Due to the presence of severe neuropathy, the pathological pattern in the epidermis can be caused by a deficiency of nerve regulatory influences (the amount of mediator released by damaged nervous structures) and inadequate amounts of catecholamines synthesized in skin cells (skin cells expressed key enzymes of catecholamine synthesis), which led to the impaired migration and differentiation. The data obtained can serve as a basis for the development of local therapy for wound defects to enhance the migration of keratinocytes. It is necessary to search for signaling pathways that block excessive proliferation of epidermal cells that form a pathologically thickened epidermis.

PS 088 Diabetic foot ulcers: How to prevent and how to treat

970

Arterial disease below the ankle in the diabetic foot: the final frontier

C.A. Manu, N.L. Petrova, P.J. Vas, K. Winkley, H. Rashid, M.E. Edmonds;
King's College Hospital, London, UK.

Background and aims: Recommendations from most guidelines suggests that peripheral arterial disease (PAD) is unlikely when Ankle Brachial Pressure Index (ABPI) is normal, that is between 0.9–1.3. The aim of this study was to evaluate the presence or absence of distal arterial disease below the ankle in limbs with normal ABPI between 0.9–1.3, as indicated by Toe Brachial Pressure Index (TBPI), Transcutaneous Oxygen ($TcPO_2$) and the associated clinical impact.
Materials and methods: The ABPI, TBPI and forefoot $TcPO_2$ were measured in both limbs of consecutive patients attending our outpatient clinic with diabetic foot ulceration. We used TBPI and forefoot $TcPO_2$ to diagnose the presence of arterial disease below the ankle, compared to measurements of ABPI per limb. We also assessed clinical outcome on a patient level, with regards to subsequent amputation and mortality.
Results: Measurements were taken in 154 patients, of which there were 121 limbs with a presumed absence of PAD as indicated by ABPI between 0.9–1.3. Within these limbs with normal ABPI range, 57% (69 limbs) had a low TBPI of <0.7, indicative of distal disease below the ankle (Group 1). The remaining 52 limbs (Group 2), had both ABPI and TBPI in the normal range. Absolute ankle pressures were similar in both groups, 159 ± 32 mmHg vs 159 ± 25 mmHg in Group 1 and Group 2 respectively, [$p = 0.478$]. However, the forefoot $TcPO_2$ was significantly lower in Group 1, 48 ± 15 mmHg vs 54 ± 12 mmHg in Group 2, [$p = 0.010$], as was their absolute toe pressure, 72 ± 21 mmHg vs 112 ± 19 mmHg respectively, [$p = 0.001$]. There were 43 patients in Group 1 and 21 patients in Group 2. More patients in Group 1 underwent minor amputation over the subsequent year; 26% vs 5%, [$p = 0.0455$]. Over the subsequent 18 months 2/43(5%) in Group 1 underwent a major amputation but none in Group 2. There was also a higher 2 year mortality in Group 1 patients, 14% vs 5% mortality in Group 2, but did not meet statistical significance, [$p = 0.267$].
Conclusion: A normal ABPI does not exclude PAD below the ankle in patients with diabetes. Over 50% of patients with normal ABPI between 0.9–1.3, have distal arterial disease in the foot which is associated with significant morbidity and mortality.

Post-exercise transcutaneous tissue oxygen tension in the detection of latent peripheral arterial disease in patients with diabetic foot

V. Fejfarova[1], J. Matuška[2], P. Piťhová[3], M. Flekač[4], J. Venerová[5], K. Roztočil[6], V. Wosková[1], M. Dubský[1], R. Bém[1], A. Němcová[1], A. Jirkovská[1], V. Lánská[1];
[1]Diabetes Centre, Institute for Clinical and Experimental Medicine, Prague, [2]MATMED, Vascular ambulance, Hodonín, [3]2nd Faculty of Medicine, Teaching Hospital Motol, Prague, [4]1st Faculty of Medicine, Charles University, Prague, [5]Military University, Prague, [6]Department of Transplant Surgery, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Assessment of arterial supply is one of the key goals in diabetic foot (DF) management. In addition to assessment of macrocirculation by ankle-brachial (ABI) or toe-brachial (TBI) indexes, the status of microcirculation is also controlled (usually by transcutaneous tissue oxygen tension, TcPO2). However, all diagnostic procedures have their own limitations in relationship to diabetes mellitus. The aim of our study was to refine TcPO2 measurement using astimulation test to enhance the detection ofa latent form of peripheral arterial disease (PAD) or arterial restenosis in previously diagnosed PAD.
Materials and methods: We initiated a multicentre trial with 26 patients with or without PAD (17/9 patients) who were treated in out patient foot clinics for DF (mean age 66.5 ± 12.8 years, diabetes duration 20.9 ± 10.1 years, HbA1c 60.4 ± 14.8 mmol/mol), underwent evaluation of macrocirculation (ankle/toe pressures, ABI, TBI, duplex ultrasound) and had baseline TcPO2 values between 30 and 50 mmHg. Each patient had TcPO2 measurement supplemented by a modified Ratschow stress physical activity test (lower limb elevation and rhythmic exercise for 2 minutes). TcPO2 values before, during (the lowest values) and after stress test and their changes (Δ = baseline TcPO2 minus the lowest TcPO2 during stress test) were evaluated in all study subjects with a total of 38 angiosomes. Patients and their limbs were divided into two groups based on duplex ultrasound findings in relevant evaluated angiosome - group A ($n = 13$) with triphasic flow, and group B ($n = 25$) with monophasic flow or proved arterial obliteration. These groups were compared in terms of all examined TcPO2 values and their possible correlations with macrocirculation findings.
Results: The stimulation test lead to a significant decrease in TcPO2 values in group A (42.8 ± 5.2 before vs. 34.4 ± 5.4 mmHg during test; $p < 0.001$), this decline was more expressed in group B (40.9 ± 5.9 vs. 25.8 ± 11.5; $p < 0.001$). Both study groups differed significantly in Δ TcPO2 (8.4 ± 2.4 in group A vs. 15.1 ± 9.3 mm Hg in group B; $p = 0.003$).These differences were most marked especially in those patients with a TcPO2 range of 30–40 mmHg (the lowest TcPO2 during the stimulation test 29.6 ± 3.6 mm Hg in group A vs. 16.7 ± 9.8 in group B; $p = 0.004$ and Δ TcPO2 7.8 ± 3.5 vs. 17.7 ± 9.5; $p = 0.02$). The lowest TcPO2 values during the stress test correlated positively with ABI ($p = 0.03$) and also with toe pressures ($p = 0.01$).
Conclusion: Stress physical activity test supplementing TcPO2 measurement used in daily podiatric practice could improve with a combination of ABI and TBI the detection of latent forms of PAD or restenosis in previously diagnosed PAD in patients with DF where the clinical signs of PAD are not always fully expressed.

Neurovascular response to pressure: a new potential predictive marker of diabetic foot ulcer

J. Vouillarmet[1], A. Josset-Lamaugarny[2], J. Saumet[2], P. Michon[1], P. Abraham[3], B. Fromy[4], D. Sigaudo-Roussel[2];
[1]Centre hospitalier Lyon sud, Pierre Benite, [2]UMR CNRS 5305, Lyon, [3]CHU d'Angers, Angers, [4]UMR CNRS 5305, Pierre Benite, France.

Background and aims: We previously described a specific cutaneous skin blood flow in response to an increase non-noxious progressive local pressure. This neurovascular reactivity permits an increase local blood flow that contribute to limit skin ischemia and by the way ulceration. This neurovascular response is impaired in patients with type 1 and type 2 diabetes but no data were available in patients with diabetic foot ulcer (DFU). We analysed, in this study, skin blood flow response of locally applied pressure in patients with DFU and in patients without DFU.
Materials and methods: Patients were recruited in a single diabetic centre. All patients had a complete record of diabetes history and foot problem. Neuropathy was assessed using the neuropathy sensitivity score (NSS), the neuropathy disability score (NDS) and by sensory tests. Basal blood flow, endothelium-dependent and endothelium-independent vasodilatations, maximal vasodilatation capacity by local heating to 44°C and skin blood flow in response to locally applied pressure were measured. All measurement were realised on the same tibia. Vasodilator responses were expressed as the maximal percent increase in cutaneous blood flow

from the baseline. Data were compared to ten healthy age-matched control subjects previously recruited (ID: NCT00160927).

Results: A total of 59 patients with type 2 diabetes were included; 29 without DFU and 30 with DFU. Patients were predominantly men (78%) with a mean age of 65 ± 11 years. Patients with DFU have a significant higher NDS score than patients without DFU (6.0 ± 0.5 vs 2.8 ± 0.6) but no difference between the two groups for NSS score (3.4 ± 0.5 vs 4.2 ± 0.5), and for cutaneous pressure perception threshold (CPPT) before (2.9 ± 0.1 vs 3.3 ± 0.2 g) and after local application of lidocaïne (4.0 ± 0.1 vs 4.2 ± 0.2 g). Basal Skin blood flow was significantly reduced in both diabetic groups compared to healthy subjects but with no difference in skin blood flow after local heating, Ach and SNP stimulation. By contrast, skin blood flow in response to pressure was significantly impaired in both diabetic groups compared to healthy subjects. The vasodilator capacity to pressure was significantly more altered in patients with DFU compared to those without DFU and lidocaine did not further decrease the vasodilation capacity to pressure in DFU group whereas it was reduced in patients without DFU.

Conclusion: This study revealed an incremental defect in skin blood flow response to pressure locally applied in patients with type 2 diabetes with a significantly more severe impairment in those with DFU. This effect occurs despite the absence of difference of the CPPT and of vascular reactivity to Ach and SNP suggesting a specific pathway.

Efficacy of long-term remote ischaemic conditioning on vascular and neuronal function in type 2 diabetes patients with peripheral arterial disease

C. Hansen[1], M.E. Jørgense[2,3], J. Fleischer[4], H. Bøtker[5], P. Rossing[1,6];
[1]Complications research, Steno Diabetes Center Copenhagen, Gentofte, [2]Clinical Epidemiology, Steno Diabetes Center Copenhagen, Gentofte, [3]National Institute of Public Health, Southern Denmark University, Copenhagen, [4]Clinical Institute of Medicine, Århus, [5]Complications research, Department of Cardiology, Århus, [6]Department of Clinical Medicine, Faculty of Health, Aarhus University AND University of Copenhagen, Aarhus, Copenhagen, Denmark.

Background and aims: Peripheral arterial disease (PAD) is a major challenge in the diabetes community, causing foot ulcers and amputations and often associated with neuropathy. When risk factor management fails to prevent PAD, only surgical intervention is offered to patients. New treatment options are therefore needed. Remote ischemic conditioning (RIC) has shown to provide cardioprotection in ischemic heart disease and improve vascular function. We aimed to investigate the efficacy of RIC on vascular and neuronal functions in individuals with type 2 diabetes and PAD.

Materials and methods: Individuals with type 2 diabetes and moderately reduced toe pressure (40 mmHg to 70 mmHg) were enrolled in a randomized placebo-controlled double blinded trial at a tertiary diabetes outpatient clinic. Patients were equally allocated to twelve weeks once-daily upper arm cuff-based treatment of either RIC treatment (4 cycles of 5 minute ischemia followed by 5 minute reperfusion) or similar treatment with a sham device with no ischemia. Primary outcome was transcutaneous tissue oxygen tension ($TcPO_2$) of the instep of the feet. Secondary outcomes were aortic pulse wave velocity, toe pressure and toe-brachial index and tertiary outcomes were markers of peripheral and autonomic nerve function: Sural nerve conductance velocity, Sural nerve action potentials, vibration perception threshold, electrochemical skin conductance and cardiovascular autonomic neuropathy indices.

Results: We enrolled 36 patients in the trial, 83% male. Participants had a mean (SD) age of 70.7 years (6.8), diabetes duration of 18.4 years (8.3), HbA_{1c} of 59.7 mmol/mol (11.2), toe pressure of 61.3 mmHg (15.1) and $TcPO_2$ average of both feet of 51.3 mmHg (10.7). Eighty percent had peripheral symmetrical neuropathy. Between group difference in change in $TcPO_2$ from baseline was −0.03 mmHg (95%CI −0.1; 0.04). *P* for group difference = 0.438. RIC did not elicit any change in secondary (Table 1) or tertiary outcome variables (not shown). Participants in the RIC group and placebo group applied treatment in 92.1% (SD 13.8) and 82.1% (SD 18.1) of possible days, respectively. Three participants experienced transient petechiae (micro bleeds) in the skin distal from the cuff. Treatment elicited no permanent adverse effects.

Conclusion: Repeated remote ischemic conditioning treatment may have no effect on tissue oxygenation, vascular or neuronal function in individuals with type 2 diabetes and moderate PAD despite excellent compliance to treatment during twelve weeks.

Table 1

	Randomization			Week 12		
	RIC	Placebo	p-value for group difference at baseline	RIC	Placebo	Difference in change from baseline, RIC vs. Placebo
Primary outcome						
Transcutaneous oxygen tension, mean feet (mmHg)	50.8 (9.9)	51.8 (11.8)	0.763	50.1 (10.0)	50.8 (9.0)	-0.03 (-0.1; 0.04) [0.438]
Secondary outcomes						
Pulse wave velocity (m/s)	2.62 (2.41;2.75)	2.54 (2.5;2.74)	0.487	2.67 (2.49;2.84)	2.56 (2.47;2.72)	0.07% (-0.08; 0.22) [0.385]
Toe pressure, mean feet (mmHg)	61.4 (15.7)	61.2 (15.0)	0.967	73.3 (14.8)	75.7 (15.3)	-0.04 (-0.2; 0.11) [0.603]
Toe brachial index, mean of both sides	-0.89 (-1.16;-0.74)	-1.02 (-1.12;-0.79)	0.684	-0.68 (-0.81;-0.62)	-0.71 (-0.83;-0.43)	-0.06% (-0.28; 0.17)[0.627]

Data are means (SD) or medians (IQR). Estimates of treatment effect are in % or absolute values (95% CI) [P values for group difference]. Models have been adjusted for baseline values of the given outcome.

The efficacy of sucrose-octasulphate dressing in neuro-ischaemic DFU considering factors influencing wound closure rate: a post-hoc analysis of the Explorer RCT

G. Rayman[1], M. Edmonds[2], R. Lobmann[3], J. Lázaro-Martínez[4], J. Martini[5], J.-M. Petit[6], A. Piaggesi[7];
[1]The Diabetes Centre, Ipswich, UK, [2]Diabetic Foot Clinic, King's College Hospital, London, London, UK, [3]Department of Endocrinology, Diabetology and Geriatrics, Klinikum Stuttgart – Bad Cannstatt Hospital, Stuttgart, Germany, [4]Diabetic Foot Unit, Complutense University of Madrid, Madrid, Spain, [5]Department of Endocrinology, Rangueil University Hospital, Toulouse, Guadeloupe, [6]Department of Endocrinology, Diabetology and Metabolism, François Mitterrand University Hospital, Dijon, France, [7]Department of Endocrinology and Metabolism, University of Pisa, Pisa, Italy.

Background and aims: According to most recent guidelines, no treatment added to optimal Standard of care (SOC) including efficient offloading has shown clear benefit in the management of diabetic foot ulcer (DFU). Efficacy of a sucrose octa-sulfate wound dressing (TLC-NOSF dressing) versus a neutral dressing (TLC) in addition to the same standard of care, in patients presenting with a neuro-ischaemic DFU was assessed in a European RCT.

Materials and methods: This double-blind RCT was conducted in 43 centres in patients presenting with a non-infected neuro-ischaemic DFU (grade IC/IIC, Texas Classification), and a surface area >1 cm^2. The primary outcome was the wound closure rate by week 20 in the ITT population (binary logistic analysis). Secondary outcomes included time to closure and adverse events occurrence (infection, notably).

Results: A total of 240 patients were randomised and received either the treatment dressing (n = 124) or the control dressing (n = 114). At Week 20, wound closure occurred in 34 patients (30%) in the control group and in 60 patients (48%) in the treatment group (adjusted odds ratio 2·60 [95% CI 1·43 to 4·73], p = 0·002). Post-hoc analysis were undertaken, considering parameters that may influence the tissue repair process (wound duration, wound area, wound location, vascular status, patients'

characteristics···), always showing favourable outcomes for the sucrose-octasulfate dressing, whatever the characteristics of the treated wound.
Conclusion: Sucrose octasulfate dressing and good standard of care is significantly more effective than neutral dressing, in the management of neuro-ischaemic DFUs, and specifically when treatment is initiated early in the wound evolution.

Real life experience of VACOped boots in the management of diabetic foot ulcers

W.T. Lim[1], H. Robinson[2], S. Rajbhandari[2];
[1]Manchester Medical School, Manchester, [2]Lancashire Teaching Hospital, Chorley, UK.

Background and aims: Offloading with Total contact cast (TCC) is the gold standard treatment for diabetic foot ulcers (DFU) and is used as standard off-loading method in our clinic. However its use can be limited due to underlying conditions such as infection or ischaemia or patients' reluctance. We use VACOped boot as a removable walker in such cases. The VACOped has an outer light weight shell and the inner lining. The inner lining is the cushion filled with thousands of styrofoam pearls that surrounds the foot. When air is extracted from the cushion with a pump, the body shaped cushion becomes hard as a cast just in a few seconds. This avoids pressure to the DFU and provides stability due to a perfectly shaped orthosis. This aim of this study was to analyse the results of VACOped boots in the healing of DFU in real life scenario.
Materials and methods: In this retrospective study we analysed records of all subjects supplied with VACOped boot from 2011 to 2017 for the treatment of DFU. The outcome of their ulcers was noted from clinical records. If patients stopped using VACOped for any reason their outcome was grouped with those stopped using it. If they changed from other off-loading device to VACOped it was analysed as the outcome of this device.
Results: VACOped were supplied to 42 patients (35 males) to treat 83 episodes of DFU during this period. The mean age was 56.7 (±11.2) years and duration of diabetes was 18.9 (±13.5) years. Of the 83 episodes of ulcers 41 (49.4%) healed in the median duration of 17 weeks with the use of VACOped. 13 (15.6%) are still continuing treatment and 29 (34.9%) stopped using it. The reason for stopping its use was the change to other device ($n = 12$), infection ($n = 3$), amputation ($n = 3$), lost to FU ($n = 7$) and other reason ($n = 4$). Out of 83 DFU episodes, 8 episodes were those who changed from TCC to VACOped. Similarly in 10 ulcer episodes, VACOped was changed to TCC.
Conclusion: The healing time with VACOped was longer than TCC but these included patients with underlying infection and ischaemia, in whom TCC is relatively contraindicated. Our data shows that VACOPed is preferred by patients, can be reused when patient has re-ulceration and is as effective as other removable cast walkers.

Severe diabetic foot infection and osteomyelitis can be successfully treated with outpatient parenteral antimicrobial therapy

S. Rajbhandari[1], A. Muir[2], J. Purcell[3], J. Orton[4];
[1]Lancashire Teaching Hospital, Chorley, UK, [2]Microbiology Dept, Lancashire Teaching Hospital, Preston, [3]Microbiology Dept, Lancashire Teaching Hospital, Chorley, [4]Lancashire Teaching Hospital, Preston, UK.

Background and aims: Administration of intravenous antimicrobials to a patient with severe diabetic foot infection can be done by outpatient parenteral antimicrobial therapy (OPAT) either at home or at day wards without the need for an overnight stay in hospital. Our microbiology department started OPAT service in 2012 and accepts referrals from hospital inpatients to facilitate early discharges and also directly from outpatient clinics to avoid admissions. Diabetes foot team has been using OPAT for severe limb threatening diabetic foot infections since it started. The aim of this study was to assess the clinical outcome of OPAT services and calculate the savings made by avoiding hospital admissions.
Materials and methods: List of subjects accepted by OPAT service over a period last 5 years from diabetes foot team was obtained from database. 49 patients (8 males) with mean age of 60.4 (±12.4) years had 57 episodes of severe diabetic foot infections and their medical records were analysed retrospectively. All patients had appropriate offloading, revascularization and regular debridement as per clinical practice. Choice of parental antibiotics was guided by allergy history and culture results. Outcome of foot ulcer was obtained from clinical record and confirmed with photographic record.
Results: 32 episodes were stepped down from hospital admission and 25 were direct referral from diabetic foot clinic. The site of infection was MTP area in 17 cases, great toe in 13, other toes in 9, hind foot in 6, rocker bottom deformity in 5, dorsum of foot in 2 and residual infection of amputation site in 5 cases. Underlying osteomyelitis was present in 47 cases and remaining 10 cases had cellulites. Cetriaxone 2 gm IV daily was given in 38 cases and Teicoplanin 10 mg/kg IV daily in 19 cases along with metronidazole for anaerobic cover. The mean duration of OPAT was 20.7 (±17.9) days and it was followed by oral antibiotics as needed. Most patients had PICC sited for central venous access and were reviewed twice a week by infection specialist and weekly at Diabetic foot clinic. Complete healing of ulcer was obtained in 42 (84%) episodes. 6 (12%) ended with amputations and 2 (4%) died. 7 cases, all of which have underlying osteomyelitis are still undergoing treatment with parental or oral antibiotics. Regarding osteomyelitis, 82.9% healed with OPAT and oral antibiotics. One patient with CKD 4 needed hospital admission due to worsening of renal function as serious adverse event. Two had minor adverse event in the form of rash. There were no cases of septicaemia or c. diff infection.
Conclusion: Our findings show that severe diabetic foot infections including osteomyelitis can be successfully treated with OPAT. It is safe, well-liked by patients and in the last 5 years OPAT service spared 1138 hospital bed days from severe diabetic foot infection treatment which saved £273120 (Euro 310, 363).

Bedside Blind Bone Biopsy (B4) for suspected diabetic foot osteitis: A reliable tool to manage medical treatment?

F. Féron, D.-C. Gauthier, M. Laloi-Michelin, A.-L. Munier, L. Salle-Teyssières, G. Pean-de-Ponfilly, E. Lecorche, F. Mougari, H. Jacquier, P.-O. Sellier, J.-D. Laredo, J.-P. Riveline, J.-F. Gautier, J.-P. Kevorkian;
Hôpital Lariboisière, Paris, France.

Background and aims: Performed by a diabetologist, B4 has been recently shown as an easy and safe procedure. To assess Exclusive Medical Treatment (EMT: offloading, wound care ± antibiotherapy) determined by B4 in suspected Diabetic Foot Ulcer (DFU) osteitis, we compared DFU outcome between proved (B4+) and ruled out osteitis (B4-) with microbial culture.
Materials and methods: A prospective observational study was conducted in our Diabetology Unit during a 21-month period (12.17.2015–09.04.2017). Among 291 patients admitted with DFU, we included 33 (11%) consecutive patients with Type 2 Diabetes Mellitus (T2DM) and clinical and/or radiological suspicion of osteitis. For each, B4 was decided by our DFU multidisciplinary board. B4 was performed ≥2 weeks after antibiotics discontinuation in case of prior exposure. A 6-week targeted antibiotherapy was indicated for proven osteitis by prolonged culture (B4+). In case of negative cultures (B4-), no antibiotherapy was

prescribed.The primary outcome was the complete DFU healing and no recurrence with EMT at 6 months.
Results: Patient characteristics and results are summarized in table 1. Mean follow-up after B4: 14 ± 6 months. Around 50% of suspected osteitis was B4-, which prevented from unneeded antibiotics without poorer healing outcomes.
Conclusion: B4 might be a reliable tool for managing EMT in suspected DFU osteitis.

	Total (n=33)	B4+ (n=16, 48,5%)	B4- (n=17, 51,5%)	p
Sex (% men)	76	81	71	0,69
Age (years, sd)	70±13	74±9	67±14,5	0,11
T2DM duration (years, sd)	18±11	19±8,5	17±12	0,27

Ten years outcome of diabetic foot ulcer with osteomyelitis in Egypt
H. Gawish, F. Kyrillos, A. Albehairy, M. Elsayed, M. Sherif, M. El-Nahas, O. State, M. Tarshoby;
Diabetes and Endocrinology Unit, Mansoura UNiversity, Egypt.

Background and aims: Osteomyelitis is an important contributing factor to impaired wound healing. However, the selection of the appropriate therapy and the effect of therapy on ulcer healing is still unclear. The study aims to identify the management outcome of patients with diabetic foot ulcer associated with osteomyelitis at Mansoura Diabetic Foot centre, Egypt and different variables affecting it
Materials and methods: A retrospective single center including all registered cases, who presented with diabetic foot ulcer complicated by osteomyelitis, treated conservatively, were recruited between July 2005 and December 2015 at our tertiary center.
Results: Of all 3544 Diabetic Foot Ulcer (DFU) presented to the clinic for this 10 years period; 331 were associated with osteomyelitis. Data of 161 ulcer were excluded; because they were either referred to orthopedic surgery or dropped their follow up. The mean age of patients was 57 ± 9.91 yrs, with male predominance of 61.8%. PAD was only present in 2.35% and severe infection in 10.6% of patients. Admission was done in 7.1% of the whole group. Sharp debridement was done for 96.5% patients while ultrasound debridement was done for 3.5% patients. Patients were classified into group 1 who showed complete healing of their ulcers during the study period and group 2 who did not show complete healing. The healing rate was 65.88% among the group and the time to heal (was 127.05 ± 82.87 days in the first group. None or delayed healing was present in 34.1% of patients. There was no significant difference between the 2 groups as regards the age, gender distribution, or other system comorbidity. Toe ulcers with osteomyelitis showed higher healing rate than ulcers over Metatarsal Heads ($P \leq 0.000$). Non-significant difference was present at the other sites of the foot ulceration. The commonest antibiotics used among the healed ulcer group were combination of quinolones and linezolid in 31.4%. Recurrence rate of ulceration was 8.9% at the same site of ulcer and new ulceration at other sites occurred in 19.6% of the healed group during the study period.
Conclusion: Around two thirds of patients presenting with osteomyelitis healed conservatively without undergoing surgical bone resection. Quinolones/linezolid combination therapy were the commonest antibiotic regimen used among the healers. Osteomyelitis affecting the metatarsal heads was the site significantly associated with delayed ulcer healing or the need for surgical intervention.

PS 089 The impact of retinopathy

979

Decreased occurrence of early diabetic retinopathy in lifestyle intervention group of the Finnish Diabetes Prevention Study
M. Uusitupa[1], A. Aro[2], A. Kauppinen[3], P. Summanen[4], G. Von Wendt[4], N. Kivinen[5], T. Selander[6], K. Kinnunen[5], J. Tuomilehto[7], S. Keinänen-Kiukaanniemi[8], J. Lindström[9], K. Kaarniranta[10];
[1]Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland, [2]Department of Ophthalmology, Karelia Central Hospital, Joensuu, Finland, [3]School of Pharmacy, University of Eastern Finland, Kuopio, Finland, [4]Department of Ophthalmology, University of Helsinki, Helsinki, Finland, [5]Department of Ophthalmology, Kuopio University Hospital, Kuopio, Finland, [6]Research Service Unit, Kuopio University Hospital, Kuopio, Finland, [7]Dasman Diabetes Institute, Dasman, Kuwait, [8]Center for Life Course Health Research, University of Oulu, Oulu, Finland, [9]Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland, [10]Department of Ophthalmology, University of Eastern Finland, Kuopio, Finland.

Background and aims: Diabetic retinopathy may occur at the time of diagnosis of Type 2 diabetes. The Finnish Diabetes Prevention Study was the first individually randomised controlled trial showing that Type 2 diabetes is preventable by changing lifestyles. The aim of the study was to find out whether participation in earlier intervention had an effect on the occurrence of retinopathy in study participants. We also examined risk factors (age, sex, fasting and 2-h glucose, HbA1c, blood pressure, serum lipids) for early retinal changes.
Materials and methods: The study included 522 individuals (mean 55, range 40–64 years) with impaired glucose tolerance who were randomised into intervention (weight loss, healthy diet and physical activity, $N = 265$) and control groups ($N = 257$). Intervention lasted for median of 4 years in 1993–2000, after which annual follow-up visits at study clinics were conducted. In years 2002–2006 (at least 5 years after stopping intervention), fundus photography was offered for all study participants in four of the five study clinics. Photographs were assessed by two experienced ophthalmologists (AA and KK), blinded for the group assignment. After exclusions of poor quality photographs the data of 214 individuals ($N = 114$ for intervention and $N = 100$ for control group) were included in the present study. Statistical comparisons were done by independent samples t-test or Chi-square with Fisher's exact test. Binary logistic regression model was used to examine multivariable adjusted association of risk factors with the risk of microaneurysms. P values <0.05 were set to indicate statistical significance.
Results: The occurrence of retinopathy (microaneurysms) was significantly higher in the control (37/100, 37%) than in the intervention group (27/114, 24%; $p = 0.029$). The only risk factor that predicted the occurrence of microaneurysms was serum triglycerides at baseline (mean ± SD 1.82 ± 0.82 vs. 1.52 ± 0.78, mmol/l, $p = 0.008$, with and without microaneurysms, respectively). In the model including age, sex, diabetes diagnosis before the retinal assessment, BMI and treatment group, the odds ratio for microaneurysms was markedly lower in intervention group (OR 0.53; 0.28–0.98, $p = 0.042$). Interestingly, adding serum triglycerides in the model weakened the association to non-significant level (OR 0.56, $p = 0.076$).
Conclusion: Lifestyle intervention in overweight and obese individuals with impaired glucose tolerance was associated with decreased occurrence of retinal microaneurysms. Elevated serum triglycerides significantly contributed to the development of early diabetic microangiopathy.
Clinical Trial Registration Number: NCT00518167

Frequent physical activity is associated with reduced incidence of severe retinopathy in type 1 diabetes: a prospective FinnDiane Study

H. Tikkanen-Dolenc[1], J. Wadén[1], C. Forsblom[1], V. Harjutsalo[1], L.M. Thorn[1], M. Saraheimo[1], N. Elonen[1], K. Hietala[2], P. Summanen[2], H.O. Tikkanen[3], P.-H. Groop[1];
[1]FinnDiane Study Group, Helsinki, [2]Helsinki University Central Hospital, Helsinki, [3]Clinic for Sports and Exercise Medicine, Helsinki, Finland.

Background and aims: Only a few studies have investigated the relationship between physical activity and diabetic retinopathy in type 1 diabetes. So far, no clear associations have been found. The aim was to study how baseline Leisure-Time Physical Activity (LTPA) and its components (intensity, single-session duration and frequency) are associated with the development of severe diabetic retinopathy during follow-up.
Materials and methods: This is a prospective observational study which is part of the Finnish Diabetic Nephropathy (FinnDiane) Study and the mean follow-up time was 10.7 ± 4.6 years. The study population consisted of 1612 patients with type 1 diabetes. Of the population, 44.7% were men and the duration of diabetes was 18.9 ± 11.7 years. LTPA was assessed at baseline using a validated self-report questionnaire. Severe retinopathy was defined as the initiation of laser treatment due to proliferative retinopathy or diabetic maculopathy or blindness (identified from the Care Register for Health Care).
Results: Of the patients 261 received laser treatment during follow-up. Higher frequency of LTPA was associated with lower incidence of diabetic retinopathy ($p \equiv 0.024$). The finding remained significant after adjustment for gender, duration, age at onset of diabetes, kidney function (eGFR), BMI, triglycerides and systolic blood pressure. When HbA_{1c} and smoking were added to the Cox regression model the association decreased to a non-significant level.
Conclusion: Frequent LTPA was associated with a lower incidence of severe diabetic retinopathy during follow-up. The total amount or the other components of LTPA (intensity or the duration of a single session) were not associated with retinopathy during follow-up.
Disclosure: **H. Tikkanen-Dolenc:** None.

Prevalence of diabetic retinopathy in China: a nationwide survey by AI-based automatic screening system

Z. Sun[1], J. Kuang[2], J. Liu[3], F. Wang[4], N. Wang[4], R. Wang[1], X. Liu[5], Z. Wang[6], Y. Luo[7];
[1]Department of Endocrinology, Zhongda Hospital, Institute of Diabetes, School of medicine, Southeast University, Nanjing, [2]The 4th People's Hospital of Shenyang, Shenyang, [3]Gansu Provincial Hospital, Lanzhou, [4]Beijing Tongren Hospital, Beijing, [5]Beijing Shanggong Medical Technology Co., Ltd, Beijing, [6]Suzhou Metro Health Medical Technology Co., Ltd, Suzhou, [7]Merck Sereno Co., Ltd, Beijing, China.

Background and aims: Diabetic Retinopathy (DR) is one of the major Diabetic Microvascular Complications. With the growing number of DM patients in China, the prevalence of DR has also dramatically increased. Nationwide study showing prevalence of DR in China is limited and current DR prevalence data varies between 24.7–37.5% in T2DM patients. The present study aims to discover accurate DR prevalence nationwide in China. An AI-based automatic screening system, AutoEye, is used to help Chinese endocrinologists to screen and evaluate DR. Prevalence were therefore assessed in 133,905 DM patients.
Materials and methods: In the present project, China Diabetic Retinopathy Screening and Prophylaxis Project, from January 2017 to November 2017, 133,905 DM patients were screened for Diabetic Retinopathy. 65,695 patients were remotely diagnosed by ophthalmologist and 68,210 patients were AI-based automatic diagnosed. 154 hospitals from 24 provinces of China participate in this project. Project is led by Chinese society of microcirculation. All of the patients were screened by retinoscopy. Diagnosis of DR is evaluated by AutoEye system (an AI-based DR screening cloud platform).
Results: Among 133,905 screened DM patients, 50351 i.e. 37.60% of DM patients were found to have DR. Mean age of subjects were 54.83 yr and mean age of DR subjects were 56.20 yr. 51.15% of screened subjects were male, whereas 48.85% were female. 32.92% subjects were from Southern region and 67.08% were from Northern region of China. Per AutoEye, the prevalence of DR in China DM patients were 37.60%. However, there was no significant difference between the prevalence of Southern and Northern area; i.e. 37.15% vs 37.83%. The present study also discovered that prevalence of DR in males and females are comparable. Prevalence of DR and the percentage of severe DR was closely related to patients' fasting plasma glucose level (FPG). For patients whose FPG was over 7%, DR prevalence was close to 46%. Interestingly, DR prevalence was also related to patients' age. DR prevalence was significantly increasing for patients over 43 yr. Therefore, DR screening should be strongly recommended for DM patients, especially those over 43 yr.
Conclusion: DR prevalence in Chinese diabetic patient is as high as 37.60% based on the AI-based automatic screening system. Mid-aged & elderly and not well controlled blood glucose level are risk factors for DR. Early screening is strongly recommended to DM patients especially those over 43 yr.

Screening for retinopathy in Danish children with type 1 diabetes

C. Herskin[1], B. Olsen[1], M. Madsen[2], P. Kjaersgaard[3], S. Fredheim[1], A. Johansen[4], K. Kristensen[5], N.H. Birkebaek[5], J. Svensson[1], K.A. Pilgaard[6], J. Johannesen[1];
[1]Department of Paediatrics, Herlev University Hospital, Herlev, [2]Aalborg University Hospital, Aalborg, [3]Herning Hospital, Herning, [4]Copenhagen University Hospital Rigshospitalet, Copenhagen, [5]Aarhus University Hospital, Aarhus, [6]Nordsjællands Hospital, Hillerød, Denmark.

Background and aims: Children with type 1 diabetes (T1D) should be screened regularly for long-term complications including retinopathy, neuropathy and nephropathy to ensure early detection and appropriate treatment. According to Danish national guidelines, screening for retinopathy should take place at the age of 12, 15 and 18 years after at least 3 years of diabetes. The aim of the study is to investigate the prevalence of retinopathy in children with T1D and to investigate if screening at 12 years of age is indicated in Denmark.
Materials and methods: All Danish children with onset of T1D in the period from 2003–2013 were included in the study ($N = 2943$). Data on retinopathy screenings from fundus photography and annual HbA1c determinations performed from 2003–2017 was retrieved from the Danish national diabetes register, DanDiabKids. The prevalence of retinopathy was determined at age 12, 15 and 18 years. In children with retinopathy, subsequent screenings were studied to reveal if retinopathy was persistent or temporary.
Results: The cohort comprised 2943 children of which 81.2% were screened at least once. Retinopathy was demonstrated in 3.1% of children who underwent screening. Of those with retinopathy 73.0% had unilateral changes and 94.6% had minimal background retinopathy (grade 1). For children with retinopathy, mean HbA1c was 73.8 ± 18.3 mmol/mol at time of first occurrence of a pathological retinopathy status. At 12 years, 1277 children were screened and retinopathy was identified in 11 children (0.9%) with mean HbA1c of 66.7 ± 9.8 mmol/mol. None presented with more than grade 1 retinopathy. Ten out of eleven children were re-screened and no retinopathy could be demonstrated at re-screening. At 15 years, retinopathy was demonstrated in 37 (2.3%) out of 1640. Mean HbA1c of those with retinopathy was 68.9 ± 17.1 mmol/mol. Nineteen of these children underwent subsequent screenings and five (26.3%) had

persistent retinopathy. At 18 years, 26 (3.1%) of 848 had retinopathy changes. Mean HbA1c was 82.6 ± 19.5 mmol/mol. 33% had persistent retinopathy. For children older than 18 years, 2 (4.4%) out of 45 had retinopathy. Mean HbA1c was 80.5 ± 10.6 mmol/mol. For the whole group of children with retinopathy, 33 were screened again and 7 (21.1%) had persisting retinopathy.

Conclusion: The overall prevalence of retinopathy in Danish children with T1D was 3.1% for all ages together. For children screened at 12 years, the prevalence of retinopathy was 0.9% and all had minimal background retinopathy. The changes were found to be temporary in those who were re-screened. Based on these results, we find no absolute indication to screen Danish children with T1D at 12 years of age for retinopathy. We propose an individualized approach for retinopathy screening at the age of 12 and for the national retinopathy screening program to begin at the age of 15 years.

Diabetic retinopathy in children and young people with type 1 diabetes in Wales

R.L. Thomas, J.M. Rafferty, S.D. Luzio, D.R. Owens;
Diabetes Research Unit Cymru, Swansea University, Swansea, UK.

Background and aims: Screening programmes for diabetic retinopathy (DR) were introduced in the UK from 2003 onwards. Annual screening from the age of 12 years was recommended by the Royal College of Ophthalmologists. In Wales, there is a single national community-based screening programme (Diabetic Eye Screening Wales, DESW) which screens all those with diabetes registered with a GP in Wales. We report the DR screening results for those Children and Young People (CYP) with type 1 diabetes aged <18 years undergoing screening for DR in Wales.

Materials and methods: The DESW employs standardised quality assured image capture and grading protocols. Canon DGi cameras are used to capture 2x45^{o} digital images per eye following mydriasis. Grading is performed by trained graders using the DESW standard grading protocol. Referable DR (RDR) is the level at which further assessment by hospital-based ophthalmologists is required and includes pre-proliferative DR (PPDR), proliferative DR (PDR) and exudative maculopathy. Data (age, gender, duration of diabetes and retinopathy grade) of CYP screened (2,347) between 2009 and 2017 were extracted from the DESW database This was linked with data (HbA_{1c}, blood pressure, cholesterol level, creatinine and BMI) from primary care.

Results: A total of 2,347 CYP (1,222 Male) were screened with a total of 10,375 screening events. At first screening the mean (SD) age was 15.2 (2.2) years, duration of diabetes median (IQR) was 5.0 (2.4–8.7) years, HbA_{1c} 79.1 (22.5) mmol/mol, systolic blood pressure 119.1 (13.8) mmHg, diastolic blood pressure 70.3 (8.8) mmHg and BMI 23.5 (4.5) kg/m^2. Of the 2,347 invited for screening 504 (21.4%) did not attend. Those who attended 1,331 (72.1%) did not have evidence of DR and 285 (15.4%) had background DR. 3 (0.2%) had RDR and a similar number 3(0.2) required referral for other eye lesions. Additionally, of those 1,331 people without DR a total of 153 (11.5%) progressed to DR during the study, developing background DR firstly with 19 (1.4%) subsequently developing RDR and 22 (1.7%) requiring referral (DR and other lesions). Of those who had DR (438) during the study DR developed at ages 12, 13, 14, 15, 16 and 17 years (in 39 [8.9%], 32 [7.3%], 48 [11.0%], 74 [16.9%], 103 [23.5%] and 142 [32.4%] respectively). The final logistic regression model after removal of non-significant variables retained duration of diabetes, HbA_{1c} and diastolic blood pressure. The presence of DR was associated with an increased duration of diabetes (OR1.27 95% CI 1.22, 1.32), increased HbA_{1c} (OR 1.03 95%CI 1.02, 1.04) and diastolic blood pressure (OR 1.03 95%CI 1.01, 1.04) after adjustment.

Conclusion: Almost 10% of DR detected occurred in those aged up to 12 years but with the majority (67.6%) occurring in those under the age of 17 years. However, only 1.2% had developed RDR by the end of the study period requiring referral and an additional 0.3% for other eye lesions. The risk of developing DR increased with increasing duration of diabetes, glycaemic control and diastolic blood pressure. More effort should be made to ensure early screening with emphasis on the importance of screening as well as enabling CYP with type 1 diabetes to understand the risks of developing and promoting healthy lifestyles.

Incidence of diabetic retinopathy in newly diagnosed subjects with type 2 diabetes over 5 years: contribution of beta cell function

S. Roy Chowdhury[1], R.L. Thomas[2], G.J. Dunseath[2], S. Luzio[2], F.S. Wong[3], D.R. Owens[2];
[1]Diabetes and Endocrinology, Princess of Wales Hospital, Bridgend, [2]Diabetes Research Unit Cymru, Swansea University Medical School, Swansea, [3]Centre for Endocrine and Diabetes Science, Cardiff University School of Medicine, Cardiff, UK.

Background and aims: Identifying risk factors in development of Diabetic Retinopathy (DR) is essential to prevent visual impairment in type 2 diabetes (T2DM). Prolonged hyperglycaemia is acknowledged as the main risk factor, represented by HbA1c, fasting plasma glucose (FPG) and to a lesser extent 2 hour post-prandial plasma glucose (PPG). The relationship with indices of β cell function remains inadequately addressed. This study aims to examine incident DR over 5 years in persons with newly-diagnosed treatment naïve T2DM with no DR at diagnosis.

Materials and methods: 233 T2DM participants were screened for DR (digital photography) and had a standardised Meal Tolerance Test (MTT) at baseline and 1, 2 and 5 years post diagnosis involving serial plasma glucose and insulin levels over 4 hours. Fasting (M_0) and postprandial (M_1) β cell responsiveness were estimated (Calculating Pancreatic Response (CPR) Program) along with HOMA-B. We compared subjects with no DR (NDR) throughout the 5 years ($n = 179$) with those who developed DR ($n = 54$). Following comparison of means of the two groups, the putative risk factors were evaluated using logistic regression methods. Multivariate analyses were adjusted for age, gender, BMI, systolic blood pressure and total cholesterol using SPSS 20 ($p < 0.05$ taken as statistically significant). We also calculated the average exposure to all measured metabolic variables (Mean) as an indicator of diabetes control over the 5 year study period.

Results: Of 233 subjects, 145 male, 88 female, mean age (SD) 54(9) years, 76.8% (179) never developed DR with 23.2% (54) developing DR during 5 years post diagnosis. 22% developed background DR after 1 year, 28% after 2 years and 50% after 5 years. All with DR at Year 5, when compared to those without, had at diagnosis a higher HbA_{1c} ($p = 0.017$) and during MTT a higher FPG ($p = 0.031$) with a reduced basal ß cell secretory function, M_0 ($p = 0.025$) and HOMA-B ($p = 0.044$). In the postprandial state, those with DR at Year 5 had a higher PPG ($p = 0.009$) associated with a significantly lower estimated β cell responsiveness: M_1 ($p = 0.000$). The contribution of fasting, postprandial, overall glycaemia and β cell function at diagnosis and over 5 years to incident DR are represented in the attached table.

Conclusion: We established an independent association between $HbA_{1c,}$ FPG and PPG, both at diagnosis and over the 5 years period, with incident DR. β cell function, fasting (M_0 and HOMA-B) and postprandial (M_1) also at diagnosis and over 5 years were independently associated with DR development. Our data further emphasizes the contribution of overall glycaemiac exposure (HbA1c) and postprandial hyperglycaemia to the risk of developing DR within 5 years of diagnosis. A reduced ß cell function is a significant contributor to this risk of developing DR.

Table: Univariate and Multivariate logistic regression depicting variables independently associated with development of Diabetic Retinopathy by 5 years from diagnosis of T2DM.

		Univariate		Multivariate	
	Number	Crude OR (95% CI)	p	OR (95% CI) (fully adjusted **)	p
HbA1c (%)	233	4.27 (1.21, 15.13)	**0.024**	4.48 (1.26, 15.96)	**0.021**

The association between C-peptide levels and the transition to referable retinopathy in patients with type 1 diabetes

A. Ochs[1], S.J. McGurnaghan[1], L.A.K. Blackbourn[1], P.M. McKeigue[2], H.M. Colhoun[1], on behalf of the SDRNT1BIO Investigators;
[1]Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, [2]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, UK.

Background and aims: Type 1 diabetes mellitus (T1DM) involves the autoimmune destruction of pancreatic β-cells. Research over the recent years using C-peptide levels, a well-established marker of endogenous insulin secretion levels, has challenged the dogma that T1DM is associated with complete destruction of pancreatic β-cells and established that a number of patients have detectable C-peptide levels. Previous research has shown associations between C-peptide levels, risk of hypoglycaemia and glucose management. The consequences of C-peptide persistence on diabetes complications are less well known. This study examines the association between C-peptide levels and the subsequent progression to referable diabetic retinopathy (DR), in a large cohort of T1DM patients.
Materials and methods: This study used a large population representative sample with T1DM, the Scottish Diabetes Research Network Type 1 Bioresource (SDRNT1BIO), in whom biosamples have been collected and who have been linked to electronic health care records and diabetic retinopathy screening data. C-peptide levels of individuals were measured on a single random measure at recruitment. The lower limit of detection of C-peptide was 3 pmol/l. Screening information was obtained from the routine screening data within the Scottish Diabetic Retinopathy Screening Programme, which has invited every diabetes patient in Scotland aged 12 and older for regular screening since 2007. Generalised linear regression techniques with complementary loglog link function for interval-censored data were used to assess the effect of (i) C-peptide persistence and (ii) C-peptide levels on transition to referable DR. Models were adjusted for previous DR grade, age at diagnosis, diabetes duration, HbA1c, total cholesterol and systolic blood pressure at recruitment. The effects of C-peptide was assessed by comparing a model excluding and including C-peptide using a Likelihood-Ratio (LR) Test.
Results: Out of the 6127 participants in SDRNT1BIO, 4595 patients attended at least two DR screenings and did not transit to a referable DR state before their recruitment. 4486 patients had a measure of C-peptide reported. The analysis was based on 18348 screenings for these patients. The absence of detectable levels of C-peptide was statistically significantly associated with increased risk of transition to referable DR (OR 1.191, LR $p < 0.05$). The graph suggests further that an increase tends to reduce the risk of transition to referable DR, however the relationship is not clear cut and a threshold of no further protection from C-peptide is not clearly apparent.
Conclusion: This study showed that C-peptide is significantly associated with transition to referable DR, a threshold of protective C-peptide levels needs to be detected.

Neuroretinal versus vascular changes in patients with type 2 diabetes compared to healthy controls

S. Jung[1], A. Bosch[2], N. Kohler[2], C. Ott[2,3], D. Kannenkeril[2], T. Dienemann[2], J.M. Harazny[2,4], G. Michelson[5], R.E. Schmieder[2];
[1]Cardiology, Friedrich-Alexander-University, Erlangen-Nuremberg, Germany, [2]Nephrology and Hypertension, Friedrich-Alexander-University, Erlangen-Nuremberg, Germany, [3]Nephrology and Hypertension, Paracelsus Medical School, Nuremberg, Germany, [4]Pathophysiology, University of Warmia and Mazury, Olsztyn, Poland, [5]Ophthalmology, Friedrich-Alexander-University, Erlangen-Nuremberg, Germany.

Background and aims: Optical coherence tomography (OCT) has evolved into an accurate and reliable high-resolution imaging technique for the measurement of retinal layer thickness in a variety of metabolic and neurological disorders. The aim of the present study was to characterize neuroretinal alterations in patients with early type 2 diabetes mellitus (T2DM) determined by spectral-domain (SD-) OCT as opposed to early vascular changes evaluated by arteriovenous ratio (AVR).
Materials and methods: In a prospective, cross-sectional, observational single center study we included a total of 73 subjects - 35 patients with early T2DM and 38 healthy controls. Clinical characteristics of all participants were obtained and fasting plasma glucose, HbA1c and other biochemical parameters were measured. To determine possible neurodegenerative retinal changes related to T2DM, retinal layer thicknesses including circular scans of the retinal nerve fiber layer (RNFL) of both eyes were measured by SD-OCT. Additionally, AVR as a maker of retinal arteriolar narrowing was determined by fundus photography.
Results: The group of patients with T2DM consisted of 12 female (34%) and 23 male (66%) patients aged 61.6 ± 6.9 years with an average HbA1c of 6.8 ± 0.9%, fasting plasma glucose of 135.3 ± 36 mg/dl and an average T2DM duration of 6.87 ± 5.9 years. The group of healthy controls included 28 female (74%) and 10 male (26%) subjects aged 57.9 ± 10 years. Age-adjusted inner retinal layer (comprising RNFL, ganglion cell layer and inner plexiform layer thickness) was thicker in patients with T2DM than in the group of healthy controls (6.46 ± 0.42 vs. 6.27 ± 0.38 mm³,

$p = 0.032$) as was total retinal thickness (8.70 ± 0.43 vs. 8.51 ± 0.41 mm³, $p = 0.037$). Mean AVR was lower among patients with T2DM compared to controls (0.769 ± 0.10 vs. 0.827 ± 0.06, $p = 0.042$). After adjustment for age and gender, the above mentioned differences in inner retinal layer thickness ($p = 0.100$) and total retinal thickness ($p = 0.101$) disappeared, whereas the difference in AVR between the two groups stayed significant ($p = 0.009$). A subanalysis of the 22 male subjects with T2DM (compared to male healthy controls) revealed a higher thickness of the circular RNFL scans in the temporal right (78.19 ± 12.84 vs. 68.90 ± 9.53 μm, $p = 0.034$) and temporal superior left sectors (138.0 ± 9.94 vs. 123.50 ± 19.60 μm, $p = 0.048$). There were no significant differences in other retinal layers or total RNFL thickness among the two subgroups, whereas AVR was lower in the group of male T2DM patients (0.778 ± 0.06 vs. 0.840 ± 0.07, $p = 0.033$).

Conclusion: In our patients with T2DM (early stage of disease, well-controlled) we observed a lower AVR than in elderly healthy controls whereas no clear signal of neurodegeneration, visualized by retinal layer thickness measurement, was detected. Our findings indicate that vascular changes precede neuronal retinal changes in patients with early T2DM. Nevertheless, evaluation of RNFL thickness by means of SD-OCT may emerge as a new and attractive option to assess neuroretinal changes during disease progression.

Functional analysis of miRNAs shuttled by extracellular vesicles from diabetic subjects reveals their role in diabetic retinopathy

A. Mazzeo, E. Beltramo, C. Gai, T. Lopatina, M. Trento, M. Porta; Dept. of Medical Sciences, University of Turin, Torino, Italy.

Background and aims: Extracellular vesicles (EVs) derived from mesenchymal stem cells cultured in diabetic-like conditions enter the pericytes, causing their detachment and migration, and stimulating angiogenesis. Diabetic patients have different EV patterns in comparison with healthy subjects. In particular, our data suggest a role for miR-150-5p, miR-21-3p and miR-30b-5p as putative biomarkers of the onset and development of diabetic retinopathy. The functional KEGG pathways of these 3 miRNAs showed that they are involved in pathways strictly correlated to the dysfunctions occurring in the early phases of retinopathy, such as adherents junctions, ECM-receptor interactions, TGF-β signaling. In this work, we aimed at further investigating the functional role of the 3 miRNAs on the homeostasis of retinal microvascular cells and characterizing EVs derived from diabetic subjects with/without retinopathy by mRNA content analysis.

Materials and methods: EVs were extracted from plasma of 7 type-1 diabetic subjects with severe retinopathy (DR, gender: 3F/4M, age 39.3 ± 5.9, disease duration 28.0 ± 12.8), age- and gender-matched with 7 healthy controls (CTR, gender: 3F/4M, age: 41.0 ± 10.6) and 7 diabetic subjects without retinopathy (noDR, gender: 3F/4M, age: 46.1 ± 11.7, disease duration: 27.3 ± 14.2). As we found miR-21-3p and miR-30b-5p increased, and miR-150-5p decreased in EV of DR patients, human retinal pericytes (HRP) and endothelial cells (HMEC) were transfected with mimics or inhibitors, as appropriate, of the 3 miRNAs, to evaluate their functional role in angiogenesis (vessel-like formation assay) and migration of retinal microvascular cells. Furthermore, EV expression of genes involved in angiogenesis was measured by *Human Angiogenesis RT² Profiler PCR Array* and confirmed by qRT-PCR and Western blotting (WB).

Results: After 48 hrs from transfection, modulation of miRNA expression increases migration in microvascular cells and vessel formation *in vitro*, confirming that the 3 miRNAs are involved in angiogenesis. mRNA analysis revealed different expression of 7 genes involved in angiogenesis in the 3 groups, while subsequent qRT-PCR and WB confirmed decreased expression of angiopoietin-1 (involved in vessel stabilization) and increased expression of the pro-angiogenic HIF-1α in DR vs CTR.

Conclusion: In conclusion, the analysis of EV mRNA content reveals differences between diabetic patients with microvascular complications, and healthy controls. miR-150-5p, miR-21-3p and miR-30b-5p, differentially expressed in EVs from DR patients and controls, seem to be related to diabetic retinopathy by inducing features of retinopathy in *in vitro* models of retinal microvasculature. These miRNAs might be taken into account as potential biomarkers of the onset/development of the disease and considered as specific targets for the prevention of this complication.

The SRPK1 inhibitor SPHINX31 stabilises retinal permeability in models of diabetes

K.P. Arkill, N. Malhi, C.L. Allen, K. Horton, J. Batson, D.O. Bates; University of Nottingham, Nottingham, UK.

Background and aims: In diabetic retinopathy (DR) microvascular damage results from ischaemia driven production of pro-angiogenic vascular

endothelial growth factor (VEGF) inducing angiogenesis and increased permeability in the retina. Small molecular inhibitors of serine-rich protein kinase-1 (SRPK1) have been shown to inhibit choroidal neovascularisation in mice by decreasing pro-angiogenic and increasing anti-angiogenic VEGF isoforms. SRPK1 inhibitors such as SPHINX31 may therefore switch splicing in DR and prevent increased vascular permeability of both the junctions or the endothelial glycocalyx.

Materials and methods: Retinal pigment epithelial (RPE) cells were exposed to either normoglycaemia (NG, 7.5mM) or hyperglycaemia (HG, 37.5mM) under normoxic (Nx, 20% O_2) or hypoxic (Hx, 1% 0_2) conditions with and without SPHINX31 (1 μM and 3 μM). SRPK1 activity and monolayer permeability were assessed by immunofluorescence and Electric Cell-substrate Impedance Sensing (ECIS). Fluorescent fluorescein angiography (FFA) was performed in streptozotocin induced diabetic Norway Brown rats ($n = 12$, 250–300 g) on day 0 and 7, using the Micron IV retinal microscope (Phoenix Technology Group, US). Animals received twice daily topical eye drops of eye formulation control buffer ($n = 5$) or SPHINX31 (200 μg/ml, $n = 6$). The ratio of interstitial to vascular fluorescence was calculated and plotted against time to determine an estimate of permeability.

Results: The ratio of nuclear to cytoplasmic SRSF1 increased significantly ($p < 0.05$) in cells treated with HG from 5.03 (NG) to 6.12 (HG). Hx induced a further increase ($p < 0.05$) to 7.25. SPHINX31 blocked these increases at both 1 μM and 3 μM whilst having no effect on the normoglycaemic, normoxic cells. Expression of tight junctional protein ZO-1 was decreased in Hx ($p < 0.001$). Inhibition of SRPK1 increased impedance across a RPE monolayer in NG and not HG. Retinal permeability was shown to significantly increase ($p < 0.01$) on day 7 $(12.67 \pm 1.09) \times 10^{-4}$ cm^{s-1} compared to day 0 $(8.85 \pm 1.29) \times 10^{-4}$ cm^{s-1} in the eye formulation control group. Following a weekly regimen of twice daily topical eye drop treatment with SPHINX31 retinal permeability stabilised on day 7 $(7.92 \pm 1.65) \times 10^{-4}$ cm^{s-1} compared to day 0 $(8.15 \pm 2.33) \times 10^{-4}$ cm^{s-1} and the control group. Our preliminary immunofluorescence results on retinal and choroidal endothelial cells also agree with the literature that there is a loss of both endothelial glycocalyx and ZO-1 proteins.

Conclusion: SPHINX31 protected the retinal endothelial permeability barrier from diabetes-associated loss of integrity and reduced the progression. SPHINX31 may therefore be a potential alternative and more specific topical therapeutic for DR.

Thiamine transporter-2 is involved in high glucose-induced damage and altered thiamine metabolism in cell models of diabetic retinopathy

E. Beltramo, A. Mazzeo, M. Porta;
Dept Medical Sciences, University of Turin, Torino, Italy.

Background and aims: High glucose-induced damage in microvascular cells *in vitro* and progression of retinopathy and nephropathy in diabetic animals are prevented by thiamine supplementation. Impaired thiamine availability facilitates metabolic damage, and renal loss of this vitamin is described in diabetic patients. Two SNPs located in the SLC19A3 gene encoding for the thiamine transporter-2 (ThTR-2) are associated with resistance to development of proliferative diabetic retinopathy and end-stage renal disease in type 1 diabetic subjects, but the mechanisms of these protective effects remain to be understood. We previously showed that diabetic-like conditions modulate ThTR-2 expression in human retinal cells. Our aim was to further investigate the involvement of the two thiamine transporters ThTR-1 and ThTR-2 and their transcription factor Sp1 in high glucose-induced damage and altered thiamine metabolism in cell models mimicking the diabetic retinopathy microenvironment.

Materials and methods: Human retinal pericytes (HRP), human microvascular endothelial cells (HMEC) and human Müller cells (MIO-M1) were cultured for 8 days in physiological glucose (NG), stable high glucose (HG) or intermittent high glucose (intHG). Cells were also cultivated in thiamine-deficient medium (noT) or high thiamine conditions (HT), to evaluate substrate influence. Transketolase (TK) activity and intracellular thiamine concentration were studied through metabolic assays, and cellular localization of the transporters by immunofluorescence staining (IF). To better mimic the retinal microenvironment and the complex intercellular exchanges, triple co-cultures were established. ThTR-1, ThTR-2 and Sp1 mRNA and protein expression were checked by RT-PCR and Western blotting.

Results: TK activity and intracellular thiamine were markedly decreased in HRP and HMEC cultured in noT, as expected, and increased in HRP cultured in HT. Increased intracellular thiamine and TK activity were found in MIO-M1 cultured in HG and intHG and, surprisingly, in HG and intHG without thiamine. IF staining evidenced cytoplasmic localization of ThTR-1 and Sp1 in all cell types. ThTR-2 showed a characteristic nuclear speckle distribution in HRP and MIO-M1, while in HMEC it was uniformly distributed in the cytoplasm. As regards co-culture models, ThTR-1 and Sp1 expression were unchanged in all cell types regardless of treatment, whereas ThTR-2 mRNA and protein expression were decreased in HRP, HMEC and MIO-M1 cultured in HG and intHG conditions, showing differences from data in single cultures.

Conclusion: Down-regulation of ThTR-2 in co-culture models mimicking the diabetic retinal microenvironment suggests its major role in thiamine transport in retinal cells and its involvement in high glucose-induced damage and impaired thiamine metabolism. As expected, altered thiamine supplementation influences TK activity. The increased intracellular thiamine and TK activity in Müller cells following deficient thiamine supplementation may be interpreted as an adaptive mechanism of these cells to counteract lack of substrate.

Effects of topical administration of SOCS1-derived peptide on retinal neuroinflammation and vascular leakage in experimental diabetes

C. Hernández[1], P. Bogdanov[1], C. Gómez-Guerrero[2], J. Sampedro[1], C. Solà-Adell[1], M. García-Ramirez[1], J. Egido[2], R. Simó[1];
[1]Vall d'Hebron Reserach Institute, UAB and CIBERDEM, Barcelona, [2]IIS Fundación Jiménez Díaz, UAM and CIBERDEM, Madrid, Spain.

Background and aims: Current treatments for diabetic retinopathy (DR) target late stages when vision has already been significantly affected. Accumulating evidence suggests that neuroinflammation plays a major role in the pathogenesis of DR, resulting in the disruption of the blood-retinal barrier, the main cause of diabetic macular edema. Suppressors of cytokine signaling (SOCS) are cytokine-inducible proteins that function as a negative feedback loop regulating cytokine responses. On this basis, the aim of the present study was to evaluate the effect of a SOCS1-derived peptide administered by eye drops (2 weeks) on retinal neuroinflammation and early microvascular abnormalities in db/db mouse model.

Materials and methods: SOCS1-derived peptide (10 mg/ml; 5 μl twice/daily) ($n = 10$) or vehicle (PBS; 5 μl twice/daily) ($n = 10$) eye drops were administered directly onto the superior corneal surface of each eye using a micropipette in 8 week-old db/db mice. Ten non-diabetic mice (db/+) matched by age served as the control group. The treatment (SOCS1-derived peptide or vehicle) was administered twice daily for 15 days. Retinal analyses were performed *in vivo* by electroretinography and *ex vivo* by using RT-PCR, Western blot and immunofluorescence measurements. Glutamate was quantified by HPLC. In addition, vascular leakage was examined by the Evans blue method.

Results: We found that SOCS1-derived peptide significantly reduced glial activation and neural apoptosis induced by diabetes, as well as retinal

levels of proinflammatory cytokines. Moreover, a significant improvement of electroretinogram parameters was observed, thus revealing a clear impact of the histological findings on global retinal function. Finally, SOCS1-derived peptide prevented the disruption of the blood-retinal barrier.
Conclusion: Our results suggest that topical administration of SOCS1-derived peptide is effective in preventing retinal neuroinflammation and early microvascular impairment. These findings could open up a new strategy for the treatment of early stages of DR.

δ opioid receptor agonism preserves the outer retina barrier in an experimental model of diabetic retinopathy: a novel therapeutic approach to treat diabetic macular edema

D.A. Duarte[1], R. Simó[2], M. García-Ramirez[2], J.B. Lopes de Faria[1], J.M. Lopes de Faria[1];
[1]Faculty of Medical Sciences, State University of Campinas (UNICAMP), Campinas, Sao Paulo, Brazil, [2]Vall d'Hebron Research Institute (VHIR) and CIBERDEM, Barcelona, Spain.

Background and aims: Macular edema is a common vision-threatening feature in patients with diabetic retinopathy (DR). Diabetic macular edema (DME) is frequently resistant to corticoid or anti-angiogenic agent treatments. Previously, we demonstrated that the agonism of the δ opioid receptor (DOR) by epicatechin (a potential scaffold for the opioid receptor ligands of the C2 and C3 positions of the epicatechin molecule) preserves the tight junction proteins in ARPE-19 cells under diabetic conditions. The aim of this study was to investigate whether the agonism of δ opioid receptor (DOR), preserves the outer blood-retinal barrier (BRB) in experimental model of diabetic retinopathy.
Materials and methods: C57BL mice were experimentally induced diabetes through streptozotocin and treated with (−)-epicatechin (used as a δ opioid receptor-agonist) in drinking water for 12 weeks ($n = 13$). To better demonstrate the possible role of the DOR in the observed effects of epicatechin, diabetic mice ($n = 13$) were underwent to intravitreous injection shRNA-DOR (10^8 TU/ml) and randomized to receive or not oral epicatechin in drinking water (aproximately 2.3 g/Kg/day). At the end, the animals were euthanized, the eyes enucleated and the retinas extracted. Human postmortem eyes were obtained from diabetic ($n = 7$) and non-diabetic donors ($n = 7$) matched by age. To be included in this study, an ophthalmoscopic examination documenting the absence of microvascular abnormalities associated with diabetic retinopathy or only mild non-proliferative diabetic retinopathy must have been performed within 2 years prior to the individual's death.
Results: The expression of DOR was demonstrated in retinal tissue in RPE and inner plexiform layers and did not change in presence of diabetes or with treatment with epicatechin. The treatment with DOR agonist prevented the upregulation of the early markers of DR (GFAP, VEGF) and the downregulation of PEDF, and tight junction proteins occludin, claudin-1 and ZO-1 ($p < 0.01$). The reduction of about 30% in DOR protein in diabetic mice submitted to intravitreous shRNA-DOR expression abolished partially the protective effects of epicatechin in DR markers and outer BRB tight junction proteins. The preservation of the RPE function observed in diabetic mice treated with oral epicatechin led to increase of the endogenous anti-angiogenic factor PEDF ($p < 0.0001$), counterbalancing the increase of VEGF levels ($p < 0.0001$). In human retina specimen, we did not found any significant difference between diabetic and non-diabetic human donors in protein content and mRNA levels of DOR in RPE or neuroretina samples. The immunohistochemistry images revealed that DOR is located in human retina mainly in RPE and inner retinal layers.
Conclusion: This set of experiments strongly indicates that (−)-epicatechin preserves the functions of the RPE and reduced the early markers of DR through the DOR agonism in diabetic retinal tissue. These novel findings designate DOR as a potential therapeutic tool to treat DR, especially diabetic macular edema.

Glucosamine is neuroprotective in diabetic retina

R. Eshwaran[1], M. Kolibabka[2], K. Kohl[2], H.-P. Hammes[2], T. Wieland[1], Y. Feng[1];
[1]Experimental Pharmacology, European Center of Angioscience, Medical Faculty Mannheim, Heidelberg University, Mannheim, [2]5th Medical Clinic, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany.

Background and aims: Diabetic retinopathy occurs in over 80% of patients suffering from diabetes for more than 20 years and is one of the leading causes of blindness in adults. Hyperglycemia hampers not only the vascular but also the neuronal function in diabetic retinopathy. Glucosamine is a hexose sugar that might be involved in glucose metabolism via the hexosamine pathway. Glucosamine exhibits anti-inflammatory and anti-oxidative effects and participates in the modulation of endothelial cell activation. It is widely used as an oral supplement in patients with osteoarthritis. The effect of glucosamine is still controversial. In this study, we compared the effects of glucosamine in the mouse retina under non-diabetic and diabetic conditions.
Materials and methods: Diabetes was induced by i.p. injection with streptozotocin in 8-week-old wild type and NDPK-B KO mice, which mimic the obvious vascular degeneration without neuronal degeneration. The mice were treated with glucosamine from 9 weeks of age on, and analyzed at 6 months. Optical Coherence Tomography (OCT) was performed to analyze retinal thickness and electroretinogram (ERG) was used to analyze the neuronal function. Retinal morphometry was assessed in retinal digest preparations.
Results: Glucosamine did not alter blood glucose and HbA1c levels, which were elevated in diabetic animals. A significant increase in body weight was seen in wild type non-diabetic animals treated with glucosamine compared with control wild type animals. In diabetic wild type and NDPK-B KO mice, treatment with glucosamine did not change the body weight. No change in food and water intake of the mice was observed with glucosamine treatment. Retinal thickness did not differ between any of the groups upon analysis with OCT. There was no alteration in the a-wave of the ERG after glucosamine treatment in wild type and NDPK-B KO retinas. However, glucosamine treatment was able to rescue the loss of the b-wave seen in diabetic wild type animals compared with non-diabetic controls. Glucosamine did not impact the b-wave in NDPK-B KO retinas. Pericyte loss and formation of acellular capillaries were not altered in non-diabetic and diabetic wild type retinas after treatment. In NDPK-B KO retinas, the formation of acellular capillaries was significantly increased, while pericyte numbers showed no change after glucosamine treatment. The ratio of endothelial cells to pericytes was increased in non-diabetic and diabetic retinas after glucosamine treatment in both wild type and NDPK-B KO retinas.
Conclusion: Our results suggest that glucosamine is neuro- but not vasoprotective in the diabetic retina.

H3K36me3 associated pericyte loss in early diabetic retinopathy

K. Kohl, M. Kolibabka, P. Friedrichs, H.-P. Hammes;
5th Medical Department, Medical Faculty Mannheim, University of Heidelberg, Mannheim, Germany.

Background and aims: Pericyte loss is one of the earliest vascular signs of diabetic retinopathy. Capillaries are hereby destabilized leading to vasoregression during the course of the disease. Gene expression changes of microarray analyses of a streptozotocin-induced diabetic mouse model point towards a distinct state of H3K36 trimethylation in the retina as early as six weeks of diabetes. The epigenetic modification H3K36me3 regulates chromatin transcription and occurs on constituous as well as facultative heterochromatin. The exact mechanisms for pericyte dropout and incipient diabetic retinopathy are not yet fully understood and need further clarification. We investigated H3K36me3 as an early mechanism in relation to pericyte loss.
Materials and methods: Pericyte numbers were determined in retinal digests by quantitative morphometry. H3K36me3 was measured photometrically in an immune-based assay.
Results: After 12 weeks of STZ-Diabetes, pericyte count of diabetic animals was lower than in normoglycemic animals (NC: 1571 ± 69.80 vs. DC: 1978 ± 93.52; $p < 0.01$; [pericytes/mm^2]; $n = 6$). After six weeks of STZ-diabetes, levels of H3K36me3 were higher in diabetic than in normoglycemic mice persisting until week 12 (6 w: 1.69 vs. 1.00; $p < 0.0001$; 12 w: 2.69 vs. 2.18; $p < 0.05$; [fold change of NC 6 w]; $n = 6$). These findings suggest that H3K36me3 is changed early during experimental diabetic retinopathy, which could lead to more severe signs of the disease.
Conclusion: Further investigations will assess the pericyte status in this animal model after six weeks to establish a timely correlation between H3K36 trimethylation and pericyte loss in early diabetic retinopathy.

Exposure of embryonic retinal cultures to starvation unravels early neurovascular mechanisms responsible for later effects in diabetic retinopathy

R. Jain[1], T. Özgümüs[2], A. Fedotkina[2], A. Zhydenko[3], I. Artner[1], V. Lyssenko[1,2];
[1]Diabetes and Endocrinology, Department. of Clinical Sciences, Lund University Diabetes Center, Malmö, Sweden, [2]Department of Clinical Science, KG Jebsen Center for Diabetes Research, University of Bergen, Bergen, Norway, [3]Chernihiv Regional Hospital, Chernihiv, Ukraine.

Background and aims: Diabetes retinopathy (DR) is a progressive disease leading to severe vision impairment and blindness. It is characterized by elevated vascular endothelial growth factor (VEGF) levels, which then alters the vascular tone (non-proliferative DR) and increases angiogenesis (proliferative DR). Although anti-VEGF therapies have been very successful in stopping the progression of DR at the proliferative DR stage, there are no drugs available to stop the progression of DR in the non-proliferative stage. Search for novel treatment modalities has not been easy, as precise molecular mechanisms by which, metabolic risk factors accelerate retinal damage are not fully elucidated. In particular, the early changes in the neurovascular unit are not well described.
Materials and methods: To study early effects of energy deficits, we developed a model of starvation exposure in retinal cultures from E18.5 embryos. We used short-term (6 hours) exposure to starvation in the *in vitro* model from the primary rodent retina. The retinal cells were after that cultured under normal physiological conditions in order to investigate long-term changes. The effects were assessed on the mRNA levels of genes involved in growth and glucose metabolism. Starvation-induced changes in transcriptomics and morphology of neurons were studied.
Results: As a validation of the model, RT-QPCR analyses showed that, immediately after starvation (short-term effects), the mRNA expression of *Vegf* and *Vegfr2* ($p < 0.05$) (expressed on neurons) was significantly upregulated compared to non-starved control retinal cultures. When starved embryonic retinal cultures were cultured for 6 days under normal physiological conditions (long-term effects), *VegfA* expression remained elevated ($p < 0.01$), while *Vegfr2* was significantly reduced ($p < 0.01$). Short-term exposure to starvation resulted in upregulation of *Glut1*, *Hif1a*, *Ppargc1a* and *Ppargc1b* genes involved in glucose, hypoxia and mitochondrial metabolism ($p < 0.01$), while downregulation of *Txnip* as compared to control retinal cultures ($p < 0.01$). After exposure was removed, expression of *Hif1a*, *Ppargc1b* and *Txnip* returned to that observed in controls, but *Ppargc1a* was significantly downregulated ($p < 0.01$). We also measured the lengths of axons in the retinal cultures. Short-term exposure had significant inhibiting effect on the length of the longest neurite (by 11 nm), while long-term effects showed significantly shorter mean total axonic length of starved retinal neurons (by 3.7 nm) ($p < 0.01$).
Conclusion: Our results demonstrate that an *in vitro* model of embryonic retinal culture, exposed to starvation may unravel early mechanisms involved in the pathogenesis of diabetes retinopathy.

PS 091 Biomarkers of nephropathy

995

Biomarkers associated with early stages of kidney disease in adolescents with type 1 diabetes

M.L. Marcovecchio[1], M. Colombo[2], R.N. Dalton[3], P.M. McKeigue[2], H.M. Colhoun[4], D.B. Dunger[1];
[1]Department of Paediatrics, University of Cambridge, Cambridge, [2]Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, [3]Guy's and St Thomas' NHS Foundation Trust, London, [4]MRC Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK.

Background and aims: To identify biomarkers associated with glomerular filtration rate (GFR) and urinary albumin-creatinine ratio (ACR) in a cohort of young people with type 1 diabetes (T1D) recruited into the Adolescent Type 1 diabetes cardio-renal Intervention Trial (AdDIT).
Materials and methods: Biomarkers were measured in non-fasting blood samples collected at the baseline AdDIT visit from 553 adolescents (45.2% females) with a median [interquartile range] age of 13.9 [12.6, 15.2] years and diabetes duration of 5.4 [3.4, 8.2] years, using the Myriad RBM platform (25 biomarkers). Participants were followed for a median of 3.9 [3.1, 4.1] years with 6-monthly visits including collection of clinical data and blood and urine samples. Estimated GFR (eGFR) was calculated with a modified Schwartz formula. eGFR trajectories were calculated for each participant by a linear slope and two categories were defined: rapid decliners, including participants with eGFR slopes <−3 ml/min/1.73 m^2 per year; and rapid increasers for participants with eGFR slopes >5 ml/min/1.73 m^2 per year. ACR was calculated as the geometric mean of three early morning urine samples and microalbuminuria defined as an ACR >3.5 (males) or >4 (females) mg/mmol in at least 2 out of three samples. Associations between individual biomarkers and eGFR and ACR were assessed using regression models adjusted for age, sex, diabetes duration (and eGFR when modelling ACR).
Results: At baseline median ACR was 1.1 [0.7, 1.5] mg/mmol and 96.4% of the study participants were normoalbuminuric. Median eGFR was 133 [119, 151] ml/min/1.73 m^2 and eGFR slopes −4.0 [−7.1, −0.5] ml/min/1.73 m^2; 46.8% of the study participants had a baseline eGFR in the hyperfiltration range (>135 ml/min/1.73 m^2). After setting a Bonferroni-corrected significant threshold of 2.0×10^{-3}, three biomarkers: Trefoil factor 3, Cystatin C and Beta-2 microglobulin were independently associated with eGFR at baseline (B coefficient [95%CI]: −0.19 [−0.27, −0.12], $p = 7.0 \times 10^{-7}$; −0.18 [−0.26, −0.11], $p = 5.1 \times 10^{-6}$; −0.12 [−0.20, −0.05], $p = 1.6 \times 10^{-3}$, respectively). Osteopontin was significantly associated with eGFR slopes (−0.25 [−0.34, −0.16], $p = 4.5 \times 10^{-8}$) as well as with the rapid decliners category (OR: 1.80 [1.40, 2.37], $p = 9.3 \times 10^{-6}$), whereas Fibroblast Growth Factor 23 (FGF23) was significantly associated with the rapid increasers category (1.74 [1.29, 2.34], $p = 2.2 \times 10^{-4}$). No significant associations were found between any of the measured biomarkers and ACR at baseline or its changes during follow up.
Conclusion: In this young population with T1D and high rates of hyperfiltration, Trefoil factor 3, Cystatin C and Beta-2 microglobulin were associated with eGFR at baseline, whereas FGF3 was associated with eGFR decline over time and Osteopontin with eGFR increases. In contrast, in this cohort predominantly normoalbuminuric there were no significant associations with ACR, in contrast to previous results in adult cohorts with T1D.

Urinary exosomal CCL21 mRNA as biomarker of diabetic nephropathy

Y. Feng, L. Lv, W. Wu, X. Zhong, B. Liu;
Zhong Da hospital, Southeast University, Nanjing, China.

Background and aims: Diabetic nephropathy (DN) is one of the common complications of diabetes characterized by variable histological changes and clinical course. Currently, renal biopsy and pathological assessment remain the standard approach in the diagnosis and prognosis of DN. Given the invasive procedures and unpredictable post-operative complications of biopsy, novel and noninvasive biomarkers are needed. We aimed to find noninvasive biomarkers reflecting the histological injury and progression of renal function in DN.
Materials and methods: A screening cohort of 4 biopsy-proven DN patients and 4 diabetic patients with normal renal function(DM) and a validation cohort of patients with 28 biopsy-proven DN patients and 24 DM patients were enrolled in our study. We isolated exosomes from urine samples at the time of renal biopsy. Urinary exosomes was identified by Western blotting (using Alix, CD63 and CD9 as exosomal markers). Kidney histological damage of DN patients was scored according to Tervaet standard. Urinary exosome profile of the packing inflammatory response related genes were assessed and its correlation with clinic and histological injury parameters were analyzed.
Results: Known exosome markers including Alix, CD63 and CD9 were identified by Western blotting. Profile of the packing inflammatory related mRNA revealed CCL-21 was remarkably upregulated in urinary exosomes of DN patients compared with DM patients ($p < 0.05$). Validation study confirmed the findings and found the correlation of CCL-21 with levels of proteinuria ($r = 0.590$, $p < 0.05$) and eGFR ($r = 0.591$, $p < 0.05$) in DN patients. Furthermore, CCL-21 was positively correlated with tubulointerstitial damage. DN patients with severe tubulointerstitial damge showed the highest expression of CCL-21 compared with DN patients with mild and moderate damage. Impressively, CCL-21 showed good performance in discriminating patients with different levels of tubulointerstitial damage.
Conclusion: In summary, urinary exosomal CCL-21 mRNA may be promising noninvasive biomarkers of diabetic nephropathy reflecting renal histological injury and renal function deterioration.

Differential expression of urinary exosomal microRNAs in type 2 diabetic kidney disease

J. Zang[1], D.A. Simpson[2], A.P. Maxwell[1], G.J. McKay[1];
[1]Centre for Public Health, Queen's University Belfast, Belfast, [2]Centre for Experiment Medicine, Queen's University Belfast, Belfast, UK.

Background and aims: Diabetic kidney disease (DKD) is a progressive microvascular complication that leads to a decline in renal function and is the most frequent cause of end stage renal disease. Currently, there is a need for improved biomarkers for the early detection of DKD. MicroRNAs (miRNAs) are short, non-coding regulatory RNA molecules that are commonly found in urinary exosomes and may reflect differential gene expression ongoing in the kidney during the disease process. We evaluated differential urinary exosomal miRNA expression in type 2 DKD (T2DKD) compared to control subjects with type 2 diabetes (T2D) and normal renal function.
Materials and methods: Exosomes were harvested from 1.1 ml of cell-free urine according to the protocol for miRCURY Exosome Urine Kit (Qiagen). RNAs were extracted using miRCURY RNA Isolation Kit (Qiagen) and cDNAs synthesised using Universal cDNA Synthesis Kit (Qiagen).Differential urinary exosomal miRNA profiles were evaluated in 14 participants with T2DKD and 15 age and gender matched individuals with T2D and normal renal function using miRCURY LNA miRNA Focus PCR Panel (Qiagen). The panels consisted of 87 miRNAs previously reported in human urinary exosomes. All miRNAs expressions were normalised using the reference genes selected by the NormFinder algorithm, using GenEx software for the analysis of quantitative PCR data. Statistical analyses were undertaken to compare the expression profiles between cases and controls using independent sample t tests and binary logistic regression to adjust for appropriate confounders (SPSS v.22).
Results: Quantitative expression data were normalised according to the NormFinder algorithm using the 3 most stably expressed miRNAs in the panels (miR-200b-3p, 30c-5p and 27b-3p). Urinary miR-21-5p, 23b-3p and let-7e-5p were significantly upregulated in T2DKD cases compared to T2D controls with good renal function ($P < 0.05$). Conversely, miR-30b-5p and 125b-5p expression were significantly lower in T2DKD cases compared to T2D controls with normal renal function ($P < 0.05$). In a binary logistic regression analysis adjusted for age, sex and mean arterial blood pressure, only miR-21-5p remained significantly associated with T2DKD (OR = 3.28, CI: 1.14–9.43; $P = 0.03$), while miR-30b-5p, 23b-3p, 125b-5p and let-7e-5p rose just above the established significance threshold ($P > 0.05$).
Conclusion: The results suggest miR-21-5p, 30b-5p, 125b-5p, 23b-3p and let-7e-5p are differentially expressed in individuals with T2DKD, although only miR-21-5p remained significant in the fully adjusted model. Further independent validation and replication are ongoing to confirm the role of these miRNAs in T2DKD aetiology, and to evaluate their sensitivity as potential biomarkers of T2DKD.

Serum mitochondrial inhibition activity is an independent risk factor for rapid decline of renal function: a Korean Genome Epidemiologic Study

H. Lee[1], S. Lee[1], J. Kim[1], H. Choi[2], Y.K. Pak[3];
[1]Internal Medicine, Eulji University Medical School, Seoul, [2]Internal Medicine, Kangwon National University Medical School, Chuncheon, [3]Physiology, KyungHee University Medical School, Seoul, Republic of Korea.

Background and aims: Serum contains persistent organic pollutants which act through aryl-hydrocarbon receptor (AhR) and inhibit mitochondrial function. Previously we reported serum mitochondrial inhibitor (MI) activity correlates with AhR bioactivity and insulin resistance. As insulin resistance is linked to the deterioration of renal function. We tested if AhR bioactivity or MI activity is associated with a decline of renal function.
Materials and methods: We measured serum AhR bioactivities and MI activities in 1,537 subjects participating Korean Genome Epidemiologic study. AhR bioactivity was measured with a novel cell-based assay using a cell line which is genetically modified to respond to AhR ligands. MI activity of serum was measured by intracellular ATP contents after treating cultured cells with serum. Excluding missing serum creatinine measurement at follow up, we analyzed 1456 subjects for their clinical parameters, specifically estimated glomerular filtration rate (eGFR), and tested if MI activity is associated with eGFR changes.
Results: Of 1456 participants, mean age was 60.3 years and 43.9% were men. Mean baseline eGFR was 80.7 ml/min/1.73 m^2. After 4 years' follow-up, mean eGFR change was −2.9 ml/min/1.73 m^2/year, and 229 (15.7%) people experienced rapid eGFR decline. In multivariate linear regression analysis, MI activity was positively associated with yearly eGFR change [beta 0.01, 95% confidence interval (CI) 0.00–0.02; $P = 0.008$]. In multivariate logistic regression analysis, the odds ratio of the first vs. forth quartile for rapid eGFR decline (eGFR decline more than 5 ml/min/1.73 m^2/year.) was 1.67 (95% CI 1.04–2.69, $P = 0.035$). Serum AhR bioactivity did not show any significant correlations, even though it correlated with MI activity.
Conclusion: Increased serum mitochondrial function inhibitor level was an independent risk factor for rapid eGFR decline, suggesting that increased MI activity is a novel risk factor for declining renal function. Further studies are needed to confirm and explore meanings of these results.

Markers of collagen formation and degradation reflect renal function and predict adverse outcome in type 1 diabetes

S. Pilemann-Lyberg[1], T.W. Hansen[1], N. Tofte[1], S.A. Winther[1], S. Theilade[1], D.G.K. Rasmussen[2], S.H. Nielsen[2], M.A. Karsdal[2], F. Genovese[2], P. Rossing[1];
[1]Steno Diabetes Center Copenhagen, Soeborg, [2]Nordic Bioscience, Herlev, Denmark.

Background and aims: Type 1 diabetic (T1D) patients have higher risk of developing chronic kidney disease (CKD), cardiovascular events (CVE) and mortality than the general population. We hypothesize that PRO-C6, a product generated during collagen type VI formation, and C3M, collagen type III degradation fragments, may be associated with renal function and have prognostic value for adverse outcome in patients with T1D.
Materials and methods: PRO-C6 and C3M in serum (sPRO-C6; sC3M) and urine (uPRO-C6; uC3M) was measured by ELISAs in 663 patients with T1D and various degrees of albuminuria ranging for normal albuminuria (<30 mg/24 h) to macroalbuminuria (≥300 mg/24 h). In 2016, patients were traced through the Danish National Death Register and the Danish National Health Register, from which data for CVE and mortality are gathered. Estimated glomerular filtration rate (eGFR) was calculated based on data from outpatient visits. Endpoints: mortality from all causes, CVE (cardiovascular death, non-fatal myocardial infarction, non-fatal stroke and coronary or peripheral arterial interventions) and eGFR-decline of ≥30%. Median follow-up ranged from 5.1 to 6.2 years. Cross sectional associations were analyzed with linear regression, and the follow-up data with Cox regressions models. Adjustment included sex, age, LDL cholesterol, smoking, HbA_{1c}, systolic blood pressure, urinary albumin excretion rate (UAER) and baseline eGFR.
Results: Of the 663 participants, 384 (56%) were male; mean ± SD age was 55 ± 13 years and baseline eGFR 81 ± 26 ml/min/1.73 m^2. Median (interquartile range) baseline UAER was 17 (8–68) mg/24-h. Higher sPRO-C6, uPRO-C6 and sC3M were at baseline associated with lower eGFR and higher UAER in both the unadjusted and adjusted analysis ($p \leq 0.007$). Higher uC3M was associated with higher eGFR and lower UAER ($p < 0.001$), but the association with UAER was lost after

adjustment. During follow up higher sPRO-C6 was associated with higher risk of mortality ($n = 58$) in both the unadjusted and adjusted analysis (HR (95% CI): 2.33 (1.37–3.96), $p \leq 0.002$). Higher sC3M was only associated with mortality in the unadjusted analysis (HR (95% CI): 2.07 (1.26–3.43), $p = 0.004$). uPRO-C6 and uC3M was not associated with mortality ($p \geq 0.07$). Higher sPRO-C6 and sC3M was associated with higher risk of CVE ($n = 94$) and eGFR-decline ≥30% ($n = 93$) in the unadjusted analysis (HR (95% CI): ≥1.81 (1.44–2.28), $p \leq 0.003$), but the associations were lost after adjustment ($p \geq 0.19$). Higher uPRO-C6 was associated with higher risk of eGFR-decline ≥30% in the unadjusted analysis (HR (95% CI): 1.30 (1.09–1.56), $p = 0.0037$), after adjustment higher uPRO-C6 was associated with lower risk of eGFR-decline ≥30% (HR (95% CI): 0.80 (0.65–0.98), $p = 0.032$). Higher uC3M was associated with lower risk of eGFR-decline ≥30% in both unadjusted and adjusted analyses (HR (95% CI) ≤0.69 (0.49–0.97), $p \geq 0.035$).

Conclusion: In type 1 diabetic patients, higher levels of serum markers representing collagen type VI formation (PRO-C6) and collagen type III degradation (C3M) were independently associated with presence of diabetic kidney disease. Moreover, higher serum PRO-C6 was an independent predictor of mortality. U-PRO-C6 and uC3M was associated with lower risk of decline in GFR.

HDL-cholesterol but not triacylglycerol variability is associated with progression of diabetic nephropathy in type 1 diabetes

F.J. Jansson[1,2], C. Forsblom[1,2], E.H. Dahlström[1,2], L.M. Thorn[1,2], V. Harjutsalo[1,3], N. Elonen[1,2], N. Sandholm[1,2], P.-H. Groop[1,2], The FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, [2]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, [3]The Chronic Disease Prevention Unit, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: Lately, a growing interest in the association between diabetic nephropathy (DN) and intraindividual variability of clinical parameters has emerged, with the impact of glycaemic instability receiving special focus. Abnormal lipid levels are known to predict both development and progression of renal complications in type 1 diabetes. We aimed to assess whether higher intraindividual variability of HDL-cholesterol and triacylglycerol add to this risk.

Materials and methods: To this prospective observational study, adults with type 1 diabetes were recruited from the nationwide, multicentre Finnish Diabetic Nephropathy Study. Progression of DN was defined as change to a more advanced level of albuminuria or as initiation of renal replacement therapy. Serial HDL-cholesterol and triacylglycerol measurements until progression or most recent date of sustained renal status were covered. Variability was assessed using coefficient of variation (CV, standard deviation/mean) in individuals with ≥3 lipid measurements and verified renal status (normal albumin excretion rate/micro-/macroalbuminuria) at baseline. Thus, 3,015 individuals (median 9 measurements during 10.1 years of follow-up) and 2,820 individuals (median 8 measurements during 10.3 years of follow-up) were included in analyses concerning HDL-cholesterol and triacylglycerol variability, respectively. To avoid overfitting, an Akaike-based fast-backward variable elimination method was implemented to reduce the number of covariates in the final Cox proportional hazards model.

Results: Intraindividual variability of HDL-cholesterol was higher among individuals experiencing progression of DN (CV 17.5 ± 7.9%) compared to those with sustained renal status (15.1 ± 6.6%), $p < 0.001$. After adjusting for covariates in the final model (BMI, use of RAAS-inhibitor, baseline triacylglycerol, HbA_{1c}, eGFR, and history of smoking), the hazard ratio for progression was 1.16 (95%CI 1.02, 1.33) for 10 percentage point increase in HDL-cholesterol variability. An independent association persisted even after inclusion of HDL-cholesterol level. Similarly, individuals with sustained renal status showed less variation of triacylglycerol (CV 29.8 ± 14.5%) than individuals who progressed (33.0 ± 17.5%), $p < 0.001$. However, in multivariable analyses comprising triacylglycerol serial mean, no association between variability and the outcome was observed.

Conclusion: In type 1 diabetes, intraindividual variability of HDL-cholesterol is associated with progression of DN, even after adjusting for HDL-cholesterol levels. We also observed higher triacylglycerol variability among progressors, however, variability does not appear to add to the robust predictive value of single-measured triacylglycerol or triacylglycerol serial mean.

Collagen type III degradation is associated with deterioration of kidney function in patients with type 2 diabetes with microalbuminuria

M. Frimodt-Moller[1], F. Genovese[2], T.W. Hansen[1], D.G.K. Rasmussen[2], S.H. Nielsen[2], H. Reinhard[1], B. von Scholten[1], F. Persson[1], P.K. Jacobsen[1], H.-H. Parving[3], M.A. Karsdal[2], P. Rossing[1,4];
[1]Steno Diabetes Center, Gentofte, [2]Nordic Bioscience, Herlev, [3]Department of Medical Endocrinology, Rigshospitalet, Copenhagen, [4]University of Copenhagen, Copenhagen, Denmark.

Background and aims: In diabetes one of the main features of the progression to diabetic kidney disease is a pathological deposition of extracellular matrix components triggering renal fibrosis. The main structural component of the fibrotic core is collagen. One of the most prominent collagens is type III (COL III), which is excessively synthesized and incorporated into the fibrotic extracellular matrix. Multiple studies in both humans and mice have suggested that MMP-9 activity is increased in diabetic kidney disease. We investigated whether a neo-epitope fragment of COL III generated by MMP-9 (C3M) was associated with deterioration of kidney function in a well-characterised type 2 diabetic population with microalbuminuria and without symptoms of coronary artery disease.

Materials and methods: The cohort included 200 participants, followed for 6.1 years. We measured C3M levels in serum (S-C3M) and urine (U-C3M) at baseline. To adjust for urine output, levels of U-C3M were normalized for urinary creatinine. The investigated endpoint was a decline in eGFR of more than 30% ($n = 42$). Cox proportional hazards regression analysis was performed for S-C3M and U-C3M both unadjusted and adjusted for traditional risk factors (sex, age, systolic blood pressure, LDL-cholesterol, smoking, HbA_{1c}, creatinine and urinary albumin excretion rate). To assess whether S-C3M or U-C3M improved risk prediction beyond traditional risk factors we calculated the relative integrated discrimination improvement (rIDI).

Results: The hazard ratio per doubling of S-C3M was 3.00 (95% CI 1.52–5.90, $p = 0.002$) in unadjusted analyses and 2.84 (95% CI 1.35–5.97, $p = 0.006$) after adjustment. Addition of S-C3M to a model containing traditional risk factors improved the rIDI by 19.8 percentage points ($p = 0.007$). U-C3M was not associated with declining eGFR.

Conclusion: S-C3M was independently associated with decline in renal function, and added significant improved discriminatory power to a model containing traditional risk factors.

C-type natriuretic peptide as a candidate marker of diabetic kidney disease

H. Lunt[1,2], T. Prickett[2], J. Warwick[1], H. Heenan[1], E. Espiner[2];
[1]Christchurch Hospital, Christchurch, [2]Medicine, University of Otago, Christchurch, New Zealand.

Background and aims: Our current clinical predictor of early diabetic kidney disease, urinary albumin, lacks sensitivity and specificity. Better markers of early kidney injury are therefore needed. One such candidate marker is C-type natriuretic peptide (CNP), as increased expression of CNP within the kidney is reportedly an early response to renal injury. CNP is a member of a family of structurally related peptides known for their roles in electrolyte homeostasis, fluid balance and chondrogenesis, which also have anti-inflammatory actions. CNP is synthesized as a precursor (proCNP) which is cleaved to release CNP and the bio-inactive amino-terminal peptide fragment (NTproCNP). We have recently identified an intact form of NTproCNP in urine collected from diabetic participants with impaired renal function which was largely absent from urine obtained from healthy participants without diabetes. This study aimed to evaluate the utility of a urine NTproCNP as a marker of early renal disease in participants with diabetes.
Materials and methods: Adult participants with established (>5-year duration) T1DM (Type 1 diabetes), or with T2DM (Type 2 diabetes) were recruited from diabetes outpatient clinics at Christchurch Hospital, New Zealand. Participants were selected to ensure that a broad range of eGFR and albumin creatinine ratio (ACR) values were present, in both T1DM and T2DM subgroups. Exclusions included prior bariatric surgery, life threatening co-morbidities and serum creatinine >250 μmol/L. Along with demographic and clinical data, blood was drawn (non-fasting) for HbA1c, serum creatinine and NTproCNP. A spot urine sample was obtained for ACR and intact NTproCNP creatinine ratio (NCR). A second urine sample was collected within three weeks to assess replication. Urine NTproCNP was analysed by a radioimmunoassay that specifically measures intact NTproCNP in urine.
Results: To date 59 T1DM (median age 54 years) and 80 T2DM (median age 64 years) participants have been recruited. The median HbA1c (mmol/mol) for T1DM participants of 63 (53–72, IQR), was lower than the median HbA1c of 70 (58–89) for T2DM participants ($p = 0.026$). Median ACR (mg/mmol) was also lower in T1DM participants when compared to T2DM participants; 1.1 (0.6–5.0) compared to 5.3 (1.1–50), $p = 0.009$. When considering results from all participants combined, the coefficients of variation for repeat spot urine measurements for NCR and ACR were 33% and 51% respectively. Median NCR was 0.22 (0.17–0.27) pmol/μmol in participants with impaired eGFR (<60 ml/min/1.73 m^2) compared to 0.13 (0.08–0.20) pmol/μmol in participants with normal, or near-normal, eGFR (>70 ml/min/1.73 m^2), $p = 0.008$. The significant inverse association of NCR with eGFR (Spearman's rho, $r = -0.36$) was stronger than that observed between ACR and eGFR; $r = -0.17$. When considering T1DM and T2DM participants separately, the significant inverse association of NCR with eGFR was observed in both these subgroups ($r = -0.34$ for both subgroups), whereas the relationship between ACR and eGFR was $r = -0.09$ and -0.15 respectively.
Conclusion: These preliminary results support the hypothesis that urine NTproCNP excretion reflects declining renal function and may be superior to urinary albumin excretion, as a marker of kidney injury in diabetes.

PS 092 Diabetic nephropathy: Predictions are hard to make

1003

Prediction models for the risk of developing nephropathy in people with type 2 diabetes. A systematic review

A.A. van der Heijden, M. Gort, P.J.M. Elders, G. Nijpels, J.W.J. Beulens;
VUMC University Medical Center, Amsterdam, Netherlands.

Background and aims: Early detection and treatment of nephropathy in people with type 2 diabetes (T2D) can be facilitated by prediction models. We aimed to identify all prediction models for nephropathy applicable to people with T2D and to assess their quality and accuracy.
Materials and methods: A systematic search was performed in PubMed and Embase in February 2017. A study was included when (I) the model was applicable to people with T2D, (II) any stage of nephropathy was the outcome, and (III) the follow-up of the development study was at least one year. Exclusion criteria were: (I) not written in English, (II) a study population with other serious physical conditions or a post-surgical population, (III) not an original model, or (IV) reporting a univariable model. Screening, full-text assessment, data-extraction (CHARMS-checklist) and risk of bias assessment (PROBAST-tool) was performed independently by two reviewers. Performance of the models was evaluated by discrimination (ability to identify those at risk), and calibration (ability to quantify the absolute risk).
Results: Of the 8,339 studies, 25 met the inclusion criteria. These studies accounted for 36 prediction models, of which 23 were based on a T2D population, and 13 on a general population and included T2D as a predictor. Only ten of the models were externally validated. The models showed poor to good discrimination during internal validation (range C-statistic: 0.59–0.97) and external validation (range C-statistic: 0.67–0.95). Calibration of the models ranged from poor to excellent in internal validation and from poor to good in external validation. Overall higher C-statistics were reported in models based on the general population. Risk of bias could be present in the models due to the lack of adjustment for model overfitting and optimism, and inappropriate handling of missing data. The models described by Schroeder et al and Elley et al showed good performance using routinely obtained patient information.
Conclusion: A high number of nephropathy prediction models are available. Less than one third of these models were externally validated, showing variable results, indicating the need for external validation of these models. The models by Schroeder et al and Elley et al seem promising considering their study quality, performance and simplicity.

Blood pressure response to RAAS inhibition predicts all-cause mortality for individuals with type 1 diabetes and albuminuria

R. Lithovius[1,2], S. Mutter[3], V.-P. Mäkinen[3], P.-H. Groop[1,2];
[1]Folkhälsan Institute of Genetics, Helsinki, Finland, [2]Abdominal Center Nephrology, Helsinki, Finland, [3]South Australian Health & Medical Research Institute, SAHMRI, Adelaide, Australia.

Background and aims: As type 1 diabetes usually manifests within the first two decades of life, the affected individuals are at high life-time risk to develop diabetic kidney disease that can substantially lower their quality of life and shorten their life span. No targeted cure exists for diabetic kidney disease, but clinical trials have shown the benefits of inhibiting the renin-aldosterone-angiotensin system (RAAS) to slow down or even halt disease progression. However, there might be patients whose RAAS treatment could be optimised to achieve better long-term outcomes. Therefore, accurate information on how patients respond to RAAS inhibition in real-world settings is highly valuable.

Materials and methods: The present pilot study is part of the Finnish nationwide FinnDiane Study. We included 287 patients with type 1 diabetes who had been prescribed a RAAS inhibitor for the first time (index date) between 1996 and 2013. Patients were then followed up to the first BP measurement after the index date (0.9 years ± 0.6 years). Inclusion criteria were as follows: index date after joining the FinnDiane study, no RAAS prescriptions ≥3 years before index date, at least one RAAS prescription for every six months after the index date, BP measured in the two years before and after the index date, and albuminuria status and HbA1C measured before and after the index date. Patients were classified into two groups: normal urinary AER (AER <20 μg/min or AER <30 mg/24 h) or albuminuria above those thresholds (end-stage renal disease excluded). A beneficial BP response was defined as a reduction in BP below 140/90 mmHg, otherwise the BP response was considered poor. In a Cox regression analysis, patients were further followed up (9.6 years ± 3.9 years) until death (19 events) or until the end of 2015.
Results: After the initiation of RAAS blockade, systolic BP was reduced by 6 mmHg and diastolic BP by 3 mmHg. Overall, 111 (39%) patients achieved a beneficial BP response. We compared three groups: patients with normal AER ($n = 201$), patients with albuminuria and a beneficial BP response ($n = 33$) and patients with albuminuria and poor response ($n = 53$). Only patients with albuminuria and poor BP response showed higher all-cause mortality (HR = 3.41 [95% CI 1.27, 9.18], $p = 0.02$) with respect to the normal AER group, whereas no excess mortality was observed in those with a beneficial BP response (HR = 2.11 [0.56, 7.97], $p = 0.27$). Albuminuria and a poor BP response was associated with a younger age of diabetes onset (11.8 vs. 17.0 and 17.9 years, $p = 0.02$) and a higher systolic BP (150 vs. 135 and 148 mmHg, $p < 0.01$) at index date compared to the beneficial BP response and the normal AER groups. There were no differences between the three groups in age, diastolic BP and HbA1C at index date, or in BMI, WHR and sex at the study enrolment.
Conclusion: The initial BP response in individuals with type 1 diabetes and albuminuria predicts all-cause mortality. Therefore, poor BP response is an important predictive biomarker for diabetic kidney disease. Further research on the causes for this phenomenon is warranted to find more effective means to protect the kidneys.
Disclosure: **R. Lithovius:** None.

1005

Sex differences in outcomes in treated diabetic kidney disease

B. Fernandez-Fernandez, M. Sanchez-Niño, A. Ortiz;
Nephrology and Hypertension department, IIS-Fundación Jiménez Díaz-Universidad Autónoma de Madrid, Madrid, Spain.

Background and aims: There is recent interest and controversy on the reasons behind the lower incidence of renal replacement therapy in women, despite a higher prevalence of chronic kidney disease (CKD). Being diabetic kidney disease (DKD) the most frequent cause of end-stage kidney failure, exploring the impact of sex on DKD progression under routine clinical practice conditions may contribute to solve the controversy. The aim was to analyze the progression of CKD and predictive factors in men and women with diabetes and CKD.
Materials and methods: Prospective cohort study of diabetic patients referred to an outpatient diabetic CKD clinic in a tertiary hospital within a healthcare system without limitations in access to nephrological care, and treated according to existing guidelines.
Results: 261 new patients were referred to the DKD clinic, two thirds of them men. Women had lower albuminuria (99.5 [15–403] vs 187 [50–592] mg/g, p 0.013) and were more frequently non-smokers (71/91, 78.0% vs 37/170, 21.9%, $p < 0.001$), but did not differ from men in other parameters such as age and baseline glomerular filtration rate (eGFR). Over a mean follow-up of 30 ± 10 months, eGFR changed by −1.2 [−4.6; 2.3] ml/min/1.73 m²/year in men and −0.8 [−4.1; 3.5] ml/min/1.73 m²/year in women. However, 48/261 (18%) patients experimented rapid progression, defined as loss of ≥5 ml/min/1.73 m²/year over the follow-up period. Women represented 15/48 (31%) of rapid progressors and 70/199 (35%) of non-progressors (ns). Albuminuria remained stable in men changing by 3.1 [−7.3; 20.3] %/year, but decreased in women, changing by −4.8 [−12.9; 7.4] %/year. The best multivariate model to predict rapid progression in men and women differed. UACR and Fractional excretion of phosphate were part of the best multivariable model predicting rapid progression in men (AUC 0.92, 95% CI 0.85 to 0.98), but were absent from the best model for women (AUC 0.90, 95% CI 0.8 to 1). The AUC for predicting rapid progression by UACR was 0.71 (95% CI 0.61 to 0.81) for men and 0.62 (95% CI 0.43 to 0.82, thus overlapping the 0.50 mark) for women, with cut-off points of 811 and 213 mg/g respectively. Around 20% of women rapid progressors had UACR >300 mg/g, vs 36% of men rapid progressors. Additionally, in women, the percentage of rapid progressors with UACR<30 mg/g was significantly higher than in men (33% vs 3%; $p = 0.0085$).
Conclusion: In women with DKD treated according to current guidelines, CKD progression is slower overall than in men and albuminuria decreases over time. However, the proportion of rapid progressors was similar in both sexes, although factors predicting rapid progression differed: albuminuria was a better predictor in men than in women. This information may be used to enrich clinical trials in rapid progressors and in women with high risk of progression.

Insulin resistance predicts incident hypertension and increasing systolic blood pressure in a Swedish cohort study

B. Daka[1], K. Ottarsdottir[1], L. Råstam[2], M.I. Hellgren[1], U. Lindblad[1];
[1]Department of Public Health and Community Medicine, Medicine, Göteborg, [2]Department of Clinical Science, Medicine, Malmö, Sweden.

Background and aims: To investigate whether insulin resistance predicts increase in systolic blood pressure and the development of hypertension in a representative cohort in Sweden.
Materials and methods: Between 2002–2005 a representative cohort based on census data was defined and 2816 ($M = 1400$) subjects (76% participation rate at baseline) were included in a survey. Data regarding lifestyle, socio-economy, stress and depression were collected using validated questionnaires. During 2012–2014 a follow-up visit was completed in 1327 ($M = 657$) (70% participation rate at visit 2) subjects consecutively recruited and similar protocols were used. Blood pressure was measured at baseline and follow up and hypertension was defined according to Joint National Comittee 7 (JNC 7) guidelines. An oral glucose tolerance test was completed at baseline and at follow-up in subjects without diabetes and diabetes was defined based on WHO recommendations 1999. Insulin resistance was defined based on homeostatic model assessment of insulin resistance (HOMA-Ir) both at baseline and at follow-up. Morning fasting blood samples were collected in all participants and stored in biobank. Multivariable logistic regressions were computed to investigate how HOMA-Ir at baseline predicts incident cases of hypertension during follow-up. Multivariate linear regressions were also computed to investigate how the change in HOMA-Ir influenced the change in systolic blood pressure during follow-up. Subjects with hypertension and or diabetes mellitus at baseline (206) and those with lack of information regarding HOMA-Ir (40) were excluded from all analysis while 1081 subjects participated in this study. All analyses were computed in IBM SPSS version 24. The interaction between sex and HOMA-Ir on incidence of hypertension and the increase of blood pressure was investigated and no significant interaction were found ($p = 0.661$). Thus, the analyses were computed for all subjects and were adjusted for sex.
Results: During the follow up of 9.6 years (SD 1.4) 156 new cases of hypertension were registered (15%), systolic blood pressure increased by 5.9 (SD 12) mmHg in the overall population and HOMA-IR increased by

12% in average. In age adjusted cross-sectional linear regression analyses HOMA-Ir was strongly associated with systolic blood pressure at baseline ($B = 1.2$ CI 0.7–1.6 $p < 0.001$) and at follow-up ($B = 1.5$ CI 0.9–2.0 $p < 0.001$). HOMA-Ir at baseline predicted the development of hypertension independent of age, sex, waist hip ratio, systolic blood pressure at baseline (OR = 1.27 CI 1.02–1.59). The change in HOMA-Ir was strongly associated with change in systolic blood pressure regardless of age, sex, systolic blood pressure, HOMA-Ir, waist hip ratio at baseline ($B = 0.8$ CI 0.3–1.3 $p = 0.002$).

Conclusion: Insulin resistance predicts the development of hypertension and the increase of blood pressure. Lifestyle intervention to improve insulin sensitivity may be effective to lower blood pressure and to prevent hypertension.

Insulin resistance prognosticate kidney disease in individuals without diabetes

M.I. Hellgren, B. Daka, U. Lindblad;
Department of Public Health and Community Medicine/Primary Health Care, Institution of Medicin, Gothenburg, Sweden.

Background and aims: Renal disease is one of the major complications in patients with Diabetes Mellitus (DM). The aim of this study is to explore whether insulin resistance affects renal function even before the development of manifest DM in men and women.

Materials and methods: In the Vara Skövde Cohort 2816 randomly selected individuals (men 49.7%) were carefully examined with blood-pressure, body weight and height, waist-circumference and fasting venous samples, drawn in the morning for serum concentrations of insulin, cholesterol, HDL, LDL and triglycerides. All participants also completed an oral glucose tolerance test (OGTT). Questionnaires concerning social life and lifestyle were completed. After ten years (9.7 years SD 1.4), a total of 1327 of the original participants consequently recruited were re-examined following the same protocol as at base-line. EGFR was calculated using CKD-EPI formula. Renal status was defined according to KDIGO taking both eGFR and albuminuria into account. According to the KDIGO classification kidney impairment is divided into four different categories depending on risk for kidney failure; normal, mild/moderately increased risk, high risk and very high risk. In this study, kidney impairment was defined as at least moderately increased risk of chronic kidney disease (eGFR ≤60 ml/min/1.73 m^2 or albuminuria 30–300 mg/g 3–30 mg/mmol) and insulin resistance was defined based on homeostatic model assessment insulin resistance (HOMAir). Participants with manifest DM ($n = 58$), with missing data for creatinine or albumin excretion in urine ($n = 38$) or with impaired kidney function ($n = 44$) at baseline were excluded from the calculations in this study, leaving 1187 for the final analyses. Binary logistic regression was used to investigate the association of HOMAir at baseline and risk of CKD at follow-up.

Results: Mean age at baseline was 48.1 years (SD 11), mean eGFR 90 ml/min/1.73 m^2 (SD 13), mean body mass index 27 kgm^{-2} (SD 3) and mean systolic blood pressure 120/70 mm Hg (men 123/72 mmHg, women 118/68 mmHg). At follow-up 47 men and 37 women had developed moderately increased risk of CKD according to KDIGO. Insulin resistance predicted an increased risk for CKD in men when adjusted for age, eGFR, albumin/creatinine ratio, BMI and hypertension at baseline, OR 1.8 (CI 1.19–2.73; $P = 0.005$). Concerning women BMI seemed to be the decisive factor, OR 1.1 (CI 1.04–1.26; $P = 0.007$) and not insulin resistance OR 1.1 (CI 0.91–2.07; $P = 0.129$).

Conclusion: Insulin resistance in men and overweight in women are associated with an increased risk to develop kidney failure after 9.7 years and risk factors in individuals with prediabetes should thus be treated intensively.

1008

Renal resistive index predicts post-bariatric surgery renal outcome in severely obese non diabetic individuals

L. Giannini, M. Seghieri, E. Santini, F. Parolini, S. Taddei, R. Bruno, A. Solini;
University of Pisa, Pisa, Italy.

Background and aims: Bariatric intervention has shown positive effects on renal function in obese subjects, even though studies where glomerular filtration rate (GFR) and renal plasma flow (RPF) have been measured rather than estimated are scanty. Postoperatively, amelioration in subclinical atherosclerosis, arterial stiffness and endothelial function may also be observed; this positive systemic effect on vasculature might be beneficial at the renal level too, potentially improving GFR. Aims of this study were to demonstrate whether metabolic surgery is able 1) to improve GFR when measured by a gold-standard technique in morbidly obese non-diabetic individuals and 2) to identify clinical, renal and systemic vascular predictors of GFR improvement.

Materials and methods: Twenty-five severely obese subjects were studied before and one year after gastric bypass surgery. GFR and RPF were measured with iohexol clearance and hippurate infusion, respectively. By ultrasonographic technique, measurements of baseline (RI) and dynamic (DRIN) renal resistive indices, renal visceral fat and systemic vascular parameters were performed.

Results: Pre-intervention subjects (47 ± 13 years, 16 F, BMI: 44.8 ± 6.0 kg/m^2) had a measured GFR (mGFR) of 86.9 ± 15.2 ml/min/1.73 m^2 and an estimated GFR (eGFR, by CKD-EPI) of 100.8 ± 18.6 ml/min/1.73 m^2. At follow-up, BMI decreased by 31% and fasting plasma glucose from 5.42 ± 1.03 to 4.75 ± 0.47 mmol/L ($p = 0.041$). eGFR did not change significantly, while mGFR increased to 109.0 ± 18.2 ml/min/1.73 m^2, ($p < 0.001$), but only when expressed by BSA, and not by height. RPF did not vary (612 ± 170 *vs* 573 ± 181 ml/min, $p = 0.345$). RI decreased (0.62 ± 0.06 *vs* 0.59 ± 0.05, $p = 0.047$), while DRIN was unmodified. Peri and pararenal fat were also reduced (from 2.10 ± 0.65 to 1.27 ± 0.52 cm and from 1.77 ± 0.67 to 0.96 ± 0.41 cm, respectively; both $p < 0.01$). Systemic vascular data showed an improvement in endothelium-dependent function (flow-mediated dilation, FMD: 4.55 ± 2.56 to 6.90 ± 2.30%, $p < 0.01$), while brachial artery diameter and baseline and hyperemic shear rate were reduced; conversely, response to nitrates was unmodified. Systemic arterial stiffness improved, as aortic pulse wave velocity (PWV) was reduced (8.34 ± 1.13 to 7.40 ± 1.12 m/s, $p = 0.03$), even when covarying by mean BP ($p = 0.05$). Carotid IMT was significantly decreased, and all parameters of carotid elasticity were significantly improved. Searching for clinical predictors of mGFR improvement after bariatric surgery (ΔmGFR), younger age ($r = -0.734$, $p < 0.001$), lower baseline fasting glucose ($r = -0.599$, $p = 0.007$) and Hb1Ac ($r = -0.603$, $p = 0.017$) were significantly associated. Interestingly, ΔmGFR was not significantly related with either ΔBMI or basal BMI. Among vascular variables, a greater improvement in ΔmGFR was inversely correlated to smaller brachial artery ($r = -0.705$, $p = 0.005$), carotid diameter ($r = -0.573$, $p = 0.032$) and lower RI ($r = -0.562$, $p = 0.029$). Such significant correlations were maintained when GFR was indexed by height. None of the measures of adiposity at baseline was associated to ΔmGFR.

Conclusion: In obese subjects with fully preserved renal function, bariatric surgery induces an improvement of GFR, renal and systemic stiffness with no relevant effect on RPF. A better glucose control, younger age and lower renal intravascular resistance can predict such improved renal function, maximising such favourable effects in relatively young individuals with healthy arteries.

Higher pulse pressure predicts initiation of dialysis in Japanese patients with diabetes: analysis using a nationwide claim database

T. Osawa[1], K. Fujihara[1], M. Yamamoto[1], M. Harada[1], M. Ishizawa[1], H. Seida[2], N. Yamanaka[2], Y. Matsubayashi[1], S. Matsunaga[1], T. Yamada[1], H. Sone[1];
[1]Department of Internal Medicine, Niigata University Faculty of Medicine, Niigata, [2]Japan Medical Data Center Co., Ltd, Tokyo, Japan.

Background and aims: Since dialysis is known to predispose patients with diabetes to a lower quality of life as well as higher rates of cardiovascular events and mortality, identifying predictors for starting dialysis is of clinical relevance in diabetes management and care. However, only a few studies have investigated predictors for initiation of dialysis.
Materials and methods: To clarify this, data from a nation-wide claim database *involving* 18,935 *participants with diabetes during 2008–16 were analyzed.* We compared 2 groups (*with and without* dialysis) by a Kaplan-Meier curve and log-rank test. Multivariate Cox regression model *was used to identify variables related to* starting *dialysis*. Hazard ratios (HRs) were compared among 4 groups divided according to combinations of HbA1c (<8 or ≥8%), systolic blood pressure (SBP) (<140 or ≥140 mmHg) and pulse pressure (PP) (<60 or ≥60 mmHg) values.
Results: Baseline of the proportion of men, BMI, SBP, diastolic blood pressure (DBP), PP, HbA1c, and prevalence of coronary artery disease *were higher in the group who started dialysis than did not. The multivariate Cox model showed that PP was most significant and independent predictor of the initiation of* dialysis. *The* HRs for initiation of dialysis for each 1 SD elevation in SBP and 1 SD elevation in PP were 1.09 (95% CI 0.81–1.48) and 1.54 (1.14–2.08), respectively. Compared with HbA1c <8% and PP <60 mmHg, the HR for those with HbA1c ≥8% and PP ≥60 mmHg was 6.32 (3.42–11.7). On the other hand, compared with HbA1c <8% and SBP <140 mmHg, the HR for those with HbA1c ≥8% and SBP ≥140 mmHg was 4.26 (2.32–7.85).
Conclusion: These findings reveal that although SBP and PP were independent predictors for starting dialysis, PP was more potent. Especially, a high risk for starting dialysis was found for those with PP ≥60 mmHg along with HbA1c ≥8% which is useful for targeting high-risk patients.

Incidence, predictors, and clinical outcomes of new onset diabetic foot ulceration after renal transplantation

P.R.J. Vas[1], A. Sharma[2], S. Cohen[3], T. Patel[3], S. Thomas[3], J. Karalliedde[2];
[1]King's College Hospital, London, [2]King's College London, London, [3]Guy's and St Thomas' Hospital, London, UK.

Background and aims: Patients with diabetic kidney disease are at high risk of diabetic foot ulceration (DFU). Whether this risk is modified after renal transplant is unclear. Importantly, there is a paucity of information on the burden and the risk factors associated with new-onset DFU development after renal transplantation. We evaluated the incidence and predictors of new-onset DFU post renal transplantation in a single centre retrospective study. Patients who underwent renal transplantation for diabetic kidney disease between 2004–2016 were evaluated.
Materials and methods: In total 144 (66% male, 26% Type 1 DM) patients were evaluated. Median (range) of follow up was 6 (3 to 13) years. The median (range) age was 62 (28 to 80) years and duration of diabetes 23 (7–60) years. Electronic patient investigation records and podiatry medical notes were reviewed.
Results: Over the follow-up period, 22 (15%) patients developed a new DFU. Patients with a DFU were of similar age, body mass index, diabetes duration and had similar pre-transplantation haemoglobin, as compared to those without a DFU. Patents who developed a DFU were more likely to have Type 1 diabetes than type 2 diabetes (29% vs. 10%), history of peripheral vascular disease (PVD) [32% vs. 8%], had higher pre-transplantation HbA1c, mean ± standard deviation (7.5 ± 1.2% vs. 6.8 ± 1.4%) and serum creatinine (809 ± 243 μmol/l vs. 660 ± 202 μmol/l) $p < 0.05$ for all. Of the cohort, 8 patients had a history of DFU pre-transplantation and all 8 developed a new onset DFU post-transplantation. Median (range) duration of healing was 5 (1–26) weeks. Site, Ischemia, Neuropathy, Bacterial Infection, and Depth (SINBAD) classification score was <3 in 14 of the 22 DFU cases. Nearly 50% of all DFU occurred within the first 1000 days post-transplantation (Figure 1). Of the 22 cases, 6 needed a minor amputation; no major amputations were documented. Patients with DFU had more than a twofold increased risk of transplant failure as compared to those without DFU (50% vs 23.3% $p = 0.02$). Mortality was 27.3% in patients with DFU compared to 20.3% without DFU $p = 0.25$
Conclusion: Close to 1 in 7 patients post renal transplantation develop a new onset DFU. Type 1 diabetes, higher pre-transplantation HbA1c, serum creatinine, history of PVD and prior DFU are associated with increased risk of new-onset DFU post-transplantation. Importantly, in this group, DFU is associated with a nearly two-fold incidence of transplantation failure. When compared with UK national audit data healing time, rates and severity of ulcer at presentation are significantly better in our cohort. Nonetheless, our results indicate a high burden of DFU post-transplantation and emphasise the requirement for regular foot surveillance in this high-risk population.

Plasma lipids are associated with diabetic kidney disease: a study of plasma lipidomics in type 1 diabetes

N. Tofte[1], T. Suvitaival[1], L. Ahonen[1], S. Theilade[1], S.A. Winther[1], M. Frimodt-Møller[1], T.S. Ahluwalia[1], P. Rossing[1,2];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]University of Copenhagen, Copenhagen, Denmark.

Background and aims: The pathophysiology of diabetic kidney disease (DKD) is incompletely understood. The aim of this study was to perform lipidomics analysis to, first, evaluate cross-sectional associations between plasma lipid levels and measures of DKD in type 1 diabetes (T1D) and, second, validate the strongest associations as predictors of the development of a combined kidney endpoint (CKE) in survival analysis.
Materials and methods: In total the study comprised 670 patients with T1D among which 312 had normoalbuminuria, 168 had microalbuminuria and 190 had macroalbuminuria. Mean ± SD baseline estimated GFR (eGFR) 82 ± 28 ml/min/1.73 m^2. Non-targeted lipidomics analyses were performed on plasma samples using ultra-high performance liquid chromatography quadrupole time-of-flight mass spectrometry. Data were pre-processed with MZmine2. Lipids with a maximum of 20% missing values were included and imputed with k-nearest neighbour algorithm. Endpoints were traced through National Health and Death Registers and eGFR was obtained from electronic laboratory records. CKE was defined as the first event of ≥30% decline in eGFR, all-cause mortality or ESRD (chronic dialysis, kidney transplantation or GFR/eGFR <15 ml/min/1.73 m^2). Median follow-up was 5.2 years. Cross-sectional associations between single lipid species and low eGFR or categorical group (normo-, micro- and macroalbuminuria) were analysed by linear regression and analysis of covariance, respectively. Correction for multiple testing was done with the Benjamini-Hochberg method. In longitudinal data, adjusted HR for the development of CKE was calculated for the lipid species that had the strongest cross-sectional association to low eGFR and albuminuria, respectively, using the Cox proportional hazards model. All models were adjusted to age, gender, HbA1c, systolic BP, smoking, BMI, statin treatment, plasma triglycerides, total plasma cholesterol and, further, eGFR and/or urinary AER, where appropriate.
Results: A total of 121 lipids from 4 different lipid classes (phosphatidylcholines (PCs), lysophosphatidylcholines (LPCs), triacylglycerols (TGs), and sphingomyelins (SMs)) were qualified and included in the analyses. Cross-sectional data demonstrated both positive and negative associations between PCs and low eGFR ($p < 0.05$), whereas PCs were all decreased in macroalbuminuria vs. normoalbuminuria ($p < 0.05$). Several SMs and medium-chain-length TGs were positively associated to low baseline eGFR and decreased in macroalbuminuria vs. normoalbuminuria ($p < 0.05$). In the longitudinal validation of the top-ranking lipids from the cross-sectional analyses, the PC(O-36:2) and SM(d40:1), were associated with a decreased adjusted HR for the development of CKE ($n = 117$; HR: 0.73 (0.57–0.95); $p = 0.02$, and HR: 0.68 (0.52–0.88); $p = 0.004$, respectively).
Conclusion: Alterations in the plasma lipid levels were associated with decreased eGFR and macroalbuminuria in this T1D study cohort (after covariate adjustment). Further, the top-lipids from the cross-sectional analysis were validated for a longitudinal predictive association to the combined kidney endpoint. The results indicate broad changes in the lipidome in relation to the pathophysiology of DKD and suggest potentially protective lipid biomarkers.

1012

Apolipoprotein C3 in diabetic nephropathy in type 1 diabetes and its role in cardiovascular disease

L. Stechemesser[1], C. Forsblom[2,3], N. Tolonen[2,3], M.-R. Taskinen[4], R. Weitgasser[5], P.-H. Groop[2,3];
[1]Paracelsus Medical University - LKH, Salzburg, Austria, [2]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland, [3]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland, [4]Heart and Lung Centre, University of Helsinki, Helsinki, Finland, [5]Department of Medicine, Diakonissen-Wehrle Hospital, Salzburg, Austria.

Background and aims: Apolipoprotein C3 (ApoC3) is a key regulator of triglyceride metabolism via its inhibitory effects on lipolysis and hepatic remnant uptake. Emerging evidence indicate that ApoC3 is an independent risk factor for cardiovascular events. The fact that glucose and insulin regulates ApoC3 expression raises the role of ApoC3 and cardiovascular risk in diabetes. We, therefore, investigated ApoC3 and its association with cardiovascular disease (CVD) in patients with and without diabetic nephropathy.
Materials and methods: This cross-sectional and prospective analysis was part of the prospective, ongoing Finnish Diabetic Nephropathy (FinnDiane) Study. Between 1994 and 2015 data were obtained from 3926 type 1 diabetes (T1D) patients at more than 80 hospitals or health centers across Finland. ApoC3 levels were explored by groups of albuminuria, CKD stages, presence of CVD as well as prediction of CVD and death. Survival curves were calculated by Cox regression analysis.
Results: At baseline, normo-, micro- and macroalbuminuria were present in 71.7%, 13.8% and 14.5% of the population ($n = 3926$, females 48%, age 37.8 ± 12.2 yrs, diabetes duration 23.2 ± 13 yrs, HbA1c 8.4 ± 1.5%). CKD stage 3–5 was diagnosed in 14.3%. Coronary heart disease or stroke (CVD) were present in 5.5% at baseline, while 16.3% developed CVD during 15-year follow-up. Compared to normoalbuminuria ApoC3 was elevated in the presence of micro- ($p = 0.013$) or macroalbumiuria ($p < 0.001$). Increasing ApoC3 levels were observed alongside progression of CKD stage ($p < 0.001$). Notably, higher baseline ApoC3 correlated with presence of CVD at baseline, development of CVD during follow-up and death. Differences in survival of those with the highest quartile of ApoC3 were independent of eGFR, triglycerides or HbA1c.
Conclusion: Baseline ApoC3 levels were elevated in T1D patients with micro- and macroalbuminuria, with impaired renal function, and with CVD. ApoC3 also predicted the development of CVD and death during follow-up.

Neutrophil elastase and myeloperoxidase mRNA levels are elevated in diabetic patients with overt nephropathy and are associated with albuminuria

S.K. Biswas[1], R.M. Rinta[1], F. Haider[1], M. Fariduddin[2], M.I. Arslan[1];
[1]Biochemistry and Molecular Biology, Bangabandhu S M Medical University, Dhaka, [2]Endocrinology, Bangabandhu S M Medical University, Dhaka, Bangladesh.

Background and aims: Neutrophil elastase (NE) and myeloperoxidase (MPO) enzymes are abundantly expressed by activated neutrophils and protect us from infection by killing pathogens. However, activation of these enzymes is known to induce oxidative stress, inflammation and tissue damage. Experimental study in mouse model of 5/6th renal ablation showed that the MPO contributes to the development and progression of chronic kidney disease. However, the contribution of NE and MPO in the pathogenesis and progression of diabetic nephropathy (DN) is not yet established. In the present study, NE and MPO mRNA levels, which are likely to be more sensitive than their circulating protein levels or

activities, were quantified in the peripheral blood leukocytes (PBL) in long-term diabetic patients. The aim of this study was to explore the association of DN with NE and MPO mRNA expressions in the PBL.

Materials and methods: A total of 70 diabetic patients with duration of diabetes >10 years were recruited and divided into 3 groups on the basis of urine albumin to creatinine ratio (ACR): normoalbuminuric or control (ACR <30 mg/g), microalbuminuric or incipient DN (ACR 30–299 mg/g) and macroalbuminuric or overt DN (ACR ≥300 mg/g). Diabetic patients with kidney failure and patients on dialysis were excluded. Total RNA from PBL was extracted and converted to cDNA. The mRNA levels of NE and MPO genes were quantified by real-time qPCR, analyzed by comparative Ct method and expressed as percentage of expression of reference gene beta-actin.

Results: The control ($n = 25$), incipient DN ($n = 27$) and overt DN ($n = 18$) groups were found similar in terms of age (mean ± SD, 53 ± 9 yrs), sex (m = 36, f = 34), body mass index (25.4 ± 3.6 kg/m^2), duration of diabetes (14 ± 2 yrs), fasting glucose (11.4 ± 4.2 mmol/L), lipid profile and leukocyte counts. Systolic BP and serum creatinine levels were found elevated in overt DN group compared to control group ($p < 0.05$). Urine albumin level [median (IQR)] was found 9 (5–16), 75 (43–168) and 1008 (402–1472) mg/L; and ACR was found 17 (7–20), 78 (55–201) and 829 (374–1790) mg/g for control, incipient DN and overt DN groups, respectively ($p < 0.001$). However, the NE mRNA level was found significantly elevated in overt DN group [1.40% (0.69–3.48)] compared to control [0.44 (0.12–1.10); $p = 0.015$] and incipient DN [0.43 (0.20–0.77); $p = 0.009$] groups. Similarly, the MPO mRNA level was also found significantly elevated in overt DN group [1.50 (0.55–2.58)] compared to control [0.27 (0.04–1.55); $p = 0.03$] and incipient DN [0.22 (0.04–1.08); $p = 0.008$] groups. However, neither NE nor MPO mRNA levels showed any significant difference between control and incipient DN groups. The NE mRNA level showed significant positive correlation with urine albumin level ($r = 0.39$, $p = 0.01$) and ACR ($r = 0.43$, $p = 0.007$). Similarly, MPO mRNA level showed significant correlation with urine albumin level ($r = 0.35$, $p = 0.03$) and ACR ($r = 0.42$, $p = 0.007$).

Conclusion: We showed here for the first time that the NE and MPO mRNA levels are elevated in the PBL in overt DN, but not in incipient DN, and are associated with albuminuria. This particular pattern of gene expression, in spite of cross-sectional nature of the study, suggests that increased expression of NE and MPO mRNA may be a consequence, rather than a cause, of DN and may contribute to the increased risk of cardiovascular disease in DN.

Sleep disordered breathing during rapid eye movement sleep and diabetic kidney disease in patients with type 2 diabetes

A. Nishimura[1], T. Kasai[2], S. Ikeda[1], T. Uchida[1], S. Kikuno[1], K. Nagasawa[1], M. Okubo[1], K. Narui[3], Y. Mori[1];
[1]Endocrinology and Metabolism, Toranomon Hospital, Tokyo, [2]Cardio-Respiratory Sleep Medicine, Department of Cardiology, Juntendo University School of Medicine, Tokyo, [3]Sleep Center, Toranomon Hospital, Tokyo, Japan.

Background and aims: Sleep disordered breathing (SDB) can induce hyperglycemia, hypertension and oxidative stress. SDB, therefore, may exacerbate diabetic kidney disease (DKD). Although several studies showed potential association between SDB and DKD, almost all studies used unattended portable monitors. Recently, a few studies showed that apnea hypopnea index during rapid eye movement sleep (REM-AHI), which can be measured only by polysomnography (PSG), is associated with glycated hemoglobin (HbA1c) and hypertension whereas non-REM-AHI is not. There are no studies, however, evaluating the association between REM/non-REM-AHI and DKD.

Materials and methods: We conducted a cross-sectional study in 303 patients with type 2 diabetes (T2D) followed in our diabetes clinic, who underwent a fully-attended PSG with no history of heart failure, active lung disease, urologic diseases or pretreated SDB. DKD was defined as the presence of albuminuria (≥3.4 mg/mmol creatinine) or declined estimated glomerular filtration rate (eGFR) (<60 mL/min/1.73 m^2). Logistic regression analysis was performed to clarify the effect of AHI or REM-AHI on the prevalence of DKD adjusted for age, sex, BMI, T2D duration, smoking, hypertension, HbA1c, non-HDL cholesterol, insulin use, ACE inhibitor/angiotensin receptor blockers use, statin use and sleep pills use. In REM-AHI analysis, patients with REM sleep <30 minutes during PSG were excluded.

Results: Characteristics of the patients are summarized in the table. Categorical AHI was independently associated with DKD ($p = 0.011$ for linear trend, OR and 95% CI for 15 ≤AHI <30, 1.541 (0.640–3.710); 30 ≤AHI, 3.078 (1.364–6.943) compared with AHI <15). Furthermore, quartile of REM-AHI was independently associated with DKD ($p = 0.034$ for linear trend, OR and 95% CI for Q2, 3.142 (1.099–8.980); Q3, 3.827 (1.263–11.601); Q4, 4.968 (1.596–15.460) compared with Q1) whereas quartile of non-REM-AHI was not ($p = 0.124$ for linear trend). Similar results were obtained when continuous AHI or REM/non-REM-AHI variables were included in the model. In addition, quartile of minimum oxygen saturation or percentage of time spent with SO2 <90 were independently associated with DKD ($p = 0.001$ and $p < 0.001$ for linear trend).

Conclusion: This is the first study to demonstrate independent association between REM-AHI and DKD in patients with T2D. REM-AHI could be a potential risk factor for DKD.

Table Characteristics of the patients

	Overall (n=303)	REM-AHI (n=182)	REM-AHI Q1	Q2	Q3	Q4	*P* value

The pathological mechanism of anaemia in diabetic patients with chronic kidney disease

K. Harada[1], Y. Yamaguchi[2], Y. Akai[3];
[1]Department of Nephrology, Diabetes and Renal Replacement Therapy, Nishinara Central Hospital, Nara, [2]Department of Nephrology and Rheumatology, Rakuwakai-Otowa Hospital, Kyoto, [3]Department of Community-based Medicine, Nara Medical University, Kashihara, Japan.

Background and aims: Anemia is a common complication in chronic kidney disease (CKD), affecting over half of all patients. Diabetes, as the major causes of CKD worldwide, is therefore the most principal cause of renal anemia. CKD patients with diabetic nephropathy (DN) develop renal anemia earlier for their degree of renal impairment than those without DN. How the renal pathological alterations in DN affect renal anemia remains to be elucidated. We conducted this study to investigate association between anemia and renal pathological findings in diabetic patients with CKD.

Materials and methods: Eighty-six patients with type 2 diabetes mellitus (DM) and proteinuria and/or renal impairment were enrolled in

this study. Renal biopsy was performed for all the patients in order to obtain definite renal diagnosis.
Results: Renal biopsy revealed that 60 patients (69.8%) had diabetic lesions and were diagnosed as DN. Hemoglobin was lower in patients with DN than in those without DN (12.0 ± 2.11 g/dL vs 13.3 ± 2.52 g/dL, $p = 0.0084$), whereas there was no significant difference of transferrin saturation (TSAT) and serum ferritin levels between both groups. DN patients had severer tubulointerstitial ($p < 0.05$) and vascular ($p < 0.0001$) damages than non-DN, however, urinary excretion of albumin/protein and estimated glomerular filtration rate (eGFR) showed no statistically significant relationship to the histological diabetic changes. To evaluate the significance of clinical and pathological parameters in the progression of anemia using multiple regression analysis, hemoglobin was positively correlated with eGFR and TSAT (eGFR; correlation coefficient 0.238, $p = 0.0313$, TSAT; correlation coefficient 0.245, $p = 0.0120$, respectively) and was inversely correlated with the severity of interstitial fibrosis and tubular atrophy (IFTA) (correlation coefficient −0.278, $p = 0.0352$).
Conclusion: Severity of IFTA could be closely associated with the development of renal anemia in CKD patients with DN. Severer tubulointerstitial damage in DN than non-DN could explain earlier manifestation of renal anemia.

Elevated systemic iron levels aggravate diabetic nephropathy

S. Altamura[1], J. Schmidt[1], K. Schreckenberger[1], K. Müdder[1], V. Peters[2], A. Wagner[3], P. Nawroth[4], M. Muckenthaler[1];
[1]Department of Pediatric Haematology, Oncology and Immunology, University of Heidelberg, Heidelberg, [2]Centre for Paediatric and Adolescent Medicine, University of Heidelberg, Heidelberg, [3]Department of Cardiovascular Physiology, University of Heidelberg, Heidelberg, [4]Department of Internal Medicine I and Clinical Chemistry, University of Heidelberg, Heidelberg, Germany.

Background and aims: Iron and diabetes are strictly related. This is clinically evident in patients affected by hereditary hemochromatosis, in which the prevalence of diabetes is about 20%. On the other side, recent studies demonstrate that in diabetic patients plasma iron and/or ferritin levels could be prognostic factors for the development of the disease. The aim of this project is to understand the role of increased iron levels in the generation of diabetic late complications. For this purpose, we have generated and characterized a mouse model of combined hereditary hemochromatosis type 4 and type 2 diabetes mellitus.
Materials and methods: To assess how increased iron levels affect the pathogenesis of diabetes and its complications, Lepr(db/db) mice affected by T2DM have been mated with the FpnC326S mouse model of hereditary hemochromatosis type 4. The main diabetic and iron parameters have been evaluated. Tissue iron content and distribution were assessed in histology while alterations in the expression of iron-related genes were analyzed in qRT-PCR and western blot. Kidney carnosine levels and PAS staining were used as markers of diabetic nephropathy.
Results: Already at 15 weeks of age, both diabetic and diabetic/hemochromatotic mice present the major hallmarks of the early T2DM: obesity, hyperglycemia and hyperinsulinemia. Diabetic mice show elevated circulating iron content which are not translated into increased hepcidin production, confirming our previously reported "iron resistance" phenotype (Altamura, 2017). The iron resistance mechanism is present also in diabetic/hemochromatotic mice, which show a 1,5-fold increase in systemic iron content compared to hemochromatotic mice. At molecular level, the liver is correctly sensing the elevated circulating iron levels, as shown by the activation of the BMP/SMAD pathway, further demonstrating that the iron resistance mechanism is dominant over this pathway. Analysis of the liver also revealed a decreased hepatic iron content in both diabetic and diabetic/hemochromatotic animals, a phenotype that occurs despite the elevated systemic iron content and the increased TfR1 mRNA expression. Histological analysis of the kidney revealed iron accumulation in the proximal tubules and in the glomeruli of 40-week old diabetic/hemochromatotic mice. At the same age, iron accumulation correlates with an increase in PAS staining and with decreased carnosine levels.
Conclusion: This study shows that type 2 diabetes mellitus causes an "iron resistant" phenotype where increased systemic iron levels are not correctly translated into hepcidin production. This mechanism is persistent also in the presence of an hemochromatotic background, further increasing the amount of circulating iron. Iron accumulation in the kidney correlates with a decrease in carnosine levels, a protective factor for diabetic nephropathy and increased PAS staining, a marker of diabetic kidney dysfunction. Taken together, these results indicate that elevated systemic iron levels, which can be considered as a diabetic complication, could aggravate diabetic nephropathy.

Serum levels of angiopoietin-like protein 4 in relation to glomerular function and nephropathy severity in type 2 diabetic patients

Y. Feng, L. Yang, C. Yu, S. Yuan, Y. Wang, N. Zhang, D. Zhao;
Beijing Key Laboratory of Diabetes Prevention and Research, Endocrinology Center, Lu He hospital, Capital Medical University, Beijing, China.

Background and aims: Diabetic nephropathy (DN) is one of the major diabetic microvascular complications that leads to end-stage kidney disease. Urinary Angiopoietin-like 4 was reported increased in STD-induced rats and in diabetic patients with microalbuminuria or macroalbuminuria. Nevertheless, whether ANGPTL4 could relate to glomerular function and DN severity is not defined in type 2 diabetic mellitus (T2DM) patients.
Materials and methods: The study complied with the Helsinki Declaration for investigation of human subjects and was approved by the competent Institutional Review Boards of the Lu He hospital. From July 2015 until January 2017, 1321 T2DM patients were recruited in the Endocrinology Center at Lu He hospital. After exclusion of the subjects with missing data or outliers, totaled 1241 patients were analyzed. The stages of DN were categorized by KDOQI Clinical Practice Guidance Diabetes and CKD based on urinary albumin-to-creatinine ratio (UACR) and/or estimated glomerular filtration rate (eGFR). Serum levels of angiopoietin-like 3 (ANGPTL3), ANGPTL4, high-sensitive C-reactive protein (CRP), vascular adhesion molecule-1 (VCAM-1), transforming growth factor-β1 (TGF-β1), neutrophil gelatinase associated lipocalin (NGAL) and vascular endothelial growth factor (VEGF) were quantified by ELISA. Multivariable-adjusted logistic analysis was performed to estimate the association of each biomarker and DN stage. Multivariable-adjusted linear regression was performed to study the association of each biomarker and eGFR or UACR. The confounding factors included were age, sex, body mass index, waist-to-hip ratio, mean arterial blood pressure, Hemoglobin A1c (HbA1c), total cholesterol, smoking, diabetic and hypertension history, anti-diabetic drugs, anti-hypertensive drugs (in class) and statins. For database management and statistical analysis, we used the SAS system, version 9.4 (SAS Institute Inc., Cary, NC).
Results: In the 1241 T2DM patients (47.62% women), age averaged (SD) 57.7 (14) years, body mass index 26.2 (3.8) kg/m^2 and eGFR 96.8 (21.4) mL/min/1.73m^2. When categorized by DN stage, 693 (55.84%) had no DN, 462 (37.23%) were in stage 3, 85 (6.85%) were in stage 4, and 1 (0.08%) was in stage 5. All patients received anti-diabetic treatment, among which 704 (56.7%) took metformin and 680 (54.8%) took insulin injection. The multivariable-adjusted odds ratios expressing the risk of DN stage ≥3 ($n = 548$) *vs.* DN <3 ($n = 693$) was 2.41 (95% CI, 1.94–3.0, $p < 0.0001$) for ANGPTL4. Except ANGPTL4, DN severity did not associate with other biomarkers ($p > 0.08$). One-SD increase of

serum ANGPTL4 levels were negatively associated with eGFR by −9.2 (95% CI, −11.9 to −6.4) ml/min/1.73 m^2 ($p < 0.0001$). Likewise, 1-SD increase of serum ANGPTL4 levels or ANGPTL3 levels were positively associated with UACR by 1.6 (95% CI, 1.3 to 1.9 mg/mmol, $p < 0.0001$) or 1.3 (95% CI, 1.0 to1.6 mg/mmol, $p = 0.0497$), respectively. Except that, other biomarkers were neither associated with eGFR nor with UACR ($p > 0.08$).

Conclusion: Serum levels of ANGPTL4 are strongly associated with DN severity. Blockade of ANGPTL4 in kidney might postpone the onset and development of DN in T2DM patients.

Post transplantation diabetes in kidney transplant recipients: time of diagnosis, impact on graft function and infectious complications

D. Cieniawski, E. Ignacak, A. Prokop, P. Miarka, K. Krzanowska, M. Kuzniewski, W. Sulowicz;
Department of Nephrology Jagiellonian University, Krakow, Poland.

Background and aims: Post transplantation diabetes mellitus (PTDM) is one of the most common complication affecting patients after organ transplantation. Development of PTDM is mainly connected with immunosuppressive treatment and individual tendency. The diagnostic difficulties are associated with high doses of drugs in the early period after transplantation and transient hyperglycemia observed in first weeks. Regardless of this, disturbances of carbohydrate metabolism are associated with a worse prognosis for both recipients and organs and the greater frequency of complications The aim of the study was to assess the incidence of PTDM, time of its diagnosis and impact on graft function and frequency of infectious complications.

Materials and methods: In prospective study we enrolled 212 consecutive kidney transplant recipients from years 2013–2014. Follow-up period was 24 months. The main endpoint was confirmation of PTDM diagnosis. All disease history reports and patients laboratory results available in the electronic systems from the first two years after transplantation were analyzed. The diagnosis of PTDM was determined according to standard criteria - two measurement of fasting plasma glucose ≥7.0 mmol/l, 2 hours glucose in OGTT (oral glucose tolerance test) ≥11.1 mmol/l or casual glycemia ≥11.1 mmol/l with standard symptoms. The frequency of infections was obtained from the hospital system information and questionnaire from patients. As clinically significant infection necessary of hospital admission or antibiotic use was assumed.

Results: The full-time follow-up was finished by 195 patients. Before kidney transplantation (ktx) diabetes was present in 13 patients. From other 199, PTDM was diagnosed in 56 cases (28.14%). In 34 graft recipients PTDM developed in first month after transplantation (60.7%). Between 2 and 6 months after ktx diabetes was confirmed in 9 patients (16.1%) and after fisrt six month in another 13 (23.2%). Patients with PTDM had significantly worse kidney graft function after 24 months of observation (eGFR 51.5 vs. 61.4 ml/min/1.73 m^2; $p = 0.002$). The same dependence was confirmed when the whole group with DM was analyzed (eGFR 52.0 vs. 61.4 ml/min/1,73m^2; $p = 0.0005$). The frequency of respiratory and urinary tract infections in first two years after ktx was higher in patients with DM (respectively 48.3% vs. 37.6%; $p = 0.170$, 46.7% vs. 41.0%; $p = 0.473$) but differences were not significantly important. The average number of respiratory tract infection was higher in patients with DM (1.24 vs. 0.94; $p = 0.167$), but reversed situation was observed in case of urinary tract infections - higher average value was obserwed in patients without DM (2.64 vs. 2.25; $p = 0.442$).

Conclusion: The incidence of PTDM is still high and is associated with a worse graft function. The highest risk of PTDM development is observed in first month after ktx. Patients with PTDM are exposed to a higher frequency of infectious complications in first two years. Frequency of respiratory and urinary tract infections is very high in first two years after ktx regardless of DM occurrence.

Ramadan fasting effects on renal function in type 2 diabetic patients

M. Abushady[1], M. Samy[1], M. bekhet[1], A. Abdullah[2];
[1]Endocrinology and Metabolism Department, Ain Shams University, Internal Medicine, Cairo, [2]Internal medicine Department, Specialized Damietta Hospital, Damietta, Egypt.

Background and aims: Ramadan fasting is a religious pillar carried out by Muslims all over the world. Concerns have been raised over how the practice of fasting from dawn to sunset affects kidney functions in diabetic Muslim patients as it represents a major shift in meal timing and content for practicing Muslims. It is hypothesized that patients with diabetic kidney may experience worsening of their kidney functions. We aimed to evaluate the effects of Ramadan fasting on kidney functions in type 2 diabetic patients.

Materials and methods: We recruited 90 patients with type 2 DM intending to fast Ramadan (2016); where the average fasting time was about 16 hours from 3 am to 7 pm. They were be divided into 30 patients with normal kidney functions and no albuminuria, 30 patients with albuminuria and normal kidney functions and 30 with albuminuria and renal impairment. Before Ramadan by two weeks and after Ramadan by two weeks, fasting blood glucose (FBG), 2hours plasma glucose (2hPG), hemoglobin A1c (HbA1c), fructosamine, serum creatinine, BUN, eGFR and albumin/ creatinine ratio were measured.

Results: On comparing the studied groups before and after fasting Ramadan, a significant reduction in HbA1c was found in all studied groups ($11.23 \pm 2.67\%$ vs $9.09 \pm 1.95\%$, $11.09 \pm 2.40\%$ vs $8.80 \pm 1.78\%$, $9.28 \pm 2.41\%$ vs $8.21 \pm 1.45\%$, $p < 0.001$, $p < 0.001$, $p = 0.04$ respectively). Regarding the kidney function parameters; there was no significant change in group I but there was a significant decline in these parameters in groups II and III; serum creatinine (1.33 ± 0.05 mg/dl vs 1.41 ± 0.23 mg/dl ,0.66 ± 0.11 mg/dL vs 0.93 ± 0.17 mg/dL , 0.70 ± 0.12 mg/dL vs 0.84 ± 0.16 mg/dL, $p = 0.101$, $p < 0.001$, $p < 0.001$ respectively), eGFR (63.07 ± 3.27 ml/min/1.73 m^2 vs 59.73 ± 13.25 ml/min/1.73 m^2, 114.00 ± 18.74 ml/min/1.73 m^2 vs 77.83 ± 16.48 ml/min/1.73 m^2, 111.70 ± 18.60 ml/min/1.73 m^2 vs 97.50 ± 21.19 ml/min/1.73 m^2, $p = 0.186$, $p < 0.001$, $p = 0.008$ respectively), urinary albumin/creatinine ratio (88.40 ± 64.86 mg/g vs 86.03 ± 86.52 mg/g, 71.43 ± 21.17 mg/g vs 112.33 ± 72.40 mg/g, 16.18 ± 7.99 mg/g vs 41.67 ± 22.0 mg/g, $p = 0.905$, $p = 0.004$, $p < 0.001$ respectively). Concerning hypoglycemia related events and need for dose reduction were significant in group I ($P < 0.001$) and ($p = 0.050$) respectively whereas group II and III showed non-significant difference in between as regards hypoglycemic events and dose modification need.

Conclusion: Ramadan fasting appears to a have significant effect on improvement of glycemic control in type 2 diabetic patients with no decline in kidney functions except in those patients with already existing albuminuria with or without abnormal kidney function.

3D kidney imaging for assessment of glomerular number and size in a mouse model of diabetic nephropathy

J. Hecksher-Sørensen, K. Fabricius, T.X. Pedersen, T. Johansen, L.N. Fink, N. Vrang, J. Jelsing, T. Secher;
Gubra, Hørsholm, Denmark.

Background and aims: Diabetic nephropathy (DN) is a major long-term complication of diabetes characterized by hypertrophy and hyperfunction of the kidney. To facilitate a rapid and unbiased evaluation of drug efficacy on glomerular size and number in preclinical studies, we investigated the use of light sheet microscopy as a new high-end 3D methodology to study glomerular changes in whole kidneys. Diabetic db/db mice subjected to unilateral nephrectomy (UNx) was used as a model.
Materials and methods: Unilateral nephrectomy (UNx) was performed in diabetic db/db mice to accelerate the development of nephropathy. The surgery was performed in 18 weeks old male db/db mice and terminated 6 weeks later. Prior to the UNx operation, mice were randomly assigned into two groups (control or UNx; $n = 8$) based on blood glucose levels. To determine the effect of accelerated DN on glomerular morphology, mice were injected with Lectin_594 prior to termination and the intact kidneys were scanned using light sheet microscopy. Using 3D image analysis, the total number of glomeruli were quantified and segmented according to their individual size.
Results: Diabetes development remained similar in db/db control and db/db UNx mice. However, at termination, kidney weight was increased in the db/db UNx group indicative of renal insufficiency leading to kidney hypertrophy. In agreement with stereological observations on histologically processed tissue sections, 3D light sheet imaging confirmed an increase in glomerular size in the db/db UNx mouse kidneys compared to db/db control mice, while glomerular numbers as expected were maintained (app. 14.000 glomeruli per kidney; see figure 1). The imaged kidneys were subsequently analyzed for Wt1, Collagen IV and podocin expression using conventional immunohistochemistry. All antigens were readily detected confirming that whole organ imaging is compatible with antibody detection and further substantiated the db/db UNx mice as a useful model of DN.
Conclusion: We have successfully applied light sheet microscopy to assess renal and glomerular hypertrophy at the whole organ level in uni-nephrectomised db/db mice. The analysis of intact organs offers a new approach for evaluating changes in key glomerular markers of DN, while maintaining the ability to perform conventional immunohistochemistry on the same tissue. This detailed analysis of all glomeruli enables improved pharmacological testing of compounds targeting this disease.

Next generation of spontaneous diabetic model of FATZO mice with intact leptin signalling develop nephropathy after high fat and high sucrose induction

J. Gorski, G. Sun, G. Zhang, Y. Wang;
Crown Biosciences, San Diego, USA.

Background and aims: Progressive albuminuria and bi-phasic changes in glomular filtration rate (GFR) are hall marks of functional deterioration of the kidney in diabetic nephropathy. However, not all diabetic rodent models can capture the development of such changes in the kidney. FATZO, a new generation of diabetic mouse model with intact leptin signaling pathway shows all the metabolic dysfunctions that mimic human patients such as obesity, dyslipidemia, diabetes and NASH. Here, we sought to further characterize the model for the evaluation of its development in diabetic nephropathy.
Materials and methods: Male FATZO mice on 5008 diet or on western diet with addition of 10% fructose (WD+fru) from age of 11 weeks were subject to monthly urine collection for albumin and creatinine measurement for 28 weeks, after which animals were treated with Lisinopril (15 mg/kg) and pioglitazone (20 mg/kg) daily for 6 weeks ($n = 8$ for each group). Animals were also monitored for GFR using a subcutaneous monitoring device (Medibeacon, US).
Results: Animals on WD+fru were heavier than those on 5008 diet. Notably, WD+fru markedly elevated urine albumin levels compared to 5008 diet in FATZO mice which resulted in higher albumin/creatinine ratio and urine albumin excretion rate (UAE) from 2 weeks on diet, while

Lisinopril treatment for 7 weeks could reduce the levels respectively. In addition, GFR was slightly elevated after 6 weeks of diet induction, which could be normalized by either pioglitazone or Lisinopril treatment.
Conclusion: We have created a mouse model with progressive albuminuria and elevated GFR that can be reversed by angiotensin-converting-enzyme (ACE) inhibitor. The model with associated dysmetabolic phenotypes including obesity and dyslipidemia can be used as an ideal tool for studying anti-diabetic nephropathy treatment.

A novel mechanism of prostaglandin E1 attenuating high glucose-induced apoptosis in renal tubular epithelial cells: a key role for the JNK/Bim pathway

Y. Zhang[1], Z. Zou[2], C. Guo[3], L. Liao[1], J. Dong[2], Z. Zhang[1];
[1]Department of Internal Medicine, Shandong Provincial Qianfoshan Hospital, Shandong University, Ji'nan, Shandong Province, [2]Department of Internal Medicine, Qilu Hospital of Shandong University, Ji'nan, Shandong Province, [3]First Clinical Medical College, Shandong University of Traditional Chinese Medicine, Ji'nan, Shandong Province, China.

Background and aims: Renal tubular damage is a critical process underlying diabetic kidney disease (DKD). Our previous study has suggested that prostaglandin E1 (PGE1) ameliorates renal tubule apoptosis in DKD rats. However, the precise mechanism remains unclear. We hypothesize that PGE1 alleviates tubular apoptosis of DKD by modulating primarily the c-Jun N-terminal kinase (JNK), a key regulator of cell apoptosis, while alleviating the gene expressions such as Bim, Bax and cleaved caspase-3 downstream related to intrinsic mitochondrial apoptosis.
Materials and methods: In the present study, we investigated the mechanism of PGE1 on the diminished apoptosis in the uninephrectomized streptozotocin (STZ)-induced diabetic rats. Renal proximal epithelial tubular cell line (HK-2) exposed to high glucose (HG) ambiance was also studied. Flow cytometry and TUNEL assays were used to detect apoptosis of renal tubular epithelial cells. Bim expression was detected by immunofluorescence. Immunohistochemical staining was introduced to detect the Bim, Bax and Bcl-2 expressions in renal tissue. The expressions of apoptosis related proteins Bim, Bax and cleaved caspase-3 were detected with western blot.
Results: Chronic exposure of the rodent tubular epithelial cells and HK-2 cells to high levels of glucose induced apoptosis ($p < 0.01$) and apoptosis related protein Bim, Bax and cleaved caspase-3 expressions ($p < 0.05$). Simultaneously, high glucose increased the phosphorylation level of JNK over time (1h, 6h, 12h, 24h, 48h), followed by the increased expression of Bim subsequently. PGE1 notably ameliorated renal tubular apoptosis in DKD rats and HK-2 cells in vitro, which was accompanied with the decreased expressions of Bim, Bax, and cleaved caspase-3 ($p < 0.05$). Treatment with anisomycin (AM), a JNK activator, resulted in an increased activation of phosphorylated JNK (p-JNK) in HK-2 cells ($p < 0.05$). Furthermore, PGE1 also reversed p-JNK expression in HK-2 cells when incubated with high glucose ($p < 0.05$) or combination of high glucose and AM ($p < 0.05$), followed by the decreased Bim protein expression.
Conclusion: Our results demonstrated that PGE1 ameliorated tubular apoptosis by modulation of mitochondrial apoptosis pathway via JNK-related Bim signaling.

Diabetic human carnosinase 1 transgenic BTBR$^{ob/ob}$ mice have reduced renal carnosine concentrations and display a higher degree of glomerular filtration barrier impairment

J. Qiu[1], F. Siegerist[2], A.-N. Rodriguez[1], D.O. Pastene[1], N. Endlich[2], B.K. Krämer[1], B.A. Yard[1];
[1]5th Medical Department, University Hospital Mannheim, Mannheim, [2]Department of Anatomy and Cell Biology, University Medicine Greifswald, Greifswald, Germany.

Background and aims: A trinucleotide repeat polymorphism in the *CNDP1* gene is associated with susceptibility to develop diabetic nephropathy (DN). Serum carnosinase 1, which is encoded by the *CNDP1* gene, degrades substrates that have been shown to exert beneficial effects in rodent models of DN, e.g. carnosine. Because of the complete lack of serum carnosinase in rodents, translation of these experimental findings to humans is difficult. We, therefore, have made human *CNDP1* transgenic mice in the BTBR$^{ob/ob}$ background to assess the role of renal carnosine in preventing glomerular damage.
Materials and methods: Chip-based gene expression profiling was performed using renal tissue obtained from diabetic wild-type and hCNDP1 transgenic BTBR$^{ob/ob}$ mice. Renal carnosine concentrations were assessed by HPLC and podocyte effacement by 3D structured illumination microscope.
Results: Renal tissue obtained from diabetic hCNDP1 displayed ~10 fold decreased levels of carnosine as compared to age-matched wild-type diabetic mice. Gene expression profiling revealed in the transgenic diabetic kidney upregulation of genes associated with kidney disease (9 of the 15 most upregulated genes) and a decreased expression of genes related to cell cycle and cell death (5 of the 15 most downregulated genes). KEGG and GO annotation analysis revealed cell adhesion and tight junction as most enriched amongst all up-regulated genes and phosphorylation/kinase activity amongst all downregulated genes. Transgenic mice displayed higher albuminuria and proteinuria levels. Using 3D structured illumination microscopy, a significantly higher slit diaphragm density indicating less podocyte foot process effacement was detected in transgenic diabetic kidneys.
Conclusion: Carnosinase 1 overexpression decreases renal tissue carnosine and aggravates glomerular filtration barrier impairment. This might be a consequence of a pathological slit membrane due to altered expression of cell adhesion and tight-junctional proteins. Further histological analysis to confirm the latter is warranted.

Apoptosis resistant modified endothelial progenitor cell (EPC) transplantation improves diabetic kidney disease (DKD)

N. Kundu, L. Asico, C. Domingues, P. Jose, S. Sen;
George Washington University, Washington, USA.

Background and aims: DKD is a major vascular complication of diabetes, which is associated with glomerulosclerosis and poor perfusion. Therefore, improving the renal perfusion may help to treat the sclerotic kidney disease. EPCs have been shown to improve tissue perfusion. Here, we investigated whether transplanting apoptosis resistant genetically modified mouse EPCs (that has p53 gene silenced, transiently, using Adenovirus ex-vivo), could improve angiogenesis and renal perfusion, in a hyperglycemic type 1 diabetes milieu. Mesenchymal stromal cells (MSC) transplantation has also been used in DKD however concern for epithelial to mesenchymal transformation following MSC transplantation remains. .
Materials and methods: We compared the efficacy of p53shEPC with MSC, Null-EPC and saline in STZ-induced type 1 diabetic C57BL/6J mouse model. 8 weeks after STZ delivery stable hyperglycemia, polyuria and proteinuria was confirmed followed by transplantation of 0.3 million EPC/ MSC bilaterally, under each kidney capsule. We compared our results with non-STZ normal C57Bl6J mouse. Urine was collected weekly for volume, protein and creatinine estimation. Blood creatine and renal blood flow was measured by laser Doppler, at sacrifice. qRT-PCR on

harvested kidneys were performed focusing on genes associated with angiogenesis
Results: Polyuria was reduced in p53shEPC transplanted animals with urine volume close to non DM animals and half the volume compared to saline and MSC group at week 4 and 6. Protenuria levels were the lowest in p53shEPC group. Plasma creatinine was lowest in p53shEPC group (3-fold lower) compared to Null EPC group Enhanced blood flow by laser doppler was also noted with delivery of p53sh-EPCs vs controls, such as null EPC (1.2 fold), saline (3 folds) at wk4&6. Markers for angiogenesis, such as eNOS mRNA (4.5 fold, $p = 0.002$) and VEGF-A mRNA (1.5 fold, $p = 0.03$) upregulated significantly post p53 silenced EPC transplantation compared to null EPC group. Capillary density staining is pending.
Conclusion: Transient silencing of p53 gene in EPCs help to improve proteinuria, plasma creatinine, diabetic polyuria and renal blood flow, most likely by helping to increase angiogenesis and perfusion and may have a prominent therapeutic role in DKD. MSC transplantation results were consistently less efficacious compared to p53silenced EPC transplantation.

Modulation of TIMP3-ADAM17 dyad limits the progression of diabetic nephropathy
R. Menghini[1], V. Casagrande[1], S. Menini[2], G. Iuliani[1], L. De Angelis[1], M. Mavilio[1], G. Pugliese[2], M. Federici[1];
[1]University of Rome Tor Vergata, Rome, [2]Sapienza University, Rome, Italy.

Background and aims: The tissue inhibitor of metalloproteinase (TIMP)3 is the most highly expressed TIMP in the kidney and we and others have recently demonstrated that loss of TIMP3 contributes to the onset and progression of Diabetic Kidney Disease in mouse models of diabetes, at least in part through the regulation of A Disintegrin and Metalloproteinase (ADAM)17. Our aim was to provide evidences that in vivo manipulation of the TIMP3/ADAM17 system may limit the onset and the progression of diabetic kidney complications.
Materials and methods: We generated a mouse model with cell-targeted overexpression of TIMP3 in myeloid cells (MacT3), which results in kidney overexpression of TIMP3 consequently to macrophage accumulation induced by diabetes, and a podocyte-specific ADAM17 knockout mice (ΔPodA17). WT, MacT3 and ΔPodA17 mice ($n = 10$ for each group) were rendered diabetic through i.p. injections of STZ (50 mg/kg) for 5 consecutive days. After 12 weeks, 24h Albuminuria was determined by ELISA and kidney morphometry was analyzed by periodic acid-shift staining (PAS). RT-PCR and western blot analysis were performed on mRNA and protein extracted from kidney cortex.
Results: in both mouse models, morphometric analyses showed a reduction in renal lesions, as assessed by lower increase in mean Glomerular Area (mGA), mean Mesangial Area (mMA) and fractional Mesangial Area (fMA) ($p < 0.002$). Consistently, 24h urine Albuminuria was significantly reduced ($p < 0.05$). Moreover, preliminary analysis of mRNA and proteins derived from renal cortex of MacT3 mice indicated that expression of TIMP3 in macrophages led to an increased TIMP3 mRNA expression ($p = 0.02$), rescuing impaired inflammatory markers (F4/80, MCP1 and IL6 ($p < 0.05$)) observed in diabetic WT mice. Protein expression of podocytes markers Podocin an WT1 ($p = 0.01$) were significantly improved whereas fibrosis markers Collagen IV and TGF beta were reduced in MacT3 diabetic mice compared with diabetic control mice.
Conclusion: Our data indicate that in vivo manipulation in rodent models of TIMP3/ADAM17 system may rescue kidney defects induced by diabetes, representing a valid approach to characterize the pathogenesis of Diabetic Nephropathy and to develop new avenues to diagnose and treat this disorder.

Salidroside ameliorates diabetic albuminuria through inhibition of Bim-mediated mitochondrial apoptosis in renal tubular cells
C. Guo, L. Liao;
Shandong Provincial Qianfoshan Hospital, Jinan, China.

Background and aims: Accumulating studies indicate that the apoptosis of tubular cells is implicated in progression of the diabetic kidney disease (DKD). How to prevent or treat the injury remains unsolved. Here, we investigate whether salidroside, a natural phenolic antioxidant compound can protect tubular cells from high glucose-induced apoptosis.
Materials and methods: Salidroside, at a dose of 70 mg/kg body weight, was orally administrated to uninephrectomized streptozotocin-induced DKD rats for up to 8 weeks. Renal function related parameters, such as 24-h urine albumin and serum creatinine (SCr) of the rats were measured. TUNEL, immunohistochemistry and western blot examinations were conducted to evaluate the anti-apoptosis activity of salidroside in DKD rats. Subsequently, human renal proximal tubule cells line (HK-2 cells) were used to further verify the activity and explore the mechanisms in vitro. Finally, the underlying pathways involved in the nephroprotective effect of salidroside were predicted by a network pharmacology approach.
Results: The vivo studies in DKD rats showed that the amounts of cells underwent apoptosis were significantly more in tubule regions than that in glomerular regions. Salidroside treatment dramatically decreased the apoptosis rate of tubular cells, inhibited the expression of Bax, cleaved caspase-3 protein, and reversed the increased serum creatinine and albuminuria in the DKD rats. In vitro studies further demonstrated that high glucose reduced cell viability and increased apoptosis by elevating Bim protein expression, which is a proapoptotic inducer of mitochondrial apoptosis. Silencing of Bim protein reduced the expression of Bax and cleaved caspase-3 protein. Salidroside significantly downregulated Bim expression and ROS production. The enrichment analysis of network pharmacology verified the above results that the nephroprotective effect of salidroside was associated with various pathways involved in anti-apoptosis signing pathwayand antioxidant processes.
Conclusion: We conclude that salidroside could significantly relieve DKD. The possible mechanisms might be the decrease in apoptosis of tubular cells via Bim and oxidative stress inhibition.

Metformin is nephroprotective in a progressive renal disease model
C.M. Borges[1], C.K. Fujihara[2], V.F. Ávila[2], D.A. Duarte[1], J.M. Lopes de Faria[1], J.B. Lopes de Faria[1];
[1]Renal Pathophysiology Laboratory, Investigation on Diabetes Complications, State University of Campinas, Campinas, [2]Faculty of Medicine, University of São Paulo, São Paulo, Brazil.

Background and aims: Chronic kidney disease (CKD) is one of the most common metabolic diseases, worldwide. Currently, the treatment of CKD is suboptimal since a large number of individuals with CKD progress to end-stage renal disease, thus requiring dialysis and/or kidney transplantation. It has been demonstrated that metformin exerts pleitropic efffects beyond its actions as glucose-lowering agent in the treatment of diabetes mellitus. The use of rats with 5/6th renal ablation (Nx) is a well-established progressive renal disease model. Previously, it has been demonstrated that metformin prevented kidney fibrosis in the Nx model. However, treatment with metformin was initiated before the development of CKD in the nephrectomised rats. The present study investigated whether metformin is nephroprotective when treatment is initiated after the rats had developed higher levels of albuminuria and higher blood pressure level.
Materials and methods: Adult male Munich-Wistar rats underwent Nx. Thirty days after the nephrectomy, the rats with a systolic blood pressure

(SBP) above 170 mmHg and albuminuria levels >40 mg/24 h were randomised into four groups: Sham group; Nx, no treatment group; Nx+M group (receiving metformin 300 mg/Kg/day - in drinking water), and Nx+L group (receiving losartan 50 mg/Kg/day - in drinking water). Twenty-four-hour urine was collected in individual metabolic cages to assess albuminuria levels using enzyme-linked immunosorbent assay (ELISA); systolic blood pressure (SBP) was estimated using a tail-cuff method. The treatments were maintained for 120 days. At the end of the study, the rats were euthanised and the kidneys were harvested and processed for histological analysis.

Results: At baseline, the 24 h urinary albumin excretion rate (UAE) and SBP were significantly higher in the Nx group than in the Sham group. After 60 days of treatment, UAE decreased from 105 ± 37 mg/24 h to 39 ± 32 mg/24 h ($p = 0.0001$) and SBP decreased from 226 ± 21 mmHg to 167 ± 17 mmHg ($p = 0.0001$) in the Nx+L group in comparison to the untreated Nx group ($n = 10$). After 120 days, UAE was 162 ± 82 mg/24 h in the Nx group; it decreased to 54 ± 38 mg/24 h in the Nx+L group ($p = 0.0001$) and to 110 ± 41 mg/24 h in the Nx+M group ($p = 0.0125$). The effect of metformin on albuminuria was independent of any change in the blood pressure and glycaemia levels. Interstitial fibrosis was significantly higher in the Nx group than in the Sham group, and it was decreased in both the Nx+M and Nx+L groups after 120 days of treatment.

Conclusion: Metformin was able to prevent a further increase in albuminuria levels and to reduce kidney interstitial fibrosis in rats with established CKD, elevated blood pressure and albuminuria. Thus, the nephroprotection confered by metformin was independent of blood pressure and glycaemic controls.

Approaches for the generation of human kidney organoids for modelling nephropathies

K. Uusi-Rauva[1,2], A. Pirttiniemi[1,2], S. Lehtonen[3], V. Fellman[1,4], P.-H. Groop[1,2], M. Lehto[1,2], FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland, [2]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland, [3]Department of Pathology, University of Helsinki, Helsinki, Finland, [4]Department of Clinical Sciences, Pediatrics, Lund University, Lund, Sweden.

Background and aims: Induced pluripotent stem cell (iPSC)-derived kidney cells enable dissection of diabetic nephropathy, or other kidney diseases, in patient-derived cells. Several approaches for the differentiation of kidney cells from iPSCs have been published, including the generation of kidney organoids. However, cell line characteristics and culture conditions may affect the end result of the differentiation. In addition, current organoid protocols cannot be used directly for high-throughput applications required for extensive functional analyses or subsequent drug screenings. Therefore, the reproducibility of one of the previously published protocols for the generation of iPSC-derived kidney organoids was tested using different cell lines and initial cell confluences. In addition, four different modified approaches with different culture systems, multiwell plate products, and amounts of cells were tested to set up more efficient and consistent organoid protocol in order to better address the needs of high-throughput analyses.

Materials and methods: This study was based on pre-established iPSC lines derived from healthy volunteers and a patient with GRACILE syndrome (OMIM:603358). The survival and the amount of intrinsic structures positive for well-established markers for kidney cells of differentiating organoids were analysed by light and immunofluorescence microscopy.

Results: Kidney organoids were managed to be generated from three out of five iPSC lines tested. However, the amount and appearance of intrinsic structures were variable between separate cell lines but also from experiment to experiment. Initial cell confluence had different effects on the outcome between separate cell lines. In general, the amount and appearance of nephrin-positive glomeruli seemed to be cell line-dependent, although in case of GRACILE kidney organoids, this phenomenon may be a sign of potential disease-associated phenotype. All tested modified approaches also allowed formation of structures positive for kidney cell markers but the total outcome of them all was not comparable to the organoids generated using the original protocol, and separate cell lines appeared to respond differently to different approaches. Nevertheless, some of the tested approaches were found to be highly promising, and may enable rather easy processing of a plateful of 24–96 kidney organoids simultaneously.

Conclusion: These results confirm that initial culture conditions may have substantial effects on the kidney differentiation, and thus, each cell line should be tested using different culture systems and cell confluences, and potential phenotypes of affected organoids need to be controlled with appropriate isogenic controls. In the future, kidney organoids generated from iPSCs of patients with nephropathy, their healthy relatives, and isogenic control cell lines using the here established, more efficient differentiation approach(es) can and will be utilised for the functional analyses of diabetic and other nephropathies.

Modelling the metabolic reprogramming of diabetic nephropathy using hESC-derived 3D kidney organoids

C. Hurtado del Pozo, P. Prado Peralta, B. Coppe, E. Garreta, N. Montserrat;
IBEC, Barcelona, Spain.

Background and aims: Diabetic Nephropathy (DN) is the leading cause of end-stage renal disease (ESRD). To date, treatment of DN is mainly based on drugs acting on glycaemic and blood pressure control, as there is no validated therapy able to stop the progression towards renal failure. One of the main impediments for developing new therapies for DN has been the lack of a good preclinical models which can recapitulate important functional, structural, and molecular features of advanced human diabetic kidney disease. Due to the increasing evidences that links kidney fibrosis and metabolic reprograming in DN, we hypothesize that early DN progression is promoted by the metabolic alterations occurring in diabetic patients. To test our hypothesis, we have first developed a DN model taking advantage of human Embryonic Stem Cell (hESC) derived kidney organoids. In our hands, this innovative system recapitulates the in vivo signature of DN including phenotypic and genetic alterations.
Materials and methods: **Kidney organoid differentiation:** Differentiation protocol was developed in our lab (Garreta et al, *under review*). **Isolation of tubular epithelial cells (TECs) from organoids:** TECs were isolated by flow cytometry from kidney organoids after incubation with fluorescein-conjugated Lotus Tetragonolobus Lectin (LTL) for five hours and further dissociation with Accumax. LTL^+ cells were cultured in REGM media. **Purification of Total RNA and Quantitative RT-PCR:** Isolation of total RNA was performed using Tri-Reagent®. 1 ug of RNA was used to synthesize cDNA. cDNAs (25 ng/well) were used to quantify gene expression by Quantitative RT-PCR (qPCR). All absolute data were first normalized to *RPLP0*. **Collagen measurement:** collagen quantification was performed using Collagen Assay Sircol™ **Trichome Masson Staining**: Trichrome Stain (Masson) Kit was used to stain paraffin sections of kidney organoids to ascertain fibrotic-like deposition.
Results: Under hypoxia and high glucose environment (diabetogenic condition) kidney organoids showed an increase in the mRNA levels of core pro-fibrotic genes (*COL1A1*, *COL3A4*, *COL4A1*, *ACTA2*) and collagen synthesis by colorimetric assay (Collagen Assay SircolTM) To check if kidney organoids can recapitulate the metabolic reprograming, previously reported in the diabetic kidney, we compared TECs from diabetic or control patients with TECs sorted from kidney organoids exposed to control and diabetogenic cell culture conditions. We observed that both cellular systems exhorted a similar metabolic profile assessed by Seahorse analysis and qPCR. Next, we inhibited fatty acid oxidation (FAO-main source of energy for TECs) exposing kidney organoids to etomoxir and further analysed by qPCR and Trichome mason staining the extent of a fibrotic-like response. The results showed that FAO inhibition results in a metabolic reprogramming (from FAO to glycolytic) together with an increase in the levels of expression of core pro-fibrotic genes.
Conclusion: The information gained here opens the door for the development of a DN model in kidney organoids. As a first proof of concept we interrogated for the effect of FAO inhibition in this system and showed that TECs metabolic reprogramming resulted in a fibrotic-like response at both transcriptomic/phenotypic level. Our model is currently being explored for the screening of epigenetic modifiers targeting FAO components serving as an unprecented tool for drug discovery in DN.

Activated TGF-β1 reduces GPx-4 protein abundance in murine podocytes

C. Hangel[1], R.H. Henning[2], A.H. Wagner[1], M. Hecker[1];
[1]Division of Cardiovascular Physiology, Institute of Physiology and Pathophysiology, Heidelberg, Germany, [2]Department of Clinical Pharmacy and Pharmacology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Background and aims: Glutathione peroxidases (GPx) protect cells from oxidative damage by catalyzing the reduction of both lipid and hydrogen peroxides. Oxidative stress has been reported to be a causative factor in the progression and complications of renal diseases. We previously showed that GPx-1 and GPx-4 expression was significantly reduced in kidney glomerular podocytes of people with type 2 diabetes (T2D). These individuals have also higher serum leptin levels, inducing the release of growth factors like, e.g. transforming growth factor β-1 (TGF-β1) from glomerular endothelial cells. As endothelial cells and podocytes are in close proximity in the glomerulus, we investigated *in vitro* the paracrine signaling mechanism causing a reduction of GPx-4 protein abundance in podocytes.
Materials and methods: Conditionally immortalized murine microvascular endothelial cells (CI-muMECs) were cultured until reaching 100% confluence and exposed to different concentrations of leptin (10–1000 ng/ml leptin) for 24 hours. Medium supernatants were analyzed for TGF-β1 concentration measured by enzyme linked immunosorbant assay (ELISA). Quantitative real-time PCR was used to detect and quantify TGF-β1 mRNA in CI-muMECs. The podocyte cell line E11 was incubated with different concentrations of TGF-β1 (1–50 ng/ml) as well as different concentrations of leptin (5–200 ng/ml) and harvested after 5 days of treatment for GPx-4 protein analysis using standard Western blot techniques.
Results: No significant difference in TGF-β1 mRNA levels between non-stimulated and stimulated CI-muMECs could be detected. In contrast, a significant ($p < 0.05$) 1.6 fold increase of activated TGF-β1 (30 ng/ml) in the medium supernatant of the endothelial cells could be detected after stimulation with 100 ng/ml leptin. Subsequently, using this concentration of TGF-β1 in co-culture experiments with podocytes resulted in a significant ($p < 0.05$) 50% decrease in the GPx-4 protein content of these cells after 5 days incubation time.
Conclusion: These results show that elevated levels of leptin in obese people with T2D may have an indirect effect on kidney podocytes via leptin binding to glomerular endothelial cells and increased release of activated TGF-β1. This paracrine TGF-β1 signaling might cause a reduction of GPx-4 protein abundance in podocytes leading to ferroptosis, a non-apoptotic iron-dependent form of regulated cell death. Ferroptosis is characterized by the execution of GPx-4 and a subsequent accumulation of lipid peroxides. This might explain a fundamental mechanism causing kidney damage in people with diabetes.

DPP-4 release in human podocytes

E. Benetti[1], V. Bordano[1], F. Barutta[2], G. Gruden[2], C. Fedele[1], A. Rosa[1], T. Klein[3], G. Miglio[1];
[1]Scienza e Tecnologia del Farmaco, University of Turin, Turin, Italy, [2]Department of Medical Sciences, University of Turin, Turin, Italy, [3]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

Background and aims: Dipeptidyl-peptidase (DPP)-4 is the pharmacological target of gliptins, drugs approved for the treatment of Type-2 diabetes mellitus. It is a membrane-bound protein expressed by different cell types, including podocytes. However, a soluble DPP-4 form is also found in serum, thus indicating the existence of at least two forms of this

enzyme, possibly playing a distinct pathophysiological role. To date, however, the mechanisms involved in determining the relative proportion of the known DPP-4 forms have not be fully elucidated. By employing human immortalized podocytes as a cellular model, the effect of relevant stimuli for this cell type on the release of DPP-4 was studied

Materials and methods: Human immortalized podocytes were exposed (48 h) to angiotensin II (1 μM), transforming growth factor (TGF)-β (10 ng/ml), phorbol 12-myristate 13-acetate (PMA; 50 nM) or forskolin (10 μM). The level of the soluble DPP-4 was evaluated in cell-conditioned media by ELISA. Moreover, DPP-4 enzymatic activity was determined both in cell extracts and conditioned media by measuring the cleavage of the substrate H-Ala-Pro-7-amido-4-trifluoromethylcoumarin. Statistical significance was assessed by the Student's t test and a $P < 0.05$ was adopted as threshold.

Results: DPP-4 was highly expressed in human immortalized podocytes. In comparison to the cell-conditioned media, a ~100-fold higher enzymatic activity was determined in cell extracts. Soluble DPP-4 level was significantly increased in the media of cells treated with angiotensin II ($P < 0.05$ *vs*control), but not with TGF-β. DPP-4 release was also dramatically increased by PMA ($P < 0.005$ *vs* control), but not by forskolin.

Conclusion: In human podocytes DPP-4 release is promoted by angiotensin II. This effect could be mediated by the activation of phospholipase C isoenzymes. Overall, modulation of DPP-4 release could contribute to the effects exerted by specific stimuli affecting podocyte biology. In addition, a better characterization of the DPP-4 biology could add new piece of evidence to the gliptin pharmacology.

(-)-Epicatechin and the colonic metabolite 3,4-dihydroxyphenylacetic acid protect against high glucose-induced stress via SIRT1 in renal tubular cells

D. Álvarez-Cilleros[1], M.-Á. Martín[1,2], L. Goya[1], S. Ramos[1];
[1]Instituto de Ciencia y Tecnología de los Alimentos y Nutrición (ICTAN-CSIC), Madrid, [2]CIBER de Diabetes y Enfermedades Metabólicas (CIBERDEM), Madrid, Spain.

Background and aims: Persistent oxidative stress plays a main role in the development and progression of the diabetic nephropathy, which is accompanied by increased production of free radicals and/or impaired antioxidant defences. Flavonoids have been found to possess beneficial effects on health and have drawn attention because of their safety. Oligomeric and polymeric flavanols are metabolised by the intestinal microbiota into various phenolic acids of low molecular weight, which are well absorbed in the colon. (-)-Epicatechin (EC), a main flavanol in cocoa, and its colonic metabolites, such as 3,4-dihydroxyphenylacetic acid (DHPAA), 2,3-dihydroxybenzoic acid (DHBA) and 3-hydroxyphenylpropionic acid (HPPA), could display some antidiabetic effects, but the mechanisms for their preventive activities related to oxidative stress in the kidney remain largely unknown. In the present work, the effects of EC and the mentioned microbial metabolites on the redox status are studied in renal proximal tubular NRK-52E cells treated with high glucose.

Materials and methods: NRK-52E cells treated for 2 h with realistic concentrations of EC, DHPAA, DHBA or HPPA (10 μM) were further exposed to 30 mM glucose for 22 h. In the experiments with the inhibitors, cells were pre-incubated with 10 μM DPI or 10 μM EX-527 for 1 h prior to EC or DHPAA incubation for 2 h followed by the glucose challenge. Generation of reactive oxygen species (ROS) and glutathione levels (GSH) were evaluated by fluorimetric methods. Activities of the antioxidant enzymes glutathione peroxidase (GPx), glutathione reductase (GR), superoxide dismutase (SOD) and catalase (CAT) were assayed by spectrophometric methods. Total levels of proteins related to oxidative stress such as ERK, JNK, p38, SIRT-1 and NOX-4 were analysed by Western blot.

Results: Pre-treatment of cells with EC or DHPAA reverted the enhanced generation of ROS induced by glucose (30 mM), but not when they were treated with DHBA or HPPA. EC and DHPAA pre-treatment also prevented the inactivation of GPx, GR, CAT and SOD induced by glucose, showing a glutathione content similar to those of control cells. Furthermore, glucose induced a diminution of SIRT-1 levels, which was avoided by EC and DHPAA. Pre-treatment of cells with EC and DHPAA prevented the increase in phosphorylated MAPKs and total NOX-4 levels provoked by 30 mM glucose. Inhibition of NOX-4 and SIRT-1 in EC- and DHPAA-pre-treated cells showed the involvement of both proteins in EC- and DHPAA-mediated protection.

Conclusion: EC and the flavanol colonic metabolite DHPAA at concentrations that are not toxic to tubular renal cells and are reachable through the diet, possess a renoprotective effect. EC and DHPAA contributed to the cellular redox balance by preventing excessive ROS generation, and activation of stress related key proteins (MAPKs and NOX-4), as well as by averting the diminution of antioxidant defences and SIRT-1 levels induced by high glucose. Further efforts are needed to define the precise role of EC and its colonic metabolites on the protection of renal function, but it could be suggested that a diet rich in EC and/or cocoa may be a potential chemopreventive tool useful for the management of diabetes.

Endothelial FGFR1 is essential for the anti-fibrotic and anti-EndMT effects of N-acetyl-seryl-aspartyl-lysyl-proline in diabetic mice

K. Kanasaki, J. Li, K. Nitta, D. Koya;
Kanazawa Medical University, Kahoku, Ishikawa, Japan.

Background and aims: Endothelial-to-mesenchymal transition (EndMT) and epithelial-to-mesenchymal transition (EMT) have been shown to contribute in organ fibrogenesis, and we have reported that the anti-EndMT effect of N-acetyl-seryl-aspartyl-lysyl-proline (AcSDKP) was associated with restoring expression of diabetes-suppressed fibroblast growth factor receptor (FGFR)1. We recently reported that the deficiency in endothelial FGFR1 resulted in EndMT and AcSDKP could not suppress EndMT in FGFR1 deficient endothelial cells. Here we investigated whether endothelial FGFR1 is critical for anti-EndMT and anti-fibrotic action of AcSDKP in diabetic kidney.

Materials and methods: In vitro analysis was performed by using human dermal microvascular endothelial cells (HMVECs) and HK-2 tubular cells. In vivo, endothelial specific FGFR1 deficient mice (FGFR^{endo}: *FGFR1*$^{fl/fl}$; *VE-cad Cre(+)*) were generated and streptozotocin was utilized for the induction of diabetes.

Results: The conditioned-media from EndMT cells (FGFR1 deficient endothelial cells) stimulated transforming growth factor-β-dependent EMT in HK2 cells. In vivo, the kidney fibrosis was induced in diabetic both control mice (*FGFR1*$^{fl/fl}$; *VE-cad Cre(-)*) and FGFR1^{endo}; the fibrosis is significantly severe in diabetic FGFR1^{endo}. The intervention with AcSDKP significantly ameliorated the kidney fibrosis in diabetic control mice, but only partially suppressed in diabetic FGFR1^{endo}. In addition, AcSDKP had no effect on EndMT but suppressed EMT in kidney of diabetic FGFR1^{endo}.

Conclusion: These data demonstrated that the endothelial FGFR1 is functional target of AcSDKP and the key molecule for combating diabetes-associated kidney fibrosis in diabetes by suppressing EndMT.

1034

The role of TNF-a-Induced Protein 2 in diabetic nephropathy

F. Barutta, S. Bellini, B. Corbetta, G. Gruden;
University of Turin, Turin, Italy.

Background and aims: Diabetic nephropathy (DN) is characterised by increased glomerular permeability to proteins. The cytosolic protein TNF-α-Induced Protein 2 (TNFAIP2) is induced by TNF-α, an inflammatory cytokine implicated in the pathogenesis of DN. Moreover, TNFAIP2 expression is affected by retinoic acid, which is a key regulator of podocyte phenotype. This raises the possibility that TNFAIP2 may play a role in DN; however, there is no information on TNFAIP2 in diabetic or other kidney diseases. Our aim was, thus to assess if TNFAIP2 expression is altered in both human and experimental DN and to investigate the potential role of TNFAIP2, by studying both functional and structural abnormalities of DN in diabetic mice knockout for TNFAIP2.
Materials and methods: *Human kidney biopsies*: TNFAIP2 protein expression was studied in kidney biopsies from type 2 diabetic patients with overt DN ($n = 15$) and control non-diabetic subjects ($n = 6$) by immunohistochemistry/double immunofluorescence. *Experimental diabetes*: TNFAIP2 expression was measured in both renal cortex sections and isolated glomeruli obtained from both diabetic (DM $n = 15$) and control (ND $n = 15$) animals after 14 weeks of diabetes by RT-PCR, immunohistochemistry, immunoblotting. *In vitro experiments*: podocytes were exposed to high glucose, mechanical stretch, TNF-α, or retinoic acid for various time periods and TNFAIP2 expression analysed by either RT-PCR or immunoblotting. Control cells were studied in parallel. *In vivo study*: Both wild type ($TNFAIP2^{+/+}$) and TNFAIP2 knockout ($TNFAIP2^{-/-}$) mice were made diabetic by intraperitoneal injection of streptozotocin. Control mice were injected with citrate buffer alone. Fourteen weeks after the induction of diabetes, mice were individually placed in metabolic cages for urine collections and blood samples taken for blood glucose and glycated haemoglobin measurements. Albumin excretion rate and creatinine clearance were measured by enzyme-linked immunosorbent assay and HPLC, respectively. Expression of podocin, synaptopodin, and fibronectin was assessed by either immunofluorescence or RT-PCR.
Results: Glomerular TNFAIP2 expression was greater in patients with DN than healthy subjects and showed a predominant podocyte distribution. Similarly, glomerular TNFAIP2 expression was upregulated in diabetic mice as compared to controls. Cultured podocytes constitutively express TNFAIP2 at both mRNA and protein level and TNFAIP2 expression was increased by high glucose, TNF-α, and retinoid acid. Diabetes was associated with reduced body weight and elevations in both plasma glucose and glycated haemoglobin levels, but no differences were seen between $TNFAIP2^{+/+}$ and $TNFAIP2^{-/-}$ mice. Albumin/creatinine ratio was significantly ($p < 0.05$) increased in the wild type diabetic animals (DM: 68.2 ± 14.0) as compared to the controls (ND: 36.7 ± 7.6) and further enhanced by TNFAIP2 deletion [(ND $TNFAIP2^{-/-}$:28.8 ± 7.9; DM $TNFAIP2^{-/-}$:144.1 ± 36.5; $p < 0.05$ DM $TNFAIP2^{+/+}$ vs DM $TNFAIP2^{-/-}$]. Moreover, diabetes-induced both podocin and synaptopodin down-regulation was further exacerbated in diabetic mice lacking TNFAIP2. Histological assessment by PAS staining showed that the degree of mesangial expansion was greater in diabetic mice $TNFAIP2^{-/-}$ than in wild type mice. Consistently, diabetes-induced fibronectin overexpression was significantly increased by TNFAIP2 deletion.
Conclusion: These results suggest a protective role of TNFAIP2 in DN.

Mesenchymal stem cells prevent progression of diabetic nephropathy by improving mitochondrial function in tubular epithelial cells

K.-U. Lee, E. Koh, J. Jang, C. Woo, S. Lee;
Asan Medical Center, Seoul, Republic of Korea.

Background and aims: Mitochondrial dysfunction is considered a major pathogenic factor in diabetic nephropathy. Renal proximal tubular epithelial cells (TECs), which are abundant in mitochondria, play an important role in its progression. Administration of mesenchymal stem cells (MSCs) was shown to attenuate overt, as well as early, diabetic nephropathy in rodents, but the mechanism of this prevention is largely unknown.
Materials and methods: We examined the preventative effects of human umbilical cord blood-derived MSCs on proximal tubular injury in streptozotocin-induced diabetes, and whether MSCs ameliorate mitochondrial dysfunction. We also investigated the molecular mechanism by which MSCs can improve mitochondrial function in TECs.
Results: MSC administration to diabetic mice reversed albuminuria and prevented both inflammation and proximal tubular injury in the kidneys. The expression of pro-inflammatory M1 macrophage markers, and arginase 1 (*Arg1*), a representative M2 macrophage marker, increased and decreased, respectively, in diabetic kidneys. Treatment with MSCs notably prevented these changes. Correspondingly, co-culture of macrophages with MSCs significantly decreased M1 macrophage markers, with a concomitant increase of *Arg1* expression. Inflammatory cytokines produced by macrophages decreased mitochondrial biogenesis in adipocytes. Similarly, conditioned media from lipopolysaccharide-activated macrophages decreased the expression of peroxisomal proliferator-activated receptor gamma coactivator 1α (*Pgc-1α*) and impaired mitochondrial function in cultured TECs. These effects were reversed by co-culture of macrophages with MSCs. In addition, *Arg1*-overexpression in macrophages reversed the *Pgc-1α* suppression observed in TECs.
Conclusion: Treatment with MSCs prevents progression of diabetic nephropathy by reversing mitochondrial dysfunction in TECs via induction of *Arg1* in macrophages.

Empagliflozin and progression of chronic kidney disease in type 2 diabetes complicated by nephrotic-range proteinuria: insights from the EMPA-REG OUTCOME trial

P. Ruggenenti[1], S. Inzucchi[2], B. Zinman[3], S. Hantel[4], A. Koitka-Weber[4,5], M. von Eynatten[6], C. Wanner[7];
[1]Istituto di Ricerche Farmacologiche Mario Negri, Clinical Research Center for Rare Diseases "Aldo e Cele Daccò" (IRCCS), Bergamo, Italy, [2]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [3]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital and Division of Endocrinology, University of Toronto, Toronto, Canada, [4]Boehringer Ingelheim International GmbH, Biberach, Germany, [5]Dept of Diabetes, Central Clinical School, Monash University, Melbourne, Australia, [6]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [7]Dept of Medicine, Division of Nephrology, Würzburg University Clinic, Würzburg, Germany.

Background and aims: In patients with diabetic kidney disease, nephrotic-range proteinuria is a major risk factor for accelerated glomerular filtration rate (GFR) loss, cardiovascular disease and all-cause mortality. In this *post-hoc* analysis of the EMPA-REG OUTCOME trial, we evaluated the effects of the sodium glucose co-transporter 2 inhibitor empagliflozin (EMPA) in patients with type 2 diabetes, established cardiovascular disease and nephrotic-range proteinuria at study inclusion.
Materials and methods: In the EMPA-REG OUTCOME trial, patients were randomised to receive EMPA 10 or 25 mg/day, or placebo (PBO), in addition to standard of care. Median observation time was 3.1 years. According to Kidney Disease: Improving Global Outcomes (KDIGO) criteria, nephrotic-range proteinuria was defined as urine albumin:creatinine ratio (UACR) ≥2200 mg/g. A mixed-model repeated measures analysis was used to evaluate changes in estimated GFR (eGFR) over time. Treatment differences in the average rate of annual loss of eGFR were assessed for pooled EMPA vs PBO using a random coefficient model. A Cox proportional hazards model was used to investigate the risk of all-cause hospitalisation as ascertained by investigator 'serious adverse event' reporting.
Results: We identified 112 patients with nephrotic-range proteinuria (PBO, $n = 42$; pooled EMPA, $n = 70$). At baseline, mean [SD] eGFR (PBO, 63.6 [23.5]; EMPA, 60.3 [19.5] mL/min/1.73 m²) and median UACR [interquartile range] (PBO, 3676 [2713–4865]; EMPA, 3532 [2701–4879] mg/g creatinine) were balanced between groups. After an acute fall in eGFR during the first 4 weeks in both groups, the PBO group experienced a steeper decline in eGFR than the EMPA group (Figure). Between week 4 to last value on treatment the annual loss of eGFR was 10.7 mL/min/1.73 m² with PBO and 4.5 mL/min/1.73 m² with EMPA; thus, yearly eGFR loss was 6.1 mL/min/1.73 m² slower with EMPA than PBO ($p = 0.0098$). Moreover, EMPA significantly reduced the risk of all-cause hospitalisation by 47% versus PBO (hazard ratio 0.53 [0.30–0.93]; $p = 0.0263$).
Conclusion: EMPA could be a new treatment option to slow GFR decline and reduce all-cause hospitalisations in patients with type 2 diabetes and cardiovascular disease at high risk for rapid loss of renal function due to nephrotic-range proteinuria.

Figure. eGFR over time in patients with nephrotic-range proteinuria at baseline

Empagliflozin improves kidney outcomes irrespective of control of blood pressure, low-density lipoprotein cholesterol and HbA_{1c}

C. Wanner[1], M.E. Cooper[2], S.E. Inzucchi[3], B. Zinman[4], U. Hehnke[5], M. von Eynatten[5], A. Koitka-Weber[2,6];
[1]Dept of Medicine, Division of Nephrology, Würzburg University Clinic, Würzburg, Germany, [2]Dept of Diabetes, Central Clinical School, Monash University, Melbourne, Australia, [3]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [4]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital and Division of Endocrinology, University of Toronto, Toronto, Canada, [5]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [6]Boehringer Ingelheim International GmbH, Biberach, Germany.

Background and aims: The EMPA-REG OUTCOME trial demonstrated the renoprotective role of the sodium-glucose co-transporter 2 inhibitor empagliflozin (EMPA) by reducing the risk of incident or worsening nephropathy by 39% vs placebo (PBO) in patients with type 2 diabetes and established cardiovascular (CV) disease. We investigated the effects of controlling the CV risk factors of blood pressure (BP), low-density lipoprotein cholesterol (LDL-C) and HbA1c on treatment differences in kidney outcomes.
Materials and methods: In EMPA-REG OUTCOME, patients were randomised 1:1:1 to EMPA 10 mg, EMPA 25 mg, or PBO. Risk of incident or worsening nephropathy was assessed in the pooled EMPA group vs PBO adjusting for control of BP, LDL-C and HbA1c at baseline and during the study as time-dependent covariates. Control of the various parameters was defined as systolic BP <140 mmHg and diastolic BP <90 mmHg, LDL-C <100 mg/dL, and HbA1c <7.5%.
Results: Adjusting for control of BP, LDL-C or HbA1c individually, HRs for time to incident or worsening nephropathy with EMPA vs PBO ranged from 0.61 to 0.67 (Figure). Adjusting for control of all 3 parameters, the HR (95% CI) was 0.65 (0.57, 0.75) (Figure).
Conclusion: EMPA reduced the risk of incident or worsening nephropathy to the same extent when analyses were adjusted for control of BP, LDL-C and HbA1c over time. These data suggest that risk reductions in kidney outcomes were preserved irrespective of control of conventional CV risk factors.

Luseogliflozin inhibits HIF-1alpha expression in renal proximal tubular epithelial cells

Y. Takiyama, R. Bessho, T. Ota;
Department of Medicine, Asahikawa Medical University, Asahikawa, Japan.

Background and aims: Recent clinical trials have demonstrated the renoprotective effects of SGLT2 inhibitors in diabetic nephropathy. However, the mechanisms of SGLT2 inhibitors on prevention of diabetic nephropathy have not been fully elucidated. Hypoxia-induced tubulointerstitial fibrosis is considered to be a common pathway for various progressive kidney diseases including diabetic nephropathy. Hypoxia inducible factor (HIF)-1α plays an important role in these pathological processes. In the present study, we assessed the effects of luseogliflozin, an SGLT2 inhibitor, on HIF-1α expression in both cultured human renal proximal tubular epithelial cells (HRPTECs) and the kidneys of diabetic *db/db* mice.
Materials and methods: We examined the expression of HIF-1α protein by Western blot, HIF-1 targeted genes by qRT-PCR and cellular hypoxia using a hypoxia-sensitive dye pimonidazole in HRPTECs. Next, eight-week-old male diabetic *db/db* mice were treated with 15 mg/kg luseogliflozin for 8 weeks. Body weight, glucose tolerance, blood pressure, and urinary albumin excretion were measured. The renal histology, immunohistochemistry for HIF-1α and megalin, hypoxia-probe pimonidazole accumulation and confocal microscopic analysis of albumin endocytosis were evaluated at the end of the study.
Results: Hypoxia (1% O_2 for 24h) markedly increased HIF-1α protein in HRPTEC, whereas luseogliflozin inhibited the expression of hypoxia-induced HIF-1α protein. In addition, luseogliflozin inhibited mRNA expression for HIF-1-targeted genes, PAI-1 and GLUT-1 under hypoxia.The inhibitors of mitochondrial respiratory complex I, rotenone or complex III, antimycin A equally suppressed hypoxia-induced HIF-1α expression. Luseogliflozin decreased staining of pimonidazole in HRPTECs under hypoxic conditions. Eight weeks after administration, luseogliflozin lowered plasma glucose levels and decreased glomerular mesangial matrix expansion as well as glomerular and interstitial fibronectin accumulation in the kidney of *db/db* mice. However, luseogliflozin failed to attenuate urinary albumin excretion. Interestingly, luseogliflozin decreased megalin expression in *db/db* mice and led to decrease Texas Red-albumin uptake, suggesting that luseogliflozin induces albuminuria in *db/db* mice through the inhibition of megalin expression, but not renal injury. Electron microscopic study revealed that luseogliflozin decreased the length of mitochondria in the renal proximal tubules of the S1 segment. Furthermore, luseogliflozin attenuated diabetes-induced HIF-1α accumulation in the kidney of *db/db* mice. These results suggest that luseogliflozin inhibits hypoxia-induced HIF-1α accumulation at least partly by suppressing mitochondrial respiration. However, luseogliflozin augmented pimonidazole staining of the S3 segment of the proximal tubules cells which expressed SGLT1, in the outer stripe of the kidney of the *db/db* mice. Because pimonidazole and HIF have different kinetics and different hypoxia thresholds, these signals showed only partial overlap at the cellular level in *db/db* mice.
Conclusion: These results suggest that luseogliflozin inhibits hypoxia-induced HIF-1α expression and dynamically changes the oxygen metabolism in the renal proximal tubular cells. The SGLT2 inhibitors may protect diabetic kidney from hypoxia-induced renal fibrosis by attenuating the expression of HIF-1α and profibrotic molecules.

Relation between urinary glucose reabsorption and kidney function in diabetic patients

O. Matar[1], L. Potier[1,2], M. Hallot-Feron[1], F. Fumeron[2], R. Roussel[1,2], G. Velho[2], M. Marre[1,2];
[1]Diabétologie, Hôpital Bichat, APHP, Paris, [2]INSERM U 1138, Paris, France.

Background and aims: Glycosuria induced by SGLT2-inhibitors protects against end stage kidney disease, but no association has been established between urinary glucose reabsorption and kidney function in diabetic patients. We examined the relationship between urinary glucose reabsorption and kidney involvement in patients with diabetes.
Materials and methods: The diabetic patients attending our tertiary referral centre were studied consecutively from September 2017 to January 2018 for their urinary glucose reabsorption according to their kidney functions: eGFR (CKD-EPI equation) >90, 90–60, <60–30, <30 mL/min/1.73 m^2, and urinary albumin excretion (normo-, micro-, and macroalbuminuria), taking into account their prevailing plasma glucose (<6, 6–11, and >11 mmol/L). Urinary glucose reabsorption was calculated as 1- Fractional Excretion of Glucose (FEGlu), where FEGLu = (Urinary glucose concentration (UGlu) × urine volume)/GFR, and GFR = Creatinine Clearance. Thus, FEGLu = (UGlu × Plasma Creatinine)/(Plasma Glucose × Urinary Creatinine concentration).
Results: 650 diabetic patients, without SGLT2 inhibitors, were studied (aged 60 ± 14 years; 41% women; 10% type 1, 76% type 2, 14% other diabetes types; BMI 29.1 ± 6.3 kg/m^2; HbA1c 9.1 ± 2.4%; median diabetes duration 14 (interquartiles (IQ) 6–22) years ; systolic/diastolic blood pressure 131(19)/73(13) mmHg), 43% with eGFR >90, 33% 90–60, 17% <60–30, 7% <30 mL/min/1.73 m^2, and 48% with normo-, 41% micro-, and 11% macroalbuminuria. The median urinary glucose reabsorption was 0.9977 (IQ 0.9665–0.9992), and differed in the patients with plasma glucose <6 mmol/L: 0.9990 (IQ 0.9978–0.9993), with 6–11 mmol/L: 0.9991(IQ 0.9963–0.9994), and with >11 mmol/L 0.9636(IQ 0.8593–0.9947), (ANOVA $p < 0.0001$). Plasma glucose accounted for only 37% of inter-individual variance of urinary glucose reabsorption. The latter varied with eGFR: >90 (0.9927), 90–60 (0.9987), <60–30 (0.9987) to <30 mL/min/1.73 m^2 (0.9920), multi-adjusted ANOVA $p = 0.0046$, and increased from normo- to macroalbuminuria ($p = 0.0105$). Urinary glucose reabsorption was significantly affected by the interactions between increasing plasma glucose levels and eGFR stages ($p < 0.0001$), and with normo-, micro-, macroalbuminuria stages ($p < 0.0001$). In patients with plasma glucose >11 mmol/L, urinary glucose reabsorption increased from 0.9458(IQ 0.8125–0.9931) for eGFR >90 mL/min/1.73 m^2 to 0.9728(IQ 0.9013–0.9976) for 90–60 mL/min/1.73 m^2 to 0.9912(IQ 0.9276–0.9982) for <60–30 mL/min/1.73 m^2 and to 0.9946(0.9764–0.9980) for <30 mL/min/1.73 m^2 ($p = 0.0087$); it was

0.9606(IQ 0.8308–0.9975) in patients with normo-, 0.9656(IQ 0.9413–0.9973) in those with micro-, and 0.9876(IQ 0.9420–0.9957) in those with macroalbuminuria ($p = 0.01$).

Conclusion: There is a strong association between elevated capacities of urinary glucose reabsorptions and severity of kidney disease in patients with diabetes. Although cross-sectional, these results support the view that mechanisms involved in urinary glucose reabsorption contribute to risk for kidney disease in diabetes.

Effects of sodium-glucose cotransporter 2 inhibitors on renal outcomes in patients with type 2 diabetes: a systematic review and meta-analysis

J. Bae[1], E. Park[2], S. Kim[2], K. Kim[1], J. An[1], H. Kim[1], J. Kim[1], S. Kim[1], S. Hahn[2], N. Kim[1];

[1]Korea University College of Medicine, Seoul, [2]Seoul National University College of Medicine, Seoul, Republic of Korea.

Background and aims: To investigate the effects of sodium-glucose cotransporter 2 (SGLT2) inhibitors on renal outcomes in patients with type 2 diabetes mellitus (T2D)

Materials and methods: We searched Medline, Embase, and the Cochrane Central Registration of Controlled Trials to identify randomized controlled trials (RCTs) of SGLT2 inhibitors up to Sep 18, 2017. RCTs comparing SGLT2 inhibitors with placebo or other oral antidiabetic drugs and reporting at least one kidney-related variable including changes in urine albumin-to-creatinine ratio and estimated glomerular filtration rate (eGFR), and development of microalbuminuria, macroalbuminuria, or end-stage renal disease in patients with T2D were selected. We performed a meta-analysis using fixed-effects model and random-effects model to calculate mean differences and relative risk for renal outcomes.

Results: A total of 45 eligible RCTs involving 45,654 patients with T2D were included in the analysis. Compared with placebo or other oral antidiabetic drugs, SGLT2 inhibitors significantly decreased urine albumin-to-creatinine ratio (mean difference −7.84 mg/g, 95% confidence interval [CI] −12.84 to −2.84, $P = 0.0021$). In addition, SGLT2 inhibitors were associated with the lower risk of developing microalbuminuria (relative risk [RR] 0.73, 95% CI 0.54 to 1.00, $P = 0.0505$) and macroalbuminuria (RR 0.68, 95% CI 0.60 to 0.77, $P < 0.0001$) compared with controls. The overall change in eGFR was comparable between SGLT2 inhibitors and controls (mean difference −0.08 mL/min/1.73 m^2, 95% CI –0.66 to 0.49, $P = 0.7833$). However, in subgroup analyses according to study duration and baseline eGFR, SGLT2 inhibitors decreased eGFR in T2D patients with the study duration of <26 weeks and baseline eGFR of <45 mL/min/1.73 m^2 compared with controls. The risk of developing ESRD tended to be reduced in SGLT2 inhibitors compared with controls (RR 0.78, 95% CI 0.43 to 1.41, $P = 0.4114$).

Conclusion: SGLT2 inhibitors were associated with the lower risk of development or progression of albuminuria, although the overall changes in renal function were comparable to placebo or other oral antidiabetic drugs in patients with T2D.

Disclosure: **J. Bae:** None.

Empagliflozin and linagliptin alleviate podocyte injury and activate glomerular autophagy in a model of type 2 diabetes

A.I. Korbut[1], V.V. Klimontov[1], Y.S. Taskayeva[1], N.P. Bgatova[1], E.L. Zavjalov[2];

[1]Research Institute of Clinical and Experimental Lymphology – Branch of the Institute of Cytology and Genetics, Siberian Branch of Russian Academy of Sciences, Novosibirsk, [2]Institute of Cytology and Genetics, Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russian Federation.

Background and aims: Podocyte injury is believed to be a cornerstone in pathogenesis of diabetic kidney disease. Recent data indicate emerging role of autophagy downregulation in diabetic podocytopathy. Accordingly, diminished autophagy could be the therapeutic target in diabetes. Inhibitors of sodium-glucose cotransporter-2 (SGLT2) and dipeptidyl peptidase-4 (DPP4) are considered as promising therapeutic agents in diabetic nephropathy, but little is known about the effects of these agents on podocytes. Thus, we aim of our study to assess the effects of SGLT2 inhibitor empagliflozine, DPP4 inhibitor linagliptin and their combination on podocyte injury and autophagy in a model of type 2 diabetes.

Materials and methods: Eight-week-old male *db/db* mice (BKS.Cg-Dock7^{m}+/+Lepr^{db}/J) were treated with empagliflozine (10 mg/kg), linagliptin (10 mg/kg), combination of these agents, or placebo for 8 weeks. Non-diabetic heterozygous *db*/+ mice were acted as control. The concentrations of insulin, glucagon, leptin and resistin in blood plasma were determined by Multiplex analysis, and body composition was assessed by MRI at week 0 and 8 of experiment. Renal structural changes were analyzed quantitatively from the light and electron microscopic images. To estimate autophagy, beclin-1 staining in glomeruli was assessed by immunohistochemistry, and volume density of autophagosomes, lysosomes, and autolysosomes in podocytes were estimated.

Results: Diabetic *db/db* mice became obese and hyperglycemic before the start of experiment and demonstrated elevated levels of leptin and insulin and increased fat percentage at week 0 and week 8 (all $p < 0.00001$). Podocytopathy in these mice was manifested by the reduction in mean number of foot processes and increase in their width. In all treated groups the number of podocyte foot processes increased significantly ($p = 0.003$ for linagliptin, $p = 0.03$ for empagliflozin and combination) and the width of podocyte foot processes decreased ($p = 0.003$ for empagliflozin and linagliptin, $p = 0.001$ for combination). Vehicle-treated diabetic mice had weak staining for beclin-1 in glomeruli (for volumetric density $p = 0.002$ vs. *db*/+ mice) and reduced autophagosome volume density in podocytes ($p = 0.04$). The volumetric density of beclin-1-positive area correlated with volume density of autophagosomes and lysosomes (both $r = 0.43$, $p = 0.04$) and width of foot processes ($r = -0.64$, $p = 0.0008$). Under the treatment, glomerular staining for beclin-1 was increased ($p = 0.03$ for empagliflozin, $p = 0.008$ for linagliptin, $p = 0.003$ for combination). Empagliflozin and linagliptin, either alone or in combination, increased volume density of autophagosomes ($p = 0.04$ for empagliflozin and combination, $p = 0.008$ for linagliptin) and autolysosomes ($p = 0.03$ for empagliflozin and combination, $p = 0.05$ for linagliptin) in podocytes.

Conclusion: The data from the current study demonstrate that both empagliflozin and linagliptin ameliorate podocyte injury and enhances autophagy in a model of type 2 diabetic nephropathy. The data provide further explanation for the mechanism of nephroprotective effect of SGLT2 and DPP4 inhibitors in diabetes.

Effect of vildagliptin added to insulin on glycaemic control in haemodialysis patients with type 2 diabetes: a randomised multicentre prospective study

A. Smagala[1], M. Munch[2], L. Meyer[3], A. Klein[1], B. Guercy[4], L. Frimat[4], S. Borot[5], D. Ducloux[5], D. Fleury[6], O. Verier[7], F. Alenabi[8], F. Chantrel[9], L. Kessler[3];

[1]CH Colmar, Colmar, [2]CH Strasbourg, Strasbourg, [3]CHRU de Strasbourg, Strasbourg, [4]CHRU de Nancy, Nancy, [5]CHRU de Besançon, Besançon, [6]CH Valenciennes, Valenciennes, [7]CHRU de Valenciennes, Valenciennes CEDEX, [8]CH de Mulhouse, Mulhouse, [9]CHRU de Mulhouse, Mulhouse, France.

Background and aims: Type 2 diabetic patients (T2D) undergoing chronic dialysis occurs for almost half of the patients starting dialysis in

European Western countries. Hemodialysis T2D patients are usually treated with insulin. Standard schema for glycemic management doesn't exist in this population with high cardiovascular risk mainly due to high risk of hypoglycemia and the limitations of HbA1C. Vildagliptin can be used in severe renal impairment and protects against hypoglycemia. The aim of the study was to evaluate the efficacy and safety of vildagliptin (50 mg/day) added to insulin, in a population of hemodialysis T2D patients.

Materials and methods: Sixty-five hemodialysis T2D patients treated with multiple daily insulin injections were randomized Insulin + Vildagliptin (Group 1: G1, $n = 32$) or Insulin regimen (Group 2: G2, $n = 33$) in a multicenter, prospective, open-label, 12 weeks-study. Glycemic control was assessed through 48h-Continuous Glucose Monitoring (*CGM- IPro2*, *Medtronic*) performed at baseline, repeated at 3-month follow-up with probe analysis. The primary end-point was the variation of mean interstitial glucose at CGM, after 3-month treatment. Secondary criteria were: CGM-Time in Range (70–180 mg/dl), time spent in hyperglycemia (>180 mg/dl) or hypoglycemia (<70 mg/dl), glycemic variability, HbA1c, glycated albumin, daily insulin requirements, tolerance, cardiovascular outcomes. Statistical analysis was performed in intention to treat.

Results: At baseline both Groups (G1 vs G2) were comparable for age (69.7 ± 7.4 vs 71.3 ± 9.6 years), duration of diabetes (23 ± 3.4 vs 23 ± 13 years), HbA1c (7.3 ± 1.1 vs 7.3 ± 1.1%) glycated albumin (611.3 ± 322 vs 666 ± 339 μmol/l, *normal range 100–285*), daily insulin needs (51.3 ± 25.4 vs 47.7 ± 29 IU/d), BMI (34.5 ± 6.4 vs 32.1 ± 6 kg/m²), severe hypoglycemia (4 vs 3 per 12 month prior to inclusion), mean glucose at CGM (163.9 ± 41.9 vs 167.4 ± 33.8 mg/dl). After 12 weeks, mean glucose of CGM decreased respectively from 163.9 ± 41.9 to 147.6 ± 32.7 mg/dl ($p = 0.2703$) in G1 and from 167.4 ± 44.8 to 160.0 ± 42.9 mg/dl ($p = 0.415$) in G2. At 12 weeks in G1 *vs* G2, time in range was higher (77.2 vs 69.5%, $p < 0.05$), time spent in hyperglycemia was lower (21.2 vs 39%, $p < 0.05$), and time spent in hypoglycemia was comparable (1.5 vs 1.4%, $p = 0.53$). Daily insulin needs (46.1 ± 23.4 vs 48.7 ± 31.7 IU/d, ns) and HbA1c (6.9 ± 0.9 vs 7.2 ± 1.1%, ns) were no different, whereas glycated albumin was lower (520.4 ± 159 vs 658.9 ± 386, $p < 0.001$). Coefficient of variation, AUC <70 mg/dl and >180 mg/dl were no different between the two groups. Two severe hypoglycemia occurred in each group, no cardiovascular outcome occurred, and digestive symptoms were comparable without acute pancreatitis

Conclusion: Adding vildagliptin to insulin in hemodialysis T2D patients doesn't modify mean glucose at CGM, but increases time in range, reduces time spent in hyperglycemia, without increasing time in hypoglycemia, and reduces glycated albumin

Safety of liraglutide vs placebo in patients with type 2 diabetes and chronic kidney disease in the LEADER trial

J. Mann[1], V. Fonseca[2], O. Mosenzon[3], I. Raz[3], H. Frimer-Larsen[4], B. von Scholten[4], T. Idorn[4], N. Poulter[5], The LEADER Trial Steering Committee and Investigators;

[1]KfH Kidney Center, Munich, Germany, [2]Tulane University Health Sciences Center, School of Medicine, New Orleans, USA, [3]Diabetes Unit, Hadassah Hebrew University Hospital, Jerusalem, Israel, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Imperial College London, London, UK.

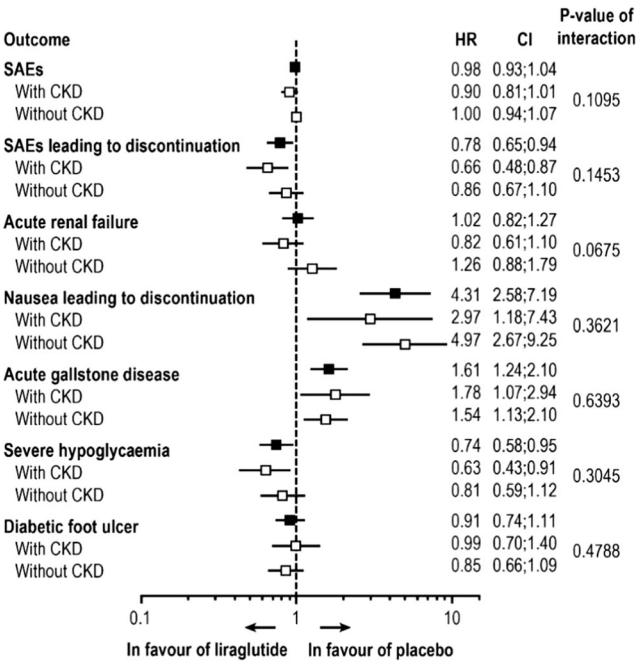
Background and aims: We assessed the safety of liraglutide vs placebo (PBO) in patients with chronic kidney disease (CKD) in the LEADER trial.

Materials and methods: LEADER was a randomised, double-blind, multicentre, placebo-controlled, cardiovascular (CV) outcome trial assessing CV and long-term safety of liraglutide up to 1.8 mg/day vs PBO plus standard of care for 3.5–5 years in 9340 patients with type 2 diabetes (T2D) at high risk for CV disease. We stratified participants according to baseline estimated GFR (eGFR) <60 (with CKD) or ≥60 ml/min/1.73 m^2 (without CKD) and analysed: serious adverse events (SAEs), SAEs leading to discontinuation, acute renal failure, nausea leading to discontinuation, acute gallstone disease, severe hypoglycaemia and foot ulcers.

Results: Mean eGFR in patients with ($n = 2158$) or without CKD ($n = 7158$) was 45.7 ± 10.9 and 90.8 ± 21.6 mL/min/1.73 m^2, respectively. There was no increased risk of SAEs or SAEs leading to discontinuation with liraglutide vs PBO in those with and without CKD (Figure); and no conclusive risk of acute renal failure in those with CKD (HR 0.82, CI 0.61;1.10) or without CKD (HR 1.26, CI 0.88;1.79) with liraglutide vs PBO. There was no difference in the risk of nausea leading to discontinuation or acute gallstone disease in patients with and without CKD. Severe hypoglycaemia risk was significantly reduced with liraglutide by 37% (with CKD: HR 0.63, CI 0.43;0.91) and non-significantly reduced by 19% (without CKD: HR 0.81, CI 0.59;1.12). Frequency of hypoglycaemia increased with decreasing eGFR. Diabetic foot ulcer risk was not increased with liraglutide in those with and without CKD (Figure).

Conclusion: In LEADER, liraglutide was as well tolerated in patients with CKD as in those without CKD.

Figure: Risk of selected adverse events with liraglutide vs placebo according at CKD at baseline



Estimated glomerular filtration rate was based on the Modification of Diet in Renal Disease formula.
CI, confidence interval; CKD, chronic kidney disease; HR, hazard ratio; SAE, serious adverse event.

Exenatide LAR improves in hypertensive type-2 diabetic patients plasma levels of cytokines involved in hypertension: an 8-month prospective intervention study

A. Rizvi[1], G. Li Volti[2], D. Nikolic[3], R. Chianetta[3], G. Castellino[3], A. Patti[3], R. Giglio[3], R. Citarrella[3], F. Provenzano[4], V. Provenzano[4], G. Montalto[3], M. Rizzo[3];

[1]Endocrinology, Diabetes and Metabolism, University of South Carolina, Columbia, USA, [2]University of Catania, Catania, Italy, [3]DIBIMIS, University of Palermo, Italy, Palermo, Italy, [4]Internal Medicine,

Partinico Hospital, Partinico, Italy.

Background and aims: Hypertension is often associated to type 2 diabetes (T2DM) and this combination increases the overall cardiovascular (CV) risk of such patients. Interleukin-2 (IL-2) and plasminogen activator inhibitor-1 (PAI-1) seem to be associated with incident of hypertension, while monocyte chemotactic protein 1 (MCP-1) is known to be a powerful mediator of inflammatory responses in hypertensive subjects. We here assessed the effects of exenatide once-weekly (long-acting release, LAR) on cardio-metabolic control, including the assessment of the 3 aforementioned cytokines in T2DM subjects with and without hypertension.
Materials and methods: Sixty T2DM subjects (41 men and 19 women; age: 60 ± 10 yrs), naïve to incretin-based therapies, were treated with exenatide LAR as add-on to metformin for 8 months. Exclusion criteria included a previous major CV event, moderate and severe renal and liver function. The cohort of subjects was subdivided in those with hypertension ($n = 18$) and without hypertension ($n = 42$). The three cytokines were measured by multiplex analysis using Luminex Magpix®. Endothelial function was assessed by flow mediated dilation (FMD) of the brachial artery, while cIMT was assessed by B-mode real-time ultrasound. Paired t-test and ANOVA were performed.
Results: Although cardio-metabolic control was similarly achieved in both groups of patients after exenatide LAR therapy (Table), plasma levels of the investigated cytokines reduced only in the subgroups of subjects with hypertension as following: IL-2 (from 8.7 ± 4.7 to 6.2 ± 2.0 pg/ml, $p = 0.0029$), MCP-1 (from 19.6 ± 7.0 to 15.9 ± 7.2 pg/ml, $p = 0.0087$), PAI-1 (from 1.7 ± 1.5 to 1.2 ± 1.4 ng/ml, $p = 0.0369$).
Conclusion: Exenatide LAR treatment was associated with similar cardio-metabolic control in T2DM patients with vs. without hypertension. However, improvements in cytokines associated with inflammation at the endothelial level and with the development of hypertension were only seen in subjects with hypertension. Whether this finding would translate into an effective CV prevention in this category of patients remains to be established by future studies.

Pulmonary function in prediabetes: dysfunction appears before the development of type 2 diabetes

A. Lecube[1], E. Sánchez[1], C. López-Cano[1], M. Sánchez[1], A. Gaeta[1], F. Purroy[1], R. Pamplona[1], M. Ortega[1], T. Vidal[1], À. Betriu[1], X. Gómez[1], M. Hernández[1], J. Olsina[1], C. Hernández[2], R. Simó[2];
[1]Arnau de Vilanova, IRBLleida, UdL, Lleida, [2]Vall d'Hebron, VHIR, UAB, Barcelona, Spain.

Background and aims: Patients with type 2 diabetes have been considered a susceptible group for pulmonary dysfunction. However, little is known regarding about the potential pulmonary dysfunction in prediabetes.
Materials and methods: We assessed pulmonary function in 4,464 non-diabetic subjects, aged between 45 and 70 years, without vascular disease and chronic pulmonary obstructive disease from the ongoing cross-sectional study ILERVAS. A normal forced expiratory volume in the first second (FEV1) was defined as a value equal or higher than 80% of that predicted, and a "non-obstructive ventilatory defect" by a forced vital capacity (FVC) <80% of the predicted value with a FEV1/FVC ratio ≥70% (Global initiative for chronic Obstructive Lung Disease). Prediabetes was defined by glycosylated haemoglobin (HbA1c) between 5.7 and 6.4% (American Diabetes Association criteria).
Results: The study population was composed of 52.1% women, age of 57 [53;63] years old, and a BMI of 28.6 [25.8;31.8] kg/m^2. The prevalence of prediabetes was 31.2%. Subjects with prediabetes, compared to the population with a normal glucose metabolism, had lower FVC (93 [82;105] vs. 96 [84;106] % of predicted, $p < 0.001$) and maximum FEV1 (94 [82;107] vs. 96 [84;108] %, $p = 0.011$), as well as a higher percentage of subjects with non-obstructive ventilatory defect (16.5% vs. 13.6%, $p = 0.015$) and FEV1 <80% (20.3% vs. 17.2%, $p = 0.017$). In addition, in the prediabetes group, HbA1c was negatively correlated with both pulmonary parameters (FVC: $r = -0.113$, $p < 0.001$; FEV1: $r = -0.079$, $p = 0.003$). The multinomial logistic regression model showed that there was a significant association between HbA1c with both non-obstructive ventilatory defect [OR = 1.42 (1.10 to 1.83), $p = 0.008$] and FEV1 <80% [OR = 1.50 (1.19 to 1.90), $p = 0.001$].
Conclusion: The negative effect of type 2 diabetes on lung function is already initiated in prediabetes, and it is related with metabolic control.

Diabetes duration, BMI, and HbA_{1c} have greater effects on Pulmonary Function (PF) than inhaled Technosphere Insulin (TI)

D.M. Kendall[1], J. Brain[2], J. Buse[3], D. Klein[4], Y. Ma[5], M. Grant[4], F. Pompilio[1], K. Smith[1];
[1]MannKind Corporation, Westlake Village, [2]Department of Environmental Health, Harvard University, Boston, [3]Medicine, University of North Carolina, Chapel Hill, [4]MannKind Corporation, Danbury, [5]Maxwell Consulting, Jericho, USA.

Background and aims: Rapidly absorbed inhaled insulin may lead to improved patient compliance and outcomes. Small, rapidly developing, non-progressive and reversible decreases in PF are seen with TI. How do these changes compare with PF changes caused by diabetes per se? Factors that contribute to PF decline were characterized and differences between diabetic subjects treated with TI versus usual care (UC) compared.
Materials and methods: The effects of diabetes duration (DUR), body mass index (BMI), and HbA1c on baseline PF and changes in PF (ΔPF) over 24 months' treatment were compared in TI versus UC patients. Two-

year PF follow up study with T1D ($N = 446$), T2D ($N = 1108$), and healthy controls ($N = 145$) were analyzed. ANCOVA identified the factors contributing to baseline PF. Mixed-model with repeated-measures analysis was performed to assess treatment effects on change in PF from baseline to end of study.
Results: Baseline analyses: In T1D, DUR was negatively correlated with FEV1 (−13 ml/y, $p = 0.003$) and FVC (−16 ml/y, $p = 0.006$). BMI and HbA1c were not significant factors. In individuals with T2D, both baseline BMI and HbA1c, but not DUR, were correlated with PF. FEV1 was negatively correlated with both BMI (-25 ml per kg/m^2, $p < 0.001$) and HbA1c (−47 ml per %HbA1c, $p < 0.001$). HbA1c at baseline was also associated with lower FVC (−97 ml/%, $p < 0.001$) and DLco (−0.35 ml/min/mmHg/%, $p = 0.004$). **24 month treatment with either TI or UC:** In T1D, baseline BMI was correlated with changes in both FEV1 (−6 ml per kg/m^2, $p = 0.019$) and FVC (−10 ml per kg/m^2, $p = 0.003$). In T2D subjects, BMI was associated with an additional 4 ml decrease in FVC per kg/m^2 ($p = 0.008$) while HbA1c affected FEV1 (−12 ml/%, $p < 0.001$), FVC (−14 ml/%), $p = 0.001$) and DLco (−119 ml/min/mmHg/%, $p = 0.0175$). The effects of baseline characteristics on PF were the same across treatment groups (TI or UC). For comparison, treatment with TI has been shown to be associated with a modest, non-progressive and reversible reduction of approximately 40 ml in FEV1.
Conclusion: The duration of diabetes, BMI, and HbA1c impact pulmonary function. Importantly, elevated BMI and HbA1c are associated with reductions in PF that exceed the observed and reversible changes seen with inhaled insulin treatment. Demographic factors impacted baseline findings equally across treatment groups. Diabetics experience above normal declines in PF as they age compared to healthy controls. TI does not produce an accelerated decline in PF after a small drop which disappears after TI cessation.

Prevalence of and risk factors for gustatory sweating amongst people with type 2 diabetes

P.L. Kristensen[1], C. Dam[1], B. Thorsteinsson[1], L. Tarnow[2];
[1]Department of Endocrinology and Nephrology, Nordsjællands University Hospital, Hillerød, [2]Steno Diabetes Center Sjælland, Region Sjælland, Denmark.

Background and aims: Gustatory Sweating (GS) is known as a complication to diabetes mellitus (DM) and is characterised by profuse sweating during or immediately after ingestion of food. Most reports on gustatory sweating have been case reports suggesting it to be a rare late diabetic complication. The aim of this study was to determine the prevalence of gustatory sweating in an unselected cohort of patients with type 2 diabetes. To generate hypothesis on the pathophysiology of GS, associations between GS and classic complications of DM were explored.
Materials and methods: In a cross-sectional study all people with type 2 DM in the DM outpatient clinic at Nordsjællands Hospital, Denmark, received a questionnaire by mail with eight questions regarding GS. Answers were paired with medical data from the electronic patient records. Prevalence of GS was primary endpoint. Association between GS and complications to DM were secondary endpoints. Univariate and multivariate logistic regression analyses were performed including the following variables: Sex, age, HbA1c, albuminuria, retinopathy and neuropathy. Variables associated with or nearly associated with GS in the univariate analyses (defined by $p < 0.15$) were included in the multivariate analysis.
Results: Out of 991 persons receiving the questionnaire, 510 people answered, four were excluded, leaving a response rate at 51%. 22% of the patients sweat in relation to ingestion of food, and 13% (95% CI: 10–16%) also in relation to non-spicy foods. In the multivariate logistic regression analysis, we found that decreasing age ($p = 0.007$) was associated with increasing probability of GS. Also presence of severe peripheral neuropathy (threshold of biothesiometry >50 V) was associated with GS ($p = 0.01$).
Conclusion: A prevalence of gustatory sweating of 13% was found in a large unselected cohort of people with type 2 DM. Gustatory sweating was associated with lower age and severe peripheral neuropathy.

Hearing loss as a complication of type 2 diabetes: preliminary findings from the population-based Hoorn study

M. Stam[1], F. Rutters[2], E. Urry[3], S.E. Kramer[1], P.M. Elders[4], J.M. Beulens[2,5], G. Nijpels[4];
[1]Otolaryngology-Head and Neck Surgery, section Ear & Hearing, VU University Medical Center and Amsterdam Public Health research institute, Amsterdam, Netherlands, [2]Epidemiology and Biostatistics, VU University Medical Center and Amsterdam Public Health research institute, Amsterdam, Netherlands, [3]Science & Technology, Sonova AG, Staefa, Switzerland, [4]General Practice and Elderly Care, VU University Medical Center and Amsterdam Public Health research institute, Amsterdam, Netherlands, [5]Julius Centre for Health Sciences and Primary Care, University Medical Centre Utrecht, Utrecht, Netherlands.

Background and aims: It is generally accepted that type 2 diabetes induces microvascular and neuropathic changes that may lead to complications of the auditory pathway from the cochlea to the cortex. However, results from epidemiological studies, which assess the association between diabetes and hearing impairment, is mixed and requires clarification. The aim of the current explorative study was to investigate the prevalence of hearing loss in a population-based diabetes cohort in the Netherlands and to assess the associations between metabolic parameters and self-reported hearing problems.
Materials and methods: Data for the present cross-sectional data analyses ($n = 1223$, aged 54–85 years) were derived from The Hoorn Study cohort. The Hoorn Study investigates the prevalence and risk factors of impaired glucose metabolism and type 2 diabetes in the Dutch city of Hoorn. Standardized procedures were conducted to measure glucose metabolism (fasting plasma glucose, 75-g oral glucose tolerance test (OGTT) and haemoglobin A_{1c} (HbA_{1c})); anthropometrics (height, waist and hip circumference); blood plasma lipid levels (triglycerides, high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C)); blood pressure; and smoking behaviour. Hearing status was determined by self-report: "Do you have severe hearing problems?" (yes/no). Preliminary data analyses included descriptive statistics, independent t-tests, chi-square tests and multiple logistic regression.
Results: The prevalence of self-reported hearing problems was 8% in the study sample ($n = 93$). Of these participants, 47 (50.5%) could be classified as having normal glucose metabolism, 35 (37.6%) as having impaired glucose metabolism, and 11 (11.8%) as having diabetes according to the WHO 2011 and American Diabetes Association 2012 criteria. The prevalence of metabolic syndrome, impaired glucose tolerance and/or diabetes was comparable between adults with and without self-reported hearing problems ($p > 0.05$). However, 2-hour glucose levels after OGTT and waist circumference were significantly higher in participants with severe hearing problems, compared to those without: 6.6 mmol/litre vs. 6.0 mmol/litre ($p = 0.02$); 95.5 cm vs. 92.3 cm ($p < 0.01$), respectively. Results from the regression analyses showed that 2-hour glucose levels after OGTT and waist circumference were significantly associated with severe hearing problems: OR: 1.11, 95% CI: 1.02–1.21; $p = 0.022$; OR: 1.03, 95% CI: 1.01–1.05; $p = 0.006$).
Conclusion: These preliminary results indicate that adults with severe hearing problems may have poorer metabolic profiles than their normally-hearing peers.

Association between hearing and renal function in young adult type 1 diabetic patients

M. Dąbrowski[1], G. Mielnik-Niedzielska[2], A. Nowakowski[3];
[1]Faculty of Medicine, University of Rzeszów, Rzeszów, [2]II Faculty of Medicine, Medical University of Lublin, Lublin, [3]Professor emeritus, Madical University of Lublin, Lublin, Poland.

Background and aims: Retinopathy and nephropathy are well-known complications of type 1 diabetes. Also impaired function of auditory organ is observed in this population. The aim of this study was to evaluate associations between hearing and renal function in a group of young adult patients with type 1 diabetes mellitus.
Materials and methods: The study group consisted of 31 patients (9 women) with type 1 diabetes, aged below 45 (mean 29.5 ± 7.0 years), with a disease duration less than 10 years (mean 4.6 ± 2.6 years) and without overt hearing impairment. In all subjects blood pressure, weight and height were measured and BMI was calculated, blood samples for laboratory tests (lipid profile, creatinine and HbA_{1c} level) were obtained and urinary albumin excretion (UAE) in the first morning urine sample was assessed. Estimated glomerular filtration rate (eGFR) was calculated according to CKD-EPI formula. Then in all patients pure-tone audiometry, transient evoked otoacoustic emissions (TEOAE) and auditory brainstem responses (ABR) were evaluated. Also eye fundus was examined within the 3 months window from audiological evaluations.
Results: In three patients eGFR was between 75.0 and 90.0 ml/min/1.73 m^2, the rest had normal eGFR, in one case UAE was at microalbuminuria range and in three patients early background retinopathy was found. In pure-tone audiometry mild hearing impairment was revealed in seven patients. These subjects had significantly lower eGFR compared to the patients with normal hearing, 108.8 vs. 121.7 ml/min/1.73 m^2, $p = 0.047$. Significant positive linear correlation was found between hearing threshold and creatinine level at frequencies 6 kHz (coefficient factor $r = 0.404$, $p = 0.001$) 8 kHz ($r = 0.372$, $p = 0.003$) and 12 kHz ($r = 0.440$, $p < 0.001$) and negative between hearing threshold and eGFR at frequencies 4 kHz ($r = -0.259$, $p = 0.042$), 6 kHz ($r = -0.411$, $p < 0.001$), 8 kHz ($r = -0.373$, $p = 0.003$) and 12 kHz ($r = -0.431$, $p < 0.001$). No association between hearing threshold and UAE was revealed. In TEOAE evaluation patients with absence of TEOAE in at least one ear (amplitude <6.0 db) had significantly higher creatinine level (0.93 vs. 0.70 mg/dl) and lower eGFR (103.1 vs. 123.3 ml/min/1.73 m^2), $p < 0.001$ in both cases. For UAE such association was not found, however, it tended to correlate negatively with TEOAE amplitude, but it did not reach significance level ($r = -0.230$, $p = 0.077$). In ABR significant negative linear correlation was found between creatinine level and latency of wave III ($r = -0.290$, $p = 0.033$) and interval I-III ($r = -0.271$, $p = 0.048$), while positive correlation with interval III-V ($r = 0.269$, $p = 0.049$). Positive correlation of eGFR with wave III latency ($r = 0.406$, $p = 0.002$) and interval I-III ($r = 0.324$, $p = 0.017$) was revealed. Also positive linear correlation between UAE and latencies of wave III ($r = 0.415$, $p = 0.002$), wave V ($r = 0.299$, $p = 0.020$) and interval I-III ($r = 0.328$, $p = 0.018$) were found.
Conclusion: This study indicate possible relationship between hearing and renal function in young adult type 1 diabetic patients, seen also at the subclinical level. Pathways directly linking hearing and renal function are unknown. Our results indicate that creatinine/eGFR and microalbuminuria are linked with hearing function through different mechanisms. Obviously, larger studies using also other markers are necessary to further analyze these relationships.

Social jetlag and sleep quality are independently associated with poor glycaemic control in type 1 diabetes

A. Rusu[1], C. Bala[1,2], A. Cerghizan[2], D. Ciobanu[1], G. Roman[1,2];
[1]Diabetes and Nutrition Diseases, Iuliu Hatieganu University of Medicine and Pharmacy, Cluj-Napoca, [2]Diabetes Centre, Emergency Clinical County Hospital Cluj, Cluj-Napoca, Romania.

Background and aims: Social jetlag (SJL) is a small recurrent circadian rhythm disruption and the most frequent form of circadian rhythm misalignment. It results from the mismatch between imposed social rhythms and internal circadian clock. Although it is accepted that circadian rhythm is involved in the regulation of metabolic processes, only recently circadian misalignment has been regarded as a potential contributor to glucose dysregulation outside of shift work settings. The main objective of this cross-sectional study was to investigate in real-life settings the effect of SJL on glycaemic control, as assessed by HbA1c, in persons with type 1 diabetes.
Materials and methods: 115 consecutive adults with type 1 diabetes presenting for an appointment in the outpatient clinic of the Diabetes Centre, Cluj-Napoca, Romania between May 2017 and January 2018 were enrolled and analysed. Data on bedtime, sleep-onset latency, and wake-up time on weekdays and weekends during the previous month were collected and used to calculate SJL, mid-sleep time during free days (MSF, an indicator of chronotype), sleep duration and sleep debt. Sleep quality over the previous month was assessed by Pittsburgh Sleep Quality Index (PSQI). A PSQI score >5 was considered as an indicator of poor sleep quality. Based on the presence of SJL, study participants were divided in 2 groups: with SJL ≥1 h and with SJL <1 h. Linear univariate and multivariate regression analyses were used to assess the association of HbA1c with SJL ≥1 h and other sleep-related parameters. Parameters associated with HbA1c in regression analysis were tested for interaction with regards to HbA1c values in addition to main effects of individual variables.
Results: Based on SJL duration, 53 participants had a SJL duration ≥1 h and 62 had a SJL duration <1 h. Compared to persons with SJL <1 h, those with SJL ≥1 h were younger, had a shorter diabetes duration, lower daily insulin doses and a lower frequency of diabetes-related retinopathy and peripheral neuropathy ($p < 0.05$ for all). Persons with SJL ≥1 h had statistically significant higher HbA1c values than those with SJL <1 h (8.7% vs. 8.0%, $p = 0.029$), independent of age, gender, diabetes duration, daily insulin dose and BMI. In multivariate regression analysis employing sleep and chronotype parameters (SJL, sleep duration, sleep debt, poor sleep quality, MSF) as predictors, only SJL ≥1 h and poor sleep quality were significant predictors of HbA1c values, explaining 22.7% ($p = 0.041$) and 23.5% ($p = 0.019$), respectively, of the HbA1c variation. Associations remained statistically significant after adjustment for age, gender, diabetes duration, daily insulin dose and BMI ($\beta = 0.233$ [$p = 0.042$] for SJL ≥1 h; $\beta = 0.235$ [$p = 0.027$] for poor sleep quality). In the analysis of interaction, SJL ≥1 h by poor sleep quality interaction terms were not statistically significant associated with HbA1c neither in the unadjusted nor in the adjusted model (p values for interaction 0.994 in unadjusted model and 0.990 in adjusted model).
Conclusion: In persons with type 1 diabetes SJL is associated with a poor glycaemic control and this association is independent of age, gender, diabetes duration, total daily insulin dose, BMI and other sleep and circadian rhythm measurements. We also showed that SJL acts independently of sleep quality in exerting a deleterious effect on glycaemic control.

Type 2 diabetes is complicated by sleep apnoea syndrome: focussing in comorbidities

S. Kawasaki[1], H. Misawa[1], R. Kaneda[1], T. Shizuku[1], Y. Tamura[1], T. Kondo[1], Y. Kondo[2], Y. Terauchi[3];
[1]Shonan Fujisawa Tokushukai Hospital, Fujisawa, [2]Odawara Municipal Hospital, Odawara, [3]Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Background and aims: Sleep apnea syndrome (SAS) is a disorder characterized by repeated episodes of apnea and hypopnea during nocturnal

sleep. Risk factors for SAS include obesity, male gender, and advanced age. Diabetic patients often have various diseases such as vascular diseases and other comorbidities. SAS in such patients may lead to acute deterioration due to nocturnal hypoxia, highlighting the importance of evaluation and appropriate treatment of SAS in routine clinical practice. The present study examined risk factors for SAS in patients with type 2 diabetes (T2DM), with special reference to microangiopathy and stable comorbidities.

Materials and methods: Among the 1,367 ambulant T2DM patients who were being treated at our institution, 483 (313 men and 170 women) who agreed to undergo a portable sleep polygraph test were evaluated to examine the prevalence of SAS and the relationships between SAS and microangiopathy or other comorbidities.

Results: Patient characteristics were as follows: age, 67.0 ± 11.9 (mean ± standard deviation) years; estimated diabetes duration, 16.4 ± 10.3 years; body mass index (BMI), 25.2 ± 4.4 kg/m^2; fasting blood sugar (FBS), 142 ± 44 mg/dL; HbA1c, 7.1 ± 1.2%; fasting blood C-peptide immunoreactivity (CPR), 3.1 ± 2.1 ng/mL; homeostatic model assessment of insulin resistance (HOMA-IR), 6.11 ± 10.8; creatinine (Cr), 1.06 ± 1.14 mg/dL; apnea-hypopnea index (AHI), 15.4 ± 14.3 (16.8 ± 14.5 in men and 12.9 ± 13.8 in women); prevalence of SAS (AHI ≥15), 40.6% (127/313) in men and 29.4% (50/170) in women. The incidences of microangiopathy were as follows: retinopathy (147/483, 30.6%) and nephropathy (233/483, 48.5%). The incidences of stable comorbidities were as follows: intracranial lesions (106/483, 22.0%), respiratory diseases (48/483, 9.9%), cardiovascular diseases (192/483, 39.8%), cancer (78/483, 16.1%), thyroid diseases (36/483, 7.7%), and mental illnesses (27/483, 5.8%). Analysis of the relationships of SAS with microangiopathy and other comorbidities showed that intracranial lesions, cardiovascular diseases, and cancer were more common among patients with SAS than among those without SAS (AHI <15) ($p < 0.05$ each), while no such association was found for microangiopathy. Multivariate analysis adjusting for known risk factors for SAS (BMI, male gender, and age) identified BMI (odds ratio, 1.25; 95% confidence interval, 1.18–1.33; $p < 0.0001$), male gender (2.11; 1.36–3.34; $p < 0.001$), and intracranial lesions (1.74; 1.07–2.83; $p < 0.05$) as independent risk factors for SAS.

Conclusion: The intracranial lesions identified were stable and diverse, ranging from infarction and hemorrhage to benign brain tumor and encephalitis. The association of intracranial lesions with hypoxia may be related to the respiratory centers, although the underlying mechanism is unknown. T2DM patients often present with various diseases such as angiopathy, infection, and cancer, and occasionally experience hyperglycemia and hypoglycemia. Therefore, it is considered that T2DM patients with obesity, male gender, and stable intracranial lesions should be carefully monitored for nocturnal hypoxia, particularly during emergency hospitalization. The present results also suggest the importance of evaluation and appropriate treatment of SAS in routine clinical practice.

Disclosure: **S. Kawasaki:** None.

Autoimmune hypothyroidism increases risk of microangiopathic complications in adult patients with type 1 diabetes

A. Rogowicz-Frontczak[1], B. Falkowski[2], A. Grzelka[1], A. Uruska[1], A. Araszkiewicz[1], D. Zozulinska-Ziolkiewicz[1];
[1]Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poznan, [2]Poznan University of Medical Sciences, Poznan, Poland.

Background and aims: Type 1 diabetes (T1DM) often coexists with other autoimmune diseases, most commonly with hypothyroidism. To date, the influence of co-occurrence of autoimmune hypothyroidism (AHT) in the course of chronic microangiopathic complications of autoimmune diabetes has not been established. Aim of the study was to assess the relationship between (AHT) and the occurrence of chronic type 1 diabetes complications.

Materials and methods: The study population comprised 342 European Caucasian participants with T1DM including 165 (49.7%) men and 167 (50.3%) women. Median participants` age was 32 (interquartile range [IQR]: 26–41) years and T1DM duration was 14 (IQR: 9–21) years. Exclusion criteria were: age <18 years, diabetes duration <5 years, hyperthyroidism, iodotherapy or thyroidectomy in the medical history, eGFR below 30 mL min^{-1}·1.73 m^{-2}, ALT or AST three times above reference interval, diabetic ketoacidosis or ketonuria at the time of enrollment to the study, neoplasms, anemia, taking drugs affecting glucose metabolism, anti-thyroid drugs and drugs affecting thyroid function except L-thyroxine. T1DM was diagnosed based on American Diabetes Association criteria and at least one out of three examined autoantibodies (against islet cells [ICA], glutamic acid decarboxylase [GAD], insulinoma-associated tyrosine phosphatase [IA-2]) had to be positive. AHT was recognized in state overt or subclinical hypothyroidism and the presence of anti-thyroid autoantibodies: ATPO (anti-thyroperoxidase) and/or ATg (anti-thyroglobulin) and ultrasonography (hypoechogeneity, parenchymal heterogeneity, lymph nodes).

Results: In the study group, 161 (48.5%) participants were diagnosed with at least one microangiopathic complication (retinopathy - 41.6%, diabetic kidney disease - 13.9%, autonomic neuropathy - 14.3% and peripheral neuropathy-20.8%). At the time of enrollment, 16.3% participants were diagnosed with AHT or had AHT in medical history. Among patients with AHT 82.7% were treated with L-thyroxine and 67.4% of them were treated effectively what means TSH concentration within reference interval. Patients with AHT were characterized by higher prevalence of microangiopathy (64.8% vs. 45.3% respectively; $p = 0.009$) in all and retinopathy (55.6% vs 38.9%; $p = 0.02$) as compared with participants without AHT. The group with microangiopathy differed significantly with classic risk factors of chronic diabetes complications such as age, T1DM duration, SBP, DBP, HbA_{1c}, TG, eGFR and hypertension prevalence. AHT turned out to be an independent predictor of microangiopathy in multivariate logistic regression analysis (odds ratio, 2.35; 95% confidence interval [CI], 1.14–4.84; $p = 0.02$] after an adjustment for other potential explanatory factors such as age, BMI, DBP, HbA_{1c} and TG.

Conclusion: Co-occurrence of autoimmune hypothyroidism with type 1 diabetes is associated with a higher incidence of microvascular complications.

Heart rate variability indices in patients with micro- and macrovascular complications of type 2 diabetes: a cross sectional study

P.S. Wadhokar[1], L. Phadke[2], S. Bhat[1];
[1]Medicine, Smt. Kashibai Navale Medical College, Pune, [2]Physiology, Smt. Kashibai Navale Medical College, Pune, India.

Background and aims: Meta-analyses of various studies have shown that in comparison to healthy subjects, reduced heart rate variability a marker of cardiac autonomic activity is strongly associated with hypertension, diabetes & myocardial infarction.There is paucity of data, suggesting the degree of association between heart rate variability indices (HRV) in type II diabetes with and without micro & macro vascular complications. It will be interesting to explore whether there is a progressive reduction in HRV with complications of type II diabetes. Results of study may pave the way for utility of HRV indices in risk stratification of complications in type II diabetes. The aim of present study was to explore the Heart Rate Variability and degree of association of HRV indices in complicated and uncomplicated type II Diabetes mellitus.
Materials and methods: 60 consenting type II diabetes patients between 30 to 70 years of both genders, enrolled during a visit at Kashibai Navale Medical College Pune India were included in the study which was approved by Institutional Ethics Committee. Exclusion Criteria: Factors affecting HRV like Previous myocardial infarction, congenital heart disease, Uncontrolled cardiac arrhythmias, Parkinsonism, Cerebrovascular accident, Thyroid disorders, Hypertrophic cardiomyopathy, Drugs (Tricyclic antidepressants, β & Calcium channel Blockers, ACE inhibitors). All patients were subjected to exercise stress test with multistage Bruce protocol, those with positive stress test were subjected to Coronary Angiography for confirmation of CHD. All patients were also tested for- 1) Presence of diabetic nephropathy (KDOQI guidelines), 2) Diabetic retinopathy (ETDRS guidelines). 3) Diabetic Peripheral Neuropathy (Toronto Expert Panel on Diabetic Neuropathy). A high sampled ECG (1 KHz) -Chronovisor HRV DX system & HRV analysis software suit version 1.1.487 Promorphosis Pvt. Ltd.Pune) in resting supine position for 15 minutes was recorded for HRV analysis. Patients were grouped as Group I - Type II DM without complications & Group II- Type II DM with Micro/Macrovascular complications.
Results: Group comparison was done using Mann-Whitney test and association was tested by χ^2 test using Epi Info.7. P value of <0.05 was considered as significant.In comparison to group I there was significant reduction in all HRV indices (SDNN, LF and HF (ms2)) in group II. HRV indices have shown a strong association with type II diabetes with complication (Odds ratio for group with complications) and with longer duration of diabetes.
Conclusion: Results have highlighted that in type II diabetes there is significant & progressive reduction in HRV, and association of HRV indices with complications were stronger compared to uncomplicated type II diabetes. Progressive reduction of HRV indices & stronger association of indices with complications of diabetes may be useful for screening of complications in type II diabetes.

Parameter	Type II DM With Complications			Type II DM Without Complications		P value

Heart rate variability in type 2 diabetes: a systematic review and meta-analysis

T. Benichou[1], B. Pereira[1], M. Mermillod[2], D. Pfabigan[3], I. Tauveron[1], S. Maqdasy[1], F. Dutheil[1];
[1]CHU Clermont-Ferrand, Clermont-Ferrand, France, [2]CHU Grenoble, Grenoble, France, [3]Peking University, Beijing, China.

Background and aims: Cardiac autonomic neuropathy in type 2 diabetes mellitus (T2DM) patients is frequent and associated with high cardiovascular mortality. Heart rate variability (HRV) is the gold standard to measure cardiac autonomic neuropathy. We aimed to conduct a systematic review and meta-analysis to evaluate the impact of T2DM on HRV parameters.
Materials and methods: The PubMed, Cochrane Library, Embase and Science Direct databases were searched on 1st October 2017 using the keywords "diabetes" AND ("heart rate variability" OR "HRV"). Included articles had to report HRV parameters in T2DM patients and healthy controls measured during 24 hours with a Holter-electrocardiogram. Measurements of HRV retieved were: RR-intervals (or Normal to Normal intervals - NN), standard deviation of RR intervals (SDNN), percentage of adjacent NN intervals differing by more than 50 milliseconds (pNN50), square root of the mean squared difference of successive RR intervals (RMSSD), total power, Low Frequency (LF), High Frequency (HF) and LF/HF ratio, as per Task Force recommendations.
Results: We included twenty-five case-control studies with 2932 patients: 1356 with T2DM and 1576 healthy controls. We noted strong evidence that T2DM patients had significantly lower RR intervals (effect size −0.61 [95% CI −1.21, −0.01]; $p = 0.01$; $I^2 = 91.6\%$), lower SDNN (−0.65 [−0.83, −0.47]; $p < 0.001$; $I^2 = 65.1\%$), lower RMSSD (−0.92 [−1.37, −0.47]; $p < 0.001$; $I^2 = 94.0\%$), lower pNN50 (−0.46 [−0.84, −0.09]; $p = 0 < 0.001$; $I^2 = 85.5\%$), lower total power (−1.52 [−2.13, −0.91]; $p < 0.001$; $I^2 = 93.5\%$), lower LF (−1.08 [−1.46, −0.69]; $p < 0.001$; $I^2 = 91.3\%$), and lower HF (−0.79 [−1.09, −0.50]; $p < 0.001$; $I^2 = 85.6\%$). LF/HF did not differ between groups (0.02 [−0.38, 0.43]; $p = 0.914$; $I^2 = 90.1\%$). Higher levels of HbA1c were associated with shorter RR intervals. Blood glucose levels were associated with both an increase in LF and HF, and with an increase in RMSSD and SDNN. Time from diagnosis of T2DM was linked with a lower level of total power and an increase in RMSSD and SDNN.
Conclusion: T2DM is associated with an overall decrease in the HRV of T2DM patients. We demonstrated that both sympathetic and parasympathetic activity were decreased, which can be explained by the metabolic deleterious effects of blood glucose levels on HRV, leading to cardiac autonomic neuropathy. Some of these parameters are modifyied by independent variables.
Disclosure: **T. Benichou:** None.

Determinants of aspirin loss of efficacy in type 2 diabetic patients

E. Paven[1], J. Dillinger[1], C. Bal dit Sollier[2], J. Riveline[3], J. Launay[4], J. Gautier[3], L. Drouet[2], P. Henry[1];
[1]Cardiology, AP-HP Hôpital Lariboisière, Paris, [2]Institut des Vaisseaux et du Sang, Paris, [3]Diabetology, AP-HP Hôpital Lariboisière, Paris, [4]INSERM UMRS-942, Paris, France.

Background and aims: Aspirin is clinically less effective for preventing atherosclerotic events in type-2 diabetic patients (T2DP). Aspirin loss of efficacy in this population is mainly related to an accelerated platelet turnover with persistent platelet reactivity or increased level of thromboxane 24h after last aspirin intake. The aim of this study was to investigate the main mechanisms associated with aspirin loss of efficacy in this population.
Materials and methods: This prospective study included consecutive stable T2DP coming for yearly check-up between March and July 2016. Aspirin loss of efficacy was defined as a persistent high platelet reactivity (HPR) using light transmission aggregometry with arachidonic acid (0.5 mg/ml - threshold >20% residual aggregation) and confirmed with serum thromboxane B2 measurement (TXB2). Assessment of aspirin efficacy was performed 24 h after last aspirin intake in patients treated for at least 8 days. An extensive study of diabetes status, insulin resistance and inflammation was performed. Data are presented as mean ± SD or median [25–75%] - Student T test, Mann-Whitney test and Spearman's rank were used for comparisons.
Results: 116 patients (mean age 65 ± 9 years old, 69% men) were included. Mean duration of diabetes was 15 y. [11–24] and 50% were treated with insulin for 9 [4–14] y. Most of the population presented associated cardiovascular risks factors (dyslipidemia: 85% - hypertension: 77% - current smoking: 16%). 43% had history of coronary artery disease or stroke. Mean BMI was 28 kg/m^2 [24–32] with an android obesity (waist circumference: 103 ± 13 cm). Using light transmission aggregometry, HPR was found in 27 (23%) patients. There was no significant difference in mean age, sex ratio and cardiovascular risk factors, in patients with or without HPR. Median duration of diabetes and insulin treatment were significantly longer in patients with HPR ($p = 0.01$ for both). Median fasting glucose was significantly higher in patients with HPR ($p = 0.02$) but HbA1c was not significantly different. HPR was strongly related to all markers of insulin resistance especially waist circumference ($p = 0.007$), HOMA-IR ($p = 0.002$), QUICKI index ($p = 0.002$), leptin ($p = 0.01$) and mean dose of weight adjusted dose of long-lasting insulin in patients treated with insulin ($p = 0.006$). Surprisingly, there was no relationship with thrombopoietin ($p = 0.38$) and inflammatory markers: IL6 ($p = 0.86$), IL10 ($p = 0.68$), IDO activity ($p = 0.98$), TNFalpha ($p = 0.31$), usCRP ($p = 0.08$). TXB2 concentration was also strongly correlated with all insulin resistance parameters, especially with HOMA-IR ($r = -0.42$, $p = 0.002$), QUICKI index ($r = -0.44$, $p = 0.0006$) and long lasting insulin dose/kg ($r = -0.43$, $p = 0.0007$) but not to inflammatory parameters.
Conclusion: Aspirin loss of efficacy is frequent in T2DP. It appears to be strongly related to insulin resistance but not to inflammation. This result could help to select a population who could benefit to alternative antiplatelet treatment.
Disclosure: **E. Paven:** None.

Risk stratification for thrombosis in type 2 diabetic patients

S. Daniels[1], D. Moreno-Martinez[1], H. Soran[2], S. Adam[2,3], J. Thachil[4], N. Dempsey-Hibbert[1], M.Y. Alexander[1], S. Jones[1];
[1]Department of Biomedicine, Manchester Metropolitan University, Manchester, [2]University Department of Medicine, Central Manchester University Hospitals NHS Foundation Trust, Manchester, [3]Faculty of Medical and Human Sciences, University of Manchester, Manchester, [4]Department of Haematology, Manchester Royal Infirmary, Manchester, UK.

Background and aims: The leading cause of mortality in type 2 diabetes mellitus (T2DM) patients is cardiovascular disease, with patients exhibiting platelet hyperreactivity and prothrombotic propensity. The mechanisms that underpin these effects however are unclear. The aim of this study was to determine which of the biochemical features associated with T2DM are responsible for increased platelet reactivity.
Materials and methods: Blood was collected from fasted healthy controls and T2DM patients. Full blood counts and biochemical profiles were analysed and platelet aggregation and flow cytometry performed to assess platelet reactivity.
Results: Platelets from healthy donors supplemented with glucose (5.0–30.0 mmol/l) for 1 hour at room temperature ($n = 10$), exhibited a significant elevation in surface expression of activated GPIIb/IIIa ($p = 0.032$), and a significant increase in mean platelet volume (MPV) (one-way ANOVA, $p < 0.001$), which was not observed with the osmotic control mannitol. Platelet aggregation in response to ADP or collagen however was not increased by acute hyperglycaemia in platelet rich plasma (PRP) or whole blood and there was no significant increase in alpha-granule secretion or GPIIb/IIIa activation following ADP stimulation. Furthermore, in T2DM patients ($n = 25$), there was no correlation with platelet reactivity and fasting glucose or HbA1c, but HbA1c did positively correlate with MPV (Pearson, $p = 0.013$). The strongest association with platelet reactivity in T2DM was with LDL-C. A significant positive correlation was observed between LDL-C and ADP-activated platelet aggregation (Spearman, $p = 0.002$, $n = 26$). Moreover, patients with LDL-C levels above 2.0 mmol/l ($n = 13$) had significantly higher platelet aggregation than patients with LDL-C below 2.0 mmol/l ($n = 13$; Mann-Whitney U test, $p = 0.027$).
Conclusion: The data demonstrates that hyperglycaemia primes rested platelets and increases platelet size, but does not alter platelet reactivity as previously reported. The most significant risk factor for platelet hyperreactivity is elevated LDL-C. This highlights the potential for LDL-C to be used as a clinical biomarker to identify diabetic patients who would benefit most from antithrombotic therapy, and suggests that lipid lowering medication may indirectly provide antithrombotic benefit.

Serum fibroblast growth factor 21 levels are positively associated with aortic arterial stiffness in patients with type 2 diabetes

B.-G. Hsu[1], Y.-C. Chen[2], D.-A. Wu[3];
[1]Tzu Chi General Hospital, Hualien, [2]Department of Psychiatry, Dalin Tzu Chi General Hospital, Chiayin, [3]Division of Metabolism and Endocrinology, Tzu Chi General Hospital, Hualien, Taiwan.

Background and aims: Elevated serum fibroblast growth factor 21 (FGF-21) levels are associated with atherosclerosis and obesity. Aortic arterial stiffness assessed by carotid-femoral pulse wave velocity (cfPWV) provides a high predictive value for the future cardiovascular disease and mortality. This study evaluated the correlation between serum FGF-21 levels and aortic stiffness in patients with type 2 diabetes mellitus (T2DM).
Materials and methods: Fasting blood samples were collected from 130 patients with T2DM. cfPWV value was measured by a validated tonometry system and cfPWV >10 m/s were used to define the high aortic arterial stiffness group according to the ESH-ESC 2013 guideline. Serum FGF-21 concentrations were determined using a commercially available enzyme immunoassay kit.
Results: In total, 45 T2DM patients (34.6%) had high aortic arterial stiffness, and showed older age ($p = 0.015$) and higher systolic blood pressure ($p < 0.001$), diastolic blood pressure ($p < 0.001$), body fat mass ($p = 0.019$), triglycerides ($p = 0.016$), fasting glucose ($p = 0.043$), glycated hemoglobin ($p = 0.034$), creatinine ($p = 0.006$), urine albumin-

to-creatinine ratio ($p = 0.004$), serum FGF-21 ($p < 0.001$) levels, and lower estimated glomerular filtration rate ($p = 0.001$) than those in a low aortic arterial stiffness group. After adjusting for factors significantly associated with aortic arterial stiffness by multivariate logistic regression analysis, serum FGF-21 level (odds ratio: 1.006, 95% confidence interval: 1.002–1.010, $p = 0.002$) was the independent predictor of aortic arterial stiffness in patients with T2DM. Multivariate forward stepwise linear regression analysis also showed that logarithmically transformed FGF-21 level (log-FGF-21, $\beta = 0.369$, $p < 0.001$) was positively associated with cfPWV values in T2DM patients.

Conclusion: Serum FGF-21 level is positively correlated with cfPWV values and is the independent predictor of aortic arterial stiffness in patients with T2DM.

Association between H-ficolin and mortality in type 1 diabetes

J.A. Oestergaard[1], C. Forsblom[2], S. Thiel[3], L. Thorn[2], F. Jansson[2], T.K. Hansen[4], P.-H. Groop[2,5], FinnDiane Study Group;
[1]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, Denmark, [2]Folkhälsan Inst of Genetics, Folkhälsan Res Center; Abd Center Nephr; Res Prog Unit, Diab & Obesity, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland, [3]Department of Biomedicine, Aarhus University, Aarhus, Denmark, [4]Steno Diabetes Center Aarhus, Aarhus, Denmark, [5]Department of Diabetes, Monash University, Melbourne, Australia.

Background and aims: Circulating levels of complement factor H-ficolin has been associated with incidence of microalbuminuria in diabetes, but it remains unknown if H-ficolin is associated with mortality. In this study, we aimed to test the hypothesis that high H-ficolin concentration is associated with mortality. In addition, we investigated the external validity of the previous finding on microalbuminuria.
Materials and methods: We studied 2439 type 1 diabetes patients from the Finnish Diabetic Nephropathy (FinnDiane) study. The study included adult patients with type 1 diabetes diagnosed before the age of 40 who had insulin treatment initiated within 1 year of diagnosis, and where data on renal status and mortality was available. 2146 patients were included in analysis of renal outcomes omitting patients with end-stage renal disease at baseline (ESRD, $n = 232$) or missing follow-up data ($n = 61$). Data on death was received from Statistics Finland until December 31 2015. Patients were grouped by the quartiles of baseline H-ficolin concentration in accordance with a previous the study. Akaike information criterion (AIC) was used to choose best adjusted Cox regression model.
Results: The patients were followed through a median of 16.6 years (IQR 15.2–17.3). 1428 patients had normal albumin excretion at baseline, 318 had microalbuminuria, 461 had macroalbuminuria and 232 patients had ESRD. All-cause mortality rate was higher among patients with H-ficolin concentration within the highest quartile (Q4) as compared with the combined group of the lower three quartiles (Q1–3), HR 1.48 (CI95% 1.17–1.88) in unadjusted Cox analysis. In adjusted analysis, HR for all-cause mortality was 1.45 (1.07–1.97) comparing Q4 to Q1–3 including the following covariates; age at baseline, age at diabetes onset, BMI, systolic blood pressure, estimated GFR, 24-hour albumin excretion rate, HbA1c and smoking status. Data on 24-hour albumin excretion rate was missing for 450 patients. However, omitting this variable from the analysis of mortality did not alter the estimate significantly. Median follow-up on renal data was 8.5 years (IQR 5.5–12.7). HR for progression from normoalbuminuria to microalbuminuria was 2.26 (CI 95% 1.62–3.18) comparing Q4 with Q1–3 in unadjusted Cox regression analysis. In an adjusted model, including 24-hour albumin excretion rate and HbA1c as covariates, HR decreased to 1.40 (CI95% 0.93–2.11) and lost statistical significance. H-ficolin was not associated with progression from microalbuminuria to macroalbuminuria or with progression from macroalbuminuria to ESRD.
Conclusion: High concentration of H-ficolin was associated with all-cause mortality in the present cohort of type 1 diabetes patients. H-ficolin was also associated with progression to microalbuminuria, but this was not statistically significant in adjusted analysis.

Positive correlates of sclerostin and association with aortic arterial stiffness in patients with type 2 diabetes

Y.-C. Chen[1], D.-A. Wu[2], B.-G. Hsu[3];
[1]Department of Psychiatry, Dalin Tzu Chi General Hospital, Chiayin, [2]Division of Metabolism and Endocrinology, Tzu Chi General Hospital, Hualien, [3]Division of Nephrology, Tzu Chi General Hospital, Hualien, Taiwan.

Background and aims: Sclerostin or dickkopf-1 (DKK1) is a canonical Wnt/β-catenin signaling pathway inhibitor and Wnt/β-catenin signaling pathway is thought to be implicated in the development of arterial stiffness. Carotid-femoral pulse wave velocity (cfPWV) is novel method to assess for aortic arterial stiffness. It is interesting to investigate whether sclerostin or DKK1 level is correlated with aortic arterial stiffness in patients with type 2 diabetes mellitus (DM).
Materials and methods: Fasting blood samples were collected from 125 patients with T2DM for biochemical data, sclerostin, DKK1 levels. cfPWV value was measured by a validated tonometry system and cfPWV >10 m/s were used to define the high aortic arterial stiffness group according to the ESH-ESC 2013 guideline. Serum sclerostin and DKK1 concentrations were determined using a commercially available enzyme-linked immunosorbent assays.
Results: Forty-six type 2 DM patients (36.8%) were defined as the high aortic arterial stiffness. Patients in the high aortic arterial stiffness had older age ($P = 0.001$) and higher systolic blood pressure ($P < 0.001$), diastolic blood pressure ($P = 0.029$), blood urea nitrogen ($P = 0.029$), creatinine ($P < 0.001$), urine albumin-to-creatinine ratio ($P < 0.001$), serum sclerostin ($P < 0.001$) levels, and lower high-density lipoprotein cholesterol (HDL-C, $P = 0.016$), and estimated glomerular filtration rate ($P < 0.001$) than those in a low aortic arterial stiffness group. After adjusting for factors significantly associated with aortic arterial stiffness by multivariate logistic regression analysis, serum sclerostin level (odds ratio (OR): 1.005, 95% confidence interval (CI): 1.002–1.007, $P = 0.002$) and HDL-C (OR: 0.949, 95% CI: 0.902–1.000, $P = 0.048$) were the independent predictors of aortic arterial stiffness in patients with type 2 DM. Multivariate forward stepwise linear regression analysis also showed that serum sclerostin level ($\beta = 0.374$, adjusted R2 change: 0.221, $P < 0.001$) was positively associated with cfPWV values in type 2 DM patients. The area under the receiver-operating characteristic

(ROC) curve predicting central arterial stiffness by sclerostin level in DM patients was 0.748 (95% CI: 0.661–0.820, $P < 0.001$).
Conclusion: Serum sclerostin level, but not DKK1, is positively correlated with cfPWV values and is the independent predictor of aortic arterial stiffness in patients with type 2 DM.

HbA_{1c} coefficient of variation is an independent risk factor for chronic complications in type 2 diabetes in the FIELD study

E.S. Scott[1,2], A.S. Januszewski[1,3], R. O'Connell[1], S. Colagiuri[4], G.R. Fulcher[2,5], A. Keech[1], A.J. Jenkins[1,3], on behalf of the FIELD study investigators;
[1]NHMRC Clinical Trials Centre, Sydney, [2]Department of Endocrinology and Diabetes, Royal North Shore Hospital, Sydney, [3]Department of Medicine, St Vincent's, University of Melbourne, Melbourne, [4]The Boden Institute, University of Sydney, Sydney, [5]Northern Clinical School, University of Sydney, Sydney, Australia.

Background and aims: Glycaemic variability (GV) is implicated in the pathogenesis of chronic diabetes complications. GV can be measured long- and short-term by fluctuations in HbA1c or fasting plasma glucose respectively. Study aims were to assess whether GV is associated with the development of micro- and macrovascular complications in the Fenofibrate Intervention and Event Lowering In Diabetes (FIELD) study, and to determine what baseline factors predict GV.
Materials and methods: The FIELD study randomised 9795 individuals to fenofibrate 200 mg daily or placebo and followed the development of vascular complications for a median of 5-years. GV was calculated as coefficient of variation (CV) and standard deviation (SD) of HbA1c and fasting plasma glucose (measured at baseline, annually and at study-end). We assessed whether GV was a predictor of microvascular and/or macrovascular complications from study year-2 onward using logistic and Cox proportional hazards regressions with adjustment for significant covariates. The primary composite endpoint was the development of microvascular disease (defined as presence of either retinopathy, albuminuria, neuropathy and/or microvascular amputations), and subsidiary composite endpoints: macrovascular disease (cardiovascular mortality, myocardial infarction, stroke, coronary and carotid revascularization), total mortality and individual vascular complications.
Results: A logistic regression model with adjustment for age, gender, glycaemic control, baseline complications and treatment allocation demonstrated that HbA1c CV was an independent risk factor for the development of microvascular complications (OR 1.13 95% CI (1.04–1.22) $P = 0.002$). All other GV parameters had similar effects. Although HbA1c CV was significantly associated with the macrovascular outcome in univariate Cox proportional hazards regression ($P = 0.002$), significance was lost in multivariate analysis. Multiple logistic regression demonstrated that HbA1c CV (quartiles Q1 = reference) was significantly associated with the development of nephropathy at 2-years (Q2: OR 1.24 (95% CI 0.97–1.59), Q3: OR 1.43 (1.12–1.82), Q4: OR 1.77 (1.38–2.25) $P < 0.001$). HbA1c CV (quartiles) was significantly associated in Cox proportional hazards multiple regression with the development of stroke (Q2: OR 1.48 (95% CI 0.93–2.35), Q3: OR 1.52 (0.96–2.41), Q4: 1.99 (1.27–3.14) $P = 0.02$) and total mortality (Q2: OR 0.97 (95%CI 0.73–1.28), Q3: 1.24 (0.95–1.62), Q4: OR 1.66 (1.29–2.14) ($P < 0.001$)). In subjects randomised to fenofibrate HbA1c CV increased compared to placebo across the study (HbA1c CV 8.98 (5.13) vs 8.58 (5.06) ($P < 0.001$, (Diff 0.39, 95% CI 0.19–0.60).
Conclusion: In Type 2 diabetes HbA1c CV is an independent risk factor for microvascular complications, stroke and total mortality. Despite higher HbA1c CV in individuals randomised to fenofibrate, fenofibrate therapy significantly reduced total cardiovascular events and all microvascular outcomes in the FIELD study.

Diabetes and cognitive function: longitudinal study of adult health (ELSA-Brasil)

M. Teixeira[1], V. Passos[1], S. Barreto[1], M. Schmidt[2], B. Duncan[2], A. Beleigoli[1], M. Fonseca[3], P. Vidigal[1], L. Araujo[4], M. Diniz[1];
[1]Faculty of Medicine, Universidade Federal de Minas Gerais, Belo Horizonte, [2]Faculty of Medicine, Universidade Federal do Rio Grande do Sul, Porto Alegre, [3]Public Health School, Fundação Oswaldo Cruz, Rio de Janeiro, [4]Public Health School, Universidade Federal do Ceara, Fortaleza, Brazil.

Background and aims: Some studies show worse performance in cognition tests for diabetes mellitus (DM) patients. Our aim is to assess the association between cognitive performance and DM. Detection of early alterations in cognitive performance among individuals with DM could be important for future potential interventions

Materials and methods: Cross-section analysis, baseline (2008–2010) of a large multicentric cohort of a developing country that has been experiencing a socio-demographic and nutritional transition in the last three decades: Brazilian Longitudinal Study of Adult Health (ELSA-Brasil). Cognitive domains was assessed by word-list learning, word-list delayed recall, word recognition tests, semantic and phonemic verbal fluency tests, and trail making test B. Multiple linear regression and generalized multiple regression with algorithmic link and gamma distribution were used to estimate the association between DM and cognitive performance. The participants were located in three subgroups: no DM, new-onset (NDM) and previous DM(PDM). Analyses were adjusted for age, sex, education, comorbidity, habits and lipids. In the final model were included results with $p < 0.05$

Results: There were 14,480 participants in this study, 45.7% male, mean 52.0 ± 9.1 years-old, 52.8% with University degree, 76.7% sedentary, 57.1% never smoked, 63.1% with BMI >25.0 kg/m^2. PDM was associated with the poorest performance in memory tests (early memory, delayed memory and words recognition) (β −0.67 [−0.98; −0.36] R2 0.21) when compared to no or to NDM, with a dose-response gradient. Results show a better cognitive performance in women and worse performance in older individuals, with lower schooling, high alcohol consumption, smoking and with higher ratio total cholesterol/ HDL-c. The results of the models between verbal phonemic fluency and new-onset and PDM shows similar performance in both groups (β −0.48 [−0.72; −0.24] R2 0.18) and (β −0.49 [−0.72; −0.26] R2 0.18), respectively after adjustments. Final model demonstrate a lower cognitive performance in the older individuals, with low schooling, hypertensive, smoking and with low physical activity level

Conclusion: There was a significant association between diabetes and cognitive performance in this population

The diabetes and dementia (DIADEM) project: assessing inpatient admissions and trends in management and hospitalisation of patients with diabetes and dementia

A. Ali, S. Dhuna, A. Puttanna, P. De;
Sandwell and West Birmingham NHS Trust, Birmingham, UK.

Background and aims: Continued advances in medicine have contributed to an ageing population and incidence of type 2 diabetes is also on the rise. As of 2015 there are 46.8 million people with dementia in the world with this rising to over 131.5 million by 2050. The worldwide prevalence of diabetes in 2015 was 387 million and due to rise to 592 million by 2035. Consequently, the combined co-morbidity of diabetes and dementia is on the increase. The DIADEM project was devised to target this specific population of patients, assessing current trends in hospital admissions with a view to reducing the health and economic burden The aim was to evaluate the current trends and outcomes of hospital admissions in patients with dementia and diabetes including availability of recent Hba1c and medication regimens for complexity and overtreatment.

Materials and methods: Patients admitted over the previous year with a coded diagnosis of dementia and type 2 diabetes were analysed for information relating to medication, admission reasons as well as in hospital glycaemic control and Hba1c prior to admission.

Results: 350 patients were assessed, median age 84 years (IQR 79–88). Admission reasons included respiratory [75 (21.4%)], urinary [68 (19.4%)] , neurological [47 (13.4%)] , cardiac [41 (11.7%)] , trauma [40 (11.4%)]. Medication history was obtained for 256 (73.1%) patients with 94 (26.9%) on diet alone, 70 (20%) treated with sulphonylurea (SU), 46 (13.1%) were treated with oral and insulin therapies and 58 (16.6%) treated with insulin alone. 311 (88.9%) patients had a recent Hba1c with 39 (11.1%) never having a recorded Hba1c. Median 137 (IQR 52–285.5) days between Hba1c reading and date of admission. Median Hba1c for the cohort was 51(IQR 44–64) mmol/mol, with 163 (46.6%) having Hba1c <53 mmol/mol and 135 (38.6%) Hba1c <48 mmol/mol. 13 (8%) had episodes of hypoglycaemia (BG <3 mmol/l) during their admission. 11 (6.8%) of these patients had Hba1c <48 mmol/mol. Only three had their diabetic medication adjusted on discharge with the rest continuing on their admission medication. Stratified by medication history for insulin, combined insulin, sulphonylurea therapies and both SU/insulin therapies, 25 (7.4%), 11 (3.1%), 11 (3.1%) and 2 people (0.6%) had Hba1c <53 mmol/mol

Conclusion: This is the first project specifically focussing on this subgroup of patients. A large number of patients are over-treated. Clinicians must consider de-intensification, favouring less complex regimes with fewer side effects and reduced risk of hypoglycaemia to reduce health and economic burden for these patients.

Disclosure: **A. Ali:** None.

1063

Impacts of metabolic health and obesity status on the development of dementia: a population-based cohort study

M. Lee[1], J.-Y. Lee[1], K. Han[2], J. Bae[1], B. Lee[1,3], E. Kang[1,3], B.-S. Cha[1,3], Y.-H. Lee[1,3];
[1]Department of Internal Medicine, Yonsei University College of Medicine, Seoul, [2]Department of Biostatistics, The Catholic University, Seoul, [3]Institute of Endocrine Research, Yonsei University College of Medicine, Seoul, Republic of Korea.

Background and aims: The risk for dementia among subjects who are metabolically healthy obese (MHO), remains uninvestigated. We aimed to evaluate the association between late-life metabolic health and obesity status and risk of incident dementia.

Materials and methods: Using the National Health Insurance System of South Korea, study population comprised 5,669,488 adults aged ≥60

years who underwent the health examinations from 2009 to 2012 without history of dementia at baseline. Subjects who met not more than one criterion using the Adult Treatment Panel-III were determined as metabolically healthy and obesity was defined as a body mass index 25 kg/m^2. Subjects were classified into four groups by metabolic profiles and obesity status, and were followed for incident overall dementia, Alzheimer's disease (AD), and vascular dementia (VaD).

Results: During a median follow up of 65 months (interquartile range [IQR] 51–74 months), dementia was developed in 363,932 subjects (6.4%). The MHO group had the lowest risk for overall dementia (hazard ratio [HR] 0.87, 95% confidence interval [CI] 0.86–0.88), whereas metabolically unhealthy non-obese (MUNO) subjects were at the highest risk (HR 1.20, 95% CI 1.19–1.21) compared to the metabolically healthy non-obese (MHNO) group. Metabolically unhealthy profiles raised the risk (up to 41% in VaD), and obesity reduced the risk (up to 15% in AD).

Conclusion: The MHO phenotype in late life was associated with decreased risk for overall dementia. Further studies in other populations are warranted to better understand current results and to predict individuals who have the most increased risk for developing dementia.

Associations between brain grey matter volumes and adipose tissue metabolism in healthy adults

J. Raiko[1], J. Tuulari[1], T. Saari[1], R. Parkkola[2], N. Savisto[1], P. Nuutila[3], K. Virtanen[1];
[1]Turku PET Centre, University of Turku, Turku, [2]Department of Radiology, Turku University Hospital, Turku, [3]Department of Endocrinology, Turku University Hospital, Turku, Finland.

Background and aims: Grey matter (GM) volume in different brain loci has been shown to vary in obesity and diabetes, but the mechanisms conveying the changes remain unresolved. Few studies have examined the associations between adipose tissue metabolic activity and brain GM volumes. We examined fatty acid metabolism in different adipose tissue depots and their associations with GM volumes in brain loci in healthy and overweight adults.

Materials and methods: 36 subjects (M/F: 12/24, mean age 39.7 ± 9.4 years and BMI 27.5 ± 5.6 kg/m^2) were imaged with positron emission tomography using fatty acid analog [^{18}F]FTHA for brown (BAT) and white (WAT) fat depots and with [^{15}O]H2O for brown fat only during cold exposure. T1-weighted MRI at 1.5T was performed to all subjects (brain and whole body scans). VBM was used to measure brain GM volumes and ROI definitions to measure intra-abdominal fat volume. 2-hour hyperinsulinemic euglycemic clamp was performed to measure whole-body insulin sensitivity (M-value).

Results: BAT NEFA uptake in cold correlated directly with GM volumes in anterior cerebellum ($r = 0.411$, $P = 0.014$), occipital lobe ($r = 0.398$, $P = 0.018$) and temporal lobe ($r = 0.408$, $P = 0.015$), while BAT perfusion in cold was linked with GM volume in anterior ($r = 0.369$, $P = 0.04$) and posterior cerebellum ($r = 0.367$, $P = 0.04$) and midbrain ($r = 0.427$, $P = 0.017$). BAT NEFA uptake associated directly with GM volume in anterior cerebellum and occipital lobe (P in both ≤0.04) when adjusted for age, gender and intra-abdominal fat volume. When intra-abdominal fat volume was replaced with M-value as a regressor of no interest, associations with anterior cerebellum, limbic lobe and temporal lobe GM volumes remained significant (P always ≤0.04).

Conclusion: BAT fatty acid metabolism associates with GM volume in anterior cerebellum and occipital lobe independently of visceral obesity and with GM volume in anterior cerebellum, limbic lobe and temporal lobe independently of whole-body insulin sensitivity. Adulthood BAT activity might be a crucial resilience biomarker that attenuates the metabolic effects of obesity and related metabolic changes.

Localised brain volume differences and cognitive status in subjects with type 2 diabetes

I.D. Wilkinson[1], L. Hunt[1], K. Teh[1], S. Tesfaye[2], D. Selvarajah[1];
[1]Academic Radiology & Metabolism, University of Sheffield, Sheffield, [2]Diabetes and Endocrinology, Sheffield Teaching Hospitals, Sheffield, UK.

Background and aims: Mild Cognitive Impairment (MCI) is thought to be a chronic sequelae of Type-2 Diabetes Mellitus (T2DM). Cerebral atrophy is known to be associated with cognitive decline, particularly in the various types of dementia. Prodronal dementia has also been associated with changes in brain parenchymal structure. The aim of this study was to identify and compare regional differences in brain volume in T2DM patients with and without MCI.

Materials and methods: Seventy-six age and gender matched subjects [30, T2DM+normal cognition (T2DM); 17, T2DM+MCI (T2DM/MCI) and 29 non-diabetic healthy volunteers (HV)] were recruited. All subjects underwent clinical and questionnaire (Addenbrooke's Cognitive Assessment [ACE-R]) assessments and high-resolution, 3D T1-weighted Magnetic Resonance Imaging at 3T. Cerebral volumes were analysed using voxel based morphometry (VBM, FSL, Oxford).

Results: Demographic data indicated that all three groups were age-matched (mean age 69.3–71.5 years, ANOVA, $p = 0.164$). Group mean T2DM/MCI ACE-R score (mean ± SD; 83 ± 4) was significantly lower compared to those of other groups (HV = 96 ± 2, T2DM = 94 ± 3; ANOVA, $p < 0.001$). The T2DM/MCI group had significantly lower regional grey matter volumes compared to HV in the left ($p < 0.0005$) and right hippocampi ($p < 0.05$), left putamen ($p < 0.05$), caudate ($p < 0.05$) and amygdala ($p < 0.05$).

Conclusion: The current study demonstrates significantly lower cortical brain volumes in areas associated with cognition (including short-term memory-retrieval) in patients who have T2DM and mild cognitive impairment. Detailed changes in neuroanatomical make-up may help elucidate diabetes-related pathological mechanisms that lead to a change in cognition associated with T2DM.

1066

Impaired olfactory function is associated with insulin resistance in adults with type 1 diabetes

A. Duda-Sobczak[1], B. Falkowski[1], A. Araszkiewicz[1], M. Chudzinski[1], M. Urbas[2], L. Borucki[2], D. Zozulinska-Ziolkiewicz[1];
[1]Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poznan, [2]Department of Otorhinolaryngology, Raszeja City Hospital, Poznan, Poland.

Background and aims: Diabetes mellitus contributes to the central nervous system degeneration and impaired olfaction is a clinical manifestation of central diabetic neuropathy. Hyperglycemia and oxidative stress play a role in the development of olfactory dysfunction in diabetic subjects, however other diabetes-related factors might also be important. The aim of the study was to assess olfactory function and insulin sensitivity in adults with type 1 diabetes (T1DM).

Materials and methods: We included 113 participants with T1DM (60 men), median age 36 (IQR 29–43), disease duration 20 (IQR 13–26) years, HbA1c 8.0 (IQR 7.2–8.9)%. The patients underwent ENT examination with nasal endoscopy to exclude other factors disabling sense of smell. Olfactory function was assessed with "Sniffin" Sticks. For the assessment of odor identification 12 pens with different odors were used and patient should select 1 of 4 presented items which best described each odor for every pen (score 0–12, normosmia: score 10–12). We assessed the metabolic control of diabetes. To assess insulin sensitivity we used indirect markers: body mass index (BMI), waist-to-hip ratio (WHR),

visceral fat index, VFI (bioimpedance analysis), triglyceride to high density lipoprotein cholesterol (TG/HDL) ratio and specific calculators (estimated glucose disposal rate, eGDR; visceral adiposity index, VAI).
Results: Hyposmia was found in 56 (49.6%) participants, median odor identification score 10 (IQR 9–11). We showed lower insulin sensitivity in hyposmia compared to normosmia group: BMI [25.5 (21.9–29.5) vs. 23.3 (21.8–26.2) kg/m^2; $P = 0.047$], WHR [0.91 (0.83–0.96) vs. 0.83 (0.76–0.89); $P < 0.0001$], VF index [5 (3–9) vs. 3 (2–5); $P = 0.005$], TG/HDL ratio [0.70 (0.45–1.09) vs. 0.51 (0.34–0.74); $P = 0.007$], eGDR [8.0 (4.9–9.3) vs. 8.9 (6.3–10.0) mg/kg/min; $P = 0.01$], VAI [2.2 (1.6–3.5) vs. 1.6 (1.2–2.8); $P = 0.01$]. Odor identification score correlated with WHR (Rs = –0.40; $P < 0.0001$), TG (Rs = –0.24; $P = 0.01$), VF index (Rs = –0.22; $P = 0.03$), TG/HDL ratio (Rs = –0.25; $P = 0.008$), VAI (Rs = –0.24; $P = 0.01$) and eGDR (Rs = 0.23; $P = 0.01$). In multivariate linear regression analysis higher WHR was independently associated with impaired olfactory function ($\beta = -0.38$; $P = 0.002$) after adjustment for age, sex, TG, autonomic and peripheral neuropathy ($R^2 = 0.25$; $P < 0.0001$). The receiver-operating characteristic (ROC) analysis indicated a WHR cut-off of 0.92 [AUC: 0.737; 95%CI: 0.647–0.828, $P < 0.0001$] best predicting olfactory dysfunction (sensitivity 0.50, specificity 0.86).
Conclusion: Higher degree of olfactory dysfunction is observed in patients with type 1 diabetes and indirect markers of insulin resistance

Linagliptin (LINA) restores the dopaminergic impairment induced by experimental diabetes in striatum and counteracts the detrimental effects of aging

G. Lietzau[1], E. Candeias[1], G. Magni[2], J. Kehr[3,4], T. Yoshitake[3], J. Skogsberg[5], T. Nyström[1], T. Klein[6], M.P. Abbracchio[2], S. Ceruti[2], V. Darsalia[1], C. Patrone[1];
[1]Dept. of Clinical Science & Education, Södersjukhuset, Internal Medicine, Karolinska Institutet, Stockholm, Sweden, [2]Dept. of Pharmacological & Biomolecular Sciences, Università degli Studi di Milano, Milan, Italy, [3]Dept. of Physiology & Pharmacology, Karolinska Institutet, Stockholm, Sweden, [4]Pronexus Analytical AB, Bromma, Sweden, [5]Boehringer Ingelheim AB, Stockholm, Sweden, [6]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

Background and aims: Recent data suggest that type 2 diabetes (T2D) may be implicated in the pathogenesis of motor system disorders, including Parkinson's disease (PD) but the underlying mechanisms are mostly unknown. We hypothesize that T2D impairs the dopaminergic system during aging in combination with structural changes in the basal ganglia, and that LINA, a dipeptidyl peptidase-4 (DPP-4) inhibitor used for the treatment of T2D, may reverse these effects. Specifically, we aimed to determine whether: 1) T2D impairs the basal and stimulated extracellular levels of dopamine (DA) in the mouse striatum, 2) T2D induces changes in neuronal and glial cellular populations, 3) LINA treatment counteracts these effects.
Materials and methods: Adult and non-diabetic/T2D middle-aged C57BL7/6 mice were used. T2D was induced by 12-month-intake of high-fat diet. LINA was administered in the chow (daily intake ~5 mg/kg/bw) for the last 3 months. To evaluate the effect of T2D on the dopaminergic system, microdialysis and HPLC were performed. To assess potential structural changes in substantia nigra and striatum, neurons (TH$^+$, DARPP-32$^+$, parvalbumin$^+$) and glia (Iba-1$^+$, GFAP$^+$, Olig2$^+$, GSTp$^+$) were quantified by immunohistochemistry.
Results: Versus control mice, middle-aged T2D mice showed a decrease in extracellular DA levels of 82% (3.38 ± 0.92 vs. 18.81 ± 6.89 fmol/10 µl, $p = 0.035$) and a blunted response to amphetamine challenge in the striatum. However, DA intracellular levels were unchanged in the diabetic vs. non-diabetic mice ($p = 0.23$). Chronic LINA treatment resulted in a strong trend towards an increase in extracellular DA (75% vs. control; $p = 0.13$) and a restoration of striatal DA signaling in T2D mice. On the structural level, T2D had no effect on neuronal and glial markers. However, we identified an age-induced decrease in the density of the parvalbumin$^+$ interneurons (70.78 ± 6.3 vs. 52.48 ± 2.5 cells/mm^2, $p = 0.035$), age-induced increase in both neuroinflammation (174.1 ± 12.65 vs. 274.3 ± 12.79 Iba-1$^+$ cell volume/µm^3, $p < 0.0001$) and gliosis (78.25 ± 6.25 vs. 166.6 ± 12.52 GFAP$^+$ cells/mm^2, $p < 0.0001$), as well as a decrease in the density of proliferating (16.41 ± 1.45 vs. 8.23 ± 1.35% of PCNA/Olig2$^+$ cells, $p = 0.0046$) and mature oligodendrocytes (1.35 ± 0.097 vs. 0.72 ± 0.137 GSTp$^+$ cells/µm^2, $p = 0.012$). LINA treatment alleviated all these age-related effects.
Conclusion: This study provides new knowledge on how T2D impairs the dopaminergic system during aging. These effects could represent one of the pathogenic mechanisms predisposing T2D patients to develop motor dysfunction disorders such as PD. We also show that LINA alleviated these changes. Finally, we identified T2D-independent aging effects in the striatum that could be normalized by LINA treatment. Overall, our results suggest a potential role for DPP-4 inhibitors against the detrimental effects of T2D and aging on the motor system.

Increased glycosuria reduces the risk of hyperuricaemia in subjects with newly diagnosed diabetes: a cross-sectional study

L. Fan[1,2], J. Chen[1], Z.L. Sun[3];
[1]Medical School, Southeast University, Nanjing, [2]China Eastern Airlines, Nanjing, [3]Department of Endocrinology, Affiliated Zhongda Hospital of Southeast University, Nanjing, China.

Background and aims: Accumulating evidences have demonstrated that sodium glucose cotransporter 2 inhibitors lowers the serum uric acid level (SUA) by increased glycosuria. However, the association between SUA and urine glucose excretion (UGE) has not been fully investigated. In this study, we evaluated the relationship between SUA and UGE in subjects with newly diagnosed diabetes (NDD).
Materials and methods: We performed a cross-sectional study. Inclusion criteria were the following: aged 18–65 years, with no previous history of diabetes, consent to participate in the study. All participants were given an oral glucose tolerance test. Urine samples were collected within 2 h of oral glucose loading for the measurement of glucose. Blood glucose, lipid profile, and uric acid were assessed. Multiple linear regression analysis and multivariate logistic regression analysis were performed to determine the association of SUA with UGE.
Results: 445 people with NDD were included in the final analysis. The prevalence of hyperuricemia in subjects with NDD was 12.8%. The low SUA group exhibited significantly higher age, plasma glucose, and UGE compared with high SUA group ($p < 0.001$), while triglycerides and BMI significantly lower than high SUA group. Multiple linear regression analysis with SUA as a dependent variable, log-transformed UGE were negatively associated with SUA when adjusted for age, sex, and BMI ($\beta = -26.4$, SE: 5.7, 95% CI: −37.6 to −15.3, $p < 0.001$). Multivariable logistic regression model showed that log-transformed UGE was significantly associated with a decreased odds ratio of hyperuricemia (Table 1). In addition, no significant correlation was found between SUA and blood glucose (Table 1).
Conclusion: In this cross-sectional study, increased UGE was negatively related to SUA in subjects with NDD. These findings suggest that subjects with high UGE have decreased risk of hyperuricemia.

Table 1 Multivariate logistic regression analysis of the factors influencing the prevalence of hyperuricemia.

Nrf2 mediated protection against hypoglycaemia induced cognitive deficits in type 1 diabetes

A.D. McNeilly, J. Gallagher, A. Dinkova-Kostova, R.J. McCrimmon; University of Dundee, Dundee, UK.

Background and aims: Hypoglycaemia in Type 1 diabetes (T1D) is associated with an increase in oxidative stress. We have previously demonstrated that recurrent intermittent hypoglycaemia (RH) in a rodent model of T1D is associated with impaired cognitive function and activation of the Nrf2 antioxidant system. This study sought to investigate whether pre-treatment with a potent Nrf2 inducer would ameliorate these cognitive deficits.
Materials and methods: A chronic stable model of insulin-treated T1D was achieved using streptozotocin (125 mg/kg i.p.) and insulin implants (Linbit). Diabetic (male C57bl6 mice $n = 8$–10/group) mice were randomly allocated to one of 3 groups: (i)T1D, (ii) T1D+RH, (iii) T1D+RH+SFN and subjected to repeated episodes of insulin-induced hypoglycaemia (3 episodes per week for 4 weeks). Sulforaphane (SFN; 50 mg/kg i.p.) or Vehicle (1% DMSO/PBS) was administered 24 hr prior to each hypoglycaemic episode. Cognition was subsequently assessed by novel object recognition (NOR) and spontaneous alternation tasks.
Results: Pre-treatment with SFN had no impact upon body weight or fasting blood glucose glucose (both p = ns). In contrast HbA1c levels were significantly lower in SFN treated animals ($p < 0.01$). Furthermore, SFN improved cognitive performance in the 24 hr NOR task ($p < 0.01$) and the spontaneous alternation task ($p < 0.01$) when compared to those receiving vehicle.
Conclusion: Treatment with SFN significantly improves RH induced cognitive impairments in a rodent model of T1D. These improvements were associated with a significant improvement in HbA1c levels. Therefore, activation of the Nrf2 antioxidant pathway offers a novel therapeutic target for the treatments of cognitive impairments associated with RH in T1D.

Decreased O-GlcNAcylation to tau phosphorylation at Thr212 site ratio is associated with mild cognitive impairment in type 2 diabetic patients

R. Huang, S. Tian, R. Cai, D. Guo, H. Lin, J. Wang, K. An, S. Wang; Department of Endocrinology, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China.

Background and aims: Aberrant O-GlcNAc modification has been associated with insulin resistance and type 2 diabetes mellitus (T2DM), as well as the pathogenesis of neurodegenerative diseases. We aimed to investigate the association between global O-GlcNAcylation, tau phosphorylation levels and mild cognitive impairment (MCI) in the whole blood of T2DM patients.
Materials and methods: Sociodemographic, clinical characteristics and cognitive performances of the enrolled T2DM subjects were extensively assessed. Global O-GlcNAcylation and tau phosphorylation levels in the whole blood were also determined using Western blot.
Results: According to Montreal Cognitive Assessment score, 24 T2DM with MCI patients and 24 with normal cognition subjects were enrolled in this study. In addition to elevated fasting blood glucose, glycated hemoglobin A1c (HbA1c), decreased fasting C-peptide and uric acid, T2DM with MCI subjects displayed a decreased O-GlcNAcylation level, while increased tau phosphorylation levels than cognitively normal controls (all $p < 0.05$). In order to reflect the combined effect, relative ratios of O-GlcNAcylation to tau phosphorylation levels showed that O-GlcNAc/

Tau-5, O-GlcNAc/p-S396, O-GlcNAc/p-S404, O-GlcNAc/p-T212 and O-GlcNAc/p-T231 were all significantly decreased in MCI subjects (all $p < 0.05$). Multivariable logistic regression analysis revealed that higher HbA1c was an independent risk factor, while increased O-GlcNAc/p-T212 was an independent protective factor for MCI in T2DM patients (OR = 2.452, 95%CI 1.061–5.668, $p = 0.036$; OR = 0.028, 95%CI 0.002–0.388, $p = 0.008$, respectively). With regard to each cognitive domain, O-GlcNAc/p-T212 was positively correlated with the scores of Auditory Verbal Learning Test-delayed recall ($r = 0.377$, $p = 0.010$), which represented delayed learning and memory function.

Conclusion: Our study suggests that decreased O-GlcNAcylation to tau phosphorylation at Thr212 site ratio in the whole blood is associated with MCI, especially with delayed memory dysfunction in T2DM subjects.

The implications of rs1887922 polymorphism of insulin degrading enzyme gene in the cognitive impairments for patients with type 2 diabetes

J. Huang;
Southeast University, Nanjing, China.

Background and aims: In recent years, efforts have been made to explore the mechanisms regarding how type 2 diabetes (T2D) increases the risk of Alzheimer's disease (AD), which will help to reveal the pathomechanisms of AD and find ways to relieve cognitive impairments in both diseases. Gene association analyses make great contribution in this flied, and the insulin degrading enzyme (IDE) gene represents a very promising gene that influences cognitive performance because of its biological function and location near late-onset Alzheimer's disease (AD) linkage peaks, i.e., the chromosome 10q. Previous molecular investigations have suggested the associations with IDE rs1887922 polymorphism and AD-related pathology, however little in known regarding its in vivo neurobiology. The present study aimed to reveal the associations between IDE rs1887922 and brain default mode network in T2D patients via genetic-imaging approach.

Materials and methods: A total of 160 patients with T2D were enrolled in the present study. 80 of the participants had intact cognitive performance, and the remaining 80 subjects were mild cognitive impairment subjects. All the participants went through cognitive evaluations, structural and functional MRI scans, and genotyping of IDE rs1887922 polymorphism. To explore the influence of rs1887922 on brain functional network, a mixed analysis of covariance (ANCOVA) with disease status (2 levels: MCI and HC) and IDE rs1887922 (2 levels: C and T) as fixed factors was performed. Finally, the behavior significances of the brain regions with gene × disease interactions were tested, and the partial correlations were applied.

Results: The main effects of disease were detected within bilateral temporal cortex, left parietal lobule and left medial prefrontal gyrus. For the IDE polymorphism, main effects were detected within right posterior cingulate, bilateral inferior parietal lobule and right medial frontal gyrus. Regarding the interaction of disease and gene, regions within bilateral superior parietal lobules were reported (corrected $P < 0.05$, determined by Monte Carlo simulation). The partial correlation analyses implied the cognitive significance of regions with interactive effects, as the functional activity within left superior parietal lobule were significantly related to the performance of episodic memory (scores of Rey-Osterrieth Complex Figure Test with 20-min delayed recall, rho = 0.67, $P = 0.002$) and general cognition (scores of MMSE, rho = 0.47, $P = 0.017$) for MCI subjects.

Conclusion: The genetic-imaging approach expanded our understanding for the mechanisms underlying the implications of IDE genetic polymorphism in T2D-related injuries of brain network, and improving the dysfunction of IDE may be a promising approach to relieving neurological and psychiatric disorders for patients with T2D.

Elevated biomarkers of oxidative stress and endothelial dysfunction are associated with reduced cognitive performance in type 2 diabetes in the CAROLINA® trial

G. Biessels[1], O. Groeneveld[1], E. van den Berg[2], S. Schnaidt[3], K. Hermansson[4], B. Zinman[5], M. Espeland[6], O. Johansen[7];
[1]Department of Neurology, University Medical Center Utrecht, Utrecht, Netherlands, [2]Department of Neurology, Erasmus MC - University Medical Center, Rotterdam, Netherlands, [3]Biostatistics and Data Sciences, Boehringer Ingelheim, Ingelheim, Germany, [4]Clinical operations, Boehringer Ingelheim, Stockholm, Sweden, [5]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, Canada, [6]Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, USA, [7]Therapeutic area cardiometabolism, Boehringer Ingelheim, Asker, Norway.

Background and aims: Type 2 diabetes (T2D) is associated with cognitive dysfunction and an increased risk of dementia, but underlying mechanisms are largely unclear. T2D is also associated with increased inflammation and oxidative stress, as well as endothelial dysfunction. We explored relationships between circulating biomarkers of inflammation, oxidation, and endothelial function, and cognitive functioning at baseline in patients with T2D at elevated cardiovascular (CV) risk participating in the CAROLINA trial.

Materials and methods: CAROLINA is a CV outcome trial assessing impact of linagliptin or glimepiride. Prior to first study drug treatment, a subset of patients without a history of dementia were recruited to participate in the cognition substudy. Circulating biomarkers of inflammation (CRP, IL-6, TNF-α), oxidation (8-iso-Prostaglandin $F_{2\alpha}$ [8-iso $PGF_{2\alpha}$]), and endothelial dysfunction (Asymmetric dimethylarginine [ADMA], Endothelin-1) were analysed at baseline. All patients underwent the Cambridge Neuropsychological Test Automated Battery, assessing psychomotor speed, mental flexibility, memory, working memory, and attention. The relation between biomarkers and cognitive functioning was evaluated with linear regression analysis adjusted for age, gender, and education.

Results: Mean ± SD age of the 37 patients (92% males, history of CHD/cerebrovascular disease 27.0%/21.6%) with T2D was 67 ± 9 years and years of formal education was 11.4 ± 4.4. Median (interquartile range) HbA1c was 6.9% (6.6%, 7.3%), diabetes duration was 8.3 (3.4, 11.1) years and MMSE was 29 (27, 30). 8-iso $PGF_{2\alpha}$ was significantly associated with worse performance on mental flexibility and attention (standardized regression coefficients −0.47 and −0.34, respectively) (table).

ADMA was associated with significant worse performance on psychomotor speed and attention (standardized regression coefficients −0.39 and −0.34, respectively) (table). No significant associations between markers of inflammation and cognitive functioning were observed. Additional adjustments for HbA1c, vascular risk factors, macrovascular disease, and use of anti-inflammatory drugs did not attenuate the results.

Conclusion: Elevated circulating biomarkers of oxidative stress and endothelial dysfunction are associated with reduced psychomotor speed, mental flexibility, and attention in T2D.

Cerebral blood flow and cognitive function in type 2 diabetes

L. Hunt[1], D. Selvarajah[1], K. Teh[1], S. Tesfaye[2], I.D. Wilkinson[1];
[1]Academic Radiology & Metabolism, University of Sheffield, Sheffield, [2]Diabetes and Endocrinology, Sheffield Teaching Hospitals, Sheffield, UK.

Background and aims: There is approximately a 2-fold increase in the risk of developing mild cognitive impairment (MCI) in patients who have Type 2 Diabetes Mellitus (T2DM). Brain perfusion Single Photon Emission Computed Tomography is often used in the clinical work-up of patients with suspected cognitive decline. However, in the context of T2DM, Cerebral Blood Flow (CBF) status in relation to MCI has not been fully investigated. This study sought to assess regional CBF in matched T2DM patients with and without MCI using a non-invasive Magnetic Resonance Imaging (MRI) technique.

Materials and methods: Seventy-four age and gender matched subjects [28, T2DM+normal cognition (T2DM); 17, T2DM+MCI (T2DM/MCI) and 29, healthy volunteers (HV)] were recruited. All subjects underwent clinical and questionnaire (Addenbrooke's Cognitive Assessment [ACE-R]) assessments along with Arterial Spin Labelling (ASL) Magnetic Resonance Imaging (MRI) to assess parenchymal perfusion within the brain. Imaging was performed at 3T. The ASL data was modelled to yield quantitative arterial CBF maps in neuroanatomical regions involved with various cognitive and memory functions.

Results: Mean T2DM/MCI ACE-R score (mean ± SD; 83 ± 4) was significantly lower in the MCI group compared to the other groups (HV = 96 ± 2, T2DM = 94 ± 3; ANOVA $p < 0.001$). There was a significantly lower mean CBF in T2DM/MCI compared to T2DM and HV in the medial temporal lobes (CBF 76.8 ml/100 g/min, ANOVA $p < 0.05$), insula (CBF 67.5 ml/100 g/min ANOVA $p < 0.005$), and frontal lobes (CBF 71.8 ml/100 g/min, ANOVA $p < 0.005$). Significant correlations were observed between ACE-R score and regional CBF measurements in the medial temporal lobes, ($p < 0.05$, $r = 0.25$) thalamus ($p < 0.05$, $r = 0.23$) and the insula ($p < 0.05$, $r = 0.29$).

Conclusion: This study demonstrates significantly lower CBF in T2DM MCI subjects in neuroanatomical regions associated with cognitive processing and memory functions. This may be essential in helping our understanding of the pathological mechanisms that occur behind the increased risk of developing cognitive impairment associated with T2DM.

The association between cognitive functioning and cerebral perfusion in patients with type 2 diabetes

B. Mankovsky[1,2], N. Zherdova[1,2], S. Makeev[3], I. Dalhuisen[4,5], E. van den Berg[4], J. de Bresser[5,6], G.-J. Biessels[4];
[1]Department of Diabetology, National Medical Academy for Postgraduate Education, Kyiv, Ukraine, [2]Center for Innovative Medical Technologies of the National Academy of Sciences of Ukraine, Kiev, Ukraine, [3]The State Institution Romodanov Neurosurgery Institute National Academy of Medical Sciences of Ukraine, Kyiv, Ukraine, [4]Department of Neurology, University Medical Center Utrecht, Utrecht, Netherlands, [5]Department of Radiology, University Medical Center Utrecht, Utrecht, Netherlands, [6]Department of Radiology, Leiden University Medical Center, Leiden, Netherlands.

Background and aims: Type 2 diabetes mellitus (T2DM) is associated with cognitive impairment, an increased risk of dementia and occurrence of cerebral small vessel disease. Impaired cerebral perfusion is one of the features of cerebral small vessel disease. We therefore investigated the association between cognitive functioning and cerebral perfusion in patients with T2DM.

Materials and methods: We examined 95 patients with T2DM (32 males, mean age 62.2 ± 5.5 years, diabetes duration 9.7 ± 6.6 years). Cognitive functioning was assessed using a standard neuropsychological test battery covering the domains memory, executive functioning, and processing speed. Cerebral perfusion was assessed using SPECT scans and quantified by comparison to a database of healthy individuals (expressed as a standard deviation). Linear regression analyses adjusted for age and gender were performed to study the association of cognitive functioning and global and regional (frontal, occipital, parietal, temporal, cerebellum, caudate nucleus, putamen, and thalamus; both left and right) cerebral perfusion.

Results: There were no statistically significant associations between cognitive functioning and global cerebral perfusion (memory B (95%-CI): −0.106 (−0.349↔0.136), $p = 0.386$; executive functioning: 0.001 (−0.216↔0.218), $p = 0.996$; processing speed: −0.189 (−0.405↔−0.028), $p = 0.087$). A worse memory domain score was associated with reduced perfusion in the thalamus (left: −0.278 (−0.242↔−0.053), $p = 0.003$; right: −0.283 (−0.237↔−0.054), $p = 0.002$). A worse processing speed domain score was associated with reduced perfusion in the left frontal lobe (−0.289 (−0.388↔−0.088), $p = 0.002$).

Conclusion: We found a strong association between reduced perfusion in the thalamus and memory impairment in patients with T2DM. This reduced perfusion might be one of the underlying functional correlates of cognitive impairment in patients with T2DM.

Influence of glycaemic variability on the results of neuropsychological testing in patients with type 1 diabetes

M. Rotkank, I. Samoilova, M. Matveeva, N. Zhukova, I. Tolmachev;
Siberian State Medical University, Tomsk, Russian Federation.

Background and aims: One of the complications of type 1 diabetes mellitus (DM type 1) is diabetic encephalopathy, the main symptoms of which are cognitive impairment. The variability of glycemia in DM type 1 plays an important role in the pathogenesis of vascular complications of DM. The aim was to determine the relationship between the results of performing neuropsychological testing and the measures of glycemic variability in patients with DM type 1.
Materials and methods: 58 patients with DM type 1 at the age of 29 (25–32) years and 20 people without DM, comparable by sex and age, were examined. All participants underwent neuropsychological testing with the Montreal Cognitive Evaluation Scale (MoCa-test), the evaluation of carbohydrate metabolism and the calculation of the measures of glycemic variability with the EasyGV calculator: standard deviation (SD), continuous overlapping net glycemic action (CONGA), lability index (LI), J-index, low blood glucose index (LBGI), high blood glucose index (HBGI), mean of daily differences (MODD), mean amplitude of glycemic excursions (MAGE), average daily risk range (ADRR). The statistical processing of the results was carried out in the IBM SPSS Statistics 20.0.0 program (significant differences were considered when $p < 0.05$).
Results: Assessment of the state of carbohydrate metabolism showed that the average level of fasting glycemia in patients with DM type 1 was 8.6(7.3–9.6)mmol/L, the average level of HbA1c was 8.4(7.5–8.9)%. According to the results of the MoCa-test, a statistically significant decrease in the score was observed in patients with DM type 1 in comparison with the control group ($p < 0.001$). Analysis of individual tasks of the MoCa-test revealed significant decrease in scores for tasks attention ($p < 0.001$), clock-drawing ($p = 0.002$) and delayed recall ($p < 0.001$). The measures of glycemic variability were calculated: SD 6.25 (3.1–7.7) mmol/L, CONGA 4.65 (3.3–7.3) mmol/L, LI 4.25 (3.3–5.1) (mmol/L)^2/h, J-index 54,15 (22.4–73.6), LBGI 3.85(2.6–5.2), HBGI 7.75 (5.6–12.5), MODD, 3.85 (2.9–5.6) mmol/L, MAGE 7.6 (4.6–8.9) mmol/L, ADRR 45.95 (28.9–57.8). Evaluation of the relationship between the results of neuropsychological testing and the measures of glycemic variability revealed a negative correlation with the measures LI ($p = 0.008$), MODD ($p = 0.005$) and ADRR ($p = 0.032$).
Conclusion: The present study showed an inverse relationship between the results of neuropsychological testing and glycemic variability. Thus, a decrease of the variability of glycemia can be used in cognitive rehabilitation in patients with DM type 1.

Novel therapeutic potential of RAAS blockers in diabetes comorbid depression

L. Lenart[1], D.B. Balogh[1,2], J. Hodrea[1], A. Barczi[1,2], A. Molnar[1,2], A. Hosszu[3], A. Vannay[4], L. Wagner[3], A.J. Szabo[4,2], A. Denes[5], A. Fekete[1,2]; [1]MTA-SE „Lendület" Diabetes Research Group, Budapest, [2]1st Department of Pediatrics, Semmelweis University, Budapest, [3]Department of Transplantation and Surgery, Semmelweis University, Budapest, [4]MTA-SE Pediatrics and Nephrology Research Group, Budapest, [5]MTA Institute of Experimental Medicine, Budapest, Hungary.

Background and aims: Comorbid depression is commonly occurring in diabetes mellitus (DM), which worsens quality of life and increases mortality. It has recently indicated that all components of renin-angiotensin-aldosterone system (RAAS) are produced also within the central nervous system and overactivated in DM. RAAS can modulate the level of brain-derived neurotrophic factor (BDNF), which is important in the neurobiology of depression and its antidepressant action. However, the interaction between the BDNF system and RAAS in DM comorbid depression has not yet been investigated. Therefore, our aim was to investigate the effect of RAAS blockers in the development of DM comorbid depression.
Materials and methods: After 5 weeks of streptozotocin-induced DM, adult, male Wistar rats ($n = 8$/group) were treated *po.* for 2 weeks with non-pressure dose of enalapril (40 mg/bwkg/day), losartan (20 mg/bwkg/day), spironolactone (50 mg/bwkg/day) or eplerenone (50 mg/bwkg/day). Untreated diabetic and healthy rats served as controls. Blood pressurewas measured and depressive-like behaviour was evaluated. Localization of BDNF was determined. The protein and mRNA levels of pro and mature BDNF, their receptors (TrkB and p75Ntr) and the potential downstream signaling molecules (p75Ntr signaling: pJNK, *Bax* and TrkB signaling: pERK, pCREB, *Bcl2*) were measured in the hippocampus.
Results: Depressive-like behaviour was observed in DM, which was improved by all RAAS blockers. BDNF is mainly produced by astroglia in hippocampus. Pro and mature BDNF, TrkB (receptor of mature BDNF), pERK, pCREB and anti-apoptotic *Bcl2* levels were decreased in DM, but were elevated by RAAS blockers. Neither DM nor RAAS blockers did not influenced the levels of p75NTR (receptor of pro BDNF), pJNK and pro-apoptotic *Bax*. Neither diabetes nor RAAS inhibitors influenced the blood pressure indicating that all these effects of RAAS blockers were independent of their antihypertensive effect.
Conclusion: Our results support that RAAS inhibition mitigates DM-associated depression. Here we identified that BDNF - TrkB - CREB signaling pathway is crucial in the development of DM-associated depression or the antidepressant effect of RAAS blockers. These findings exploring a new therapeutic horizon for RAAS inhibitors in treatment of depression in DM and signaling could be a basis of future drug development treating DM-induced complications.

Glycation gap variation in human diabetes is associated with fructosamine-3-kinaseSNP rs3848403 but does not explain linked difference in enzyme activity

S.J. Dunmore[1], F. Naseem[1], A. Watkins[2], J.E. Brown[3], A.U. Nayak[4], A. Nevill[1], B.M. Singh[1,5];
[1]Diabetes Research Group, University of Wolverhampton, Wolverhampton, [2]Division of Child Health, Obstetrics and Gynaecology, University of Nottingham, Nottingham, [3]Aston Research Centre for Healthy Ageing, Aston University, Birmingham, [4]Department of Endocrinology & Diabetes, University Hospitals of North Midlands NHS Trust, Stoke on Trent, [5]Wolverhampton Diabetes Centre, New Cross Hospital, Wolverhampton, UK.

Background and aims: The glycation gap (GGap) is a consistent discrepancy between HbA1c and prevailing glucose concentrations (estimated HbA1c based on fructosamine (fHbA1c)) which we have shown to be associated with risk of diabetic complications and recently demonstrated to be potentially caused by erythrocyte activity of the deglycating enzyme fructosamine-3-kinase (FN3K). We hypothesised that the 3-fold difference in FN3K activity between dichotomised highly positive GGap (higher than expected HbA1c compared with fHbA1c, exhibiting a higher incidence of complications) and negative GGap (HbA1c<fHbA1c) might be explained by differences in genotype of known FN3K SNPs.
Materials and methods: We evaluated FN3K SNPs rs1056534, rs1046896, and rs3848403 using real-time PCR of genomic DNA extracted from whole blood of patients with diabetes dichotomised for GGap status ($n = 130$, 73 -ve, 57 +ve GGap, matched demographics). Ethical approval from UK National Research Ethics Service Committee.
Results: The FN3K SNPs rs1056534 and rs1046896 did not differ between the -ve GGap and +ve GGap groups. The SNP rs3848403 had 3 allele combinations C/T (85%), T/T (12%) and C/C (3%), the distribution of which was significantly between GGap groups ($X^2 = 6.901$, $p = 0.032$). These were reallocated into heterozygous (C/T) and homozygous (T/T or C/C) and this distribution again differed significantly between groups ($X^2 = 5.458$, 6.901, $p = 0.019$). In binary logistic regression ($X^2 = 54.469$, $p < 0.001$) GGap status was associated with BMI ($p < 0.001$) and the dichotomised allelic status of C/T vs T/T or C/C ($p = 0.044$) but not age, type of diabetes or the rs3848403 SNP triple status independently of the dichotomised status. The Odds Ratio (95% CI) of -ve GGap being associated with allelic heterogeneity or +ve GGap with homogeneity was 3.7 (1.0 to 13.1).
Conclusion: We have shown for the first time that a FN3K SNP, rs3848403, is associated with glycation gap status, a SNP previously associated with variations in HbA1c only. There is a 35–40% misalignment with GGap status in groups that really divergent for this characteristic. We did not find that the FN3K activity /concentration appeared to be dictated by the SNP although there is a very strong link between GGap and FN3K. We are currently undertaking transcriptomic studies of these dichotomised GGap samples in order to further understand possible contributors to FN3K activity variation such as splice variation.

Impact of hypoglycaemia on the platelet activity and fibrinolysis in patients with type 1 diabetes

I.R. Jarek-Martynowa[1], K. Sarkisova[2], E. Koksharova[1], E. Mishina[1], M. Shestakova[1], L. Nikankina[1], L. Chirkova[1], M. Shamkhalova[1];
[1]Endocrinology Research Centre, Moscow, [2]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation.

Background and aims: Hypoglycemia can be a risk factor for adverse cardiovascular and cerebrovascular events. However, changes in platelets and coagulation hemostasis during hypoglycemia have not been extensively studied. During hypoglycemia, a wide spectrum of physiologic responses are activated that could have potential vascular biological effects. To date, the role played by catecholamines, the sympathetic nervous system, and neuroendocrine hormones on activating adhesion molecules and influencing fibrinolytic balance is incompletely understood. The aim of this study was to assess the impact of insulin-induced hypoglycemia on the platelet activity, and fibrinolysis in patients with type 1 diabetes.
Materials and methods: We studied 15 patients with type 1 diabetes (9 male and 6 female, age 24.4 ± 5.6, A1C 9.07 ± 2.3%) without microvascular complications during hyperinsulinemic (1 mU/kg/min) hypoglycemic clamp protocol. Induced platelet aggregation in whole blood using thrombin receptor activating peptide 6 (tRaP-6), collagen, arachidonic acid, adenosine-diphosphate, ristomycin was measured during hypoglycemia (plasma glucose(pg) 2.3 ± 0.1 mmol/l), euglycaemia (pg 4.4 ± 0.4 mmol/l), hyperglycemia (pg ≥12 mmol/l) and recovery phase by multiple electrode platelet aggregometry (Multiplate). Plasminogen activator inhibitor (PAI-1), tissue plasminogen activator (tPA) was determined by ELISA. Statistical analysis was performed with SPSS 22.0 for Windows, $p < 0.05$.
Results: Platelets aggregation induced collagen ($p = 0.001$), thrombin ($p = 0.003$), adenosine- diphosphate ($p = 0.016$), arachidonic acid ($p = 0.05$) was significantly increased during 20-min of hypoglycemia compared with euglycemia. Plasma PAI-1 activity were significantly different during hypoglycemia as compared with euglycemia ($p = 0.001$) and as compared with recovery phase ($p = 0.018$). Plasma concentrations of tPA did not alter during either hypoglycemic clamp in individuals with type 1 diabetes.
Conclusion: The present study confirmed that platelet activation is promoted by hypoglycemia and that hypoglycemia decreases systemic fibrinolytic balance by increasing PAI-1 activity while maintaining tPA values. Thus, at least two separate mechanisms for increasing thrombosis are activated by hypoglycemia in individuals with type 1 diabetes.

Elastic and adhesive properties of erythrocyte and platelet membranes in patients with type 2 diabetes

V. Shyshko[1], G. Melnikova[2], T. Mokhort[3], E. Konstantinova[2], T. Tolstaya[2], A. Petrovskaya[2];
[1]City Endocrinology Dispensary, Minsk, [2]A.V. Luikov Heat and Mass Transfer Institute of the National Academy of Science of Belarus, Minsk, [3]Belarusian State Medical University, Minsk, Belarus.

Background and aims: In this study we propose the use of the atomic force microscopy (AFM) method to analyze the changes in the elastic properties of erythrocyte and platelet membranes in patients with type 2 diabetes mellitus (T2D) at the nanolevel. Aim**:** To evaluate the elastic and adhesive properties of erythrocyte and platelet membranes in patients with T2D.
Materials and methods: Patients with T2D were included. The mean age was 55 (50, 59) years, mean HbA1c level was (9.1 (8.30, 10.4)%.). Men and women were age-matched, the duration of T2D was 5 to 10 years. Blood was taken at the time of hospitalization in the department of endocrinology. Criteria for exclusion: presence of acute vascular events (MI, stroke) in anamnesis, reconstructive interventions on large vessels. Erythrocytes for studies were isolated from stabilized venous blood of patients with ethylenediamine triacetate potassium K3EDTA (Aldrich), fixed with 0.5% glutaraldehyde solution and applied to mica substrates at a temperature of 20 ± 5°C. Venous blood was stabilized with 3.8% r-rum sodium citrate to isolate platelets.The elastic modulus (E, MPa) and the adhesion strength (F, nN) were estimated by the AFM method of the Johnson-Kendell-Roberts model using an atomic force microscope using standard silicon probes NSC 11, rigidity 3 N/m ("MikroMacsh"), radius

the curvature is 50 nm. The strength of adhesion was calculated based on the measured values of the tip detachment from the sample surface.
Results: The results of the study of erythrocytes have shown that two ranges of values can be distinguished-less than and above 100 MPa. For the strength of adhesion, two ranges of values were identified - less than and more than 15 nN. For erythrocyte membranes, E values less than 100 MPa and F above 15 nN prevail, while the mean values of these parameters for men and women do not differ within the experimental error. Similar to the characteristics of red blood cells for platelet membranes, there are no differences in E for men and women, the tendency of the predominance of higher adhesion strengths persists. Platelets F in women (16.8 (12.6, 26.4) is significantly higher than in men (12.0 (8.6; 12.8) ($p = 0.022$).A negative correlation was established between platelet F (15.9 (10.4;24.3) and the age of the patients ($R = -0.30$, $p < 0.05$). It has been established that an increase in erythrocytes F correlates with platelet F ($R = 0.64$, $p < 0.05$) in patients with T2D, in particular in women ($R = 0.67$, $p < 0.05$), but not in men. F erythrocytes at a level of HbA1c of less than 6.5% is significantly higher (24.35 (19.9; 25.5) than in HbA1c more than 6.5% (15.40 (11.8, 20.8) ($p < 0.05$) (more than 60%).
Conclusion: 1The method of atomic force microscopy makes it possible to study the properties of erythrocyte and platelet membranes in patients with T2D that will later allow the use of results in the development of drugs for the treatment of microangiopathies. In patients with T2D, E values of erythrocytes prevail values less than 100 MPa and F above 15 nN. An increase in age in patients with T2D is accompanied by a decrease in F erythrocytes. As the level of HbA1 increases, there is a decrease in F erythrocytes.

Diabetes augments atherosclerotic inflammation in diabetic LDLr-/- mice

A. Midtgaard-Thomsen[1,2], L. Thoren[1], T.K. Hansen[3], G. Rakipovski[1], C.K. Mogensen[1];
[1]Global Research, Måløv, [2]Medicinsk Endokrinologisk Afdeling, Aarhus, [3]Steno Diabetes Center Aarhus, Aarhus, Denmark.

Background and aims: Mice are the most frequently used preclinical species for atherosclerotic studies. However, mice never develop unstable plaque; hence the translation of these mouse models for human atherosclerotic lesion and increased diabetic cardiovascular risk is unclear. The aim of this study was to characterize the cellular and molecular composition of the atherosclerotic aorta and atherosclerotic plaque in a diabetic mouse model.
Materials and methods: LDLr-/- mice (JAX, USA, Stock 2207; 6–8 weeks of age) were divided into three groups ($n = 23$/group) having two groups on a western type diet (WD) and one group on standard low caloric chow diet. After 8 weeks of diet intervention one of the WD fed groups were rendered diabetic by low dose streptozotocin injections (I.P., 60 mg/kg × 3). Mice were kept on their respective diets for another 9 weeks before termination. HbA1c, body weight and blood glucose were monitored throughout the study period. At termination, aortas were dissected free and images were taken for *en face* analysis. Immune cell composition of murine aortas was analyzed by flow cytometry and gene expression in plaque and plaque-free areas of the atherosclerotic aortas was analyzed.
Results: It was demonstrated that diabetes causes a significant increase ($p < 0.05$) in percentage of monocytes and neutrophils ($VD^-Cd45^+Cd11b^+Ly6c^+$ as % of $VD^-CD45^+CD11b^+$) in murine aortas even though diabetes caused no difference to the plaque area measured by *en face*. Furthermore, diabetes suppresses M2-like macrophage appearance (CD206 MFI on $VD^-CD45^+Cd11b+$). Gene expression analyses showed diabetes increases IL-6 expression in plaque-free area of aorta ($p < 0.05$) whereas IL-6 expression in plaque areas was not altered by diabetes.
Conclusion: Recruitment and infiltration of monocytes and neutrophils and increased levels of IL-6 can drive the plaque progression in mice, which has also been correlated to increased risk of cardiovascular events in humans. This may potentially play an important role for the increased cardiovascular risk observed in humans with diabetes. Looking at cellular and molecular composition of murine aortas for plaque areas and plaque free-areas can aid in the understanding of plaque development in mice and hopefully be able to better understand the development in humans.

Serum calcification propensity is associated with all-cause mortality in type 1 diabetes

D.J. Mulder[1], P.R. van Dijk[2,1], H. Hop[1], A. Pasch[3], F. Waanders[4], H. van Goor[5], H.J.G. Bilo[1,2];
[1]Internal Medicine, University of Groningen, Groningen, Netherlands, [2]Diabetes Centre, Isala, Zwolle, Netherlands, [3]Department of Biomedical Research, University of Bern, Bern, Switzerland, [4]Internal Medicine, Isala, Zwolle, Netherlands, [5]Department of Pathology and Medical Biology, Division of Pathology, University of Groningen, Groningen, Netherlands.

Background and aims: Type 1 diabetes mellitus (T1DM) is accompanied by increased incidence of atherosclerosis and mortality. A novel in vitro blood test provides an overall measure of calcification propensity by monitoring the maturation time (T_{50}) of calciprotein particles in serum. Accelerated T_{50} indicates a diminished ability of serum to resist calcification. Moreover, T_{50} levels strongly and independently predict all-cause mortality in various patient populations. Aim of our study was investigate the longitudinal association of T_{50} with micro- and macrovascular complications and all-cause mortality in T1DM.
Materials and methods: As part of a prospective cohort study, 283 T1DM patients were examined annually. Clinical and biochemical data from measures from 2002 until last available follow-up were analysed.
Results: T_{50} levels were measured among 216 patients (57% male) with a mean age of 45 (11) years, diabetes duration of 23 [16, 30] years, BMI of 26 (4) kg/m^2, systolic blood pressure of 130 (18) mmHg and HbA1c of 60 [51, 68] mmol/mol. Mean T_{50} level among all patients was 339 (59) minutes. There were no significant correlations between T_{50} levels and baseline characteristics. Patients in the upper T_{50} tertile (369 to 466 seconds) had a significant longer diabetes duration as compared to patients in the middle (317 to 368 seconds) and lowest (129 to 316 seconds): 25 [19, 33] vs. 21 [16, 30] and 20 [14, 29] years. During the 15 [6, 16] year follow-up period, there were 93 new micro- and 44 macrovascular events and 25 patients died. There were no differences between T_{50} tertiles for both micro- and macrovascular complications. Patients in the lowest tertile had the best overall survival (15.9 years (95% 15.5, 16.4)) as compared to both the middle (14.6 years (95%CI 13.8, 15.5), $p = 0.003$) and the highest tertile (15.0 (95%CI 14.2, 15.8), $p = 0.004$).
Conclusion: This is the first study to investigate the calcification propensity T_{50} score in T1DM. Higher T_{50} values were associated with all-cause mortality in this T1DM population. Although these results need confirmation in larger populations, it may lead to novel diagnostic or therapeutic approaches.

Glucagon-like peptide-1 receptor agonist, liraglutide, alters immune populations during regression of atherosclerosis

R. Bruen[1], S. Curley[2], S. Kajani[2], M.E. O'Reilly[2], F.C. McGillicuddy[2], O. Belton[1];
[1]Diabetes Complications Research Centre, School of Biomolecular and Biomedical Science, Conway Institute, University College Dublin,

Dublin, [2]Diabetes Complications Research Centre, School of Medicine, Conway Institute, University College Dublin, Dublin, Ireland.

Background and aims: Atherosclerosis development is governed by biologically active macrophages and dendritic cells (DCs). We recently showed that the glucagon-like peptide-1 receptor (GLP-1R) agonist, liraglutide (Lir), alters these immune cell subsets. We hypothesised that Lir can alter immune populations halting progression and inducing regression of pre-established atherosclerosis in the apolipoprotein E deficient ($ApoE^{-/-}$) atherosclerotic mouse model.
Materials and methods: Wild-type C57BL/6 bone marrow-derived macrophages (BMDMs) were treated with Lir to examine phenotypic shifts. Alongside this, a high-fat (60%) high-cholesterol (1%) diet (HFHCD) was fed to $ApoE^{-/-}$ mice for 8–12 weeks to induce atherosclerotic disease. Mice received 300 μg/kg Lir daily during weeks 3–8 to investigate disease progression and weeks 8–12 to examine regression of established disease. *En face* analysis was employed to quantify atherosclerotic lesions in aortae from $ApoE^{-/-}$ mice. Human atherosclerotic plaques and serum from patients pre- and post-Lir treatment were also investigated. Gene expression analysis, ELISA and flow cytometry were used to interrogate inflammatory mediators.
Results: Lir halted early disease progression in $ApoE^{-/-}$ mice (HFHCD 2.03 ± 0.18% vs HFHCD+Lir 1.36 ± 0.28%, $*p < 0.05$). This result mirrored significant decreases in inflammatory M1 (TNF-α, HFHCD 2.50 ± 0.38 vs HFHCD+Lir 0.15 ± 0.01, $**p < 0.01$) and increases in anti-inflammatory M2 gene expression (IL-10 HFHCD 0.84 ± 0.07 vs HFHCD+Lir 2.46 ± 0.32, $**p < 0.01$) in BMDMs. Pro-inflammatory monocytes were also markedly reduced (HFHCD 59.27 ± 2.97 vs HFHCD+Lir 16.79 ± 4.47, $**p < 0.01$). Pro-resolving M2 BMDMs were significantly elevated (HFHCD 37.45 ± 2.49% vs HFHCD+Lir 73.36 ± 3.84%, $*p < 0.05$). Importantly, Lir induced regression of pre-established atherosclerotic lesions (HFHCD 6.81 ± 0.33% vs HFHCD+Lir 4.02 ± 0.38%, $***p < 0.001$), decreased M1 (HFHCD 18.07 ± 3.32% vs HFHCD+Lir 5.67 ± 1.71%, $**p < 0.01$) and increased M2 populations (HFHCD 71.32 ± 13.04% vs HFHCD+Lir 94.24 ± 1.71%, $**p < 0.01$). DCs from lymph nodes of Lir-treated mice were also elevated (HFHCD $5.63e^5 \pm 1.05e^5$ vs HFHCD+Lir $1.37e^7 \pm 1.14e^7$ ns, $p = 0.0952$), during regression. Serum samples from patients pre- and post-Lir treatment resulted in significant reductions of pro-atherogenic sCD163 (Pre-Lir 3.18 ± 0.30 vs Post-Lir 2.69 ± 0.17, $***p < 0.001$) and atherosclerotic plaques showed reduced TNF-α secretion (PBS 135.10 ± 67.48 vs Lir 61.32 ± 37.55, ns $p = 0.0927$).
Conclusion: Lir is an atheroprotective agent both altering early disease progression, late stage disease regression and human atherosclerotic disease via modulating immune cells towards pro-resolving mediators.

The macrophage activation marker sCD163 during prolonged fasting

N. Rittig[1], A. Bak[1], N. Jessen[2], J. Møller[3], H. Grønbæk[4];
[1]Department of Internal Medicine and Endocrinology (MEA) and Medical Research Laboratory, Aarhus University Hospital, Aarhus C, [2]Research Laboratory for Biochemical Pathology, Institute for Clinical Medicine,, Aarhus C, [3]Department of Clinical Biochemistry, Aarhus University Hospital, Aarhus C, [4]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus C, Denmark.

Background and aims: Prolonged fasting causes insulin resistance and accelerated lipolysis. These metabolic features are characteristic for conditions such as obesity, diabetes mellitus type 2 (DM2) and non-alcoholic fatty liver disease (NAFLD). Plasma concentration of the macrophage activation marker sCD163 is known to be elevated in subjects suffering from obesity, DM2- and NAFLD compared with healthy lean subjects. We have earlier shown how LPS exposure caused elevated sCD163 concentrations and was positive correlated with insulin resistance as well as accelerated lipolysis in both healthy and diabetic patients. For these reasons we hypothesized that sCD163 concentrations would increase during prolonged fasting.
Materials and methods: We investigated nine healthy lean (mean BMI = 21 kg/m^2) and nine obese (mean BMI = 36 kg/m^2) male subjects in a randomized crossover trial with two interventions: I) following an overnight fast (control) and II) following a 72 h fast period. Both interventions were followed by similar metabolic measurements including ^{3}H-glucose and ^{3}H-palmitate tracer infusion to investigate glucose and lipid metabolism, indirect calorimetry to estimate lipid oxidation rate, and a hyperinsulinemic euglycimic clamp to quantify insulin sensitivity. Two-way repeated measure ANOVA (RM-ANOVA) and a linear regression analysis were used in the statistical analyses.
Results: We found a significant 17% reduction in sCD163 concentrations when comparing 72 h fasting with control conditions (RM-ANOVA main effect, $p = 0.002$) with no difference between lean and obese subjects (RM-ANOVA interaction, $p = 0.36$). We did not find any linear correlations between the reduction in sCD163 concentration and the changes in glucose infusion rate ($p = 0.90$), endogenous glucose production ($p = 0.91$), palmitate rate of appearance ($p = 0.15$), free fatty acid concentrations (0.56) and lipid oxidation rate ($p = 0.87$).
Conclusion: To our surprise we found a reduction in sCD163 concentrations during prolonged fasting but no association with changes in insulin resistance. These results are novel and may suggest involvement of distinct mechanisms in the physiologic and pathophysiologic development of insulin resistance and accelerated lipolysis.

Anti-atherosclerotic activity of trigonal GLP-1R/GIPR/GCGR agonists in ApoE KO mice

T. Hübschle[1], S. Meister[1], D. Hein[1], S. Schmidt[1], M. Medem[1], D. Albrecht[1], A. Schröder[1], D. Ströbel[2], B. Alka[2], T. Tran[2], S. Pfeiffer-Marek[2], M. Bossart[2];
[1]Sanofi-Aventis Deutschland GmbH, R&D Diabetes TA, Frankfurt am Main, [2]Sanofi-Aventis Deutschland GmbH, R&D, Frankfurt am Main, Germany.

Background and aims: Evaluate the potential anti-atherosclerotic effect of trigonal GLP-1R/GIPR/GCGR agonists in the ApoE knockout (KO) mouse model, an animal model that is characterized by atherosclerotic plaque development with a morphology resembling human atherosclerosis.
Materials and methods: Male ApoE KO mice were implanted with osmotic minipumps (ALZET™) filled with either vehicle (sterile acetate buffer, pH 4.5), the trigonal GLP-1R/GIPR/GCGR agonists SAR1 or SAR2 (150 μg/kg/day) or with liraglutide (600 μg/kg/day) for four months. Vehicle treated mice of the background strain (C57Bl/6J) were used as healthy controls. Body weight and food intake was monitored throughout the study on a weekly basis.
Results: In contrast to wild type C57Bl/6J mice, ApoE KO mice receiving vehicle developed early atherosclerotic lesions on the total inner surface of the aorta as measured with oil red O staining in absolute and relative plaque area using quantitative and automated image analysis. Treatment with the trigonal GLP-1R/GIPR/GCGR agonists SAR1 or SAR2 agonists at the dose of 150 μg/kg/day led to a significant reduction of atherosclerotic plaques by 63% and 73%, respectively, relative to vehicle treated controls. A 4-fold higher dose of the GLP-1R monoagonist liraglutide reduced aortic plaque burden in ApoE KO mice by 37%. However, the efficacy seen with the trigonal GLP-1R/GIPR/GCGR agonists was superior to the benefit induced by liraglutide. Compared to vehicle treatment, both trigonal GLP-1R/GIPR/GCGR agonists robustly

lowered the blood lipids total cholesterol, LDL-cholesterol and triglycerides. Further, their efficacy on blood lipids was superior to the beneficial effect elicited by the GLP-1 analog liraglutide.
Conclusion: Trigonal GLP-1R/GIPR/GCGR agonists SAR1 and SAR2 exhibited strong anti-atherosclerotic activity in ApoE KO mice. The benefit was superior to the effects elicited by the GLP-1R monoagonist liraglutide.

Carbohydrate metabolism disorders in heart failure patients: a complex relationship

B. Kurmanbekova, G. Osmankulova;
Chronic heart failure, NCCIM, Bishkek, Kyrgyzstan.

Background and aims: Simultaneous flow of diabetes mellitus (DM) and chronic heart failure (CHF) determine the adverse prognosis of patients, creating difficulties in their management for both cardiologists and endocrinologists. Identifying the latent flow of carbohydrate metabolism disorders (CMD) in CHF patients in a timely manner, as well as influence on the key pathogenetic links in their development, we can achieve a significant reduction in the social and economic burden. Study purpose: to evaluate the prevalence of latent CMD in association with neurohormonal profile indicators in patients with CHF
Materials and methods: 174 hospitalized patients with CHF II-IV (NYHA) ischemic etiology without CMD in anamnesis, receiving basic for CHF and CHD therapy. Such parameters as: height, weight, BMI, systolic and diastolic blood pressure, FINDRISC scale points, fasting and postprandial glucose levels, HbA1C, lipid profile, eGFR, daily proteinuria, Nt-proBNP, aldosterone and insulin concentrations with assessment of HOMA-IR and standart oral glucose tolerance test were conducted.
Results: Among 174 patients with CHF II-IV (NYHA) using OGTT, in 50.6% patients was revealed latent CMD: 59 (33.9%) patients had impaired glucose tolerance (IGT), in 29 (16.7%) - DM was newly diagnosed, 86 (49.4%) patients were without CMD. The largest number of FINDRISC points was observed in group with newly diagnosed DM compared with patients with IGT and without CMD. Insulin concentrations were increased in each study groups with CHF and CHD, but was significantly higher in patients with CMD compared with patients without CMD. IR was identified in all patients with CHF and CHD, what is more, its level increased with the growth of CMD explicity and was highest in DM group compared with IGT and without CMD groups. Elevated levels of Nt-proBNP had a linear relationship with CHF severity, but did not differ in groups. Aldosterone levels increased in all patients with CHF, regardless of the CMD presence, but was significantly higher in DM group. Correlation analysis determined strong interrelation between IR and: BMI, FINDRISC points, fasting and postprandial glucose levels, HbA1C, insulin concentrations, but not with ejection fraction, NYHA class and CHF duration.
Conclusion: The presence and progression of IR in association with neurohormonal profile in patients with CHF ischemic etiology emphasizes the importance of early detection of latent CMD. It will improve quality of life, prognosis and their survival, and will also reduce the financial costs of health care in all countries

Chronic hyperglycaemia in GLUT4-overexpressing H9C2-cells reveals diabetic heart failure mechanisms

B. Stratmann, Y. Mattern, D. Tschoepe;
Diabeteszentrum, Herz- und Diabeteszentrum NRW, Ruhr Universität Bochum, Bad Oeynhausen, Germany.

Background and aims: Chronic hyperglycaemia is an established cardiovascular risk factor. The mode of action of glucose or glucotoxic metabolites on the cellular entity and metabolic system remains elusive. Glucotoxic induced enhanced GLUT4 surface presentation may account as a possible mechanism to the development of diabetic heart failure. We established a GLUT4 overexpressing H9C2-cell line to analyse effects of hyperglycemia on GLUT4 trafficking and cellular metabolism.

Materials and methods: A stably GLUT4-*c-myc* overexpressing H9C2-cell line was generated for analyzing GLUT4 presentation, glucose influx as well as the effects on metabolic key components. Analysis of functional effects was achieved by means of flow cytometry, automated cell counting procedures, mRNA and protein analysis by RT-QPCR and Western blotting and glyoxalase enzyme activity assay. Chronic hyperglycaemia was induced by adjusting medium glucose content from 5 to 30 mM glucose.
Results: Under chronic hyperglycaemia a 6.7fold increase of GLUT4 was detected onto the cell surface by flow cytometry, resulting in a more than 3fold glucose influx (measured by NBDG-uptake for 60 min) and pronounced lactate production (1.3fold increase compared to 5mM). Increased GLUT4 presentation was not caused by pronounced protein expression due to hyperglycaemia. Cell proliferation decreased under hyperglycaemic conditions as well as cell viability (measured as Trypan Blue-Uptake for necrotic cells) indicating hyperglycaemia-induced apoptosis. This could be verified by PI/Annexin staining (1.5fold increase compared to 5mM) and cleavedPARP/PARP analysis using Western Blotting (2.2fold increase in cleavedPARP per PARP compared to 5 mM glucose). Increasing levels of Ddit3 point to methylglyoxal-induced apoptosis. Under hyperglycaemic conditions the addition of 10 μM methylglyoxal to the culture medium further increased GLUT4 presence on the cell surface indicating a possible role of glycotoxic metabolites in this scenario. Concomitantly, the glyoxalase 1 activity was found to be diminished under hyperglycaemic conditions. Chronic hyperglycaemia (30 mM for more than 3 months) induced a diabetic heart failure phenotype with significantly reduced levels of IRS1 (−31% RNA expression vs. 5 mM, $p < 0.01$), CPT1 (−17% protein expression vs. 5 mM, $p < 0.05$), AMP-kinase as an indicator of energy starvation (−22% protein expression vs. 5 mM, $p < 0.001$) and extraordinary high levels of Na-K-ATPase levels (+125% protein expression vs. 5 mM, $p < 0.05$).
Conclusion: The above described cell culture model is feasible for detection of metabolic alterations in cardiomyocytes following chronic hyperglycaemia and point to a contribution of reactive glucose metabolites to the scenario of diabetic heart failure. Substantial effects of long term hyperglycaemia are attributable to the generation of reactive glucose metabolites like methylglyoxal that accumulate due to increasing amounts of intracellular glucose and reduced activity of the detoxifying system Glyoxalase 1.
Disclosure: **B. Stratmann:** None.

Exendin-4 alleviates diabetic cardiomyopathy in mice by regulating Sirt1/PGC1α

M. Guan, Y. Cai, S. Fang, L. Xu, Y. Zhang, L. Wang;
Dept. Endocri & Metab, Nanfang Hospital, Southern Medical University, Guangzhou, China.

Background and aims: To investigate the protective effect of Exendin-4 on diabetic cardiomyopathy in mice and the potential mechanism involved.
Materials and methods: Type 2 diabetic mice were induced by streptozotocin (STZ) combined with high-fat diet (HFD). C57BL/6J mice were randomly divided into 3 groups: control group (Con), diabetic control group (DM-Con) and diabetic group with Exendin-4 treatment (DM+Ex-4). Exendin-4 was administered intraperitoneally (i.p., 1nmol/kg, qd) to the DM+Ex-4 mice for 8 weeks. Physiological indicators, such as blood glucose and weight, were recorded. RT-PCR was used to examined the transcription levels of genes related to myocardial hypertrophy and fibrosis, and mitochondrial function related genes, including PGC1α, NRF and CytoC. The expressions of oxidative stress markers and Sirt1/PGC1 proteins were measured by Western blot. Myocardial structural changes were detected by HE staining.
Results: Compared with the Con group, the DM-Con group showed significantly increased blood glucose and blood lipids ($P < 0.001$), which were improved by Exendin-4 treatment. The expressions of ANP, BNP, TGFβ1, CytoC1 and NOX1 in diabetic myocardial tissue were significantly increased ($P < 0.05$), while Sirt1, PGC1α, NRF and SOD1 were markedly decreased ($P < 0.05$). Interestingly, the Exendin-4 treatment resulted in obviously reduced expressions of ANP, BNP, TGFβ1, CytoC1 and NOX1 compared with the DM-Con group ($P < 0.05$), and increased expressions of Sirt1, PGC1α, NRF and SOD1 ($P < 0.05$).
Conclusion: Exendin-4 prevents myocardial injury in diabetic mice by improving mitochondrial function and inhibiting oxidative stress through the Sirt1/PGC1α signaling pathway.

Myocardial flow reserve assessed by Cardiac ^{82}Rb PET/CT is associated with albumin excretion in patients with type 1 diabetes

E. Hein Zobel[1], S. Abitz Winther[1], P. Hasbak[2], B. von Scholten[1], L. Holmvang[3], A. Kjær[2], P. Rossing[1], T. Hansen[1];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]Department of Clinical Physiology, Nuclear Medicine & PET and Cluster for Molecular Imaging, Rigshospitalet, Copenhagen, [3]Department of Cardiology, Rigshospitalet, Copenhagen, Denmark.

Background and aims: To evaluate myocardial flow reserve (MFR) and coronary artery calcium (CAC) in persons with type 1 diabetes with or without albuminuria and in non-diabetic controls; in addition we evaluated the association of MFR and CAC with retinopathy, another microvascular complication. MFR reflects the function of large epicardial arteries and myocardial microcirculation. CAC represents structural aspects of atherosclerosis.
Materials and methods: Cross-sectional study in type 1 diabetes, stratified by normoalbuminuria ($n = 30$) and presence of or historical macroalbuminuria ($n = 30$), and in non-diabetic controls ($n = 30$). MFR (pharmacological stress flow/rest flow) was evaluated by cardiac ^{82}Rb positron emission tomography/computed tomography. CAC content was quantified using the Agatston score.
Results: MFR was similar in patients with normomalbuminuria (NORMO) and controls (3.1 ± 0.8 *vs* 3.0 ± 0.79; $p = 0.74$). Patients with macroalbuminuria (MACRO) had lower (impaired) MFR compared to NORMO (2.1 ± 0.9 *vs* 3.1 ± 0.8; $p < 0.0001$). The CAC score (median[IQR]) was higher in NORMO compared to controls (72[22–247] *vs* 0[0–81], $p = 0.018$), and comparable between MACRO and NORMO. MFR was comparable in patients with diabetes and simplex or no retinopathy ($n = 24$ and $n = 12$, 2.8 ± 0.84 vs 3.3 ± 0.77, $p = 0.11$), but lower in proliferative ($n = 24$) compared to simplex retinopathy (2.1 ± 0.97 vs 2.8 ± 0.84, $p = 0.02$). The CAC score was comparable between groups of retinopathy. In multivariate linear regression lower MFR was associated with higher urinary albumin creatinine rate, higher age, lower eGFR and smoking ($R^2 = 0.39$). Higher CAC was associated with lower MFR, higher age and 24-hour systolic blood pressure ($R^2 = 0.34$).
Conclusion: Myocardial microvascular function was comparable in non-diabetic controls and patients with type 1 diabetes and normoalbuminuria; but impaired in the presence of microvascular complications (macroalbuminuria and proliferative retinopathy). Coronary calcification was elevated in diabetes, however not explained by albuminuria.

Stereological quantification of key pathological features in a uninephrectomised db/db mouse model of diabetic nephropathy

T.T. Johansen, T.X. Pedersen, N. Vrang, J. Jelsing, T. Secher, L.N. Fink;
Gubra ApS, Hørsholm, Denmark.

Background and aims: Diabetic nephropathy (DN) is a long-term complication of diabetes characterized by increasing albuminuria and reduced

kidney function. Approximately one third of patients with type 2 diabetes develop DN with DN being the predominant cause of end-stage renal disease. To aid further understanding of disease mechanisms and development of new treatment options, translatable and stable rodent models that recapitulate features of human DN are essential.

Materials and methods: Uni-nephrectomy (UNx) was performed in female db/db mice to accelerate diabetes-induced renal pathology. UNx or sham surgery was performed in db/db or db/+ mice (7–8 weeks of age, $n = 8$–16 mice per group). The study was terminated 11 or 16 weeks after surgery. Plasma samples were obtained for assessment of blood glucose, HbA1c and blood urea nitrogen (BUN), and urine samples were collected for albumin-to-creatinine ratio (ACR) analysis. Estimates of renal hypertrophy were determined by stereology and renal fibrosis by image analysis of picrosirius red staining.

Results: UNx in db/db mice lead to a slight increase in fed blood glucose compared to db/db sham (16 weeks; 27.6 ± 1.6 vs. 22.3 ± 2.1 mmol/l; $p < 0.05$) but did not alter body weight or HbA1c (16 weeks; 8.8 ± 0.6 vs. 8.1 ± 0.5%). Total kidney and glomerulus volume were markedly higher in db/db UNx compared to both db/db sham and db/+ sham (16 weeks; 124.4 ± 6.0 vs. 85.9 ± 3.3 and 65.6 ± 2.9 kidney volume mm^3; $p < 0.001$; 2.66 ± 0.15 vs. 1.94 ± 0.12 and 1.46 ± 0.07 glomerulus volume mm^3; $p < 0.001$ db/db UNx vs. db/+ sham; $p < 0.01$, db/db UNx vs. db/db sham). Kidney fibrosis was increased in both db/db UNx and db/db sham vs. db/+ sham control (16 weeks; 12.7 ± 1.3 and 10.7 ± 1.8 vs. 5.7 ± 0.8 total collagen mg; $p < 0.05$). BUN was transiently increased in db/db UNx compared to both db/db sham and db/+ sham at 4 weeks post-surgery, but not at 11 or 16 weeks. Urine ACR increased progressively over time and was significantly increased in db/db UNx and sham at week 5, 10 and 15 compared to db/+ sham (15 weeks; 2263.1 ± 505.2 and 1748.4 ± 445.2 vs. 43.9 ± 6.9 ACR μg/mg; $p < 0.001$ db/db UNx vs. db/+ sham; $p < 0.01$ db/db sham vs. db/+ sham).

Conclusion: Diabetes and unilateral nephrectomy were combined to exacerbate renal pathology. Renal hypertrophy and increased glomerular volume in the db/db UNx model indicate renal compensation potentially leading to glomerular alterations and increased urinary ACR. Further characterization of renal features reflecting human DN is ongoing to refine the db/db UNx model and provide improved pre-clinical testing possibilities for drugs targeting DN.

Disclosure: **T.T. Johansen:** None.

1090

A novel surgery-induced rat model of diabetic nephropathy displaying kidney hypertrophy, albuminuria and pronounced tubular fibrosis

M.V. Østergaard, T. Secher, T. Johansen, P.G.J. Pedersen, N.E. Zois, T.X. Pedersen, J. Jelsing, N. Vrang, K. Fosgerau, L.N. Fink;
Gubra aps, Hørsholm, Denmark.

Background and aims: Diabetic nephropathy (DN) is a long-term complication of diabetes characterized by albuminuria and loss of kidney function, which affects up to one third of all diabetes patients. For more than a decade no new therapies targeting DN have been introduced, partly due to the lack of preclinical animal models reflecting key features of human DN. Here, we aimed to establish a novel preclinical model of DN in pancreatectomized uni-nephrectomized rats displaying progressive albuminuria and histopathological features of late stage DN.

Materials and methods: Diabetes was surgically induced in male Sprague-Dawley rats by 90% pancreatectomy (Px) resulting in stable blood glucose levels of >20 mmol/L. To accelerate the progression of DN, unilateral nephrectomy (UNx) was performed simultaneously to Px in another rat cohort. At 11 and 21 weeks after Px and 11 weeks after Px-UNx, urinary creatinine, albuminuria and NGAL, and plasma creatinine and cystatin C were quantified. Kidneys were processed for histology and stereology as well as next generation sequencing.

Results: Kidney hypertrophy was observed in Px rats 11 and 21 weeks post-surgery (0.53 ± 0.01 and 0.57 ± 0.01% of BW, respectively, vs 0.35 ± 0.02%, sham control, $p < 0.01$) and was further increased in Px-UNx rats 11 weeks post-surgery (Px-UNx 0.94 ± 0.04% of BW, $p < 0.001$ vs Px 11 wks and Px 21 wks). Renal fibrosis was significantly induced in Px vs Ctrl rats as determined by quantitative histology of picro-sirius red staining of total kidney collagen (127 ± 21 Px 11 wks and 227 ± 46 Px 21 wks vs 39 ± 11 mg Ctrl, $p < 0.05$ and $p < 0.001$, respectively). Renal fibrosis was further augmented in Px-UNx rats 11 weeks post-surgery (334 ± 81 mg, $p < 0.001$ vs Px 11 wks and $p < 0.01$ vs Px 21 wks). Urinary albumin excretion was significantly increased in Px-UNx rats vs Ctrl (albumin-to-creatinine ratio; 11,504 ± 5,366 vs 233+112 μg/mg, $p < 0.05$), while urinary NGAL excretion was increased by 21 weeks after Px and 11 weeks after Px-UNx vs Ctrl (NGAL-to-creatinine ratio; 3.2 ± 0.6 and 12.1 ± 3.5 vs 0.3 ± 0.023 μg/mg, both $p < 0.001$). Plasma creatinine and cystatin C were reduced 21 weeks post-surgery in Px vs Ctrl rats (creatinine; 13.3 ± 0.4 vs 17.9 ± 1.4 μmol/L, $p < 0.01$ and cystatin C; 1511 ± 87 vs 2411 ± 286 ng/mL, $p < 0.01$). Both plasma creatinine and cystatin C levels were significantly increased in Px-UNx rats 11 weeks vs Px 21 weeks post-surgery (creatinine; 20.9 ± 1.2 μmol/L, $p < 0.001$ vs Px 21 wks and cystatin C; 2463 ± 29 ng/mL, $p < 0.01$ vs Px 21 wks) and returned to levels similar to Ctrl rats. Finally, gene expression of proteins encoding podocyte markers nephrin, podocin, and WT-1 were significantly reduced in Px-UNx vs Ctrl rats, while gene expression of kidney injury markers NGAL and KIM-1 were significantly increased.

Conclusion: The novel Px-UNx model of DN develops extensive renal hypertrophy and fibrosis 11 weeks post-surgery; a nephropathy phenotype that is more progressed than in the Px model after 21 weeks. Furthermore, the Px-UNx model displays increased urinary albumin and NGAL excretion as wells as increased plasma creatinine and cystatin C. Thus, Px in combination with UNx in rats represents a novel, strong alternative to streptozotocin-induced diabetes and genetic models for pre-clinical drug development targeting DN.

Prediabetes and diabetes are associated with wider retinal arterioles and venules: the Maastricht study

W. Li[1], M. Schram[1], T. Berendschot[2], J. Schouten[2], A. Kroon[1], C. van der Kallen[1], R. Henry[1], A. Koster[3], P. Dagnelie[4], N. Schaper[1], F. Huang[5], B. ter Haar Romeny[5], C. Stehouwer[1], A. Houben[1];
[1]Department of Internal Medicine & School for Cardiovascular Diseases (CARIM), Maastricht University Medical Center+, Maastricht, [2]Department of Ophthalmology, Maastricht University Medical Center+, Maastricht, [3]Department of Social Medicine, Maastricht University, Maastricht, [4]Department of Epidemiology, Maastricht University, Maastricht, [5]Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands.

Background and aims: Retinal vascular calibers are biomarkers of cardio-metabolic risk. Previously, it has been shown in population-based cohort studies that wider retinal arterioles are associated with diabetes and impaired fasting glucose. However, the association of wider retinal venules and diabetes was found in non-caucasian ethnicities only. The aim of the present study was to investigate the association of glucose metabolism status with retinal arteriolar and venular diameters in a predominantly Caucasian population.

Materials and methods: In a population-based cohort study with oversampling of T2DM ($n = 2339$, 50.1% men, aged 59.7 ±8.2 years; 98.8% Caucasian), we determined retinal microvascular diameters [MU] (Rhino software) and glucose metabolism status (OGTT; normal glucose metabolism (NGM) [$n = 1363$], prediabetes [$n = 366$], or T2DM [$n = 610$]). Differences were assessed with multivariable regression analyses adjusted for age, sex, waist circumference, smoking, systolic-BP, lipid profile, the use of lipid-modifying and/or blood-pressure-lowering

medication, eGFR, albuminuria, and prior CVD. Individuals with retinopathy were excluded.

Results: Adjusted analyses showed that both central retinal arteriolar equivalent(CRAE) and central retinal venular equivalent(CRVE) were wider in prediabetes (CRAE: $B = 0.93$, 95% CI −1.43 to 3.30; CRVE: $B = 2.94$, 95% CI −0.78 to 6.66), and in T2DM (CRAE: $B = 3.47$, 95% CI 1.06 to 5.88; CRVE: $B = 3.88$, 95% CI 0.08 to 7.68) versus normal glucose metabolism (CRAE: P for trend = 0.006; CRVE: P for trend = 0.035). In addition, HbA1c was associated with wider CRAE after full adjustment ($B = 1.10$ [0.004 to 2.20], $P = 0.049$), but was not associated with CRVE.

Conclusion: Prediabetes and diabetes are independently associated with both wider retinal arterioles and venules, in a predominantly Caucasian population. These findings support the concept that microvascular dysfunction is an early phenomenon in disturbed glucose metabolism.

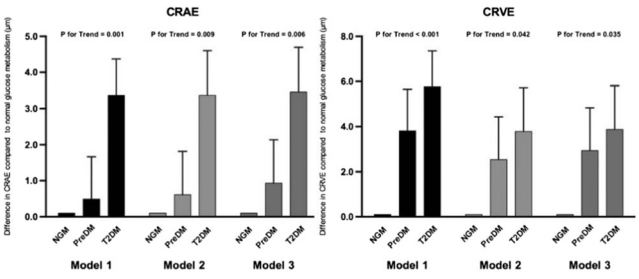

Figure 1. Multivariable adjusted differences in retinal microvascular diameters between individuals with prediabetes and T2DM compared with NGM. Bars represent the mean difference with standard error with NGM. NGM is the reference and is set to zero Model 1: adjusted for age and sex. Model 2: additionally adjusted for waist circumference, smoking, systolic-BP, lipid profile, the use of lipid-modifying and/or blood-pressure-lowering medication. Model 3: additionally adjusted for eGFR, albuminuria, and prior CVD.

Microvascular reactivity and nutrients profile in patients with type 2 diabetes and metabolically healthy volunteers with overweight or obesity

J. Veleba[1], L. Belinova[1], P. Janovska[2], H. Kahleova[1], H. Malinska[1], K. Velebova[1], E. Stolarikova[1], J. Kopecky, Jr.[1], K. Bardova[2], O. Kuda[2], J. Hansikova[2], V. Melenovsky[1], J. Kopecky, Sr.[2], T. Pelikanova[1];
[1]Institute for Clinicial and Experimental Medicine, Prague, [2]Academy of Sciences of The Czech Republic, Prague, Czech Republic.

Background and aims: Important features of type 2 diabetes (T2D) include endothelial dysfunction, insulin resistance and disruption of nutrients metabolism. The aim of our work is to investigate microvascular reactivity in relation to acute hyperinsulinemia, nutritional stimulation and adipose tissue composition by patients with T2D and overweight or obese subjects with normal glucose metabolism.

Materials and methods: We enrolled 20 patients with type 2 diabetes (T2D) on metformin treatment and 20 volunteers (C) with overweight or obesity and with normal glucose metabolism. All subjects underwent the hyperinsulinemic euglycemic clamp combined with indirect calorimetry, meal test using standard breakfast, biopsy of subcutaneous adipose tissue and assesment of plasma acylcarnitines (AcylCN) and aminoacids profiles. Parameters of the endothelial function - Augmentation Index (AI) reflecting arterial stiffness and Reactive Hyperemia Index (RHI) reflecting microvascular reactivity were measured by finger pulse plethysmography before and during the clamp and before and after the meal test.

Results: AI decreased in response to meal test in C (12.43 ± 1.86 vs. 4.02 ± 2.11; $p < 0.001$) as well as in DM2 (15.37 ± 2.37 vs. 4.13 ± 2.61; $p < 0.001$), FRHI did not change during the meal test neither in C (0.39 ± 0.08 vs 0.33 ± 0.09; ns.) nor in DM2 (0.14 ± 0.07 vs 0.1 ± 0.007; ns), but we found significant difference between the groups ($p < 0.001$). AI decreased in response to hyperinsulinemia in C (10.41 ± 1.13 vs. 6.4 ± 1.17; $p < 0.001$), whereas did not change in DM2 (8.2 ± 2.41 vs. 6.51 ± 2.11; ns.). FRHI tended to decrease in response to hyperinsulinemia (C: 0.39 ± 0.06 vs. 0.34 ± 0.06; ns. DM2: 0.14 ± 0.07 vs. 0.09 ± 0.07; ns.) and we found significant difference between the groups ($p < 0.01$). We proved higher level of C2-AcylCN and C4-AcylCN and lower level of C16-AcylCN in DM2. Glucogenic and branched aminoacids concentrations (alanine, proline, valine, leucine and isoleucine) were higher in DM 2 than in C. Concentrations of other amino acids did not differ significantly. We found a higher capillaries - adipocytes ratio in histological examination of adipose tissue in C (0.46 ± 0.11 vs. 0.40 ± 0.05; $p < 0.05$). Correlation between AcylCN concentrations and endothelial function parameters was clinically and statistically insignificant. We found a negative relationship between RHI and proline concentration ($r = -0.31$; $p < 0.01$), positive correlation between AI and phenylalanine concentration ($r = 0.34$; $p < 0.01$) and positive correlation between RHI and capillaries - adipocytes ratio ($r = 0.35$, $p < 0.01$).

Conclusion: Arterial stiffness decreased in DM 2 and C during postprandial state, whereas in response to hyperinsulinemia decreased only in C. Microvascular reactivity was not influenced by interventions, but was always higher in C. We observed higher concentrations of short chain AcylCN and glucogenic and branched aminoacids and lower vascularization of subcutaneous adipose tissue resulting in reduced vascular reactivity in DM 2.

Dermal microvessel density in adults with type 1 diabetes is dependent on metabolic control

A. Adamska, A. Araszkiewicz, S. Pilacinski, A. Gandecka, A. Grzelka, K. Kowalska, A. Malinska, M. Nowicki, D. Zozulinska-Ziolkiewicz;
Poznan University of Medical Sciences, Poznan, Poland.

Background and aims: In patients with diabetes, functional changes in microcirculation and subclinical vascular pathology precede clinical manifestation of microangiopathic complications. Objective of the study was to evaluate the association between established vascular risk factors and density, maturity and reactivity of dermal blood vessels in adults with type 1 diebetes.

Materials and methods: We included 148 adult patients (87 men, 61 women) with type 1 diabetes, median (IQR) age 40.5 (30.5–49) years, diabetes duration 21 (17–29.5) years. Data on the medical history and treatment of diabetes were collected using a questionnaire. The participants underwent physical examination with anthropometric measurements. We determined parameters of metabolic control of diabetes and assessed accumulation of advanced glycation and products (AGEs) using AGE-Reader device. Skin biopsy was performed 10 cm above the lateral malleolus using 3 mm biopsy punch. In the immunohistochemical (IHC) analyses anti-CD133, anty-CD34, anti-CD31, and anti-vWF autoantibodies were used. All histology sections from a single patient were processed in the same IHC experiment. Microvessel density (MVD) was calculated using "hot spots technique". Microvascular function was examined by single-point laser-Doppler flowmetry (LDF). Data were analyzed using Statistica version 10.

Results: Median MVD, calculated for both papillary and reticular dermis, defined by CD31 antigen expression was 38 (19–56) per 1 mm^2. The median CD34+ blood vessel density was 121 (100–155) per 1 mm^2, CD133+ 79 (63–92) per 1 mm^2, and vWF 50 (40–69) per 1 mm^2. An average CD34/CD31 index in dermal biopsies was 2.78, vWF/CD31 ratio was 1.32 and CD133/CD31 ratio was 1.75. In multivariante regression analysis the CD34/CD31 index was positively associated with serum triglyceride concentration (Beta: 0.26, $p = 0.012$) and negatively associated with serum HDL cholesterol concentration (Beta: −0.22, $p = 0.027$), both independently from age, sex, diabetes duration, BMI, HbA1c value,

presence of hypertension, and eGFR. In LDF the area under thle blood flow/time curve (AUC) correlated positively with CD31+ MVD ($r = 0.21, p = 0.011$) and negatively with CD34+ MVD ($r = -0.20, p = 0.017$).
Conclusion: Atherogenic dyslipidemia is associated with increased formation of new blood vessels, characterized by high expression of CD34 and low reactivity in laser Doppler flowmetry. Conversely, chronic hyperglycemia and excessive formation of advanced glycation end products may result in decreased vascularity.

PS 103 Diabetes from childhood to adults

1094

Gut microbiota in children with type 1 diabetes differs in composition and functionality in comparison with MODY 2 and healthy controls
L. Sánchez-Alcoholado[1], I. Leiva-Gea[2], B. Martín-Tejedor[2], D. Castellano-Castillo[1], I. Moreno-Indias[1], A. Urda-Cardona[2], F.J. Tinahones[1], J.C. Fernández-García[1], M.I. Queipo-Ortuño[1];
[1]Clinical Management Unit of Endocrinology and Nutrition, Virgen de la Victoria University Hospital, Laboratory of Biomedical Research Institute of Malaga (IBIMA), University of Malaga, CIBERobn, Málaga, [2]Clinical Management Unit of Pediatrics, Materno-Infantil Hospital, Málaga, Spain.

Background and aims: Type 1 diabetes mellitus (T1DM), an organ-specific autoimmune disease, is associated with compositional differences in gut microbiota. Maturity Onset Diabetes of the Young 2 (MODY2) is a monogenic cause of diabetes. We compared gut microbiota profile and functional capacity between healthy controls and children with T1DM and MODY2, and evaluated the relationship between intestinal microbiota, intestinal permeability and glycemic levels.
Materials and methods: Case-control study in 15 children with T1DM, 15 children with MODY2 and 13 healthy children. Metabolic control and potential factors modifying gut microbiota were controlled. Microbiome composition was determined by 16S rRNA pyrosequencing and bioinformatics analysis by QIIME software.
Results: We found a significant decrease in the microbiota diversity in T1DM with respect to healthy controls. A significant increase in the relative abundance of *Bacteroides*, *Ruminococcus*, *Veillonella*, *Blautia* and *Streptococcus* genera, and a decrease in the relative abundance of *Bifidobacterium*, *Roseburia*, *Faecalibacterium* and *Lachnospira* was found in T1DM. MODY2 showed a significant increase in *Prevotella* abundance and a significant decrease in *Ruminococcus* and *Bacteroides*. Moreover, significant correlations between the serum levels of IL-1B and gut microbiota composition were found in T1DM patients. Gut permeability (determined by serum zonulin levels) was significantly increased in MODY2 and T1DM. PICRUSt analysis found that T1DM was increased in genes related to lipid and amino acid metabolism, ABC transport, lipopolysaccharide biosynthesis, arachidonic acid metabolism, antigen processing and presentation and chemokine signaling pathways compared to MODY2 and healthy controls.
Conclusion: Gut microbiota in T1DM differs at taxonomic level respect to MODY2 and healthy controls, but also at functional level, involving different metabolic pathways. Moreover, T1DM was associated with a low-grade inflammatory gut microbita profile. The specific gut microbiota profile found in T1DM could represent an environmental risk factor associated with the autoimmunity process and, through gut microbiota modulation, might constitute a potential target for the prevention of T1DM.

Metabolomic profiling of exhaled breath in relation to glycaemic variability in paediatric patients with type 1 diabetes: a prospective cross-sectional study
S.C. Schmidt[1], P. Trefz[2], J.K. Schubert[2], W. Miekisch[2], D.-C. Fischer[1];
[1]Paediatrics, University Medicine Rostock, Rostock, [2]Anaesthesiology and Intensive Care Medicine, University Medicine Rostock, Rostock, Germany.

Background and aims: Type 1 diabetes mellitus (T1DM) is the most common chronic metabolic disease in paediatric patients, for whom non-invasive and thus painless metabolic monitoring is particularly attractive. A prominent example is breath analysis, although previous studies on

exhaled concentrations of volatile organic compounds (VOCs) in diabetic breath yielded contradictory results. It is not yet known how the chemical composition of exhaled breath changes in the course of metabolic adaptation to endogenous insulin deficiency, and more specifically in relation to glycaemic variability.

Materials and methods: Blinded continuous glucose monitoring (CGM) and breath analysis with proton transfer reaction time-of-flight mass spectrometry (PTR-ToF-MS) were combined in a prospective cross-sectional study design. Data was recorded every 5 minutes for 9 consecutive hours including 2 standardised meals. Glycaemic variability was assessed as SD and CV of interstitial glucose concentration as well as time in target range (3.9–10.0 mmol/L), and mean alveolar VOC concentrations were calculated as time-normalised AUCs. Between-group differences were tested for significance with either unpaired two-sample Student's t-test or Mann-Whitney *U* test, as appropriate, and bivariate rank correlation coefficients were calculated according to Spearman.

Results: Out of 360 quasi-molecular ions detected in exhaled breath of 45 children and adolescents, mean alveolar concentrations of methylamine (median [parts per billion by volume (ppbV)] 12.2 (range [ppbV] 5.4–36.9) vs 7.3 (3.4–18.3)), acetone (255.0 (212.6–295.2) vs 223.3 (183.5–261.7)), isopropanol (1015.6 (597.6–2740.0) vs 600.7 (319.6–1053.3)) and pentanal (6.3 (3.1–14.1) vs 3.5 (1.9–5.8)) were significantly elevated (all $p < 0.001$) in paediatric T1DM patients on either multiple daily injections (MDI) or continuous subcutaneous insulin infusion (CSII) compared to healthy controls matched for age (12–16 years) and sex. No significant correlations were found between mean alveolar VOC concentrations, mean interstitial glucose concentration and measures of glycaemic variability.

Conclusion: Distinct VOC profiles in exhaled breath mirror metabolic alterations occurring with T1DM, although not linearly related to well-established markers of glycaemic control, i.e. blood glucose concentration and glycaemic variability. Regardless, breath analysis might be a powerful tool for non-invasive real-time metabolic monitoring, especially in paediatric patients.

Predictors of loss to follow up in youth with type 2 diabetes: comparing the US Pediatric Diabetes Consortium and European Pediatric Diabetes Prospective cohorts

S. Wiegand[1], G.J. Klingensmith[2], S. Lanzinger[3], W.V. Tamborlane[4], T. Reinehr[5], P. Cheng[6], M. Bauer[7], R.L. Gal[6], R.W. Holl[3], C. Kollman[6];
[1]Pediatric Endocrinology and Diabetology, Charité Universitätsmedizin Berlin, Berlin, Germany, [2]Department of Pediatrics, Barbara Davis Center for Childhood Diabetes, University of Colorado, Aurora, USA, [3]Institute of Epidemiology and Medical Biometry, University of Ulm, Ulm, Germany, [4]Pediatric Endocrinology, Yale University, New Haven, USA, [5]Department of Pediatric Endocrinology, Diabetes, and Nutrition Medicine, University of Witten/Herdecke, Datteln, Germany, [6]Jaeb Center for Health Research, Tampa, USA, [7]Department of Pediatric and Adolescent Medicine, University of Linz, Linz, Austria.

Background and aims: Youth with T2D have been shown to have greater social disadvantage than youth with type 1 diabetes or the general population. Clinicians also report that T2D youth are not seen in follow up consistently, thus creating difficulty in diabetes management and timely identification and treatment of complications and co-morbidities. This study was designed to determine predictors for loss to follow up (LFU) and assess differences in predictors between continents.

Materials and methods: Youth with T2D enrolled from Jan 2012 to Dec 2015, age 10 - ≤16.5 at the last visit, were identified in both the Pediatric Diabetes Consortium (PDC) and Central European Pediatric Diabetes Prospective Follow Up (DPV) Registry. T2D was determined by no beta cell autoantibodies detected in the presence of diabetes, using ADA/ISPAD guidelines. Characteristics at enrollment were aggregated to identify those associated with loss to follow up. In PDC, attempts to contact patients were made >3 times using several means before LFU was determined. In DPV, patients/families were contacted by phone if they missed follow up appointments.

Results: In all, 677 were eligible for inclusion, 463 in DPV and 214 in PDC. Both cohorts reported a high rate of LFU prior to 18 years of age (76% in DPV and 54% in PDC). In multivariable analysis, age predicted LFU in both cohorts with those <13 less likely to be LFU than those ≥15 years of age ($p < 0.001$). Youth ≥15 years had a 91% LFU in the DPV and 87% LFU in the PDC. Diabetes treatment was also a risk in both cohorts, $p = 0.03$ in PDC; $p = 0.02$ in DPV, patients treated with "lifestyle modification only" had highest risk for LFU. Of concern, 48% in PDC and 64% in DPV of those on insulin also were LFU. In the PDC but not in the DPV, those residing a greater distance from the clinical site (≥80 km) were at significantly higher risk of LFU than those within 8 km (82% vs 36%). Gender, minority status, diabetes duration, and HbA1c did not predict LFU in either cohort.

Conclusion: Loss to follow up is a serious problem in both T2D Registries. Identifying ways to help vulnerable T2D youth maintain consistent medical care is a major health issue in adolescent T2D and most likely contributes to poor outcomes.

The effects of type 1 diabetes on hand and foot posture and mobility of young patients

P. Francia[1], L. Capirchio[2], U. Santosuosso[1], M. Sorelli[3], B. Piccini[2], A. Vittori[1], G. Iannone[4], M. Gulisano[1], S. Toni[2];
[1]School of Human Health Sciences, Florence, [2]Diabetes Unit Meyer Children's Hospital, Florence, [3]Dept. of Information Engineering, University of Florence, Florence, [4]National Association of Movement Sciences (ANIMO), Florence, Italy.

Background and aims: It is known that limited joints mobility can affect the quality of movement and could also adversely affect the body development of young subjects with Type 1 Diabetes Mellitus (T1DM). In particular, it is well known how diabetes mellitus can reduce hand and ankle joints range of motion and modify their posture. The aim of this study was to investigate using a new method how diabetes affects hand and foot posture in young T1DM patients.

Materials and methods: We enrolled 20 young T1DM patients: (M/F:11/9), mean age 13.8 ± 3.8 yrs, BMI: 19.5 ± 4.7 kg/m^2, diabetes duration 4.6 ± 3.6 yrs, mean HbA1c 8.2 ± 1.2% and 46 young subjects practicing soccer and dance: (M/F:30/16), mean age 12.6 ± 2.1 yrs, BMI: 18.9 ± 2.6 kg/m^2. In these subjects, we evaluated hand posture (analysis of frontal plane image of Prayer sign test). In particular, the inclination of the fifth metacarpal and phalanges bones were evaluated in addition to the angles at the metacarpophalangeal and interphalangeal joints. Ankle joint mobility and posture were evaluated (inclinometer and sagittal plane image of the ankle and lower limb) with the foot and leg in the same position used for the evaluation of joint mobility (patients lying). Moreover, trunk flexibility (sit & reach test), muscle strength (hand grip) and lifestyle (IPAQ-C, IPAQ-A) were evaluated. The individual sporting history was investigated by a specific questionnaire.

Results: The analysis of hand images showed the presence in diabetic patients of a higher extension of the fifth metacarpophalangeal joint (patients group: 34.7 ± 11.0°; control group: 18.6 ± 8.5°) and higher flexion of the proximal interphalangeal joint (patients group: 11.0 ± 5.1°; control group: 0.4 ± 9.8°). In comparison to controls, the patient group showed a higher inclination of the fifth metacarpal joint (42.4 ± 11.2° vs 34.4 ± 8.4°; $p < 0.005$) and a lower inclination of the proximal phalanx (4.9 ±

6.0° vs 15.7 ± 6.1°; $p < 0.001$). Moreover, the tests performed showed a significantly higher ankle joint mobility in young dancers (155.8 ± 10.3°) compared to patients and soccer group (126.8 ± 15.5°; $p < 0.001$) and patients group (127.3 ± 33.7°; $p < 0.001$). No significant correlations were found between the parameters investigated.

Conclusion: Young patients with T1DM can show abnormal posture of the hand. Regarding the analysis of the hand images the results of this pilot study indicate that the metacarpophalangeal joint and the proximal interphalangeal joint take a different posture in patients with T1DM. The prayer sign test could hinder the recognition of the presence of an abnormal distal interphalangeal joint flexion. All this indicates that diabetes could affect hand posture and mobility from the first years of disease onset.

Disclosure: **P. Francia:** None.

1098

Epidemiology of acute diabetes complications (coma) according to the Federal Diabetes register of the Russian Federation (2013–2016)

A.Y. Mayorov[1], O.K. Vikulova[1], A.V. Zheleznyakova[1], M.A. Isakov[1,2], O.G. Melnikova[1], I.V. Kononenko[1], M.V. Shestakova[1], I.I. Dedov[1]; [1]Diabetes Institution, Endocrinology Research Centre, Moscow, [2]Aston consulting group, Moscow, Russian Federation.

Background and aims: Despite the improvement in the quality of diabetes care in the Russian Federation (RF), the increased availability of modern hypoglycemic drugs and insulins, coma remain one of the causes of death in patients with diabetes. Aim of the study was to assess dynamic of epidemiological characteristic of acute complications in adult patients with type 1 diabetes (T1D) and type 2 diabetes (T2D) in 2013–2016.

Materials and methods: The database of the Federal Diabetes register of 81 regions included in the online register system. The data exported from online register, powered by Microsoft Dynamics CRM platform. The analysed number of patients with T1D/T2D: 0.23/3.48 mln in 2013, 0.23/3.65 mln in 2014, 0.24/3.75 mln in 2015, 0.24/3.81 mln in 2016. Statistics performed by SPSS, 24.0.0.1. The indicators of coma for 2013–2016 were estimated for 10,000 adult patients with diabetes (>18 years).

Results: In 2016, the prevalence of coma in the RF averaged 225.9 with T1D and 11.6/10,000 adults with T2D. Totally in 2016, 165 new cases of coma for both types of diabetes were registered, an average of 0.4/10,000 adults. At the same time, interregional differences in the prevalence of coma were from 0 to 4.2/10,000 adults. The frequency of new cases of coma in the dynamics of 2013–2016 had a tendency to decrease: from 0.9 to 0.4/10,000 adults. Depending on the type of diabetes, the frequency of new cases of coma was also reduced: with T1D - from 5.7 to 3.4, with T2D - from 0.6 to 0.2/10,000 adults. When assessing dynamics by type of coma, it was found that the frequency of ketoacidotic coma decreased with both types of diabetes: with T1D - from 3.6 to 1.6, with T2D - from 0.2 to 0.1/10,000 adults; frequency hypoglycemic coma: with T2D - without the dynamics of 0.1/10,000 adults, while with T1D there was an increase in the frequency of 0.9 to 1.5/10,000 adults. When evaluating the structure of coma in a dynamic, redistribution was evident in their forms. So in 2013, the most frequent was with T1D ketoacidotic coma - 79.9%, hypoglycemic coma - 17.2%. In 2016, the structure changed: the proportion of hypoglycemic coma increased to 40.7%, and ketoacidotic coma decreased to 56.6%. With T2D, the difference between the ratio of ketoacidotic and hypoglycemic coma in 2013 and 2016 expressed in a lesser degree than with T1D, but also a tendency to increase the proportion of hypoglycemic coma: in 2013 ketoacidotic - 51.7%, hypoglycemic - 37.5%, and in 2016 - 48.3% and 46.1%, respectively. The mean duration of diabetes at the time of coma development increased with T1D from 3.8 to 9.1 years, with T2D from 3.5 to 7.0 years.

Conclusion: It is established that the dynamics of the frequency of development of coma in 2013–2016 in adult patients with diabetes in the RF has a stable tendency to decrease: 1.5 times with T1D and more than 2.5 times with T2D. It can be assumed that this is due to the improvement in the quality of diabetes care and glycemic control in general, as well as the use of modern medicines. Attention is required to draw to the high frequency of coma in T1D, the development of coma with a longer duration of diabetes, an increase in the proportion of patients with hypoglycemic coma. Significant interregional differences in the frequency of coma registration require additional analysis.

Rehabilitation for children and adolescents with diabetes

R. Schiel[1], R. Stachow[2], T. Hermann[3], I. Satzke[4], T. Büttner[5], S. Koch[6], K. Enderlein[7], R. Bambauer[8], A. Steveling[9], E. Bollow[10], R. Holl[10], DPVWiss Initiative; [1]MEDIGREIF-Inselklinik Heringsdorf GmbH, Seebad Heringsdorf, [2]Fachklinik Sylt, Westerland, [3]Fachklinik Prinzregent Luitpold, Scheidegg, [4]MEDIAN Kinderklinik „Am Nicolausholz, Bad Kösen, [5]Deutsche Rentenversicherung Rheinland-Pfalz, Edelsteinklinik, Fachklinik für Kinder- und Jugendrehabilitation, Bruchweiler, [6]Fachklinik Gaißach der Deutschen Rentenversicherung Bayern Süd, Gaißach, [7]MEDIGREIF Parkklinik, Greifswald, [8]Formerly Institute for Blood Purification, Homburg, [9]Ernst-Moritz-Arndt-University, Internal Medicine A, Greifswald, [10]Institut für Epidemiologie und medizinische Biometrie, ZIMBT, University of Ulm, Ulm, Germany.

Background and aims: Medical rehabilitation plays an important role in the treatment of children/adolescents with diabetes. It was the aim of the survey to analyze trends in the number of patients admitted to rehabilitation, the quality of diabetes care, the incidence of acute complications, risk factors for cardiovascular co-morbidities and the familial status over a period of 13 years.

Materials and methods: Currently 7 hospitals offer in-patient rehabilitation for children/adolescents with diabetes in Germany. Six hospitals participated in the survey. All children/adolescents (n = 7163) who participated in an in-patient rehabilitation 01/01/2004–31/12/2016 were included. Clinical/familial data were assessed: age, sex, family situation, type/duration of diabetes, insulin dosage, self-monitoring, acute complications, height, body weight, blood pressure and laboratory parameters.

Results: During the study period the patients took part in 10,987 in-patient rehabilitation procedures. The yearly number of patients participating in rehabilitation remained stable. There was no change in the quality of diabetes control (HbA1c: $p = 0.30$, fasting blood glucose: $p = 0.80$). The incidence of severe hypoglycaemia decreased ($p < 0.001$). The incidence of ketacidosis remained stable ($p = 0.18$). The frequency of blood glucose self-monitoring increased ($p < 0.001$). The same was true for patients treated with CSII ($p < 0.001$), whereas the numbers of patients treated with CT or ICT decreased (both $p < 0.001$). There was no change in patients' total insulin dose ($p = 0.01$). Regarding the family status the survey revealed the following trends: During the study period there was a decrease in the number of patients living with both parents ($p < 0.001$), whereas the percentage of children and adolescents living with the mother or father alone increased ($p < 0.001$). Moreover the number of patients living in native German families decreased ($p < 0.001$). The percentage of children and adolescents with diabetes living in mixed cultural families or having a background of immigration increased ($p < 0.001$).

Conclusion: There is a change in medical rehabilitation: The number is stable, the proportion of patients using CSII increased, the number of patients living with single parents and the percentage of patients from culturally mixed families increased also.

Acute effects of the combination of acarbose and gastric distension, with a water preload, on the postprandial blood pressure response to oral sucrose

H. Pham, L. Trahair, L. Phillips, C.K. Rayner, M. Horowitz, K.L. Jones;
Adelaide Medical School, University of Adelaide, Adelaide, Australia.

Background and aims: Postprandial hypotension (PPH), a fall in systolic blood pressure (BP) of >20 mmHg within 2 hours of a meal, predisposing to syncope and falls, occurs in ~15% of healthy people >65 years and ~35% of patients with type 2 diabetes (T2DM). There currently is no satisfactory treatment. The underlying mechanisms are heterogeneous, including the rate of small intestinal nutrient delivery and absorption, release of gastrointestinal hormones and changes in splanchnic blood flow and autonomic nerve function. We have shown that the α-glucosidase inhibitor, acarbose, used widely in the management of T2DM, attenuates the magnitude of the fall in BP, in healthy older subjects and patients with PPH. Nutrient or non-nutrient gastric distension also attenuates the fall in postprandial BP but the effects may be more transient. We aimed to determine whether gastric distension and acarbose have additive effects to attenuate the fall in BP induced by oral sucrose in healthy older subjects.
Materials and methods: 10 healthy older subjects (2M, 8F; mean age: 74 ± 1.4 yr; BMI: 26.2 ± 1.1 kg/m^2) were studied on 4 separate occasions in a randomised, crossover design. After an overnight fast, subjects received either (i) a drink of 100 g sucrose dissolved in 300 ml of water (control treatment: C), (ii) a 300 ml water 'preload' 15 minutes before a drink of 100 g sucrose in 300 ml of water (distension treatment: D), (iii) a drink of 100 g sucrose with 100 mg acarbose in 300 ml of water (acarbose treatment: A) or (iv) a 300 ml water 'preload' 15 minutes before a drink of 100 g sucrose with 100 mg acarbose dissolved in 300 ml of water (acarbose and distension treatment: AD). BP was measured with an automated device at baseline (before intervention) and at 3-min intervals for 120 min after the sucrose drink. The maximum fall in systolic BP was calculated as the primary endpoint. Data are mean values ± SEM.
Results: The studies were well tolerated. There were no differences in baseline (t = 0 min) systolic BP among the 4 treatments (C: 133 ± 4 mmHg vs. D: 128 ± 3 mmHg vs. A: 125 ± 4 mmHg vs. AD: 130 ± 4 mmHg; P = 0.19). Between t = 3 and 120 min, there was a treatment effect (P = 0.016) for acarbose, so that the maximum fall in systolic BP from baseline was less during treatments with acarbose (A: −10.9 ± 2.7 mmHg and AD: −10.9 ± 2.2 mmHg) compared with control (C: −17.6 ± 3.1 mmHg). There was no difference between the acarbose treatments with or without gastric distension (P = 0.55) and no effect of gastric distension alone (D: −20.8 ± 3.2 mmHg, P = 0.64) (*Figure*).
Conclusion: In healthy older subjects, an acute dose of acarbose (100 mg) attenuates the fall in systolic BP after an oral sucrose load. This effect was not potentiated by concurrent gastric distension. These observations support the use of acarbose, but not gastric distension, in the management of PPH in diabetes.

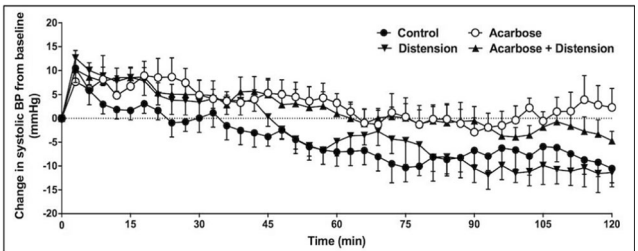

Figure: Acute effects of acarbose (100mg) with and without a 300ml water preload (distension), distension alone and control on the change in systolic BP from baseline after a 100g sucrose drink in healthy older subjects (n=10).

Intraocular lens implantation for cataract in type 2 diabetes: The Fremantle Diabetes Study Phase II

J.J. Drinkwater, W.A. Davis, D.G. Bruce, T.M.E. Davis;
School of Medicine, The University of Western Australia, Fremantle, Australia.

Background and aims: Cataracts are a leading cause of visual impairment. Although associated with type 2 diabetes (T2D), there are few contemporary data allowing quantification of the contribution of T2D to cataracts severe enough to warrant intraocular lens (IOL) implantation. This study aimed to compare the incidence of IOL implantation in community-based people with T2D and matched individuals without diabetes.
Materials and methods: The Fremantle Diabetes Study Phase II (FDS2) recruited a representative cohort of 1,499 people with T2D from a postcode defined community between 2008 and 2011. These participants were age-, sex- and postcode-matched to four de-identified people without diabetes randomly selected from the Australian electoral roll who were resident in the same catchment area. Hospitalisation data from the West Australian Data Linkage System were used to determine the cataract-associated IOL status of individuals in both groups during follow-up to end-December 2016. Those with prevalent IOL at baseline were excluded. Age-specific incident rates (IRs) and incident rate ratios (IRRs) for IOL implantation were calculated. A Cox regression model using age as time-scale and diabetes status as the sole independent variable was used to determine the effect of T2D on incident IOL implantation. This was then adjusted for age at baseline, sex, and Charlson's comorbidity index (CCI) excluding diabetes-specific components.
Results: The total eligible sample (n = 6316) comprised 1183 FDS2 and 5133 matched participants without diabetes (mean ± SD age 63.3 ± 11.0 years at entry, 52.6% male). The median [IQR] diabetes duration of those with T2D was 8.7 [2.0–14.0] years. During 6.1 [5.6–7.7] years of follow up, 311 FDS2 (26.3%) and 963 matched participants (18.8%) were hospitalised for first IOL implantation, representing IRs of 44.8 (95% CI 39.9–50.0) and 30.3 (28.4–32.2) per 1000 person-years, respectively. The crude IRR for FDS2 versus matched non-diabetic participants was 1.48 (1.30–1.68). Age-specific IRs, IRRs and incident rate differences are shown in Table 1. The IRRs decreased with increasing age from seven times higher in the 45–54 year age group to 31% higher in 75–84 year olds. The T2D participants had significantly higher IRs in all age-groups, apart from those aged >85 years. T2D increased the risk of IOL by 63% (HR 1.63 (1.43–1.84)) in an unadjusted Cox regression model and by 60% after adjustment (1.60 (1.40–1.81)). Male sex and younger age were associated with a significantly lower risk of IOL (HR 0.84 (0.75–0.94) and 0.81 (0.80–0.82) per year, respectively). There was no significant association between CCI and IOL implantation.
Conclusion: These data show that T2D adds substantially to the high rate of progression of cataracts to IOL implantation in a geographical area with a climate associated with increased ultraviolet light exposure. Younger people with T2D are at particularly high risk and should be encouraged to adopt multi-faceted cataract prevention strategies.

Table 1: Incident rates and incident rate ratios of IOL

Age Group	45-54	55-64	65-74	75-84	85+	45+
IR of IOL in T2D group*	9.19	17.37	53.65	103.74	147.91	45.82
IR in matched cohort*	1.28	8.22	33.93	79.06	84.74	31.39
IRR (Exact 95% CI)	**7.17 (2.07-27.86)**	**2.11 (1.39-3.16)**	**1.58 (1.28-1.94)**	**1.31 (1.06-1.61)**	1.75 (0.88-3.23)	**1.46 (1.28-1.66)**

Lipid peroxidation is associated with impaired vascular function but not with glucose control or variability in type 1 diabetes

M. Prázný[1], J. Škrha jr.[1], T. Pelcl[1], J. Šoupal[1], P. Kačer[2], J. Škrha[1];
[1]3rd Department of Internal Medicine, Charles University in Prague, Prague, [2]BIOCEV, Prague, Czech Republic.

Background and aims: Oxidative stress plays an important role in the development of diabetes complications. It was hypothesized that high glucose variability, a typical clinical feature of Type 1 diabetes (T1DM), may additionally - beyond permanent hyperglycemia - contribute to the generation of oxidative stress. Although it may be useful to identify diabetic patients at high risk for vascular complications using biomarkers and/or functional tests of vasculature, no easy and reliable tests exist so far. To contribute to the development of such test(s), we evaluated the associations between skin microvascular reactivity (MVR), glucose variability (GV) and a novel group of serum biomarkers of oxidative stress - reactive aldehydes formed by lipid peroxidation.
Materials and methods: We included 56 T1DM patients younger than 50 years (mean age 32 ± 8 yrs, HbA_{1C} 62 ± 12 mM/M or 7.8 ± 1.5% DCCT, DM duration 14 ± 6 yrs). Reactive aldehydes with C-chain length from 6 to 12 (hexanal to dodecanal) and malondialdehyde (MDA) were measured by mass spectrometry. Masked continuous glucose monitoring collected glucose data for 12 days to evaluate mean blood glucose and parameters of GV (SD, CV and CONGA). Skin MVR was measured by laser Doppler fluxmetry on the forearm during post-occlusive reactive hyperemia (PORH) and thermal hyperemia (TH). Percent change in flow was calculated from baseline to peak value during stimulations.
Results: PORH was negatively associated with octanal and MDA ($r = -0.48$, $p = 0.0003$ and $r = -0.33$, $p = 0.017$, respectively). Time to maximal perfusion during PORH was negatively associated with nonanal, decanal, undecanal and dodecanal ($r = -0.31$, $p = 0.027$; $r = -0.31$, $p = 0.025$; $r = -0.47$, $p = 0.0005$ and $r = -0.29$, $p = 0.037$, respectively). TH was negatively associated with octanal, nonanal, decanal and MDA ($r = -0.55$, $p < 0.0001$; $r = -0.31$, $p = 0.021$; $r = -0.27$, $p = 0.048$ and $r = -0.43$, $p = 0.001$, respectively). No associations were found between glucose control, GV and reactive aldehydes and similarly, MVR was not associated with glucose parameters as well.
Conclusion: In our cross-sectional observational study, higher levels of reactive aldehydes originating in lipid peroxidation were associated with impaired skin MVR in T1DM. Parameters of glucose control and GV were not associated with lipid peroxidation or MVR in our study. We therefore suggest that other than simple glycemic mechanisms may be probably more important in the process of reactive aldehydes generation in T1DM. As our study was not designed to show causality between lipid peroxidation and vascular dysfunction, further research should evaluate the role of reactive aldehydes in the development and/or prediction of diabetic vascular complications.

The p300 modulates eNOS expression in endothelial cells exposed to high glucose in vitro

G. Formoso, P. Di Tomo, P. Lanuti, M.P.A. Baldassarre, C. Pipino, S. Miscia, A. Pandolfi, A. Consoli;
University G. D'Annunzio, Chieti Scalo, Italy.

Background and aims: Vascular functional homeostasis is mainly controlled by endothelial Nitric Oxide Synthase (eNOS) expression and activity. In diabetes, the molecular mechanisms modulating eNOS cellular levels are not fully elucidated. Sirtuin 1 (SIRT1) is a deacetylase enzyme (HDAC) able to modulate histones and transcription factors acetylation in response to the cellular metabolic state. We previous demonstrated that in Human Umbilical Vein Endothelial Cells (HUVECs), 25mM glucose (HG) compared to 5mM (NG) increased cellular levels of both eNOS and SIRT1. Since cellular adaptation mechanisms are the result of a constant balance between the activity of acetylase (HAT) and deacetylase (HDAC) enzymes, aim of the present work was to investigate whether p300, a transcriptional co-activator with HAT activity required in key cellular processes, such as those regulated by Forkhead box protein O1 (FoxO1) and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB), could be modulated by HG.
Materials and methods: HUVECs were obtained from umbilical cord by a standard procedure and were grown in the presence of NG (5mM) or HG (25mM) concentration for 48 hours. Cellular levels of eNOS and SIRT1 were assessed by Western Blotting as well as by Cytometric Analysis. FoxO1 and NF-kB nuclear localization was evaluated by Imaging Flow Cytometric Analysis (AMNIS). Data are expressed as fold increase over the NG condition (± Standard Deviation). Statistical analysis were performed using One-Way ANOVA or Student t-test. Value of $p < 0.05$ were considered statistically significant.
Results: In HG conditions, a significant increase in total and nuclear p300 protein levels ($p < 0.05$) was observed. This was associated with an enhanced total, nuclear and acetylated FoxO1 protein levels as well as with an augmented nuclear translocation of NF-kB p65 ($p < 0.05$). All of these modifications could contribute to increasing eNOS protein levels. Pretreatment with 20 μM Anacardic acid, a specific p300 inhibitor, was able to block ($p < 0.05$) the HG induced increase in total, nuclear and the acetylated FoxO1 protein levels, NF-kB p65 nuclear translocation, as well as the eNOS expression. This suggests that the eNOS transcription is regulated by HAT enzymes, such as p300.
Conclusion: In our cellular model, HG induced an increase in p300 (an HAT) which was necessary for the concomitant modulation of FoxO1 and

NF-kB levels and cellular distribution as well as for the enhanced eNOS protein levels. Thus, the elevated SIRT1 (a HDAC) levels observed after HG exposure could be interpreted as the result of a cellular adaptation in response to the increased p300 HAT activity. Our data extend the available information regarding the mechanisms potentially implicated in the hyperglycemia-induced modulation of the eNOS expression and activity, which in turn is responsible for the altered vascular Nitric Oxide bioavailability in diabetes.

Disclosure: **G. Formoso:** None.

Circulating succinate concentrations are associated with arterial stiffness in type 1 diabetes

J.-M. González-Clemente[1,2], G. Llauradó[3,2], V. Ceperuelo-Mallafré[4,2], A. Cano[1], L. Albert[1], N. Keiran-Fernández[4,2], I. Mazarico[1], S. Fernández-Veledo[4,2], J. Vendrell[4,2];
[1]Department of Endocrinology and Nutrition, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, [2]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Instituto de Salud Carlos III, Madrid, [3]Department of Endocrinology and Nutrition, Hospital del Mar, Institut Hospital del Mar d'Investigacions Mèdiques (IMIM), Barcelona, [4]Endocrinology and Nutrition Section, Hospital Universitari Joan XXIII, Institut d'Investigació Sanitària Pere Virgili (IISPV), Universitat Rovira i Virgili, Tarragona, Spain.

Background and aims: Cardiovascular disease (CVD) is the main cause of death in patients with type 1 diabetes mellitus (T1DM). Succinate, a citric acid cycle intermediate, is considered a marker of hypoxia and ischemia. The succinate/SUCNR1 axis has been linked to pathophysiological mechanisms involved in the development and progression of chronic diabetic complications, including CVD. The aim of our study was to evaluate the circulating succinate concentrations and to assess its relationship with arterial stiffness (AS) in T1DM patients.

Materials and methods: Eighty-four patients with T1DM (35–65 years old) and without established CVD were consecutively evaluated for: 1) clinical and anthropometric characteristics (including classical cardiovascular risk factors), 2) microvascular complications, 3) AS, measured by aortic pulse-wave velocity (aPWV) assessed by applanation tonometry (gold standard) and 4) circulating succinate concentrations using a fluorimetric assay. T1DM patients were compared with healthy controls (n = 30), patents with obesity (n = 40) and persons with type 2 diabetes mellitus (T2DM) (n = 20).

Results: Patients with T1DM [age 50.1 ± 9.3 years, 50% men, 36.9% active smokers, T1DM duration 19.0 (15.9–27.5), BMI 26.0 ± 4.2 kg/m^2 and HbA_{1c} 7.9 (7.1–8.7)%] had an increase in circulating succinate concentrations as compare to healthy subjects (85.5 (68.7–108.4) vs. 22.0 (11.5–39.2); p < 0.001), but these concentrations were not different from those in patients with obesity (85.5 (68.7–108.4) vs. 81.0 (65.0–96.5); p = 0.809) or with T2DM (85.5 (68.7–108.4) vs. 118.5 (89.5–135.0); p = 0.131). These results did not change after adjusting for age, gender and BMI. In T1DM, circulating succinate concentrations were positively associated with BMI (r = 0.288, p = 0.009) and aPWV (r = 0.280, p = 0.010). aPWV was one of the main independent variables associated with circulating succinate concentrations after adjusting for classical cardiovascular risk factors (β = 0.267; p = 0.014).

Conclusion: Patients with type 1 diabetes mellitus and without established cardiovascular disease have an increase in circulating succinate concentrations as compared to healthy controls. This increase is similar to that found in persons with obesity or with type 2 diabetes mellitus. Additionally, this increase is positively correlated with arterial stiffness, which supports a potential role of succinate in the development of cardiovascular disease in type 1 diabetes mellitus.

Oral glycine treatment attenuated AGE-RAGE-ROS axis by restoring glyoxylase system in the aorta of diabetic rats

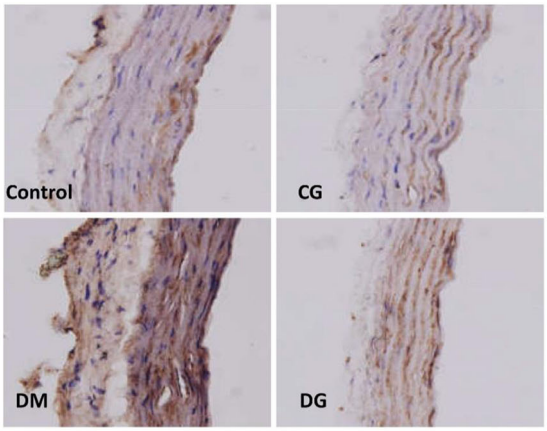
Z. Wang, J. Zhang, L. Chen, J. Li, H. Zhang, X. Guo;
Peking University First Hospital, Beijing, China.

Background and aims: The accumulation of advanced glycation endproducts (AGEs) can activate the receptor of AGEs (RAGE) and induce oxidative stress, thus underlying macrovascular complications in diabetes mellitus. Extensive studies have found that glyoxalase-1 (Glo-1) and its cofactor glutathione (GSH) can degrade a major precursor of AGEs, thus protecting against AGEs formation. Glycine is a crucial precursor of glutathione synthesis and its protective effects against oxidative stress have been reported. In this study, we aimed to investigate the effects of glycine on the AGE-RAGE-ROS axis in the aorta of diabetic rats and the possible underlying mechanisms.

Materials and methods: The STZ-induced diabetic rats were treated with or without glycine (1% in drinking water) for 12 weeks. GSH, 3-nitrotyrosine, MDA and SOD were measured in the aorta homogenates. The AGEs in the aorta were measured by ELISA and immunohistology. The expressions of aortic RAGE, NF-κB and Glo-1 were analyzed by western blot and immunohistology.

Results: Compared with the control group, the expressions of AGEs (p < 0.05), RAGE (p < 0.01) and NF-κB (p < 0.001) exacerbated in diabetic rats, but were attenuated after glycine treatment (p < 0.05, p < 0.01, p < 0.01 respectively). The levels of aortic 3-nitrotyrosine and MDA increased in the diabetic rats (p < 0.05), but were down-regulated in the glycine-treated group (p < 0.05). The SOD activity in the aorta decreased in the diabetic group (p < 0.01), but was elevated after glycine treatment (p < 0.05). The expression and activity of Glo-1 (p < 0.01) and the levels of GSH (p < 0.001) decreased in the diabetic group, but were restored significantly after glycine treatment (p < 0.05, p < 0.01 respectively).

Conclusion: Our results showed that oral glycine treatment might work by promoting GSH synthesis and enhancing the activity and expression of Glo-1 to suppress both the formation of AGEs and the activation of AGEs-RAGE-ROS axis, thus protecting against the macrovascular complications in diabetic rats.



Immunostaining of aortic AGEs. Control: healthy rats receiving water. CG: control rats with glycine treatment. DM: diabetic group with water; DG: diabetic group with glycine treatment.

Glucose-dependent insulinotropic polypeptide suppresses arterial remodelling in mice: role of a calcium-mediated signalling pathway in vascular endothelial cells

Y. Mori, H. Kushima, M. Koshibu, T. Saito, M. Hiromura, K. Kohashi, M. Terasaki, T. Hirano;
Diabetes, Metabolism, and Endocrinology, Showa University School of Medicine, Tokyo, Japan.

Background and aims: Glucose-dependent insulinotropic polypeptide (GIP) exhibits direct cardiovascular actions in addition to its well-known insulinotropic effect. However, the role of GIP in peripheral artery disease remains unclear. Here we evaluated effects of GIP against peripheral arterial remodelling in mouse models.
Materials and methods: Nine-week-old male wild-type (C57BL/6) and GIP receptor knockout (GIPR-KO) mice were randomly assigned to treatment with either vehicle or GIP (50 mmol kg^{-1} day^{-1}) on Day 1, and subsequently subjected to left femoral artery wire injury to induce arterial remodelling on Day 3. Mice were killed by an overdose of anaesthesia and the injured arteries were collected to assess morphometric changes on Day 29, or endothelial regeneration on Days 4, 8, 13, and 17. Human umbilical vein endothelial cells (HUVECs) were used for western blotting and measurement of intracellular cAMP production, cytosolic calcium levels, and nitric oxide (NO) production.
Results: No difference was detected in physiological and biochemical parameters between the treatment groups. In the assessment of morphometric changes, the genetic deletion of GIPR led to exaggerated neointimal hyperplasia after arterial injury (1.3-fold). In contrast, GIP (1-42) treatment suppressed neointimal hyperplasia compared with vehicle treatment by 50%. We further assessed the effects of GIP on endothelial regeneration. Endothelial cells determined as being CD31-positive were almost completely absent from the lumen 1 days after wire insertion. Subsequently, endothelial cells gradually covered the lumen (5 and 10 days), mainly starting from the uninjured area, with endothelial regeneration being completed at 14 days after the injury. In comparison with vehicle treatment, GIP (1-42) treatment significantly increased the endothelial cell-covered area of the lumen assessed at 5 days after the injury. (1.5-fold). In HUVECs, GIPR protein levels were significantly higher than in human aortic smooth muscle cells, and GIP (1-42) increased cytosolic calcium levels without affecting intracellular cAMP levels. GIP also dose-dependently increased NO production, which was completely abrogated by inhibiting AMP-activated protein kinase (AMPK). Furthermore, GIP increased phosphorylation of AMPK along with endothelial NOS. GIP-induced AMPK phosphorylation was abolished by inhibiting phospholipase C or calcium-calmodulin-dependent protein kinase kinase, but not adenylate cyclase or liver kinase B1, suggesting the existence of a calcium-mediated GIPR signalling pathway. In high-glucose-culturing conditions (25 mmol/l), GIPR protein levels of HUVECs were significantly decreased compared with those in normal-glucose-culturing conditions (5.5 mmol/l). However, GIP still significantly increased AMPK phosphorylation under high-glucose conditions, even though this effect was slightly albeit not significantly (two-way ANOVA: interaction, $p = 0.25$) blunted compared with that observed normal glucose conditions (55% vs 35%).
Conclusion: We demonstrated that the activation of GIPR exhibits protection against peripheral arterial remodelling in mice, and the involvement of a novel calcium-mediated GIPR signalling pathway in vascular endothelial cells.

The cardiovascular benefits associated with liraglutide in the LEADER trial are sustained when analysing both first and recurrent MACE

S. Verma[1], S.C. Bain[2], T. Idorn[3], S. Rasmussen[3], D.D. Ørsted[3], M.A. Nauck[4], LEADER Publication Committee on behalf of the LEADER Trial Investigators;
[1]Division of Cardiac Surgery, Li Ka Shing Knowledge Institute of St. Michael's Hospital, University of Toronto, Toronto, Canada, [2]Swansea University Medical School, Swansea, UK, [3]Novo Nordisk A/S, Søborg, Denmark, [4]Diabetes Center Bochum-Hattingen, St Josef Hospital (Ruhr-Universität Bochum), Bochum, Germany.

Background and aims: In patients with type 2 diabetes and high risk for cardiovascular (CV) events, the LEADER CV outcomes trial (N = 9340) showed risk of a first major adverse CV event (MACE) was reduced with liraglutide vs placebo when added to standard of care. Here we further examined liraglutide treatment effects on both first and recurrent ("total observed") CV events, including: 1) a composite MACE endpoint: CV death, non-fatal stroke or non-fatal myocardial infarction; 2) expanded MACE (also included coronary revascularisation and hospitalisation for heart failure or unstable angina); and 3) individual CV endpoints.

Materials and methods: A post hoc analysis utilising an extension of Cox regression modelling of time to event data, with additional sensitivity analyses.
Results: In total, 1302 first and 303 recurrent MACEs occurred: liraglutide, 735 events; placebo, 870 events. Risk for total observed MACEs was reduced by 14% with liraglutide vs placebo (HR = 0.86, 95% CI 0.78–0.95). Corresponding analyses for all other CV endpoints suggested risk reductions with liraglutide, with the exception of hospitalisation for unstable angina (Table). Sensitivity analyses using other regression models confirmed the results (Table).
Conclusion: The reduction in risk of first event with liraglutide in LEADER was sustained in this post hoc analysis; this is of clinical relevance to individuals who are at risk of or who have experienced a MACE, and confirms the robustness of the data.

Raw yogurt supplementation prevents the dyslipidaemia, glucose intolerance and oxidative stress induced liver dysfunction in high fat diet fed obese rats

S.A. Nishad, J.F. Tisha, S. Lasker, F. Parvez, M. Zamila, M.M. Rahman, M.C. Shill, H.M. Reza, M.A. Alam;
Pharmaceutical Science, North South University, Dhaka, Bangladesh.

Background and aims: The main objective of this experiment was to determine and expose the responses of Yogurt supplementation on oxidative stress, diabetes, inflammation and fibrosis in High-Carbohydrate and high-fat (HCHF) diet induced obese rats.
Materials and methods: Twenty eight Wistar male rats of 175–195 g were divided into four groups: Control, Control + Yogurt, HCHF and HCHF + Yogurt. After 8 weeks of treatment with Yogurt (5% of powdered chow diet w/w) all animals were weighed and sacrificed.Blood and tissue samples were collected to evaluate biochemical assay as well as histological staining of liver tissue sections were also done.
Results: Yogurt supplementation showed improved blood glucose tolerance in HCHF + Yogurt group compared to the HCHF group. We have seen that liver enzymes ALP, ALT and AST were increased in HCHF group which is significantly normalized in HCHF + Yogurt group rats. Moreover, Yogurt supplementation also exhibited a significant reduction of the oxidative stress markers such as MDA, NO, and APOP level.Yogurt supplementation also prevented inflammatory cells infiltration, collagen deposition and fibrosis in HCHF diet fed rats.
Conclusion: The findings of this study suggest that Yogurt supplementation prevents metabolic syndrome as well as nonalcoholic fatty liver disease in rats.

Trends of infections in adults with and without diabetes, U.S. 2000–2014

J. Harding[1], E. Gregg[1], M. Pavkov[1], L. Perreault[2];
[1]Centers for Disease Control and Prevention, Atlanta, [2]University of Colorado Denver School of Medicine, Aurora, USA.

Background and aims: People with diabetes (DM) are at an increased risk for infections compared with people without DM. As cardiovascular disease (CVD) and mortality complications of DM continue to decline, it is unknown if non-CVD complications, such as infections, are also decreasing. We estimated infection-related hospitalizations during 2000–2014 in adults aged ≥18 years with and without DM in the general U.S. population
Materials and methods: Infection-related hospitalisation rates were calculated using the National Inpatient Sample for the number of discharges (ICD-9 CM primary diagnosis code: 001-139, 480-486, 041.12, 682, 785.4, 040.0, 590.0; 060-066; 080-088; 042, 997.31, 136.9; 998.5) and the National Health Interview Survey for population estimates, by diabetes status. Joinpoint regression was used to assess trends over time.
Results: Among men with DM, age-standardised hospitalization rates per 1,000 persons, increased from 21.7 (95%CI: 20.4–23.0) in 2000 to 28.0 (27.1–28.9) in 2014, and from 9.2 (9.0–9.4) to 10.3 (10.1–10.4) in men without DM. Among women with DM, rates increased from 24.9 (23.5–26.2) in 2000 to 32.5 (31.5–33.4) in 2014, and from 8.5 (8.7) to 10.1 (10.0–10.3) in women without DM. All trends were significant $p < 0.05$, Figure.
Conclusion: Overall, rates of infection-related hospitalisations have increased since 2000. Adults with DM have greater excess risk of infection-related hospitalisations than those without DM, and this excess risk has increased over time.

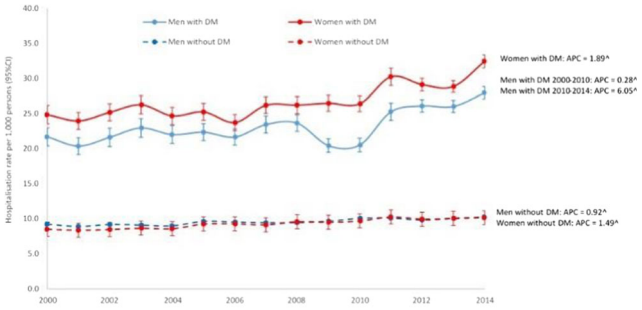

Figure Age-standardized rates of infection-related hospitalisations, per 1,000 persons, in men and women with and without diabetes between 2000 and 2014.

The longitudinal association between type 2 diabetes and fractures in a large Dutch cohort of older women

P.J.M. Elders[1], T. Merlijn[1], A.A. van der Heijden[1], G. Nijpels[1], C. Netelenbos[2], K. Swart[1];
[1]General Practice and Elderly Care, VU University Medical Centre, Amsterdam, [2]Internal Medicine, Endocrine Section, VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: Type 2 diabetes mellitus (T2DM) has been associated with an increased fracture risk. Glycemic control might be of influence. We examined the association of T2DM and fractures during a 3-yr follow up period in a large primary care sample of older women.
Materials and methods: Data were used from a randomized pragmatic trial among 25,613 women aged 65–90 years in a primary care setting. All participants with ≥1 established risk factors for fractures ($n = 11,331$) and a subsample of the participants without risk factors was followed up ($n = 5020$), including all remaining participants with T2DM. Outcomes were assessed by patient questionnaires after 18 and 36 months and fractures were verified in medical records. Self-reported baseline T2DM was verified with GP medical records, from which baseline HbA1c concentrations were derived as well. Baseline vertebral fractures assessment and BMD measurements were done in a subsample of participants with ≥1 risk factors for fractures ($n = 4310$). The main outcome was fractures over the 3-yr follow up period. Secondary outcomes were hip fractures, falling, baseline vertebral fractures, BMD of the hip and the lumbar spine. Depending on the outcome, Cox, logistic, or linear regression models were used to examine the associations.
Results: T2DM was verified in 1,578 out of 11,331 (13.9%) participants with ≥1 risk factors for fractures with a mean HbA1c of 51.7 mmol/mol. In the selective subsample of participants without risk factors for fractures 1,052 out of 5020 (21.0%) participants had T2DM, with a mean HbA1c of 49.3 mmol/mol. Oral anti-diabetes drugs was used in 78.5% and insulin in 15.4% of the participants with T2DM. Among the participants with ≥1 risk factors for fractures, 163 out of 1,578 (10.3%) participants with T2DM sustained a fracture versus 1,101 out of 9,537 (11.5%) participants without T2DM. T2DM was not associated with incident fractures of any type (adjusted HR = 1.00, 95% CI = 0.84 to 1.19). A significantly higher BMD of the hip and the lumbar spine was observed in the women who underwent a BMD measurement (Table). Among the women without risk factors for fractures, 70 out of 1,052 (6.7%) participants with T2DM sustained a fracture versus 380 out of 3968 (9.6%) participants without T2DM. T2DM was associated with a reduced fracture risk (adjusted HR = 0.68, 95%CI = 0.52 to 0.88) (Table). HbA1c among women with T2DM (analysed in quartile categories) was not associated with any of the outcomes.
Conclusion: T2DM was not associated with fractures in older women who already were identified with an increased fracture risk based on other factors. Moreover, women without fracture risk factors and T2DM had a reduced fracture risk. We postulate that this reduced risk is mediated through a higher BMD.

Table. Results of regression analyses of the association between T2DM and fracture related outcomes among women with and without established clinical risk factors for fractures.

	Prospective fractures HR (95%CI)	Prospective hip fractures HR (95%CI)	Prospective falling OR (95%CI)	Baseline vertebral fractures OR (95%CI)	Baseline BMD hip B (95%CI)	Baseline BMD lumbar spine B (95%CI)

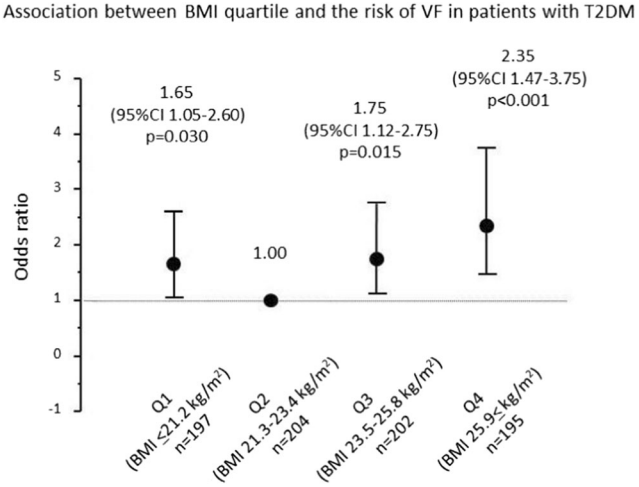
Association of body mass index with the risk of vertebral fractures in patients with type 2 diabetes

I. Kanazawa, M. Notsu, K.-I. Tanaka, T. Sugimoto;
Shimane University Faculty of Medicine, Izumo, Japan.

Background and aims: Several studies suggest that obesity may be a risk factor for fracture although the relationship between body mass index (BMI) and fracture risk is unknown in type 2 diabetes (T2DM). We thus aimed to examine the association between BMI and the prevalence of vertebral fracture (VF) in Japanese patients with T2DM.
Materials and methods: In this cross-sectional study, 798 subjects (500 men and 298 women) with T2DM were enrolled. Bone mineral density (BMD) of femoral neck (FN) was measured by the dual-energy X-ray absorptiometry. VF was defined by semi-quantitative method using lateral X-ray films of the thoracic and lumbar spine. The association of BMI quartiles (Q1; ≤21.2 kg/m^2, Q2; 21.3–23.4 kg/m^2, Q3: 23.5–25.8 kg/m^2, Q4; ≤25.9 kg/m^2) with the presence of VF was examined.
Results: According to BMI increase, urinary N-terminal cross-linked telopeptide of type-I collagen (uNTX), a bone resorption marker, was significantly decreased, and FN-BMD, FN-T score, and FN-Z score were significantly increased. Subjects in Q2 quartile had less prevalence of VF (29.4%) compared to others in Q1 (43.1%), Q3 (28.6%), and Q4 (41.5%). Multiple logistic regression analyses adjusted for age, gender, duration of diabetes, HbA1c, estimated glomerular filtration rate, and serum albumin showed that Q1, Q3, and Q4 were significantly associated with an increased VF risk compared to Q2 as a reference [Q1; odds ratio (OR) = 1.91, 95% confidence interval (CI) 1.24–2.95, $p = 0.004$, Q3; OR = 1.65, 95%CI 1.07–2.55, $p = 0.023$, and Q4; OR = 2.18, 95%CI 1.39–3.41, $p < 0.001$]. Moreover, these associations remained significant after additional adjustment for femoral neck T score and uNTX (Figure). When the associations were examined separately in men and women, same tendencies were observed as the results of total subjects although some associations became insignificance because the number of the subjects was reduced.
Conclusion: This is the first study to show that both overweight and underweight were associated with the BMD-independent risk of VF in patients with T2DM. Therefore, body weight modification should be considered to protect diabetes-related bone fragility.



Multiple logistic regression analysis adjusted for age, gender, duration of diabetes, HbA1c, eGFR, albumin, FN-T score, and uNTX was performed with the presence of VF as a dependent variable and BMI quartile as an independent variable.

Diabetes is associated with elevated risks of osteoarthritis, osteoporosis and rheumatoid arthritis

S. Molsted[1], A.-S.D. Bjørkman[1], M.B. Andersen[1], O. Ekholm[2];
[1]Department of Clinical Research, Nordsjaellands University Hospital, Hillerød, [2]National Institute of Public Health, University of Southern Denmark, København, Denmark.

Background and aims: Previous studies have reported elevated prevalence of musculoskeletal pain in patients with type 2 diabetes compared to age and gender matched general populations or non-diabetes populations. Musculoskeletal pain may be barriers to exercise training, which is important in the diabetes treatment. The question remains as to whether the pains are the results of an elevated prevalence of arthritis. The aim of this study was to investigate the association between diabetes (DM) and osteoarthritis (OA), osteoporosis (OP) and rheumatoid arthritis (RA).
Materials and methods: All data were self-reported and provided by the Danish National Health Survey 2013. The exposure variable was DM and the outcome variables included arthritis, back pain, shoulder/neck pain, and physical activity. Multiple logistic regression analyses adjusted for age, gender and BMI were performed.
Results: In total 109,218 individuals (≥40 years old) were included. Diabetes was reported by 9238 (8.5%), aged 65.6 ± 11.0 (mean ± SD) years, males 55.6%, and the BMI was 28.9 ± 5.5 kg/m^2. In those without DM ($n = 99{,}980$) the mean age was 59.2 ± 11.8 years, males 46.7%, and the BMI was 25.8 ± 4.4 kg/m^2. In individuals with DM vs those without DM, OA was reported by 43.5% vs 29.4%, $p < 0.0001$, OP by 6.4% vs 4.8%, $p < 0.0001$, and RA by 15.1% vs 7.6%, $p < 0.0001$, respectively. Back pain was reported by 60.6% vs 51.4%, $p < 0.0001$, and shoulder/neck pain was reported by 56.0% vs 51.5%, $p < 0.0001$, in individuals with and without DM, respectively. Diabetes was associated with OA (OR 1.33 (95% CI 1.25–1.41)), OP (1.29 (1.13–1.46)), and RA (1.71 (1.57–1.85)). Diabetes was associated with back pain 1.27 (1.21–1.34) and shoulder/neck pain 1.29 (1.22–1.36). In a sub analysis of those with DM, being physically active ($n = 6220$ (71.6%)) was inversely associated with back pain 0.65 (0.57–0.73) and shoulder/neck pain 0.76 (0.68–0.86).
Conclusion: Diabetes was associated with significantly elevated odds of having arthritis and musculoskeletal pain. The most frequent arthritis in individuals with DM was OA. The most pronounced association was found between DM and RA. The association between DM and RA in

this study may not be a link between the autoimmune diseases type 1 diabetes and RA as the majority of the individuals with DM may have had type 2 diabetes as result of the exclusion of individuals with an age below 40 years. The link between diabetes and RA may be a result of the chronic inflammation that is present in the two diseases. Another hypothesis of the association between DM and RA could be linked to medication. Whilst steroids are used in the treatment of RA, steroids also increases the risk of the development of type 2 diabetes. Furthermore, pains from RA may also increase the risk of physical inactivity, which is a type 2 diabetes risk factor. The reported pains may have negative impacts on the level of physical activity in individuals with diabetes. Health care professionals should remember to inform patients with DM, that musculoskeletal pain and arthritis not are contra-indications to exercise training. Thus, as exercise training is a recognized element in the treatment of DM and arthritis, it may have positive effects on glycemic control and musculoskeletal pain at the same time.

Age-influenced higher cellular RAGE sensitivity associated with enhanced apoptosis and impaired osteogenic differentiation in type 2 diabetes

M. Phimphilai[1], P. Pothachareon[2], P. Kongtawelert[2];
[1]Internal Medicine, Chiang Mai University, Chiang Mai, [2]Biochemistry, Chiang Mai University, Chiang Mai, Thailand.

Background and aims: Preclinical studies have demonstrated impaired osteoblast differentiation in type 2 diabetes (T2DM), which is related to skeletal accumulation of advanced glycation end products (AGEs). Our previous study also showed impaired osteogenic differentiation in peripheral blood-derived mononuclear cell (PBMC) taken from patients with T2DM, which might be related to higher cellular receptor of AGEs (RAGE) sensitivity and cellular apoptosis. One of the potential mechanisms of that higher RAGE sensitivity is RAGE-dependent NF-κB activation that perpetuates *AGER* (RAGE) expression in a feed-forward manner, entailing NF-κB amplification and cellular apoptosis. This study aimed to further elucidate whether higher cellular RAGE sensitivity enhanced cellular apoptosis and retarded osteogenic differentiation, as well as to elucidate whether higher cellular RAGE sensitivity occurred in NF-κB-dependent manner.
Materials and methods: This cross-sectional study included 40 patients with T2DM and 30 age-matched non-diabetic controls (NDM). Venous blood was collected to measure serum pentosidine and isolate PBMC.
Results: Ninety percent of PBMC-isolated from NDM expressed osteoblast-specific genes including *RUNX2/PPAR*, *ALPL*, *COL1A1* and *BGLAP* (NDM-D) while only 40% of PBMC-derived from T2DM expressed those genes (DM-D). That 40% of cells in DM-D expressed *RUNX2/PPAR*, *ALPL*, *COL1A1* and *BGLAP* higher than that of PBMC-derived from DM with poor osteogenic differentiation (DM-ND) by 3.8, 7.3, 5.9 and 4.3 folds, respectively. Multivariate analysis demonstrated that being diabetes increased the risk for osteogenic differentiation impairment by 13.5 folds (OR 13.5; 95% CI 3.21–77.91; $p < 0.001$). By using age- and pentosidine-matched NDM-D as a reference group, *AGER* and *BAX/BCL2* expression in DM-ND were 6.6 and 5 folds higher than reference while the expression of those genes in DM-D were similar to those of reference, suggesting the existing of higher cellular RAGE sensitivity and apoptosis only in DM-ND. In contrast to the expression of *AGER* and *BAX/BCL2*, the expression of *IκB-α*, *IL1-β* and *TNF-α* was similar in both DM-D and DM-ND comparing to reference, suggesting that *NFκB*-associated genes were not overexpressed in DM-ND. Interestingly, *AGER* expression positively correlated with age ($r = 0.470$, $p = 0.003$). Multivariate analysis demonstrated that age, *AGER* and *BAX/BCL2* expression were factors determining osteogenic differentiation potential of the PBMC-derived from DM.
Conclusion: This study demonstrated *AGER* and *BAX/BCL2* overexpression only in PBMC-isolated from diabetes with poor osteogenic differentiation. Therefore, this study not only demonstrated the existing of higher cellular RAGE sensitivity but also strengthened the linkage between defect in osteogenic differentiation and either higher cellular RAGE sensitivity or apoptosis. That higher RAGE sensitivity increased with age and was conceivably occurred in NFκB-independent manner. Being diabetes was an independent risk factor of osteogenic differentiation impairment while age, higher cellular RAGE sensitivity and apoptosis were factors influencing osteogenic differentiation in type 2 diabetes.

Musculoskeletal impairment in patients with type 2 diabetes and arthritis is associated with beta cell dysfunction

O.P. Zaharia[1,2], D. Pesta[1,2], P. Bobrov[3,2], Y. Kupriyanova[1,2], K. Bódis[1,2], Y. Karusheva[1,2], J.-H. Hwang[1,2], V. Burkart[1,2], K. Müssig[1,4], J. Szendroedi[1,4], M. Roden[1,4];
[1]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University, Düsseldorf, [2]German Center for Diabetes Research (DZD), München-Neuherberg, [3]Institute for Biometrics and Epidemiology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University, Düsseldorf, [4]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Düsseldorf, Germany.

Background and aims: Abnormal insulin secretion may affect the integrity of musculoskeletal structures in patients with type 2 diabetes (T2D). We hypothesized that in patients with T2D and arthritis (T2+A) musculoskeletal impairment is inversely associated with beta-cell function. To this end, we compared patients T2+A with T2D patients without arthritis (T2-A) and healthy humans (control, CTRL).
Materials and methods: Analyses included participants of the German Diabetes Study: T2+A: $n = 12$, age 62 ± 9 years, BMI 34.8 ± 7.2 kg/m^2; T2-A: $n = 22$, 59 ± 13 years, 32.8 ± 6.5 kg/m^2 and CTRL: $n = 18$, 42 ± 16 years, 25.3 ± 4.1 kg/m^2. Arthritis-related symptoms were assessed using validated questionnaires (Western Ontario and McMaster Universities Osteoarthritis Index). Knee extension force (KEF) and grip strength were measured by dynamometry and range of motion (ROM) by goniometry. Participants underwent glucagon-stimulation and intravenous glucose tolerance tests (IVGTT) to assess beta-cell function and hyperinsulinemic-euglycemic clamp tests for whole body insulin sensitivity (WBIS). Statistical analyses were adjusted for age, sex and BMI.
Results: Glycemic control was similar in T2+A and T2-A (HbA1c; 53 ± 6 vs. 51 ± 11 mmol/mol), but impaired compared to CTRL (33 ± 3 mmol/mol, both $p < 0.05$). WBIS was comparable in T2+A and T2-A, but approximately 2.5-fold lower than in CTRL (both $p < 0.05$). Across all groups, WBIS inversely correlated with scores for joint pain, stiffness and functional limitations ($r = -0.62$, $p < 0.05$). Beta-cell function, as assessed from C-peptide rise following glucagon stimulation (ΔC-peptide), was comparable in T2+A and T2-A (2.8 ± 1.3 vs. 3.3 ± 1.4 ng/ml) and lower than in CTRL (3.5 ± 1.6 ng/ml, both $p < 0.05$). ROM in T2+A patients was 8% lower compared to T2-A and 19% lower compared to CTRL (both $p < 0.05$). In T2+A patients, ROM was negatively correlated with total C-peptide secretion in IVGTT ($r = -0.64$, $p < 0.05$). KEF in T2+A patients was 18.7 ± 11.4 kg, 2.5-fold lower than in CTRL (46.9 ± 11.7 kg, $p < 0.05$) and was inversely correlated with ΔC-peptide ($r = -0.99$, $p < 0.05$). Grip strength and KEF were highly correlated in all groups ($p < 0.0001$). Consistently, in T2+A patients, grip strength also negatively correlated with parameters of beta-cell function (ΔC-peptide, $r = -0.62$, $p < 0.05$).

Conclusion: Patients with type 2 diabetes and arthritis exhibit lower muscle strength and range of motion, both of which associate with impaired beta-cell function.

Diabetes can accelerate sarcopenia in the diaphragm

M. Yamamoto[1], M. Takemoto[2], A. Matsuzaki[3], H. Masuyama[4], M. Koshizaka[1], Y. Maezawa[1], K. Yokote[1];
[1]Department of Clinical Cell Biology and Medicine, Chiba University Graduate School of Medicine, Chiba, [2]School of Medicine, International University of Health and Welfare, Department of Diabetes, Metabolism and Endocrinology, Chiba, [3]International University of Health and Welfare, Ichikawa Hospital, Department of Urology, Chiba, [4]International University of Health and Welfare, Ichikawa Hospital, Department of Respiratory Internal Medicine, Chiba, Japan.

Background and aims: The diaphragm is a skeletal muscle that is involved not only in respiration but also in swallowing and lymphatic functions and maintaining posture. Diaphragm dysfunction may lead to a decrease in the activities of daily living, especially in the elderly, and this lower physical activity may in turn negatively affect blood glucose metabolism. Only a few studies have described diaphragm thickness in patients with diabetes. Diaphragm thickness is usually evaluated using ultrasonography (US). However, because evaluation of diaphragm thickness using US is not routinely performed, it is difficult to assess it in a retrospective manner. Therefore, in this study, we developed a new method to evaluate diaphragm thickness in patients with diabetes using computed tomography (CT) and evaluated the correlation between US and CT findings. Then, we evaluated the relationship among diaphragm thickness, age, and blood glucose metabolism.
Materials and methods: We prospectively evaluated the diaphragm thickness of 50 patients with diabetes using both US and CT. The relationship between the US and CT findings were evaluated using Spearman's rank correlation coefficient. Diaphragm thickness using US was evaluated between the 9th and 10th intercostal space in the neutral spine position, and the results were expressed as a sum of left and right measurements. The diaphragm thickness using CT was evaluated in the zone of apposition on contact with the thoracic cavity between the most frontal and dorsal positions, and the results were expressed as a sum of left and right measurements.
Results: The mean diaphragm thickness was 3.35 ± 0.64 mm and 3.73 ± 1.00 mm using US and CT, respectively. The diaphragm thicknesses evaluated using both US and CT were significantly correlated with each other ($r = 0.3809$, $P = 0.0063$). Then, we studied the data of 106 patients with tuberculosis who had undergone CT and had a high morbidity of diabetes. The diaphragm thickness was positively correlated with body weight ($r = 0.2911$, $P = 0.0088$) and negatively with age and HbA1c ($r = -0.4493$, $P < 0.0001$; $r = -0.5507$, $P < 0.0001$, respectively). Moreover, the diaphragm thickness was significantly lesser in patients with diabetes than in those without diabetes.
Conclusion: A thin diaphragm has been found to be related to poor prognosis among patients with acute pneumonia in intensive care units. Our results indicate that diabetes can accelerate sarcopenia of the diaphragm. Because the diaphragm has multiple functions, sarcopenia of the diaphragm in patients with diabetes might affect prognosis.

Sarcopenia is associated with decreased insulin secretion and increased arterial stiffness in Japanese elderly patients with type 2 diabetes

S. Moyama[1,2], Y. Hamamoto[1,2], H. Kuwata[1,3], T. Kurose[2], D. Yabe[2], Y. Seino[2,3];
[1]Center for Metabolism and Clinical Nutrition, Kansai Electric Power Hospital, Osaka, [2]Center for Diabetes Research, Kansai Electric Power Medical Research Institute, Osaka, [3]Center for Diabetes, Endocrinology and Metabolism, Kansai Electric Power Hospital, Osaka, Japan.

Background and aims: It is known that factors such as inflammatory stress and insulin resistance in addition to the aging relate to the loss of skeletal muscle mass and arterial stiffness, but yet the underlying mechanisms are still unknown. Asian patients with type 2 diabetes mellitus (T2DM) are characterized by non-obese, decreased insulin secretion and less-insulin resistance compared to Caucasian, and the pathophysiology of sarcopenia and atherosclerotic disease in Asian T2DM remain unclear. The aim of this study is to examine the relationship between sarcopenia and insulin secretion/sensitivity and arterial stiffness in Japanese elderly patients with T2DM.
Materials and methods: This was a cross-sectional study. The subjects aged 65 years or older hospitalized for diabetes education during the period of 2016 and 2017 ($n = 108$; male = 54.6%, mean age 72.4 ± 5.3 years). The exclusion criteria were: (i) using insulin or steroid; (ii) having overt chronic diabetic complications; (iii) uncontrolled cardiovascular, pulmonary or peripheral artery disease. The grip strength (GS) and body composition (SMI; skeletal muscle index, PBF; percent body fat) were measured using the standard handgrip dynamometer and the bioelectricity impedance measuring device (InBody S10). Based on the diagnostic criteria of the Asian Working Group for Sarcopenia, subjects were divided into 3 groups; sarcopenia group (loss of SMI and GS), pre-sarcopenia group (loss of SMI or GS) and non-sarcopenia group (normal SMI and GS). We evaluated the arterial stiffness by brachial-ankle pulse wave velocity (baPWV) adjusted by age, gender and systolic blood pressure based on the previous report. We examined the relationship between sarcopenia/adjusted baPWV and age, body mass index, SMI, PBF, glycemic control (HbA1c), insulin secretion [the homeostasis model assessment of beta-cell function (HOMA-β), 24h-urinary C-peptide immunoreactivity (CPR), C-peptide index (CPI)] and insulin resistance [the insulin resistance index of HOMA (HOMA-IR)].
Results: The prevalence of sarcopenia (Group S), pre-sarcopenia (Group PS) and the rest (Group NS) were 17.6%, 16.7% and 62.0%, respectively. HbA1c, HOMA-IR and HOMA-β were not significantly different among 3 groups. However, 24h-urinary CPR and CPI in Group S were significant lower than those in Group NS. Furthermore, adjusted baPWV was higher in Group S compared to Group NS. The logistic regression analysis revealed the association of sarcopenia with age and adjusted baPWV.
Conclusion: Our data suggest that sarcopenia was associated with decreased insulin secretion and increased arterial stiffness in Japanese elderly patients with T2DM, suggesting its underlying mechanisms in this population.

Table. Comparisons of insulin resistance, insulin sensitivity and arterial stiffness

	Group S (n=19)	Group PS (n=18)	Group NS (n=56)
HOMA-IR	1.9 ± 1.0	2.7 ± 2.4	2.6 ± 1.5
HOMA-β	27.7 ± 16.5	39.2 ± 29.4	40.9 ± 35.1
24h-urinary CPR (μg)	56.9 ± 29.5**	83.8 ± 72.4	106.2 ± 44.6
C-peptide index	1.1 ± 0.5*	1.6 ± 0.9	1.5 ± 0.7
adjusted baPWV	14.6 ± 14.9*	9.0 ± 17.7	5.5 ± 12.4
Odds ratio (95% confidence interval) for the risk of sarcopenia from the logistic regression analysis			
Age	1.15 (1.03-1.27)		
HbA1c	1.35 (0.87-2.08)		
adjusted baPWV	1.06 (1.02-1.10)		

Values are expressed as mean ± standard deviation, *P < 0.05, **P < 0.01 (vs. Group NS)

Type 2 diabetes, body mass index and cancer mortality: a population-based matched cohort study

N.N. Alam[1], A.K. Wright[2,3], M.K. Rutter[2,4], D. Ashcroft[3], M. Sperrin[5,6], A.G. Renehan[1];
[1]Division of Cancer Sciences, University of Manchester, Manchester, [2]Endocrinology and Gastroenterology, University of Manchester, Manchester, [3]Centre for Pharmacoepidemiology and Drug Safety, University of Manchester, Manchester, [4]Manchester Diabetes Centre, Manchester University NHS Foundation Trust, Manchester, [5]Farr Institute of Health Informatics Research, University of Manchester, Manchester, [6]Centre for Health Informatics, University of Manchester, Manchester, UK.

Background and aims: Compared to people without diabetes, those with type 2 diabetes (T2D) have higher cancer mortality - which is the second commonest cause of death in these individuals. Obesity may explain the link between T2D and cancer mortality. Here, we test the hypotheses that: (i) most cancer deaths are from obesity-related cancers (ORCs); and (ii) among individuals with T2D, there is a positive association between BMI (at diagnosis of T2D) and cancer mortality.
Materials and methods: Using the UK Clinical Practice Research Datalink, an incident cohort of 176,886 patients with T2D was derived and was matched to 852,946 controls without diabetes; all people had linked records for hospitalisation and mortality (1998 to 2015). The primary outcome was cancer morality, sub-divided into 13 ORCs or non-ORCs defined by the International Agency for Research on Cancer (2016). The secondary outcome was all-cause mortality. We derived gender-specific hazard ratios (HRs) and 95% confidence intervals (CIs), using Cox models, to determine: (i) the impact of T2D on risks for ORCs, non-ORCs and mortality relative to controls; and (ii) the associations of BMI with cancer mortality among individuals with T2D.
Results: Compared with the control population, T2D was associated with higher risk of total cancer mortality in men (HR: 1.22, 95% CI: 1.18–1.26) and women (1.31, 1.26–1.37), and a higher risk of death from ORCs in men (1.84, 1.72–1.96) and women (1.47, 1.39–1.56). T2D was associated with increased risk of death from non-ORCs in men (1.06, 1.02–1.11) and women (1.18, 1.12–1.25). Among 145,769 individuals with BMI recorded before T2D diagnosis, BMI was *negatively* related to all-cause mortality (obesity paradox), and we observe an inverse relationship with total cancer mortality. There was no association between BMI and mortality from ORCs combined, though there were strong positive associations for mortality from certain ORCs, such as endometrial cancer (e.g. obese II [BMI 35.0–39.9] versus normal, HR: 4.40, 1.51–12.84).
Conclusion: The findings support the notion that obesity-related mechanisms contribute to the higher cancer mortality in T2D compared to the general population. However, the elevated risk for non-ORC deaths suggests that other pathways are involved. In people with T2D, BMI predicts cancer mortality for only some ORC sub-types; a finding that requires further investigation.

Increased methylglyoxal protein modification in hyperglycaemia induces an inflammatory phenotype in endothelial cells by activation of the unfold protein response

M. Xue, Z. Irshad, A. Ashour, P.J. Thornalley, N. Rabbani;
Clinical Sciences Research Laboratories, University Hospital, Translational Medicine Section, Division of Biomedical Sciences, Warwick Medical School, University of Warwick, Coventry, UK.

Background and aims: Endothelial cells in hyperglycemia develop an inflammatory phenotype characterized by increased inflammatory signalling, expression of adhesion molecules, secretion of inflammatory cytokines and processes supporting atherosclerosis. They accumulate methylglyoxal (MG) and MG-derived advanced glycation endproduct (AGE)-modified proteins in hyperglycemia - suppression of which prevents development of the inflammatory phenotype. Our aim is to identify cell signalling involved in promotion of the inflammatory phenotype by increased cellular MG protein glycation.
Materials and methods: Human aortal endothelial cells (HAECs) were incubated in primary culture with 5 mM (model normoglycemia) or 20 mM glucose (model hyperglycemia) glucose for 6 days. Activities of glyoxalase 1 (Glo1), MG reductase and MG dehydrogenase was assessed by spectrophotometric assay. For Glo1 knockdown studies, HAECs were transfected with GLO1 siRNA or non-targeting control siRNA. Cellular MG and cell protein content of major MG-derived AGE, MG-H1, was determined by stable isotopic dilution analysis liquid chromatography-tandem mass spectrometry. Markers of unfolded protein response (UPR) activation in the cytosol and endoplasmic reticulum (ER), heat shock protein 70 (HSP70) and glucose regulated protein-78 (GRP78), were assayed by Western blotting. Interleukin-8 (IL-8) was assayed by ELISA.
Results: When HAECs were incubated in high glucose concentration, the cellular content of MG was increased 2-fold, compared to low glucose concentration control (2.27 ± 0.21 versus 1.29 ± 0.03 pmol/10^6 cells, $n = 3$; $P < 0.01$). There were concomitant increases in cell protein MG-H1 content and flux of MG-H1 free adduct excretion into the culture medium. Glo1 activity of HAECs was 1862 ± 178 mU/mg protein and decreased 21% in high glucose concentration cultures. MG reductase and MG dehydrogenase activities were undetectable. High glucose concentration increased cellular HSP70 and GRP78 by 37% and 51%, respectively ($P < 0.01$), indicating activation of the UPR in cytosol and ER. Silencing of Glo1 had a similar effect in low glucose concentration controls and potentiated increase of HSP70 and GRP78 in high glucose concentration cultures, indicating that the UPR is activated by increased MG-modified proteins. UPR activation is linked to increased histone-lysine N-methyltransferase SET7 expression and inflammatory signalling, prevented by Glo1 overexpression in high glucose concentration cultures. A marker of this is secretion of IL-8 which was increased in high glucose cultures (28.2 ± 1.2 versus 16.5 ± 2.6 ng/ml, +71%, $P < 0.01$). Increased inflammatory response in high glucose concentration cultures was corrected by treatment with inducer of Glo1 expression, *trans*-resveratrol-hesperetin (tRES-HESP) combination.
Conclusion: Increased MG and MG-derived AGE formation in endothelial cells promotes an inflammatory phenotype through activation of the UPR. The UPR provides surveillance of proteome quality; the challenge of increased MG glycation proteome damage triggers inflammatory signalling. This provides a link between cellular AGE accumulation and vascular inflammation, implicated in vascular complications of diabetes for which tRES-HESP may provide a new approach to therapy.

Higher plasma methylglyoxal levels are associated with incident cardiovascular disease and mortality in individuals with type 2 diabetes

N.M.J. Hanssen[1], J. Westerink[2], J.L.J. Scheijen[1], Y. Van der Graaf[2], C.D.A. Stehouwer[1], C.G. Schalkwijk[1], SMART study group;
[1]Maastricht University, Maastricht, [2]University Medical Center Utrecht, Utrecht, Netherlands.

Background and aims: The dicarbonyl compounds methylglyoxal (MGO), glyoxal (GO) and 3-deoxyglucosone (3-DG) are byproducts of glycolysis and highly reactive. Of these, MGO in particular has been identified as a potential key player in diabetic cardiovascular disease (CVD). Therefore, several compounds that inhibit formation of dicarbonyl compounds are under active investigation. Whether plasma dicarbonyl levels are associated with CVD in type 2 diabetes is unknown.
Materials and methods: We included 1003 individuals (mean age 59.1 ± 10.5 years, 69.3% male, 61.6% prior CVD) with type 2 diabetes from the Second Manifestations of ARTerial disease cohort (SMART). We measured plasma MGO, GO and 3-DG levels at baseline with mass spectrometry. Median follow-up of CVD events was 8.6 years. Data were analyzed with Cox regression, adjusting for sex, age, smoking, systolic blood pressure, total cholesterol, HbA1c, BMI, prior CVD and use of lipid-modifying, and blood pressure- and glucose-lowering medication. Missing data were replaced using a multiple imputation method. Hazard ratios (HR) are expressed per standard deviation Ln-transformed dicarbonyl.
Results: 287 individuals suffered from at least one CVD event ($n = 194$ fatal events, $n = 146$ myocardial infarctions, $n = 72$ strokes); 346 individuals died and 60 individuals underwent an amputation. Higher MGO levels were associated with total (HR: 1.26; 95%CI: 1.11–1.42) and fatal CVD (1.49; 1.30–1.71), and with all-cause mortality (1.25; 1.11–1.40), myocardial infarction (1.22; 1.02–1.45) and amputations (1.36; 1.05–1.76). MGO levels were not apparently associated with stroke (1.03; 0.79–1.35). Higher GO levels were significantly associated with fatal CVD (1.17; 1.00–1.37), but not with other outcomes. 3-DG was not significantly associated with any of the outcomes.
Conclusion: Plasma MGO and GO levels are associated with cardiovascular mortality in individuals with type 2 diabetes. Influencing dicaronyl levels may therefore be a target to reduce CVD in type 2 diabetes.

Carbamylated HDL and all-cause mortality in type 2 diabetes

K. Tan, S. Shiu, J. Lam, A. Lee, Y. Wong;
Medicine, University of Hong Kong, Hong Kong, Hong Kong.

Background and aims: Carbamylation, a process of post-translational modification of proteins, causes alterations in the structural and functional properties of proteins and contributes to the progression of chronic diseases like renal and cardiovascular disorders. Although carbamylation is previously considered only quantitatively important in uremic conditions, recent studies have shown that carbamylation of proteins can take place even in the absence of uremia by an alternative mechanism mediated by myeloperoxidase. We have previously shown that lipoproteins are subjected to carbamylation in diabetes and carbamylated HDL (cHDL) is dysfunctional. We aim to evaluate whether cHDL is associated with all-cause mortality in patients with type 2 diabetes.
Materials and methods: Plasma cHDL concentration was measured in the baseline samples of 990 type 2 diabetic patients followed up in a teaching hospital specialist diabetes clinic by an in-house sandwich ELISA using polyclonal rabbit anti-human cHDL antibody. All-cause mortality was ascertained from hospital electronic medical records.
Results: During a mean follow-up of 14 years, 102 subjects died from all causes. Baseline plasma cHDL levels were significantly higher in subjects with a fatal outcome (45.7 ± 19.6 ug/ml versus 35.6 ± 16.3, $p < 0.01$) whereas there were no significant differences in HDL-cholesterol levels (1.17 ± 0.30 mmol/l versus 1.22 ± 0.33 respectively). Plasma cHDL was a significant independent predictor of all-cause mortality even after adjustment for age, gender, body mass index, duration of diabetes, smoking, systolic blood pressure, HbA1c, LDL-cholesterol, cardiovascular disease and lipid lowering therapy at baseline ($p < 0.001$, odds ratio 1.027, 95% CI 1.016–1.038).
Conclusion: Elevated plasma cHDL was independently associated with all-cause mortality in patients with type 2 diabetes, and cHDL may play a pathological role and contributes to the adverse outcome.

Modulation of diagnostic strategy and treatment resulting from coronary artery calcium score assessment in type 2 diabetic patients

S. Charriere[1,2], C. Marsot[1,3], L. Balaire[1,3], M. Moret[1], S. Villar-Fimbel[1], A. Lecus[1], A. Villard[1], P. Douek[4,3], P. Moulin[1,2];
[1]Endocrinology department, cardiovascular hospital, Hospices Civils de Lyon, Lyon, [2]Lyon 1 university, INSERM U1060, Lyon, [3]Lyon 1 university, Lyon, [4]Radiology department, cardiovascular hospital, Hospices Civils de Lyon, Lyon, France.

Background and aims: New ESC-EASD guidelines propose coronary artery calcium score (CAC) to assess cardiovascular (CV) risk and prefilter functional explorations of silent coronary insufficiency in patients with type 2 diabetes (T2D). The aim of our study was to study the influence of the CAC score assessment on subsequent CV explorations and prescription of CV prevention therapies in a cohort of T2D patients in clinical practice.
Materials and methods: A retrospective monocentric study, including 461 T2D patients aged 45–85 years old in primary prevention, who consecutively had a CAC assessment between in jan-2015 and dec-2016, was conducted in our center. Demographic data, diabetes duration, microvascular complications, all treatments (including oral antidiabetic agents, hypolipidemic drugs, anti-hypertensive drugs, anti-aggregants) and subsequent CV explorations were systematically recorded from the electronic files (exhaustively was above 98%).
Results: Patients were 62.3 ± 8.9 (mean ± SD) years-old, with a 13.6 ± 9.1 years of diabetes duration. They had 2.1 ± 0.8 additional CV risk factors. CAC distribution is CAC 0-9 44%, CAC 1-299 35%, CAC ≥300 21%. In the group CAC ≥300, patients were older, with a longer diabetes duration, had more hypertension and microvascular complications, and were more frequently treated by insulin, statins, aspirin than in the two other groups ($p < 0.05$). In multivariate analysis, the CAC score was significantly associated with age, sex, diabetes duration, HTA and diabetic nephropathy ($p < 0.05$). In the group CAC ≥300, 75% of patients underwent a functional CV test, versus 21.6% in the group CAC 10-299 and 1.4% in the group CAC 0-9 ($p < 0.001$). In the group CAC ≥300, only 24% of patients had a significant myocardial ischemia and only 10% of positive coronary angiography. Whereas the prescription of renin-angiotensin system blocking drugs was not significantly influenced by the CAC score ($p = 0.169$), statins and anti-aggregants prescriptions were markly increased after the CAC from 66% to 92% ($p < 0.001$) for statins and from 38.5 to 99% for anti-aggregants ($p < 0.001$).
Conclusion: In clinical practice, the CAC score assessment can contribute to pre-select patients with an increased probability of for silent coronary insufficiency. However, the screening efficiency remains low in our cohort. Nevertheless, the CAC assessment appears very useful to guide clinicians for selectively intensifying CV prevention treatment such as statin or aspirin. The efficiency of such strategy based on CAC assessment remains to be tested in a randomized clinical trial.
Disclosure: **S. Charriere:** None.

Change in circulating levels of endothelial progenitor cells in young adults with type 1 diabetes: a 2-year follow-up from the observational METRO study

M. Maiorino, G. Bellastella, M. Caputo, P. Cirillo, V. Pernice, M. Longo, K. Esposito;
Department of Medical, Surgical, Neurological, Metabolic, Sciences and Aging, University of Campania "Luigi Vanvitelli", Naples, Italy.

Background and aims: Diabetes mellitus is characterized by a defective mechanisms of vascular repair caused by an impaired regenerative capacity of endothelial progenitor cells (EPCs). EPCs reduction may represent one of the mechanisms linking the elevated vascular risk to diabetes mellitus. The aim of this study was to evaluate the change in circulating levels of EPCs in a population of young type 1 diabetic patients over a period of 2 years. To this purpose we used data of the Management and technology for Transition (METRO) study, a longitudinal observational study of type 1 diabetic patients in transition from the pediatric clinic to the adult diabetes care center.
Materials and methods: The study population included 204 type 1 diabetic patients aged 18–30 years which completed a 2-year follow-up: 84 were treated with continuous subcutaneous insulin infusion (CSII) and the remaining 120 were treated with multiple daily injections of insulin (MDI). Circulating levels of seven EPCs phenotypes were determined by flow cytometry. All clinical and biochemical measurements, including the indexes of glycemic control and glucose variability, lipid profile, and blood pressure, were collected at baseline and after 2 years.
Results: At baseline, both CSII and MDI groups were well matched for demographic and clinical characteristics. Similarly, EPCs cell counts did not differ between the two groups. There was a significant reduction of mean amplitude of glucose excursion (MAGE) (mean difference within group −1.1 ± 2.1 mmol/L, $P < 0.001$), and blood glucose standard deviation (BGSD) (mean difference within group −0.3 ± 1.1 mmol/L, $P < 0.001$) in the CSII group but not in MDI group. All EPCs phenotypes, except CD34+CD133+ cells, increased in CSII group, with significant differences as compared to MDI group regarding CD34+ [mean difference between groups 21, 95%CI (5 to 37)], CD34+KDR+ [13, 95%CI (5 to 20)], and CD34+KDR+CD133+ [6, 95%CI (2 to 10)] cell count. At univariate analysis, change in MAGE and SD negatively correlated with change in EPCs levels in CSII group, but not in MDI group. There was no association between changes in all clinical variables evaluated and EPCs in both groups. Multivariable regression analysis adjusted for age, smoking, BMI, and weight identified the reduction of MAGE as an independent predictor for increasing levels of both circulating CD34+ ($P = 0.020$) and CD34+KDR+ ($P = 0.004$) cell count ($P = 0.022$).
Conclusion: Over a 2 year follow-up, young type 1 diabetic patients treated with insulin pump showed an increase in circulating EPCs levels, which correlated with the improvement in glucose variability.

Pulse wave velocity is an independent risk factor for cardiovascular events, mortality and progression in diabetic kidney disease in patients with type 1 diabetes

T.W. Hansen[1], M. Frimodt-Møller[1], S. Theilade[1], S.A. Winther[1], N. Tofte[1], T.S. Ahluwalia[1], P. Rossing[1,2];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]University of Copenhagen, Copenhagen, Denmark.

Background and aims: The prognostic significance of carotid-femoral pulse wave velocity (cfPWV) - the gold standard measure of arterial stiffness - remains to be determined in patients with type 1 diabetes (T1D). We investigated the predictive value of cfPWV for development of cardiovascular events (CVE), mortality and decline in renal function in T1D.
Materials and methods: Prospective study including 652 patients with T1D and various degrees of albuminuria, ranging from normoalbuminuria (<30 mg/24 h), microalbuminuria (30–299 mg/24) to macroalbuminuria (≥300 mg/24 h). cfPWV was measured at baseline using the SphygmoCor device. Endpoints were traced through National Registers until 31st December 2016 and comprised: a composite CVE (cardiovascular death, non-fatal myocardial infarction, non-fatal stroke and coronary or peripheral arterial interventions); mortality; progression from normo- to micro/macroalbuminuria or from micro-to macroalbuminuria; and decline in estimated glomerular filtration rate (eGFR) ≥30%. Median follow-up ranged between 5.2–6.2 years. Slope estimates of eGFR and urinary albumin excretion rate (UAER) were calculated for a median of 5.5 years. Adjustment included sex, age, mean arterial pressure, LDL cholesterol, smoking, HbA_{1c}, UACR and eGFR at baseline. Hazard ratios (HR) were calculated per 1 standard derivation (SD) increase in cfPWV.
Results: Of the 652 participants, 363 (56%) were male; mean ± SD age was 54 ± 13 years, cfPWV 10.5 ± 3.38 m/s and eGFR 81 ± 26 ml/min/1.73 m^2. Median numbers of eGFR and UACR measures during follow-up were 6.0 and 17.0, respectively. Mean ± SD yearly decline in eGFR was 0.9 ± 2.5 ml/min/year and the median (interquartile range) of yearly change in UACR was −3.5 (−13.0–8.7)%. Higher cfPWV was associated with an increased risk of all endpoints in unadjusted analyses ($p \leq 0.0005$). After adjustment, higher cfPWV remained significantly associated with all endpoints: composite CVE ($n = 81$; HR: 1.31; $p = 0.045$); all-cause mortality ($n = 48$; HR: 1.39; $p = 0.033$); progression from normo- to micro/macroalbuminuria or from micro-to macroalbuminuria ($n = 95$; HR: 1.31; $p = 0.036$); and decline in eGFR ≥30% ($n = 90$; HR: 1.39; $p = 0.015$). Higher cfPWV was associated with a steeper decline in eGFR and a steeper increase in UACR in both unadjusted ($p \leq 0.002$) and adjusted ($p \leq 0.009$) analyses.
Conclusion: In patients with T1D, higher arterial stiffness was consistently associated with at higher risk of CVE, mortality and progression of diabetic kidney disease independent of other risk factors. Measurement of cfPWV may have a promising role in risk stratification in T1D.

The visceral adiposity index predicts cardiovascular events both in cardiovascular disease patients with and in those without diabetes

C.H. Saely[1,2], A. Vonbank[1,2], C. Heinzle[2], D. Zanolin[2], B. Larcher[1,2], A. Mader[1,2], A. Leiherer[2,3], A. Muendlein[2,3], H. Drexel[2,4];
[1]Medicine I, Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [2]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [3]Private University in the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Division of Angiology, Swiss Cardiovascular Center, University Hospital Berne, Berne, Switzerland.

Background and aims: The visceral adiposity index (VAI) is a validated tool for the evaluation of visceral adiposity, using waist circumference, serum triglycerides, age and gender to diagnose this metabolic abnormality. It has recently been associated with cardiovascular risk in primary care patients. No data are available on the association of the VAI with mortality in patients with cardiovascular disease (CVD).
Materials and methods: We therefore prospectively recorded the incidence of cardiovascular events over a mean follow-up period of 7.9 ± 3.1 years in a large cohort of 1858 consecutive patients with established cardiovascular disease (1599 patients with angiographically proven coronary artery disease and 259 patients with sonographically proven peripheral artery disease). The VAI was calculated according to the Amato formula; type 2 diabetes (T2DM) was defined according to the ADA Definition.
Results: At baseline, the VAI was significantly higher in CVD patients with T2DM than in those who did not have diabetes (347 ± 331 vs. 228 ± 200; $p < 0.001$). Prospectively, 585 vascular events occurred; the event rate was significantly higher in patients with T2DM than in those who did

not have diabetes (46.8% vs. 31.3%; $p < 0.001$). After multivariate adjustment, the VAI significantly predicted cardiovascular events in CVD patients with T2DM (standardized adjusted hazard ratio (HR) 1.24 [1.09–1.42]; $p = 0.007$) as well as in those who did not have T2DM (HR 1.18 [1.06–1.31]; $p = 0.014$).

Conclusion: We conclude that the VAI predicts cardiovascular events both in CVD patients with and in those without diabetes.

Effects of variability in blood pressure, glucose and cholesterol concentrations, and body mass index on mortality and cardiovascular outcomes in the general population

S.-H. Lee[1], M. Kim[1], K. Han[1], Y.-M. Park[2], H.-S. Kwon[1], K.-H. Yoon[1]; [1]The Catholic University of Korea, Seoul, Republic of Korea, [2]National Institutes of Health, Research Triangle Park, USA.

Background and aims: Variability in metabolic parameters, such as fasting blood glucose (FBG) and cholesterol concentrations, blood pressure (BP), and body weight can affect health outcomes. We investigated whether variability in these metabolic parameters has additive effects on the risk of cardiovascular outcomes in the general population.

Materials and methods: Using nationally representative data from the Korean National Health Insurance System, 6,748,773 people who were free of diabetes mellitus, hypertension, and dyslipidemia, and who underwent three or more health examinations during 2005–2012 were followed to the end of 2015. Variability in FBG and total cholesterol (TC) concentrations, systolic BP, and body mass index (BMI) was measured using the coefficient of variation (CV), standard deviation (SD), and variability independent of the mean (VIM). High variability was defined as the highest quartile of variability. Participants were classified numerically according to the number of high variability parameters; e.g., a score of 4 indicated high variability in all four metabolic parameters.

Results: There were 54,785 deaths (0.8%), 22,498 cases of stroke (0.3%), and 21,452 myocardial infarctions (MIs) (0.3%) during a median follow-up of 5.5 years. The risk of all-cause mortality, MI, and stroke increased significantly with the number of high-variability metabolic parameters. In the multivariable adjusted model comparing a score of 0 versus 4, the hazard ratios (95% confidence intervals) were 2.19 (2.03–2.36) for all-cause mortality, 1.56 (1.36–1.79) for stroke, and 1.47 (1.26–1.72) for MI. These relationships were independent of the baseline FBG, systolic BP, TC, and BMI values. Similar results were obtained when modeling the variability using the SD and VIM.

Conclusion: High variability of glucose and lipid levels, BP, and BMI was an independent predictor of cardiovascular events. There was a dose-response relationship between the number of high-variability parameters and cardiovascular outcomes.

Vascular effects of raivaroxaban compared to aspirin in type 2 diabetic patients with high cardiovascular risk

F. Pistrosch[1,2], H. Mehling[3], C. Axthelm[4], F. Schaper[5], E. Henkel[2], I. Weigmann[2], K. Kreutzfeld[2], U. von der Osten[6], C. Köhler[2], A.L. Birkenfeld[1,2], M. Hanefeld[2];
[1]Medizinische Klinik 3, Universitätsklinik Carl Gustav Carus, Dresden, [2]GWT TU Dresden GmbH, Dresden, [3]Studienzentrum Charite Berlin, Berlin, [4]Cardiologicum Pirna, Pirna, [5]Diabetesschwerpunktpraxis, Dresden, [6]Bayer Pharma GmbH, Leverkusen, Germany.

Background and aims: Endothelial dysfunction is most likely involved in both initiation and propagation of arteriosclerosis. Recent studies with the direct factor Xa inhibitor Rivaroxaban (RIV) in combination with low dose Aspirin (ASS) demonstrated a greater reduction of major cardiovascular events compared to ASS alone in patients with proven cardiovascular disease. Therefore we asked the question whether treatment with RIV could influence endothelial function in a high risk population for development of arteriosclerosis.

Materials and methods: We conducted a multi-centre prospective randomized open label study in type 2 diabetic patients with high cardiovascular risk and subclinical inflammation to compare the effects of RIV 5 mg b.i.d. vs. ASS 100 mg q.d. on forearm blood flow during reactive hyperemia (measured by forearm occlusion plethysmography), skin blood flow during reactive hyperemia (measured by laser Doppler fluxmetry) and arterial stiffness (measured by pulse wave velocity).

Results: 164 patients (mean age 64.2 ± 7.4 yr, mean diabetes duration 10.9 ± 5.2 yr) were eligible for analysis of the primary objective - the change of forearm blood flow during reactive hyperemia (20 weeks of treatment - baseline measurement) between ASS ($n = 81$) and RIV ($n = 83$) treatment. Baseline post-ischemic forearm blood flow was not different between treatment groups. As shown in figure 1, there was a significant improvement of post-ischemic forearm blood flow after RIV ($p = 0.016$; ANOVA for repeated measures) compared to ASS. Laser Doppler fluxmetry revealed a comparable finding: skin blood flow during reactive hyperemia increased by 11.7 ± 66.9 units after 20 weeks of RIV treatment compared to −8.4 ± 54.1 units after ASS ($p = 0.043$). Pulse wave velocity did not differ between RIV and ASS after 20 weeks of treatment (9.3 ± 1.3 m/s vs. 9.4 ±1.2 m/s). There were more bleeding events with RIV treatment (8 patients) compared to ASS (2 patients).

Conclusion: Treatment with direct factor Xa inhibitor RIV resulted in a significant improvement of forearm blood flow and skin blood flow during reactive hyperemia - a marker of endothelial function. Our findings suggest that besides anticoagulatory potency RIV has pleiotrophic effects on vascular function. However treatment with RIV was associated with an increased risk of bleeding.

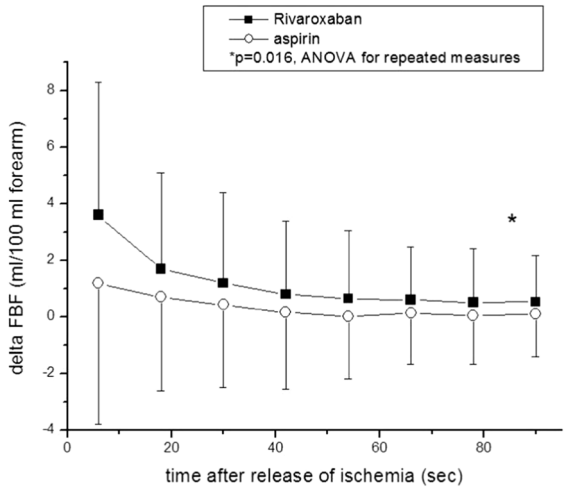

Figure 1: Post-ischemic forearm blood flow: difference between 20weeks of treatment and baseline measurement.

Second-hand-smoking and cardiovascular risk of women with type 2 diabetes

M. Gourine[1], K. Bentadj[2], S. Mostefa-Kara[2], A. Cherrak[3], S. Halimi[4], M. Belhadj[5];
[1]Internal Medicine, Medical School of Oran/University Hospital of Oran, Oran, Algeria, [2]Cardiovascular private hospital Kara, Oran, Algeria, [3]Internal Medicine, Medical School/University Hospital of Oran, Oran, Algeria, [4]University Joseph Fourier, Medical school, Grenoble, France, [5]Internal Medicine, Medical School, Oran, Algeria.

Background and aims: The increased relative risk of cardiovascular disease for women by diabetic status is not fully explained with the own presence of cardiovascular risk factors. As observed with active smoking, second hand smoking is linked to numerous adverse health effects, such as CHD. Nonetheless, it is not systematically looked for and is not included in the cardiovascular risk scores. A better understanding of the role of second hand smoking of women exposed to smoke is needed. So, our study aimed to investigate whether second hand smoking is linked with cardiovascular disease in type 2 diabetes women.
Materials and methods: We conducted a multicentre prospective case control study between January 2014 and June 2015 in outpatient clinic. Women with confirmed type 2 diabetes, aged 30 years or older, not pregnant and without history of neoplasia were included. Cases were defined as those who had a new confirmed diagnosis of cardiovascular disease. Cardiovascular disease was considered in the presence of acute coronary syndrome, silent myocardial infarction displayed at ECG, angina confirmed by a non-invasive test, stroke (ischemic, haemorrhagic or transitory), or peripheric vascular disease, diagnosed for less than 3 months. Controls were free from any cardiovascular disease. All the patients gave their fully oral informed consent for participating. We used the software SPSS.20 for all the statistical analysis.
Results: 714 patients met the inclusion criteria. Active smoking was not widespread among both groups (2 patients in the case group and 4 patients for controls). Finally, analyses were restricted to the 708 non-smokers women: 235 cases and 473 controls. Cases and controls shared similar characteristics on education, occupation and marital status. Patients with a cardiovascular disease were slightly older, had a longer duration of diabetes and a worse glycaemic control than controls. Hypertension, hypercholesterolemia, sedentary lifestyle, family history of CHD, microvascular complications were significantly more frequent in the case group when compared with the control group. Our study also disclosed that 16.9% of women were exposed to second-hand smoking. It was more often encountered in the case group (32.8%) than in the control group. After conditional logistic regression, second hand smoking was significantly associated with cardiovascular disease **(crude OR 4.87; CI95%: 3.22–7.38 ; $p < 10^{-3}$),** even after multiple adjustment **(adjusted OR 4.77; CI95%: 2.84–8.02).** *(Table 1)*
Conclusion: Second-hand smoking is frequent among algerian women with type 2 diabetes. It leads to a greater risk of cardiovascular disease and should be considered for individual risk evaluation in type 2 diabetic women.

Second hand smoking	OR	CI 95%	p-value
Unadjusted	4.87	3.22 – 7.38	$< 10^{-3}$
Adjusted on age	5.30	3.42 – 7.98	$< 10^{-3}$
Adjusted on age and cardiovascular risk factors	4.32	2,68 – 6.97	$< 10^{-3}$
Additional adjustment on HbA1c and duration of diabetes	4.32	2.55 – 6.80	$< 10^{-3}$
Additional adjustment on albuminuria	4.77	2.84 -8.02	$< 10^{-3}$

Cardiovascular risk factors : age, hypertension, sendentary lifestyle, family history of CHD, dyslipidemia, BMI.

Table 1 : association of second hand smoking and risk of cardiovascular disease by conditionnal logistic regression model

Genome-wide association study on coronary artery disease in individuals with type 1 diabetes

N. Sandholm[1,2], E. Valo[1,2], E.H. Dahlström[1,2], C. Forsblom[1,2], V. Harjutsalo[1,3], P.-H. Groop[1,2];
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, [2]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, [3]The Chronic Disease Prevention Unit, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: Cardiovascular deaths are the most common cause of premature mortality in type 1 diabetes (T1D), and the risk of cardiovascular disease (CVD) and mortality rates increase steeply in parallel with diabetic kidney disease. While there is evidence that genetic factors for CVD in the general population also affect individuals with diabetes, there are also genetic loci affecting CVD and CVD mortality particularly in individuals with diabetes. This study aims to assess the role of known genetic factors, and to identify additional genetic factors affecting the risk of coronary artery disease (CAD) in individuals with T1D.
Materials and methods: The study comprised 4824 Finnish individuals with T1D from the Finnish Diabetic Nephropathy (FinnDiane) study and the National Institute of Health and Welfare T1D studies with genome-wide genotyping data, and data on CAD available. CAD events included myocardial infarction, coronary bypass surgery or coronary balloon angioplasty. Controls were limited to those without hard CAD events, and with age ≥35 years and diabetes duration ≥15 years. Genotyping was performed with Illumina HumanCoreExome chips at the University of Virginia. After quality control, additional genotypes were imputed with Minimac3 using the 1000 Genomes Phase 3 reference panel. The genome-wide association study (GWAS) on CAD was analysed with score test using RVTESTS software, adjusted for sex, age, kinship matrix and genotyping batch. Data included 8,746,446 variants with minor allele frequency (MAF) ≥0.01 and imputation quality (R^2) ≥0.6.
Results: Data included 936 cases with CAD. Mean age at the time of first CAD event was 52.4 years (SD 10.2 years, range 20–90 years), and

duration of T1D was 38.1 years (SD 10.4, range 4–64 years). A total of 44% of CAD cases were women, a much higher proportion than in the general population. GWAS revealed a locus with genome-wide significant association (p value $<5 \times 10^{-8}$) near the defensin beta 127 (*DEFB127*) gene, with a MAF of 0.02 and an OR of 3.49 [95% CI 2.24–5.44]. Variants in 26 loci reached a suggestive p value $<10^{-5}$, including rs1537372 in the established 9p21 locus for CVD in the general population (OR = 1.30 [95% CI 1.17–1.45], $p = 1.54 \times 10^{-6}$); association in 9p21 reached genome-wide significance when the model was adjusted for the year of diabetes diagnosis. Among the previously identified loci, also rs2681472 in *ATP2B1* was nominally associated with CAD (p = 0.036), even though not withstanding correction for multiple testing.

Conclusion: We identified a novel susceptibility locus near *DEFB127* for CAD in individuals with T1D, along with 25 other suggestive loci that require further validation.

Type 1 diabetes: defining the best cut-off points of arterial stiffness for predicting cardiovascular risk according to the Steno Type 1 Risk Engine

G. Llaurado[1,2], A. Cano[3], L. Albert[3], I. Mazarico[3], M. González-Sastre[4], J. Vendrell[5,2], J.-M. González-Clemente[3,2];
[1]Department of Endocrinology and Nutrition, Hospital del Mar, Institut Hospital del Mar d'Investigacions Mèdiques (IMIM), Barcelona, [2]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Instituto de Salud Carlos III, Madrid, [3]Department of Endocrinology and Nutrition, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, [4]Ophthalmology Department, Parc Taulí Hospital Universitari, Institut d'Investigació i Innovació Parc Taulí I3PT, Universitat Autònoma de Barcelona, Sabadell, [5]Endocrinology and Nutrition Section, Hospital Universitari Joan XXIII, Institut d'Investigació Sanitària Pere Virgili (IISPV), Universitat Rovira i Virgili, Tarragona, Spain.

Background and aims: Cardiovascular disease (CVD) is the main cause of death in type 1 diabetes mellitus (T1DM). Recently, a specific score risk has been developed for predicting CVD: the Steno Type 1 Risk Engine. However, it includes 11 variables, which makes its clinical use somewhat cumbersome. The aim of our study was to assess the relationship between the Steno Type 1 Risk Engine and preclinical atherosclerosis measured as arterial stiffness (AS) in order to identify potential cut-off points of interest in clinical practice.

Materials and methods: One-hundred and seventy-nine patients with T1DM (18–65 years old) without established CVD were consecutively evaluated for: 1) clinical and anthropometric data (including classical cardiovascular risk factors), 2) microvascular complications and 3) AS measured by aortic pulse-wave velocity (aPWV) assessed by applanation tonometry (gold standard). The Steno Type 1 Risk Engine was used to estimate 10-year cardiovascular risk and patients were divided in 3 groups: low (<10%; $n = 105$); moderate (10–20%; $n = 53$) and high risk (≥20%; $n = 21$).

Results: 179 patients were included (50.8% men, age: 41.2 ± 13.1 yrs, duration of diabetes 16 (12–23) yrs). As compared to the low and moderate-risk groups, patients in the high-risk group were older (32.5 ± 8.3, 50.8 ± 6.0 and 60.7 ± 6.6 yrs; p for trend <0.001), had higher prevalence of hypertension (14.3%, 37.7% and 66.7%; p for trend <0.001) and dyslipidaemia (36.4%, 77.8% and 89.5%; p for trend <0.001). They also had higher BMI (24.3 ± 3.2, 26.6 ± 3.8 and 27.8 ± 4.4 kg/m^2; p for trend <0.001), higher insulin resistance (eGDR: 9.2 ± 1.8, 7.0 ± 2.1 and 5.5 ± 1.8 mg kg^{-1} min^{-1}; p for trend <0.001), worse glycaemic control (HbA1c: 7.6%, 8.0% and 8.5%; p for trend <0.001) and higher prevalence of microvascular complications (27.2%, 43.4% and 81.0%; p for trend <0.001). aPWV increased in parallel with estimated cardiovascular risk (6.4 ± 1.0, 8.4 ± 1.3 and 10.3 ± 2.6 m/s; $p < 0.001$; $r = 0.777$; $p < 0.001$). The C-statistic of aPWV was 0.914 (95% CI: 0.873–0.950) for predicting moderate-high risk and 0.879 (95% CI: 0.809–0.948) for high risk according to the Steno Type 1 Risk Engine. The best cut-off points of aPWV were 7.3 m/s (Sensitivity (Se): 86% and Specificity (Sp): 83%) and 8.7 m/s (Se: 76% and Sp: 86%) for moderate-high and high-risk, respectively.

Conclusion: Arterial stiffness was highly correlated with the scores obtained from Steno Type 1 Risk Engine. We have identified two cut-off points of arterial stiffness that can clearly discriminate moderate-high and high-risk T1DM patients, which could be of great interest for clinical practice.

A novel targeted approach for the reduction of vascular events in diabetes

M. Almutairi[1], C. Tiede[2], K. Kearney[1], N. Pechlivani[1], F. Hawkins[1], N. Oxley[1], D. Tomlinson[2], R. Ajjan[1];
[1]Division of Cardiovascular & Diabetes Research, Leeds Institute of Cardiovascular and Metabolic Medicine (LICAMM), University of Leeds, Leeds, [2]School of Molecular and Cellular Biology, Astbury Building, University of Leeds, Leeds, UK.

Background and aims: Cardiovascular disease remains the main cause of mortality in patients with diabetes and an enhanced thrombotic environment is one of the mechanisms implicated. The increased incorporation of antifibrinolytic proteins into diabetes clots is contributes for hypofibrinolysis, a key abnormality precipitating vascular thrombosis in this condition. Our aim was to modulate incorporation of the potent antifibrinolytic protein, plasmin inhibitor (PI), into diabetes clots using a novel technology that involves small conformational proteins termed Affimers.

Materials and methods: A large library of random Affimers ($n = 3 \times 10^{10}$) was screened for PI binding using phage display. After multiple panning rounds, high affinity PI-binding Affimers were isolated and tested for modulation of fibrin clot lysis using *in vitro* and *ex vivo* techniques. Validated turbidimetric assays were employed to assess fibrinolysis, applying purified proteins, plasma and whole blood systems. Laser scanning confocal and electron microscopy were used to ensure integrity of the fibrin clots.

Results: A total of 167 high affinity PI-binding Affimers were isolated. Of these, 22 had distinct sequences and were subsequently subcloned and expressed in large quantities in *E. coli*. Using purified proteins, one Affimer (termed A68) consistently inhibited PI-induced prolongation of clot lysis at concentrations as low as 0.5 μg/ml. When tested in individual plasma samples form 12 patients with type 1 diabetes, the addition of A68 resulted in reduced clot lysis time from 549 ± 33 to 408 ± 23 seconds (26% reduction, $p < 0.01$). Similar results were obtained when A68 was tested using plasma from 12 patients with type 2 diabetes. Moreover, when tested in whole blood, A68 reduced clot lysis time from 2224 ± 113 seconds in control samples to 1436 ± 68 seconds after the addition of A68 (35% reduction in lysis time, $p < 0.01$). A68 had no significant effect on fibrin clot ultrastructure as assessed by confocal.

Conclusion: We describe, for the first time, the use of Affimer technology to modulate the hypofibrinolytic environment in diabetes. This targeted

approach has the potential to ameliorate the thrombotic milieu in diabetes without increasing the risk of bleeding. Future *in vivo* studies are warranted to assess the role of Affimers in preventing vascular thrombosis.

Negative carotid artery remodelling in early type 2 diabetes and increased carotid plaque vulnerability in obesity as assessed by magnetic resonance imaging

E. Laugesen[1], P. Høyem[1], S. Thrysøe[1], E. Hansen[1], A. Mikkelsen[1,2], B. Kerwin[3], P.L. Poulsen[1], T.K. Hansen[1], W.Y. Kim[1];
[1]Aarhus University Hospital, Aarhus, Denmark, [2]Department of Procurement and Clinical Engineering, Aarhus, Denmark, [3]University of Washington, Seattle, USA.

Background and aims: Ischemic stroke from carotid plaque embolism remains a major cause of morbidity in type 2 diabetes (T2DM) patients. However, the effect of early T2DM and obesity on carotid remodeling and plaque burden remains elusive. We assessed carotid remodeling and plaque composition by carotid magnetic resonance imaging (MRI) in short duration T2DM patients compared to a sex- and age-matched control group.
Materials and methods: 100 T2DM patients (duration <5 years) and 100 sex- and age-matched controls underwent bilateral carotid artery MRI in a 1.5 T MRI scanner. Plaque burden was quantified by normalized wall index, maximum wall thickness, maximum wall area, and minimum lumen size. Plaque morphology was quantified by calcified plaque volume, necrotic core volume, and loose matrix volume.
Results: MRI data were available for 149 and 177 carotid arteries from T2DM patients and controls, respectively. Adjusted for age and sex, T2DM was associated with increased plaque burden indicated by a higher normalized wall index (ratio 1.03 (95% CI 1.002; 1.06), $p = 0.03$), and negative remodeling indicated by a lower minimum lumen area (ratio 0.81 (0.74; 0.89), $p < 0.001$), and lower maximum wall area (ratio 0.94 (0.88; 1.00), $p = 0.048$) compared to controls. In both T2DM and controls, BMI ≥30 kg/m^2 was associated with an 80% increase in total calcified plaque volume, and a 44% increase in necrotic core volume compared to BMI <25 kg/m^2.
Conclusion: Short duration T2DM was associated with increased carotid plaque burden and negative remodeling. Obesity was associated with increased carotid artery necrotic core volume and calcification independently of diabetes status.

Risk of peripheral artery disease according to diabetic nephropathy and severe diabetic retinopathy in patients with type 1 diabetes

M. Kallio[1,2], V. Harjutsalo[2,3], C. Forsblom[2,4], P.-H. Groop[2,4], FinnDiane Study Group;
[1]Abdominal Center, Vascular Surgery, University of Helsinki and Helsinki University Hospital, Helsinki, [2]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, [3]Chronic Disease Prevention Unit, National Institute for Health and Welfare, Helsinki, [4]Abdominal Center, Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland.

Background and aims: Peripheral artery disease (PAD) is associated with increased premature mortality. Critical limb ischemia (CLI) is a severe form of PAD. Without revascularization the condition leads to lower limb amputation in 50% of patients. Most patients undergo revascularization and/or lower limb amputation. The aim of this study was to assess the impact of diabetic nephropathy (DN) and severe diabetic retinopathy (SDR) on the risk of CLI in patients with type I diabetes.
Materials and methods: The study comprised 4694 patients with type 1 diabetes who participated in the Finnish Diabetic Nephropathy Study (FinnDiane) before the year 2010. As ankle-brachial index (ABI) measurement alone or claudication are unreliable methods to detect PAD, especially in patients with diabetes who often have neuropathy attenuating the symptoms, we utilized clinical events of CLI as a sign of PAD. Therefore, PAD criteria were formed combining clinical data on ABI and toe pressure measurements, pulse palpation and radiological imaging data. Data on amputations and revascularizations were first identified from the standardized questionnaires at baseline as well as from the Finnish Care Register for Health Care. Thereafter, medical records were thoroughly reviewed to ascertain each event. DN status was categorized as having normo-, micro- or macroalbuminuria or end stage renal disease (ESRD). SDR was defined as a history of laser photocoagulation. Risk of PAD was evaluated using multivariable logistic regression analysis in a cross-sectional manner.
Results: There were 104 PAD events at the baseline visit with median duration of diabetes of 20.8 (IQR 11.3–30.5) years. The risk of PAD increased with each stage of DN. After adjustment for sex, age at onset of diabetes, duration of diabetes, HbA1c, HDL cholesterol, systolic blood pressure and history of smoking the risk in patients with ESRD was 14.9-fold (95% CI 6.4–34.6) compared with patients with normoalbuminuria. The odds ratio (OR) for patients with micro- and macroalbuminuria was 1.2 (0.4–3.8) and 3.2 (1.3–7.7), respectively. The risk of PAD was markedly increased with also in patients with SDR, OR = 3.0 (1.2–7.8).
Conclusion: We showed that in patients with type 1 diabetes DN is strongly associated with a higher risk of PAD. Also SDR independently from DN increased the risk of PAD. Early detection and treatment, as well as specific interventions, targeting changes both in the kidney and the retina could possibly lead to a decrease in the risk of PAD in patients type 1 diabetes.

Long-term role of peripheral angioplasty in diabetes patients with peripheral arterial disease

Z. Yan, Y. Li, L. Chang, Z. Zhao, H. He, H. Zhang, Z. Zhu;
Department of Hypertension and Endocrinology, Daping Hospital, Third Military Medical University, Center for Hypertension and Metabolic Diseases, Chongqing, China.

Background and aims: This study is aimed to evaluate the influence of peripheral angioplasty (PTA) on the long-term prognosis of diabetic patients with peripheral arterial diseases.
Materials and methods: A total of 312 diabetes patients with peripheral arterial diseases were given PTA treatment (lower extremity arterial balloon dilatation and/or stent implantation) from March 2009 to September 2017 in Daping hospital, Chongqing. 221 were followed up until September 2017. Their ankle-brachial index (ABI), blood pressure, blood glucose, glycosylated hemoglobin, blood lipids, serum creatinine, and high-sensitivity C-reactive protein (hsCRP) were measured in the 1, 3, 6 months, and every year after PTA treatment.
Results: The mean follow-up was 3.53 ± 1.12 years. The average ABI was 0.64 ± 0.21 before PTA treatment, and it was significantly increased on the 1, 3, 6 months and 1 year after PTA treatment (0.86 ± 0.19, 0.89 ± 0.14, 0.82 ± 0.20, 0.79 ± 0.22; $P < 0.05$ or 0.01). Among them, 15 (6.8%) patients received major amputations and PTA treatment were given in the

contralateral limb of 21 (9.5%) patients. Restenosis occurred in 36 (16.3%) patients and 14 (6.3%) of them suffered restenosis in 1 year after PTA treatment, higher than other time points ($P = 0.0127$). Logistic regression analysis showed that hs-CRP was an independent risk factor for restenosis (OR = 1.890, 95%CI: 1.011~3.902, $P = 0.031$).

Conclusion: PTA treatment can effectively improve blood supply of lower limb in diabetic patients with peripheral arterial disease. Lower extremity arterial restenosis most probably occurred in 1 year after PTA treatment. High hs-CRP level can predict the higher risk of lower extremity arterial restenosis.

PS 108 Adverse cardiovascular disease events

1134

Hospitalisations for major adverse cardiovascular events in patients with diabetes from 1989 to 2015 in the north of Portugal

C. Neves[1], J. Neves[2], F. Lopes[3], S. Castro Oliveira[2], M. Pereira[2], A. Oliveira[2], D. Carvalho[1];

[1]Department of Endocrinology, Diabetes and Metabolism, Centro Hospitalar São João; Institute for Research and Innovation in Health Sciences; Faculty of Medicine University of Porto, Porto, [2]Department of Endocrinology, Diabetes and Metabolism, Centro Hospitalar São João; Faculty of Medicine University of Porto, Porto, [3]Department of Codification, Centro Hospitalar São João, Porto, Portugal.

Background and aims: Diabetes is an important risk factor for major adverse cardiovascular events (MACE). Although the increased risk for MACE is well known, the variation over time of hospitalizations for MACE in patients with diabetes remains incompletely characterized. Our aim was to evaluate the proportion of hospitalizations due to MACE in a central hospital in the North of Portugal, comparing the periods between 1989–1998, 1999–2008 and 2009 and 2015.

Materials and methods: We evaluated retrospectively the hospitalizations due to MACE including stroke or transient ischemic attack (TIA), acute coronary syndrome (ACS) and heart failure from the Hospital Coding Centre. We have studied the distribution by age, causes and duration of admissions. Statistical analysis was performed with Student's t-test and chi-squared test. A two-tailed p value <0.05 was considered significant.

Results: A total of 1033842 hospitalizations occurred during the study period. We observed a significant decrease of the proportion of MACE hospitalizations over the three periods of evaluation, both in non-diabetic patients (23.5% in 1989–1998, 13.5% in 1999–2008 and 9.7% in 2009–2015, $p < 0.001$) and in patients with diabetes (29.9% in 1989–1998, 18.9% in 1999–2008 and 13.4% in 2009–2015, $p < 0.001$). The proportion of MACE admissions among all admissions remained significantly higher in patients with diabetes over the three periods (29.9% vs 23.5% in 1989–1998, 18.9% vs 13.5% in 1999–2008 and 13.4% vs 9.7% in 2009–2015, $p < 0.001$ for each period). Patients with diabetes were older that patients without diabetes in all periods (1989–1998: 67.3 ± 6.1 vs 65.3 ± 9.7 years, 1999–2008: 69.6 ± 8.5 vs 67.2 ± 1.2 years, 2009–2015: 71.6 ± 10.8 vs 69.4 ± 15.3 years; $p < 0.001$ for each period). There was a significant decrease in time of MACE hospitalization over the three periods, although it remained significantly higher among patients with diabetes over the period (1989–1998: 11.8 ± 9.2 vs 11.0 ± 9.1; 1999–2008: 10.2 ± 4.9 vs 9.3 ± 6.0; 2009–2015: 9.9 ± 9.6 vs 8.8 ± 8.5 days; $p < 0.001$ for each period). Patients with diabetes presented a higher proportion of stroke or AIT (1989–1998: 12.1% vs 8.1%; 1999–2008: 5.2% vs 4.0%; 2009–2015: 3.9% vs 3.5%; $p < 0.001$ for each period), acute coronary syndrome (1989–1998: 10.8% vs 9.5%; 1999–2008: 9.1% vs 6.6%; 2009–2015: 5.3% vs 3.8%, $p < 0.001$ for each period) and heart failure (1989–1998: 8.2% vs 6.1%; 1999–2008: 5.0% vs 3.2%; 2009–2015: 4.2% vs 2.4%, $p < 0.001$ for each period) compared with patients without diabetes in all three periods.

Conclusion: We observed a significant decrease of MACE hospitalization among patients with diabetes from 1989 until 2015 in a central hospital in the North of Portugal. However, MACE admissions remain higher in patients with diabetes comparing with patients without diabetes. The higher incidence of MACE in patients with diabetes highlights the importance of improving the prevention and treatment of cardiovascular disease in this population.

The maximum glucose peak during an oral glucose tolerance test is associated with greater arterial stiffness: the Maastricht Study

Y.D. Foreman[1,2], M.C.G. Brouwers[1,2], S.J.P. Eussen[2,3], M.M.J. van Greevenbroek[1,2], R.M.A. Henry[1,2], C.J.H. van der Kallen[1,2], K.D. Reesink[2,4], M.T. Schram[1,2], N.C. Schaper[2,5], C.D.A. Stehouwer[1,2];

[1]Dept. of Internal Medicine, Maastricht University Medical Centre +, Maastricht, [2]Cardiovascular Research Institute Maastricht (CARIM), Maastricht University, Maastricht, [3]Dept. of Epidemiology, Maastricht University, Maastricht, [4]Dept. of Biomedical Engineering, Maastricht University, Maastricht, [5]School for Public Health and Primary Care (CAPHRI), Maastricht University, Maastricht, Netherlands.

Background and aims: The 75-gram OGTT has traditionally been used for the formal diagnosis of (pre)diabetes. Recently, the maximum glucose peak during an OGTT has become a topic of interest, as it was found to be associated with an adverse cardiovascular risk profile. In the present study, we aimed to investigate the association between the maximum glucose peak during an OGTT and arterial stiffness, independent of glucose metabolism status (GMS), i.e. normal glucose metabolism, prediabetes and type 2 diabetes (T2D).
Materials and methods: Cross-sectional data from The Maastricht Study, an observational population-based cohort study enriched with individuals with T2D, was used. All participants with a complete 7-point OGTT were included for analysis ($N = 2{,}804$, aged 59.8 ± 8.2 years, 51.8% men). Maximum OGTT Glucose peak Increase from Baseline (MOGIB; mmol/l) was calculated as the highest glucose value during the OGTT minus the baseline glucose value. Carotid femoral pulse wave velocity (cf-PWV) and carotid distensibility coefficient (carDC) were used as measures of arterial stiffness. The associations of MOGIB with cf-PWV and carDC were investigated via multiple linear regression with stepwise adjustment for age, sex, GMS (or alternatively for HbA_{1c}), BMI, smoking status, mean arterial pressure, physical activity, lipid profile, use of lipid-modifying and antihypertensive medication, prior cardiovascular disease and retinopathy, estimated GFR, and urinary albumin excretion.
Results: In age- and sex-adjusted analyses, MOGIB was statistically significantly associated with cf-PWV (regression coefficient (β) 0.106 [95% confidence interval: 0.077; 0.134] m/s, $p < 0.001$), and carDC (−0.185 [−0.257; −0.114] 10^{-3}/kPa, $p < 0.001$). These associations remained statistically significant after additional adjustment for GMS or HbA_{1c}. The association between MOGIB and cf-PWV attenuated after full adjustment: β was 0.036 [−0.006; 0.078] m/s ($p = 0.091$) in the full model that included GMS, and 0.070 [0.034; 0.107] m/s ($p < 0.001$) in the full model that included HbA_{1c}. The association between MOGIB and cf-PWV was stronger with increasing age (p for interaction with age = 0.025). The association between MOGIB and carDC, however, was not statistically significant after full adjustment. The β was −0.082 [−0.185; 0.022] 10^{-3}/kPa ($p = 0.123$) and −0.026 [−0.117; 0.065] 10^{-3}/kPa ($p = 0.575$) in the full models that included GMS and HbA_{1c}, respectively.
Conclusion: These data show that the maximum glucose peak during an OGTT is independently associated with greater aortic stiffness (cf-PWV), which is known to be an independent risk factor for cardiovascular disease, but not with carDC. Further studies are needed to elucidate how these findings translate to glucose fluctuations in daily practice.

Quantitave myocardial blush evaluation correlates with infarct size and systolic left ventricle function in patients with type 2 diabetes and stemi

J. Gumprecht[1], K. Nabrdalik[1], H. Kwiendacz[1], E. Radzik[2], K. Pigoń[2], M. Basiak[2], E. Nowalany-Kozielska[2], A. Tomasik[2];
[1]Department of Internal Disease, Diabetology and Nephrology, School of Medicine with the Division of Dentistry in Zabrze, Medical University of Silesia, Katowice, Zabrze, [2]Second Department of Cardiology, School of Medicine with the Division of Dentistry in Zabrze, Medical University of Silesia, Katowice, Zabrze, Poland.

Background and aims: HORIZONS AMI and CADILLAC studies provide conflicting results regarding validity of the visual assessment of myocardial blush grade (MBG) and TIMI myocardial perfusion grade (TMPG) in diabetic STEMI patients. Cardiac magnetic resonance studies, performed 48 hours up to 7 days post myocardial infarction episode, indicate clearly that diabetic patients present higher volume of oedema and microvascular obstruction. Since patients with type 2 diabetes (T2DM) are at high risk of worse prognosis following STEMI it is important to find the methods identifying patients who are at risk of having a larger infarct size and reduce LVEF early enough. The aim of the study was to evaluate the association between myocardial perfusion and infarct size as well as left ventricular function among STEMI patients with T2DM who were treated with primary percutaneous intervention (pPCI).
Materials and methods: A total of 104 consecutive STEMI patients with T2DM treated with pPCI were enrolled into this observational study. Myocardial perfusion was reassessed with the Quantitative Myocardial Blush Evaluator (QuBE). For infarct size assessment, we utilized peak activity of creatine kinase and troponin T concentration area under the curve (AUC) measured on hospital admission, at 12, 24, and 72 hours following STEMI. Echocardiographic evaluation of left ventricle systolic function was performed on the day of hospital discharge. Forward stepwise linear regression modeling has been used for assessment of relation between angiographic data and enzymatic infarct size and left ventricle function.
Results: Patients with T2DM and a QuBE score below the median value (9.0 arb. units) had significantly inferior procedural outcome than those with a QuBE score equal to or above the median value: epicardial flow in infarct-related artery was significantly slower (higher number of corrected TIMI frame count cTFC; $p = 0.004$) with a significantly higher peak CK-MB value ($p = 0.027$), troponin T AUC ($p = 0.01$) and worse EF ($p = 0.039$).
Conclusion: Diminished myocardial perfusion is associated with significantly larger infarct size and lower left ventricle systolic function among patients with T2DM. QuBE seems to be operator independent reliable predictor of infarct size and reduced left ventricle function in this group of patients.

Table 1. Demographic and clinical characteristics of patients divided according to median QuBE value of < 9 or ≥ 9.

Differences in external validity of SGLT2-I cardiovascular outcome trials in general type 2 diabetes populations: a large observational study in European countries

K.I. Birkeland[1], J. Bodegard[2], A. Norhammar[3], J.G. Kuiper[4], W. Beekman-Hendriks[5], M. Thuresson[6], A. Kooy[7];
[1]Oslo University Hospital, Oslo, Nydalen, Norway, [2]AstraZeneca Nordic-Baltic, Södertälje, Sweden, [3]Karolinska Institutet, Stockholm,

Sweden, [4]PHARMO Institute for Drug Outcomes Research, Utrecht, Netherlands, [5]AstraZeneca, Den Haag, Netherlands, [6]Statisticon AB, Uppsala, Sweden, [7]University Medical Center and Bethesda Diabetes Research Center, Groningen, Netherlands.

Background and aims: Strict enrolment criteria for clinical trial patients assessing cardiovascular (CV) safety and efficacy of antihyperglycaemic drugs in type 2 diabetes (T2D) may not be representative for the general T2D population resulting in low external validity of the results. Recent cardiovascular outcome trials (CVOTs) have shown paradigm shifting results in the benefit of sodium-glucose cotransporter-2 inhibitors (SGLT-2is), and further studies will report soon (Table). Study criteria vary substantially between the CVOTs, and may affect the representativeness of a study population for the general T2D population. The aim of this analysis was to evaluate this representativeness in four SGLT-2i CVOTs collected from the general T2D populations in European countries.
Materials and methods: T2D patients in 2015 were included from the Netherlands (the PHARMO Database Network) and mandatory full-population registries in Norway and Sweden. Given the available data in each country, key inclusion and exclusion criteria were only defined by diagnoses, procedures, and drug treatment to facilitate comparability between countries. External validity was defined by dividing number of patients filling the CVOT's key enrolment criteria by the total enrolled T2D-population for the respective country.
Results: In total, a T2D population of 564,351 patients was identified in the Netherlands ($n = 36,213$), Norway, ($n = 149,782$), and Sweden ($n = 378,356$). All three populations showed a CV disease baseline prevalence of 25–35% and high proportions using cardiovascular (CV) preventive drugs. The CVOT patients were slightly younger compared to the general T2D population and had higher CV prevalence at baseline of 41%, 66% and 99% for DECLARE, CANVAS and EMPA-REG respectively. DECLARE had a more than 1.7-fold higher external validity compared to CANVAS and more than 3-fold compared to EMPA-REG or VERTIS. Variation in the representativeness between countries may be partly explained by the differences in age, CV disease prevalence and CV preventive drugs in the T2D populations, all being important to the key enrolment criteria.
Conclusion: In large T2D populations from European countries, consistent patterns of external validity for all studies were found despite some differences in patient characteristics. DECLARE had the highest external validity, followed by CANVAS, EMPA-REG, and VERTIS, indicating that DECLARE examines patients most representative of the general T2D patient in the studied countries.

	The Netherlands	Norway	Sweden
Baseline general T2D population

The REMOVAL trial: metformin reduces progression of mean carotid intima-media thickness (cIMT) in never smokers with type 1 diabetes

J.R. Petrie[1], N. Chaturvedi[2], I. Ford[1], M.C.G. Brouwers[3], N. Greenlaw[1], I. Hramiak[4], A.D. Hughes[2], A.J. Jenkins[5], B.E.K. Klein[6], R. Klein[6], P. Rossing[7], C.D.A. Stehouwer[3], N. Sattar[1], H.M. Colhoun[8], for the REMOVAL Study Group;
[1]University of Glasgow, Glasgow, UK, [2]University College London, London, UK, [3]University of Maastricht, Maastricht, Netherlands, [4]St Joseph's Health Care, London, Canada, [5]University of Sydney, Sydney, Australia, [6]University of Wisconsin, Madison, USA, [7]Steno Diabetes Center, Gentofte, Denmark, [8]University of Edinburgh, Edinburgh, UK.

Background and aims: In REMOVAL, metformin reduced the rate of progression of the tertiary carotid outcome (averaged maximal cIMT) over three years in middle-aged adults with longstanding type 1 diabetes but did not significantly reduce progression of the primary outcome (averaged mean cIMT). We now report subgroup analyses for the primary outcome (the only subgroup analyses that were pre-specified).
Materials and methods: 3-way interaction terms with treatment and time were calculated for the following baseline variables: age, duration of diabetes, baseline HbA1c, BMI, LDL cholesterol, systolic BP (all by above or below median), baseline cIMT (by tertiles), sex (male or female), smoking (ever or never), insulin pump user (yes or no) and history of cardiovascular disease (present or absent).
Results: The 3-way interaction term was significant for only one of the 11 pre-specified subgroup analyses: smoking status ($p = 0{\cdot}0373$). Of 428 randomised participants, [(mean ± SD) age 55 ± 8·5 years, HbA1c 8·0 ± 0·82%, BMI 28·4 ± 4·3 kg/m², 59% male, duration of diabetes 34 ± 10·8 years, 12% with a history of cardiovascular disease, 82% on statin therapy], 227 (53%) were never smokers, 144 (34%) were ex-smokers and 57 (13%) were current smokers. Mean ± SD duration of smoking was 22 ± 13·2 years. The primary outcome mean cIMT was reduced by metformin in the 227 never smokers (−0·012 mm per year, 95% CI −0·021 to −0·002; $p = 0{\cdot}0137$) but not in the 201 ever smokers (0·003 mm per year, 95% CI −0·008 to 0·014; p=0·5767).
Conclusion: While subgroup analyses should be treated with caution, these data suggest that metformin may reduce progression of mean carotid IMT in type 1 diabetes in the absence of the powerful cardiovascular risk factor of smoking. This provides further support for a wider role of metformin in cardiovascular risk management.

Effects of liraglutide on cardiovascular events in patients with type 2 diabetes and polyvascular disease: results of the LEADER trial

B. Zinman[1], S. Verma[2], D.L. Bhatt[3], S.C. Bain[4], J. Mann[5], M.A. Nauck[6], R.E. Pratley[7], M.M. Michelsen[8], T. Monk Fries[8], S. Rasmussen[8], L.A. Leiter[2], LEADER Publication Committee on behalf of the LEADER Trial Investigators;
[1]Lunenfeld Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Canada, [2]Li Ka Shing Knowledge Institute of St. Michael's Hospital, University of Toronto, Toronto, Canada, [3]Brigham and Women's Hospital Heart and Vascular Center and Harvard Medical School, Boston, USA, [4]Institute of Life Science, Swansea University, Swansea, UK, [5]Friedrich Alexander University of Erlangen, Erlangen, Germany, [6]Diabetes Center Bochum-Hattingen, St. Josef-Hospital (Ruhr-University Bochum), Bochum, Germany, [7]Florida Hospital Translational Research Institute, Orlando, USA, [8]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: Polyvascular disease can predict cardiovascular (CV) events. In LEADER, liraglutide significantly reduced major adverse CV events (MACE) vs placebo. In a post hoc analysis, we assessed CV outcomes by history of single or polyvascular disease at baseline.

Materials and methods: In LEADER, 9340 patients with type 2 diabetes (T2D) and high CV risk were randomised 1:1 to liraglutide vs placebo, both as add on to standard of care (median follow-up = 3.8 years). The primary outcome (MACE) was a composite of CV death, nonfatal myocardial infarction, or nonfatal stroke. The secondary outcome (expanded MACE) also included hospitalisation for unstable angina, coronary revascularisation, or hospitalisation for heart failure. Cox regression was used to compare CV outcomes in patient risk groups stratified by number of atherosclerotic vascular territories (coronary, cerebrovascular and/or peripheral artery disease). Polyvascular disease was defined as ≥2 and single vascular disease as 1 atherosclerotic vascular territory.
Results: In LEADER, 6775 patients (72.5%) had documented atherosclerotic CV disease (ASCVD). Of these, 1536 patients (23%) had polyvascular and 5239 (77%) had single vascular disease. Patients with polyvascular disease had a higher risk of CV outcomes than those with single vascular disease (MACE: HR 1.52, 95% CI 1.33–1.73; expanded MACE: HR 1.45, 95% CI 1.31–1.62, CV death: HR 1.41, 95% CI 1.13–1.75). Liraglutide reduced MACE consistently in patients with polyvascular (HR 0.82, 95% CI 0.66–1.02) and single vascular disease (HR 0.82, 95% CI 0.71–0.95) vs placebo. In patients without ASCVD at baseline, the HR for liraglutide vs placebo for MACE was 1.08 (95% CI 0.84–1.38). Results were similar for expanded MACE and CV death (Table). No significant interactions were found across risk groups for CV outcomes (Table), with the exception of expanded MACE (p interaction = 0.03).
Conclusion: In patients with T2D, polyvascular disease was associated with greater risk of CV outcomes vs single vascular disease. Liraglutide appeared to reduce consistently CV outcomes in patients with single and polyvascular disease vs placebo. A trend towards a neutral response was observed in patients without ASCVD.

Table: Cardiovascular outcomes in patients treated with liraglutide vs placebo by number of vascular territories involved at baseline

Outcome	Vascular disease	n with event/N analysed (%)		HR [95% CI]	Treatment by subgroup interaction
		Liraglutide	Placebo		
MACE	Polyvascular	142/757 (18.8)	173/779 (22.2)	0.82 [0.66–1.02]	*p*=0.15
	Single	338/2646 (12.8)	398/2593 (15.3)	0.82 [0.71–0.95]	
	No ASCVD	128/1265 (10.1)	123/1300 (9.5)	1.08 [0.84–1.38]	
Expanded MACE	Polyvascular	220/757 (29.1)	255/779 (32.7)	0.86 [0.71–1.03]	*p*=0.03
	Single	541/2646 (20.4)	633/2593 (24.4)	0.82 [0.73–0.92]	
	No ASCVD	187/1265 (14.8)	174/1300 (13.4)	1.12 [0.91–1.38]	
CV death	Polyvascular	54/757 (7.1)	60/779 (7.7)	0.92 [0.63–1.32]	*p*=0.16
	Single	114/2646 (4.3)	165/2593 (6.4)	0.67 [0.53–0.85]	
	No ASCVD	51/1265 (4.0)	53/1300 (4.1)	0.99 [0.67–1.45]	

Interaction *p* value is for test of homogeneity of treatment group difference among all 3 subgroups with no adjustment for multiple tests. No ASCVD = no documented evidence of atherosclerotic disease in any of 3 vascular territories at baseline.

Effect of 12 weeks continuous positive airway pressure on day and night arterial stiffness in patients with type 2 diabetes and obstructive sleep apnoea, a randomised trial

C. Krogager[1], A. Banghøj[2], P.L. Poulsen[3], M.G. Kirkegaard[4], L. Tarnow[2], K.W. Hansen[5], E. Laugesen[3];
[1]Clinical medicine, Aarhus University, Aarhus, [2]Cardiology, nephrology and endocrinology, Nordsjællands Hospital, Hillerød, [3]Endocrinology and internal medicine, Aarhus University Hospital, Aarhus, [4]Sleep Disorders Clinic, Elective Surgery Centre, Regional Hospital Silkeborg, Silkeborg, [5]Diagnostic centre, Regional Hospital Silkeborg, Silkeborg, Denmark.

Background and aims: Type 2 diabetes and obstructive sleep apnea (OSA) are associated with high cardio vascular risk. Both are characterized by increased arterial stiffness, which is a marker of cardiovascular risk capable of predicting cardio vascular events independent of traditional risk factors. Previous studies have reported a decrease in arterial stiffness when OSA is treated with continuous positive airway pressure (CPAP). Few trials are randomised and no studies are evaluating the effects in patients with diabetes. The aim of this randomised study is to evaluate the effect of CPAP treatment on arterial stiffness in patients with T2DM and OSA.
Materials and methods: We included 72 patients with type 2 diabetes, newly diagnosed OSA and apnea hyponea index (AHI) ≥15 events/hour. The patients were recruited from outpatient clinics at three Danish hospitals. Patients were randomised to 12 weeks CPAP treatment or to a control group. Arterial stiffness was evaluated by measurement of pulse wave velocity (PWV) at baseline, 4 weeks and after 12 weeks using the SphygmoCor device (office PWV). Ambulatory blood pressure and arterial stiffness were evaluated using the Mobil-O-Graph device (day and night PWV).
Results: At baseline AHI was 35 events/hour (±15.4), office PWV was 10.7 m/s (±2.6), nighttime PWV was 8.9 m/s (±1.1) and nighttime systolic blood pressure (BP) was 125 mmHg (±12.7). Apart form BMI, 36 vs. 33 kg/m^2, there were no difference at baseline between the two groups. In the CPAP group, the average median nightly CPAP usage was 5.41 hours. Primary outcome analysis was performed using a repeated measures analysis of variance. After 12 weeks of treatment, AHI in the CPAP group was 0.8 events/hour (±0.52). Nighttime PWV was 9.1 (±1.1) vs. 9.0 (±1.3) m/s in the control group and nighttime systolic BP was 125.2 (±13.7) vs. 126 (±12.9) mmHg in the control group, No difference in office PWV was seen, −0.62 m/s 95%CI (−1.45 to 0.20), $p = 0.14$ vs. −0.22 m/s 95%CI (−0.95 to 0.51), $p = 0.56$ in the control group. There was no difference in night time PWV after 12 weeks of CPAP treatment −0.036 m/s 95%CI (−0.17 to 0.10) $p = 0.61$. Change in nighttime BP was also non significant, −1.35 mmHg 95%CI (−5.54 to 2.85) vs. 2.54 mmHg 95% (−1.64 to 6.72) $p = 0.23$ in the control group. Furthermore, no difference in daytime BP or PWV was found.
Conclusion: In conclusion, among patients with type 2 diabetes and OSA, CPAP treatment for 12 weeks did not alter arterial stiffness or blood pressure when compared to a control group receiving no treatment.

Association between allopurinol and cardiovascular events and all-cause mortality in diabetes: a population-based cohort study

A. Weisman, G.A. Tomlinson, L. Lipscombe, B.A. Perkins, G.A. Hawker;
University of Toronto, Toronto, Canada.

Background and aims: Higher uric acid (UA) is associated with cardiovascular events and mortality. Allopurinol, a UA-lowering therapy, may reduce risk of these outcomes. Despite the high prevalence of elevated UA in diabetes, the association between allopurinol and cardiovascular events and mortality in diabetes is unclear.
Materials and methods: A population-based cohort was constructed using administrative data in Ontario, Canada. Subjects with diabetes entered on receipt of a new prescription for allopurinol after age 66 (April 1/2002–March 31/2012) and were followed until a composite of all-cause mortality, stroke, myocardial infarction or revascularization. A Cox proportional hazards model was used for each sex, with time-varying allopurinol exposure modeled as yes/no, dose categories and cumulative dose.
Results: Over a median [IQR] follow-up time of 4.7[1.8–7.8] years, the composite outcome occurred in 16,262/23,103 males and 10,566/15,313 females. Allopurinol exposure was associated with a reduction in the composite outcome in a dose-response manner but there was no cumulative dose effect (Table 1).

Conclusion: Any allopurinol exposure and higher allopurinol doses were associated with reduced cardiovascular events and mortality in a large diabetes cohort. Potential mechanisms include an acute reduction of oxidative stress and endothelial dysfunction.

Table 1: Hazard ratios by sex

	Males (n=23,103)		Females (n=15,313)

Disclosure: **A. Weisman:** None.

PS 109 Dyslipidaemia and diabetes

1142

Hypercholesterolaemia impairs GLP-1 action on platelets: effect of a lipid-lowering treatment with simvastatin

C. Barale[1], C. Frascaroli[2], K. Bonomo[2], F. Cavalot[2], I. Russo[1];
[1]Clinical and Biological Sciences, University of Turin, Orbassano, [2]San Luigi Gonzaga Hospital, Orbassano, Italy.

Background and aims: Glucagon-Like Peptide-1 (GLP-1) exerts a role in glucose homeostasis and cardiovascular system. GLP-1 in platelets increases the inibitory effects of the nitric oxide (NO)/PKG/VASP pathway, and reduces oxidative stress. Aim of the study was to verify GLP-1 effects on platelet function in hypercholesterolemia and the role of a lipid-lowering therapy with statin.
Materials and methods: In platelet samples from 45 hypercholesterolemics (M/F:26/19; age:50 ± 2 years, total cholesterol (TC):273 ± 7 mg/dl, c-HDL:62 ± 3 mg/dl, triglycerides:173 ± 16 mg/dl, c-LDL:183 ± 6 mg/dl) and 20 controls (M/F:12/8; age:51 ± 2 years) we evaluated GLP-1(7-36), or Liraglutide (100 nmol/l) influence on: i) antiaggregating effects of the NO-donor sodium nitroprusside (SNP) (Born's method); ii) the SNP-induced pVASP-ser239 levels; iii) the oxygen species (ROS) production (DCF-DA). These evaluations were repeated in hypercholesterolemics after a 3-month treatment with Simvastatin 40 mg/die ($n = 18$) or only diet therapy ($n = 22$).
Results: In hypercholesterolemics, if compared with controls, the effects of GLP-1(7-36) and Liraglutide on platelet responses were significantly lower. In particular, in the presence of GLP-1(7-36): i) the percent increase of the anti-aggregating effects of SNP was 8 ± 4 vs 23 ± 5 ($p < 0.03$) with ADP, 9 ± 3 vs 32 ± 7 ($p < 0.0001$) with collagen and 8 ± 3 vs 30 ± 8 ($p < 0.002$) with arachidonic acid (AA); ii) the percent increase of the SNP-induced pVASP levels was 5 ± 4 vs 33 ± 6 ($p < 0.0001$); iii) the percent reduction of ROS synthesis was 12 ± 5 vs 32 ± 9 ($p < 0.04$). In the presence of Liraglutide: i) the percent increase of the anti-aggregating effects of SNP was 11 ± 3 vs 34 ± 6 ($p < 0.0001$) with ADP, 17 ± 3 vs 35 ± 6 ($p < 0.004$) with collagen, 19 ± 2 vs 33 ± 5 ($p < 0.003$) with AA; ii) the percent increase of the SNP-induced pVASP was 5 ± 4 vs 40 ± 6 ($p < 0.0001$); iii) the percent reduction of ROS synthesis was 16 ± 7 vs 42 ± 9 ($p < 0.04$). In hypercholesterolemics, Simvastatin treatment induced a significant decrease of TC (from 288 ± 12 to 206 ± 9 mg/dl, $p < 0.0001$) and c-LDL (from 198 ± 10 to 120 ± 9 mg/dl, $p < 0.0001$), and in platelets: i) improved the sensitivity to the inhibitory NO/PKG/VASP pathway because the percent antiaggregating effects of NO rose from 51 ± 5 to 67 ± 3 ($p < 0.01$) with ADP, from 35 ± 4 to 55 ± 7 ($p < 0.02$) with collagen, from 41 ± 2 to 49 ± 3 ($p < 0.03$) with AA and the fold increase on basal values of SNP-induced pVASP rose from 8 ± 2 to 15 ± 2 ($p < 0.02$). However, Simvastatin treatment failed to modify platelet sensitivity to GLP-1 effects. For instance, in the presence of Liraglutide: i) the percent increase of the antiaggregating effects of SNP passed from 7 ± 3 to 9 ± 2 (ns) with ADP, from 8 ± 3 to 10 ± 3 (ns) with collagen, from 9 ± 1 to 11 ± 3 (ns) with AA, ii) the percent increase of pVASP, on values with SNP alone, passed from 6 ± 3 to 8 ± 2 (ns), iii) the percent reduction of the AA-induced ROS levels passed from 16 ± 5 to 20 ± 5 (ns). In hypercholesterolemics on diet therapy alone no significant difference was observed for lipid or platelet parameters.
Conclusion: Hypercholesterolemia is a condition of resistance to GLP-1 effects on platelets. The treatment with Simvastatin improved lipid profile and platelet sensitivity to NO but does not revert the impaired platelet responses to the *in vitro* GLP-1 effects.

Investigating the role of glucagon-like peptide 1 on reverse cholesterol transport in a state of early atherosclerosis

S. Curley[1], R. Bruen[2], S. Kajani[1], M. O'Reilly[3], E. Dillon[4], O. Belton[2], F. McGillicuddy[1];

[1]School of Medicine, University College Dublin, Dublin, [2]School of Biomolecular and Biomedical Sciences, University College Dublin, Dublin, [3]School of Public Health, University College Dublin, Dublin, [4]Conway Institute Proteomics Core, University College Dublin, Dublin, Ireland.

Background and aims: Glucagon-like peptide 1 (GLP-1) is a hormone secreted in the gut in response to food intake that promotes satiety as well as having anti-inflammatory effects. Clinical trials have indicated potential cardiovascular benefits of liraglutide, a GLP-1 analogue, in patients with diabetes. Diabetes is a major risk factor for development of atherosclerosis, a cardiovascular disease characterised by invasion of lipid-laden macrophages into the artery wall, inducing a chronic inflammatory state. Indeed, an important athero-protective pathway, reverse cholesterol transport (RCT), is attenuated by inflammation. This study hypothesized that liraglutide may exert cardioprotective effects via modulation of the RCT pathway *in vivo*.
Materials and methods: Apolipoprotein E knockout mice were fed a high-fat, high-cholesterol diet (HFHCD) for two weeks to induce atherosclerosis. Once-daily s.c. injections of either 300 μg/kg liraglutide ($n = 16$) or PBS ($n = 11$) were administered for a further six weeks, during which time the diets were maintained. Low-fat diet-fed (LFD) mice acted as a control. As an *in vivo* method to track cholesterol movement along the RCT pathway, ^{3}H-cholesterol loaded J774 macrophages were injected into the i.p. cavity and ^{3}H-cholesterol levels in the plasma, liver, bile and faeces analysed. Size-exclusion chromatography was performed on plasma samples to isolate the different lipoproteins.
Results: Consistent with its weight loss effect, liraglutide treatment decreased epididymal and subcutaneous adipose weight compared to HFHCD mice. Liraglutide had no significant effect on either plasma or liver ^{3}H-cholesterol levels however it did significantly increase cholesterol clearance to faeces ($p < 0.05$) compared to HFHCD (Figure 1) - Mann Whitney test. Cholesterol mass on isolated VLDL fractions was significantly increased with HFHCD feeding compared to LFD ($p < 0.001$), an effect that was almost completely abrogated by liraglutide treatment ($p < 0.01$) - two-way ANOVA. Mass spectrometry was performed on isolated HDL fractions, revealing significant changes in the HDL proteome, in particular the complement system, with liraglutide treatment ($p < 0.05$) - two sample t test.
Conclusion: We conclude that liraglutide plays a role in promoting cholesterol clearance in a state of early atherosclerosis. Results also indicate that liraglutide treatment affects lipoprotein particles - integral components of RCT - with cholesterol and protein composition being altered in VLDL and HDL respectively. As most patients present with an advanced state of the disease rather than a developing state, we are currently investigating the effect of liraglutide treatment in pre-established atherosclerosis.

Role of HDL and apolipoprotein A1 in the modulation of glucagon levels

G.C. Mannino, A. Fuoco, E. Mancuso, C. Di Fatta, R. Spiga, C. Averta, F. Andreozzi, G. Sesti;
Department of Medical and Surgical Sciences, University of Catanzaro Magna Graecia, Catanzaro, Italy.

Background and aims: Individual's lipid pattern and lipoprotein levels are recognized as important predictors of the development of type 2 diabetes mellitus, and major contributors to the increased risk of cardiovascular disease. Several evidences suggest that HDL and Apolipoprotein A-1 (ApoA1) positively modulate β-cell function. However, their effects on α-cellular function are unknown. The aims of our study were to investigate the existence of a causal role of HDL/ApoA1 in the modulation of glucagon levels and to assess the molecular mechanisms underlying this association in an experimental model of pancreatic α-cells.
Materials and methods: We analyzed a cohort of 130 well-characterized Italian non-diabetic subjects enrolled in the CATAnzaro Metabolic Risk factors (CATAMERI) study, who underwent an oral glucose tolerance test. To assess HDL and ApoA-1 direct effects on glucagon secretion we treated 10 weeks old CD1 mice with HDL or ApoA1 (10 mg/kg; i.p.) for 3 consecutive days. In addition, pancreatic α-TC1 clone 6 cells were treated with HDL (32 μM) or ApoA-1 (20 μM) for 24 h and pre-exposed to AKT inhibitor VIII (210 nM) for 2 h. Specific siRNAs were employed to downregulate ABCA1 and ABCG1, which are the main mediators of ApoA-1 and HDL in pancreatic β-cells. Expression levels of pre-proglucagon were determined by RT-PCR, glucagon concentration was measured by ELISA assay, and the phosphorylation status of the PI3K/Akt/FoxO1 signaling pathway was estimated via Western blot.
Results: We observed a significant inverse correlation between circulating glucagon and HDL cholesterol levels ($r = -0.299$, $p < 0.003$), after adjusting for age, sex, BMI, smoking and dyslipidemic status. Mice exposed to HDL or ApoA1 showed a ~30% reduction in circulating glucagon levels following a hypoglycemic stimulus compared to controls ($p = 0.0001$). αTC1 cells pre-incubated with HDL or ApoA-1 respectively showed 40% and 47% reduction of glucagon expression and secretion after exposure to low glucose levels (2 mM, $p < 0.02$). Exposure of αTC1 cells to HDL and ApoA1 stimulated both Akt and FoxO1 phosphorylation; in this state, FoxO1 is excluded from the nucleus and unable to start preproglucagon transcription. The use of Akt inhibitor VIII blocked the

effects of HDL and ApoA1 on glucagon expression and secretion and restored αTC1 cell response to low glucose levels. The reduction of ABCA1 and ABCG1 expression by selective siRNA showed that the inhibitory effect of ApoA1 was specifically mediated by ABCA1, while HDL requires the expression of both receptors to achieve maximum effect.

Conclusion: These data suggest a new role of HDL and ApoA-1 on glucose homeostasis mediated by their effect on α-cellular function.

Association of FADS1 genetic variation with free fatty acid levels and type 2 diabetes-related traits

H. Lokvancic[1], S. Mandal[2], M. Adilovic[1], M. Sterner[3], G. Gremsperger[3], E. Ahqvist[3], Z. Velija Asimi[2], B. Prnjavorac[4], A. Causevic[2], L. Groop[3], S. Semiz[1];
[1]International University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [2]University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [3]Lund University Diabetes Centre, Malmoe, Sweden, [4]General hospital Tesanj, Tesanj, Bosnia and Herzegovina.

Background and aims: Fatty acid desaturase (FADS) catalyzes the biosynthesis of highly unsaturated fatty acids (FA) from precursor essential fatty acids. Common variants of *FADS1* gene are associated with cardiometabolic traits, such as Type 2 diabetes (T2D), dyslipidemia, and coronary artery disease (CAD). Here we examined the association of rs174550 (T>C) polymorphism with T2D risk and its related traits, as well as with FA levels in a population from Bosnia and Herzegovina (BH), which has high T2D prevalence of 12.3%.

Materials and methods: Our study included 390 T2D patients and 252 unrelated nondiabetic control subjects. Biochemical parameters, including fasting glucose (FG), fasting insulin (FI), HOMA-B, HOMA-IR, TG, total cholesterol (TC), and lipoprotein levels, were measured in all participants. A subgroup of 96 T2D patients (NT-T2D) that were not treated with oral antidiabetics, lipid-lowering, and other drugs were also studied to dissect the potential drug effects on these phenotypic measures. Detection and quantification of 17 different free fatty acids (FFAs) was done by employing gas chromatography/mass spectrometry. Genotyping analysis was performed by Mass Array Sequenom iPlex platform in cooperation with Lund University Diabetes Centre, Malmo, Sweden.

Results: Importantly, here we report for the first time association of *FADS1* rs174550 variant with lower levels of C14:0 ($B = –0.109$ 95% CI –0.200; –0.019, $p_{add} = 0.019$) and C18:0 FFAs ($B = 0.066$ 95% CI 0.002; 0.129, $p_{add} = 0.042$), while positive association was observed for C18:1 FFA upon adjustment for age and gender ($B = 0.104$ 95% CI 0.013; 0.196, $p_{add} = 0.026$). Furthermore, our results demonstrated that upon adjustment for age and gender, rs174550 variant was also associated with waist circumference ($B = 0.042$ 95% CI 0.002; 0.082, $p_{add} = 0.038$) in control subjects and with BMI ($B = 2.907$ 95% CI 0.548; 5.265, $p_{add} = 0.016$) in NT-T2D patients. We showed that this *FADS1* variant was also associated with HOMA-B ($B = 18.10$ 95% CI 2.254; 33.94, $p_{rec} = 0.026$), FI ($B = 0.419$ 95% CI 0.006; 0.832, $p_{rec} = 0.047$), FG ($B = 0.052$ 95% CI 0.008; 0.097, $p_{add} = 0.022$), TC ($B = 0.505$ 95% CI 0.065; 0.945, $p_{add} = 0.025$) and HDL-cholesterol levels ($B = 0.120$ 95% CI 0.014;0.226, $p_{dom} = 0.027$) in control subjects upon adjustment for age, gender, and/or BMI. In T2D patients it was associated with FG levels ($B = −0.085$ 95% CI −0.162; −0.008, $p_{dom} = 0.031$), diastolic blood pressure ($B = 0.029$ 95% CI 0.003;0.055, $p_{add} = 0.028$), and C-reactive protein (CRP) levels ($B = −0.588$ 95% CI −1.026; −0.149, $p_{add} = 0.009$).

Conclusion: Importantly, here we report for the first time association of *FADS1* variant with levels of selected long-chain FAs that might modulate CAD risk in T2D patients. Interestingly, our previous studies suggested that these FFAs, such as C14:0 and C18:1, were also associated with progression and optimal control of T2D. In line with this, here we also showed the association of rs174550 with waist circumference, BMI, pancreatic B-cell function, fasting insulin and glucose levels in this sample of BH population. This *FADS1* variant was also associated with dyslipidemia, hypertension, and levels of CRP inflammatory marker, which is line with its suggested role in CAD development.

PEARL, a non-interventional study on real-world use of alirocumab in German clinical practice: results in patients with and without diabetes

K.G. Parhofer[1], B. von Stritzky[2], N. Pietschmann[2], W. Paar[2];
[1]Medical Department IV - Grosshadern, University of Munich, Munich, [2]Medical Department, Sanofi-Aventis Deutschland GmbH, Berlin, Germany.

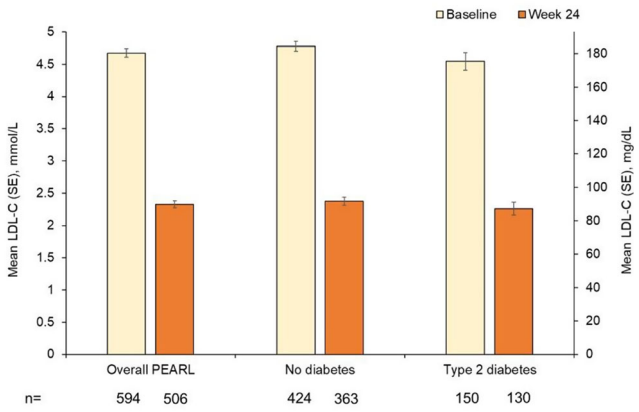
Background and aims: The updated 2017 ESC/EAS Task Force guidance recommends that PCSK9 inhibitors should be considered for patients with atherosclerotic cardiovascular (CV) disease who are not adequately treated with maximally tolerated statins. PEARL assessed efficacy and safety of the PCSK9 inhibitor alirocumab (ALI) in patients with hypercholesterolaemia in a real-world setting. Here, we present data from the overall PEARL population and those with no diabetes mellitus (DM) or type 2 DM (T2DM).

Materials and methods: PEARL was an open, prospective, multicentre, non-interventional study conducted in Germany. Enrolled patients ($n = 619$) should have LDL-C >1.81 or 2.59 mmol/L (70 or 100 mg/dL; depending on CV risk) despite maximally tolerated non-ALI lipid-lowering therapies (LLTs), and subsequently received ≥1 dose of ALI 75 or 150 mg every 2 weeks (Q2W) prior to enrolment. All patients received ALI; dose was adjusted based on physicians' clinical judgment throughout (duration: 24 weeks). The primary efficacy endpoint was LDL-C reduction from baseline (LDL-C prior to ALI therapy) to Week (W)24.

Results: In total, 27.6% of patients had DM, of whom 5.9% had type 1 DM (not further discussed) and 91.1% T2DM. Overall, 45.3% were statin intolerant (unable to tolerate ≥2 statins) and 27.6% were partially statin intolerant (unable to tolerate sufficient statin dose to reach LDL-C <1.81 or 2.59 mmol/L, depending on CV risk). Before the start of ALI therapy, 23.5% of patients were on statin only, 47.9% were on LLT (ezetimibe, fibrates and/or bile acid sequestrants) combined with statin, 10.1% were on LLT combination therapy without statin therapy and 1.8% were on other LLTs (no information available: 16.7%). A similar distribution was seen in patients with T2DM. Overall, initial ALI dose was 75 mg Q2W in 72.9% of patients and 150 mg Q2W in 24.5%, comparable with patients with no DM (72.8% and 24.9%) and with T2DM (73.4% and 24.0%). LDL-C levels at baseline and W24 are shown in Figure 1. Least-squares mean percent change from baseline to W24 in LDL-C was −48.6% for all patients, −49.0% for those with no DM and −47.4% for those with T2DM. During the study, 20.4% of all patients received a dose increase from 75 mg to 150 mg Q2W and 4.0% had a dose decrease from 150 mg to 75 mg Q2W. Corresponding percentages were 17.8% and 1.9% for patients with no DM and 28.1% and 0.7% for those with T2DM. In patients with DM, mean (SD) HbA1c level was 6.9 (1.2)% at baseline and 6.7 (1.0)% at W24. Overall, adverse events were reported in 10.3% of patients, with myalgia (7.3%) the most common; 13.4% of patients discontinued therapy.

Conclusion: PEARL showed that, in a real-world setting, ALI reduced LDL-C levels in patients with high CV risk, including those with no DM and with T2DM. ALI efficacy and safety were consistent with those observed in the ODYSSEY Phase 3 programme.

Figure 1. Mean LDL-C at baseline and W24 for the overall PEARL study population, patients with no DM and patients with T2DM† (ITT analysis)



†Patients with type 1 DM were not further analysed due to the low number of patients included in this group (n=10).

Frequency of high blood pressure and dyslipidaemia in type 1 and type 2 diabetes: results from the International Diabetes Management Practices Study (IDMPS)

H. Ilkova[1], G. Kaddaha[2], J.J. Gagliardino[3], P. Aschner[4], F. Lavalle[5], A. Ramachandran[6], J.C. Mbanya[7], M. Shestakova[8], J.-M. Chantelot[9], J.C.N. Chan[10];

Ramachandran's Diabetes Hospitals, Chennai, India, [7]Biotechnology Center, Doctoral School of Life Sciences, Health and Environment, and Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon, [8]Endocrinology Research Center, Moscow, Russian Federation, [9]Sanofi, Paris, France, [10]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, The Prince of Wales Hospital, Shatin, Hong Kong SAR, China.

Background and aims: Appropriate disease management in people with diabetes requires combined control of blood glucose levels and associated cardiovascular risk factors such as blood pressure and serum lipid profiles. We investigated the proportions of people with high blood pressure (HBP) and abnormal lipid profiles associated with their diabetes in the developing world.
Materials and methods: The IDMPS is a global observational survey on the management and patterns of care of people with T1D and T2D in the developing world. The proportions of people with HBP (>130/80 mmHg) and abnormal lipid profiles (LDL-C ≥2.59 mmol/l) associated with their diabetes were determined for participants enrolled from 24 countries across Africa, the Middle East, South Asia and Eurasia between 2016 and 2017.
Results: In people with T1D ($N = 2000$), 20% and 30% had HBP and abnormal lipid profiles, respectively (**Table**). All were prescribed corrective therapy; however, target levels were only achieved by 50% of the population. In people with T2D ($N = 6283$), the frequency of both HBP and abnormal lipid profiles increased over time; control of these complications was worse than in T1D. In total, 27.1% of people with T1D attained 2/3 targets (glycaemic, BP or lipid control) compared with 16.0%–26.5% of people with T2D. However, only 5.1% of people with T1D and T2D achieved the triple target of HbA_{1c} <7%, BP <130/80 mmHg, and LDL-C <2.59 mmol/l overall.
Conclusion: Many people, particularly those with T2D, have concomitant HBP and lipid abnormalities that are poorly controlled; these increase the burden of disease-induced complications and increase the costs of care.

Table. Blood pressure and lipid metabolism in people with T1D and T2D

	T1D N=2000	T2D life style N=50	T2D OGLD N=3637	T2D OGLD + insulin N=1936	T2D insulin alone N=660
Age (mean), years	34.0	54.7	56.4	57.8	59.9
Female sex	51.2	50.0	49.7	56.5	53.6
Disease duration (mean), years	13.1	4.4	7.6	12.8	13.5
Hypertension (HBP ≥130/80 mmHg)	19.9	48.0	61.3	74.3	71.4
HBP treated and BP <130/80 mmHg	48.6	14.9	19.6	16.8	15.8
Abnormal lipid profile	28.9	50.0	65.3	75.9	68.8
LDL-C <2.59 mmol/l	50.7	25.9	47.4	50.5	43.8
HDL-C ≥1.03 mmol/l	75.8	81.5	61.3	57.6	65.1
TG <1.69 mmol/l	85.9	74.1	72.0	71.3	78.1
Target attainment*					
2 of 3 targets attained	27.1	16.0	26.5	16.5	16.0
All targets attained	8.1	0	6.2	1.7	2.9

Data are % unless otherwise specified.
*BP control defined as BP ≥130/80 mmHg; lipid control defined as LDL-C <2.6 mmol/l; HbA_{1c} control defined as <7 %/individually defined.
HBP, high blood pressure; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; OGLD, oral glucose-lowering drug; TG, triglycerides

Effects of a polyphenol-rich diet on postprandial lipoprotein composition

G. Della Pepa, C. Vetrani, M. Vitale, L. Bozzetto, G. Costabile, P. Cipriano, A. Mangione, L. Patti, G. Annuzzi, G. Riccardi, A.A. Rivellese; Federico II University, Naples, Italy.

Background and aims: Postprandial dyslipidemia is an independent cardiovascular risk factor that could be influenced by dietary habits. A polyphenol-rich diet has been shown to reduce postprandial triglyceride plasma levels in high cardiometabolic risk individuals. It is not known if dietary polyphenols could also influence lipids composition of plasma lipoproteins. Therefore, our aim was to evaluate the effects of a polyphenol-rich diet on postprandial lipoprotein composition in high cardiometabolic risk individuals.
Materials and methods: Seventy-eight individuals, 35–70 year-old, with high waist circumference and one more component of metabolic syndrome, were randomly assigned to follow a high-polyphenol (HighP) or low-polyphenol (LowP) diet. The two experimental diets were isocaloric, similar for macronutrient composition and fibre and vitamin content. At baseline and after 8-week intervention, the participants consumed a high-fat test meal with a similar composition as the assigned diet. At fasting and 2, 4, and 6 hours after the test meal, blood samples were collected for measuring cholesterol (Chol) and triglyceride (Tg) content in chylomicrons, VLDL1, VLDL2, LDL (separated by density-gradient ultracentrifugation) and HDL (phosphotungstic acid/magnesium chloride precipitation method). Apolipoprotein B-48 (Apo B-48) was measured (ELISA) in VLDL1 at fasting and at 4 hours and 6 hours after the test meal.

Results: Dietary adherence was optimal with no significant changes in body weight. VLDL1 postprandial areas under the curve (AUCs) were significantly lower after HighP than LowP diet for Chol (1.48 ± 0.98 vs. 1.91 ± 1.13 mmol/L·6 h, $p = 0.014$, final values corrected for baseline) and Tg (4.70 ± 2.70 vs. 6.02 ± 3.07 mmol/L·6 h, $p = 0.005$), with no significant changes in Chol/Tg ratio and apo B-48 concentration. LDL Tg AUCs were higher after HighP than LowP diet (1.15 ± 0.33 vs. 1.02 ± 0.35 mmol/L·6 h, $p < 0.001$), with a lower Chol/Tg ratio (14.6 ± 4.0 vs. 16.0 ± 3.8, $p = 0.007$). HDL Tg AUCs were lower after HighP than LowP diet (1.20 ± 0.41 vs. 1.34 ± 0.37 mmol/L·6 h, $p = 0.013$). Chol AUCs tended to be lower ($p = 0.07$) with no significant change in Chol/Tg ratio.
Conclusion: A diet naturally rich in polyphenols reduces lipid content in VLDL1 and modifies the composition of LDL that are richer in triglycerides and likely larger, and HDL that are instead poor in triglycerides. These modifications may configure a less atherogenic postprandial lipoprotein profile.

The burden of dyslipidaemia and association with metabolic parameters in young adults with type 1 diabetes

R. Zaidi[1], M. Belbehri[2], C. Lucas[2], S. Bajaj[2], J. Brake[1], F. Cook[1], P.J. Weston[1], A. Scroxton[1], K. Hassanin[2];
[1]Diabetes and Endocrine Department, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, [2]School of Medicine, University of Liverpool, Liverpool, UK.

Background and aims: Dyslipidemia is a strong risk factor for cardiovascular disease in type 1 diabetes (T1D). The relationship of dyslipidemia with glycaemic control has been studied comprehensively in older adults with T1D, with limited data in young adults (18–25 years old). Recently, there has been a global rise of weight gain and obesity in this age group, including those with T1D, with rising prevalence of dyslipidemia. The aims of this study were: 1) to measure the prevalence of dyslipidemia and b) identify its relationship to glycaemic control and other metabolic markers in young adults with T1D at a tertiary hospital in the UK.
Materials and methods: We conducted a cross-sectional study of patients attending the Young Adult Diabetes Clinic over 12 months (2016–2017), using data from the online medical records and laboratory system. The eligibility criteria were: 1) patients aged 18–25 years old, 2) with T1D and 3) measured lipid profile/s in the preceding 12 months. Dyslipidemia was defined as total cholesterol/HDL-C ratio (TC/HDL-C) ≥3.5. Patients were then separated into two study groups based on the value of TC/HDL-C ratio - 'Normal lipid group' (TC/HDL-C <3.5) and 'dyslipidemia group' (TC/HDL-C ≥3.5). Baseline characteristics and metabolic features compared between the groups included a) gender difference, b) duration of T1D, c) percentage CHO counting d) HbA1c, e) BMI, f) total cholesterol (TC), g) triglycerides (TG), h) HDL-C, i) LDL-C, j) thyroid stimulating hormone (TSH), k) estimated glomerular filtration rate (eGFR) and l) liver function tests - alanine aminotransferase (ALT), aspartate aminotransferase (AST) and gama glutamyltransferase (GGT).
Results: In total, there were 108 patients, including 34 in the dyslipidemia group (*v.* 74 in the normal lipid group). The prevalence of dyslipidemia, therefore, was 31.5%. In the dyslipidemia group, the male: female ratio was 1:1.6 (*v.* 1.2:1), with a mean duration of T1D of 10.51 years (*v.* 9.29 years, $p = 0.33$). 53% of patients were CHO counting (*v.* 44%, $p = 0.40$). The median BMI was 26.20 (*v.* 23.17, $p = 0.01$) with median HbA1c of 78.50 mmol/mol or 9.3% (*v.* 71.51 mmol/mol or 8.7%, $p = 0.02$). Median TC (4.92 *v.* 3.83 mmol/L, $p < 0.0005$), TG (1.8 *v.* 0.8 mmol/L, $p < 0.0005$) and LDL-C (2.93 *v.*1.86 mmol/L, $p < 0.0005$) levels were significantly higher, whilst HDL-C (1.15 *v.* 1.56 mmol/L, $p < 0.0005$) levels were significantly lower in the dyslipidemia group. Median ALT (14.0 *v.* 13.59 U/L, $p = 0.90$), ALP (83.38 *v.* 89.50 U/L, $p = 0.65$), TSH (1.93 *v.* 1.73 mU/L, $p = 0.09$) and eGFR (90 mL/min/1.73 m^2 in both groups) levels were similar in the two groups, but GGT levels (17.59 *v.* 12.0 U/L, $p < 0.0005$) were higher in the dyslipidemia group, albeit within normal range. None of the patients in either group were on lipid lowering therapy.
Conclusion: The pattern of dyslipidemia seen in this cohort of young adults with T1D is similar to that in the older population with other types of diabetes. The high prevalence of dyslipidemia in this population, particularly in females, who were overweight, with longer duration of T1D and more sub-optimal glycaemic control, is concerning for high risk of cardiovascular morbidity in the future. Whilst there is a lack of strong association of dyslipidemia with other metabolic parameters in this cohort, long-term follow up of these is required.

Background and aims: Vascular complications are the main cause of death and disability in people with type 2 diabetes (T2D). We assessed the occurrence of complications during the first year of follow-up of DISCOVER, a global, observational study of patients with T2D initiating second-line glucose-lowering therapy.
Materials and methods: Patients with data available at 6 or 12 months were included. Microvascular complications comprised new diagnoses or procedures related to retinopathy, neuropathy, nephropathy or erectile dysfunction. Macrovascular complications comprised new diagnoses or procedures related to coronary or peripheral artery disease or heart failure.
Results: In 11 430 patients from 34 countries, new microvascular and macrovascular complications were reported in 6.6% and 4.7% of patients, respectively, with substantial variations across countries. Proportions of patients with new macrovascular complications are shown in the figure. The proportion of patients with new microvascular complications was higher in those with vs without microvascular disease at baseline (9.8% vs 5.9%, $p < 0.001$). The same was observed for new macrovascular complications in patients with vs without macrovascular disease at baseline (16.9% vs 2.9%, $p < 0.001$).
Conclusion: Rates of new vascular complications over 1 year were strikingly high in presumably low-risk patients with short T2D duration, highlighting opportunities for early aggressive risk-factor modification.

Figure. Proportion of patients for whom new macrovascular complications were documented in the first year of follow-up.

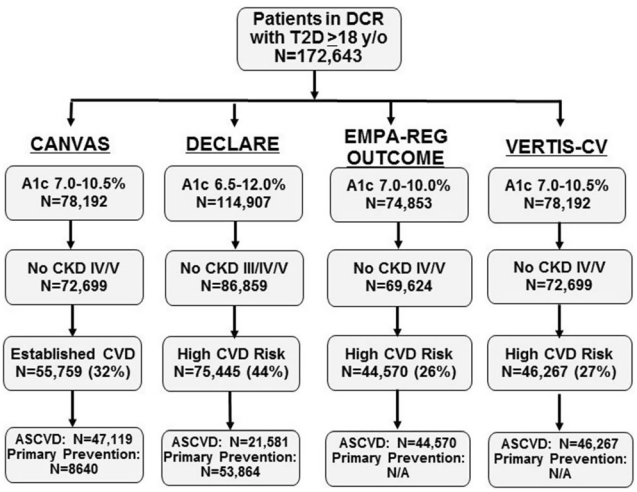
Eligibility varies across the 4 sodium-glucose cotransporter-2 inhibitor cardiovascular outcome trials in adults from the Diabetes Collaborative Registry

E.T. Wittbrodt[1], D. Chamberlain[1], S.V. Arnold[2], F. Tang[2], M. Kosiborod[2];
[1]Medical Affairs, AstraZeneca, Wilmington, [2]St. Luke's Mid America Heart Institute, Kansas City, USA.

Background and aims: The US FDA requires cardiovascular (CV) risk assessment for type 2 diabetes (T2D) medications. Due to differences in eligibility criteria among CV outcome trials (CVOTs), the generalizability of trial populations to US adults with T2D is unknown. We used the Diabetes Collaborative Registry (DCR) to assess the percentages of adults with T2D who would have met eligibility criteria for the pivotal CVOTs of the 4 US marketed sodium-glucose cotransporter-2 inhibitors (SGLT-2i).
Materials and methods: This was a retrospective cross-sectional study using data from the DCR, a US outpatient diabetes registry that comprises 374 sites and 5114 providers. For this analysis, we excluded adults with T1D, prediabetes, diet-controlled T2D, and missing A1C measurements. Major inclusion and exclusion criteria of the CVOTs, including A1C, CKD, and CV history, were used to determine the % eligible for each, all, or none of the CVOTs. The 10-year ASCVD risk for the primary prevention cohorts was calculated with ACC ASCVD risk estimator.
Results: Among 172,643 adults with T2D, mean age was 68 years, 43% were women, mean A1C was 7.8%, 64% had ASCVD, and 10-year risk was 29% in those without ASCVD. Proportions of potentially eligible adults for CVOTs were CANVAS 32%, DECLARE 44%, EMPA-REG OUTCOME 26%, and VERTIS-CV 27% (Figure); 20% were eligible for all 4 trials, and 48% for none of the trials. Patients who were ineligible for any of the trials were slightly younger (mean age 67 years), more likely women (47%), had less ASCVD (56%), and a lower 10-year risk of ASCVD among those without established disease (25%).
Conclusion: Large variability exists in the proportion of T2D adults potentially eligible for each of the SGLT-2i CVOTs. While patients who were ineligible for the CVOTs were lower risk than those eligible, the burden of ASCVD and underlying risk of these patients remains high. Eligibility for any of the CVOTs was greater than anticipated due to the relatively high CV risk profile of patients in the DCR compared to the general US population with T2D. The defined study populations in CVOTs must be carefully considered when comparing with patients seen in routine clinical practice.



Supported by: DCR is funded by AstraZeneca and Boehringer Ingelheim

1152

Rates of major adverse cardiovascular events and mortality with basal insulin by liraglutide use: a DEVOTE sub-analysis

M.F. Ranthe[1], K. Brown-Frandsen[1], S.S. Emerson[2], S.P. Marso[3], D.K. McGuire[4], T.R. Pieber[5], N.R. Poulter[6], B. Zinman[7], R. Grøn[1], M. Lange[1], A.C. Moses[8], P. Örsy[1], R.E. Pratley[9], on behalf of the DEVOTE Study Group;
[1]Novo Nordisk A/S, Søborg, Denmark, [2]University of Washington, Seattle, USA, [3]HCA Midwest, Kansas City, USA, [4]University of Texas Southwestern Medical Center, Dallas, USA, [5]Medical University of Graz, Graz, Austria, [6]Imperial College London, London, UK, [7]Mount Sinai Hospital, University of Toronto, Toronto, Canada, [8]Novo Nordisk Inc., Plainsboro, USA, [9]Florida Hospital, Orlando, USA.

Background and aims: Cardiovascular (CV) safety profiles for insulin degludec (degludec) and insulin glargine 100 units/mL (glargine U100) were established by the DEVOTE and ORIGIN trials. In the LEADER trial, the glucagon-like peptide-1 analogue liraglutide significantly reduced the risk of major adverse cardiovascular events (MACE; CV death, non-fatal myocardial infarction or non-fatal stroke) and mortality vs. placebo in patients with type 2 diabetes (T2D) and high CV risk. This *post hoc* analysis of DEVOTE compared associations between concomitant liraglutide vs. no liraglutide use and the risk of MACE and all-cause mortality in patients with T2D and high CV risk, independent of the basal insulin assigned.

Materials and methods: In DEVOTE, patients with T2D and high CV risk ($n = 7637$) were randomised 1:1 to degludec or glargine U100. HRs for MACE and all-cause mortality were calculated using a Cox regression model adjusted for treatment and time-varying liraglutide use at any time in the trial, without interaction testing. Sensitivity analyses adjusted for baseline covariates included age, sex, smoking, T2D duration, CV risk, insulin therapy, race, BMI, HbA_{1c}, LDL, HDL and liver/kidney function.

Results: At baseline, 436 (5.7%) patients were on liraglutide: 187 (2.4%) started and 210 (2.7%) stopped liraglutide thereafter. Mean liraglutide exposure from randomisation was 731 days. Liraglutide use was associated with significantly lower HRs for MACE and all-cause mortality vs. no liraglutide use (Table). Multiple sensitivity analyses confirmed these results. There was no significant difference in the rate of severe hypoglycaemia with liraglutide use vs. no liraglutide use (HR: 0.79 $[0.51; 1.24]_{95\%\ CI}$). A similar result was obtained following adjustment for additional baseline covariates (HR: 0.89 $[0.57; 1.40]_{95\%\ CI}$). Mean total insulin doses were comparable for patients who received liraglutide at any time (0.9 ± 0.7 units/kg) and those who never received liraglutide (1.0 ± 0.8 units/kg).

Conclusion: In this *post hoc* analysis of DEVOTE, liraglutide use was associated with a lower MACE and all-cause mortality rate in basal insulin users providing additional support to the results from the LEADER trial.

Table: MACE and all-cause mortality by liraglutide use in DEVOTE

	Degludec/glargine U100 with concomitant liraglutide use		Degludec/glargine U100 with no concomitant liraglutide use		Liraglutide use vs no liraglutide use (HR [95% CI])	Two-sided *p*-value
	Number of events	Events per 100 patient-years of observation	Number of events	Events per 100 patient-years of observation		
MACE	25	2.91	656	4.74	0.62 [0.41; 0.92]	0.02
CV death	8	0.91	270	1.90	0.47 [0.23; 0.96]	0.04
Non-fatal MI	15	1.73	298	2.13	0.82 [0.49; 1.37]	0.45
Non-fatal stroke	5	0.57	145	1.03	0.56 [0.23; 1.37]	0.20
All-cause mortality	13	1.48	410	2.88	0.50 [0.29; 0.88]	0.02

Liraglutide effects in insulin-treated patients in LEADER

C. Tack[1], S. Jacob[2], C. Desouza[3], S.C. Bain[4], M.A. Nauck[5], J. Petrie[6], N.R. Poulter[7], R.E. Pratley[8], H.B.K. Stegmann[9], H. Bosch-Traberg[9], E. Startseva[9], B. Zinman[10], LEADER Publication Committee on behalf of the LEADER Trial Investigators;
[1]Radboud University Medical Center, Nijmegen, Netherlands, [2]Praxis für Prävention und Therapie, Kardio Metabolisches Institut, Villingen-Schwenningen, Germany, [3]Veterans Affairs Medical Center, Omaha, USA, [4]Swansea University Medical School, Swansea, UK, [5]Diabetes Center Bochum-Hattingen, St Josef Hospital (Ruhr-Universität Bochum), Bochum, Germany, [6]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, UK, [7]International Centre for Circulatory Health, Imperial College, London, UK, [8]Florida Hospital Translational Research Institute, Orlando, USA, [9]Novo Nordisk A/S, Søborg, Denmark, [10]Lunenfeld–Tanenbaum Research Institute, Mt. Sinai Hospital, University of Toronto, Toronto, Canada.

Background and aims: Combining glucagon-like peptide 1 (GLP-1) analogues and insulin has complementary benefits, but long-term data are sparse. In the LEADER cardiovascular (CV) outcomes trial, rates of major CV events and hypoglycaemia were lower when liraglutide vs placebo was added to standard of care. A substantial number of patients in this trial were treated with insulin, providing detailed information on the combination insulin + GLP-1 for a median follow-up of 3.8 years.

Materials and methods: This post hoc subgroup analysis assessed metabolic parameters (HbA_{1c}, weight, systolic BP and LDL cholesterol), severe hypoglycaemia and CV outcomes by baseline insulin use: no insulin vs basal-only vs other. The LEADER trial included 9340 patients; at baseline, 5171 (55%) patients were not on insulin treatment, 3159 (34%) were on basal-only insulin and 1010 (11%) were treated with other insulin regimens (9.7% premix). Insulin use at baseline was balanced overall between randomised treatment groups, but fewer patients randomised to liraglutide (29%) vs placebo (43%) initiated in-trial insulin.

Results: In the basal-only subgroup, liraglutide reduced HbA_{1c} vs placebo (estimated treatment difference [ETD] −0.48%, 95% CI −0.57; −0.38), with a significant reduction in severe hypoglycaemia rate (estimated rate ratio 0.42, 95% CI 0.26; 0.68). Liraglutide also reduced weight (ETD −2.5 kg, 95% CI −3.0; −2.1) and there were trends for reductions in systolic BP (ETD −1.1 mmHg, 95% CI −2.4; 0.1) and LDL cholesterol (ETD −1.3 mg/dL, 95% CI −3.6; 1.0). The CV risk reduction observed with liraglutide in the full trial population was similar in the basal-only subgroup (estimated HR 0.84, 95% CI 0.70; 1.00). Results were similar in the no-insulin subgroup. There was heterogeneity in the results for the smaller, other insulin subgroup with reductions in HbA_{1c} and weight, but no significant differences in other endpoints.

Conclusion: In basal insulin-treated patients with T2D and high CV risk, treatment with liraglutide improved glycaemic control, reduced body weight and halved the severe hypoglycaemia risk, with a similar CV risk reduction to patients not on insulin.

Arrhythmias and heart rate increase in the LEADER trial and relation to risk of cardiovascular events

M. Husain[1], S.C. Bain[2], J.F.E. Mann[3], M.A. Nauck[4], N. Poulter[5], F.M.M. Baeres[6], B. Goldman[6], A.B. Thomsen[6], S. Marso[7], LEADER Publication Committee on behalf of the LEADER Trial Investigators; [1]Ted Rogers Centre for Heart Research, Toronto General Hospital Research Institute, Toronto, Canada, [2]Swansea University Medical School, Swansea, UK, [3]Friedrich Alexander University of Erlangen, Erlangen, Germany, [4]Diabetes Center Bochum-Hattingen, St Josef Hospital (Ruhr-Universität Bochum), Bochum, Germany, [5]Imperial College London, London, UK, [6]Novo Nordisk A/S, Søborg, Denmark, [7]HCA Midwest Health Heart & Vascular Institute, Kansas City, USA.

Background and aims: Epidemiological data suggest that a higher resting heart rate is associated with a higher risk of cardiovascular (CV) events and death. Glucagon-like peptide-1 receptor agonists can increase heart rate. In the LEADER trial, liraglutide significantly reduced the risk of major adverse CV events ([MACE]; CV death, non-fatal myocardial infarction and non-fatal stroke) by 13% vs placebo (PBO) in people with type 2 diabetes (T2D) and high CV risk.

Materials and methods: In a post hoc analysis from LEADER, we evaluated the frequency of arrhythmias and, for patients with heart rate increases <10 or ≥10 bpm at 6 months, the risk of CV events. In LEADER, 9340 patients with T2D and high CV risk were randomised 1:1 to add liraglutide or PBO to standard of care, and followed for 3.5–5 years. Serious adverse events and non-serious medical events of special interest related to heart rate were systematically collected and reviewed. Cox regression analysis was used to evaluate the risk of CV events in patients with heart rate increases <10 bpm or ≥10 bpm at 6 months.

Results: Mean heart rate increased by 3 bpm for liraglutide vs PBO. The overall frequency of cardiac arrhythmias was 4.9% in both arms, based on adverse event reporting. The types and rates of arrhythmias reported were generally similar in both arms, with low numbers for most arrhythmias and numerically fewer events of ventricular tachycardia and cardiac arrest in the PBO and liraglutide arms, respectively (Table). In total, 3002 (64.3%) patients receiving liraglutide and 3683 (78.8%) receiving PBO had a heart rate increase from baseline <10 bpm at 6 months. Among these patients, liraglutide significantly decreased the risk of MACE (HR [95% CI]: 0.84 [0.73–0.96], $p = 0.01$) and non-significantly decreased the risk of heart failure hospitalisation (0.81 [0.65–1.02]; $p = 0.07$) vs PBO. A total of 1435 (30.7%) patients receiving liraglutide and 750 (16.1%) receiving PBO had a heart rate increase from baseline ≥10 bpm at 6 months. In this subgroup, liraglutide non-significantly decreased the risk of MACE (HR [95% CI]: 0.92 [0.72–1.17], $p = 0.51$) and heart failure hospitalisation (0.94 [0.63–1.43], $p = 0.78$) vs PBO.

Conclusion: The increased mean heart rate observed with liraglutide was not accompanied by an overall higher frequency of arrhythmias vs PBO. Liraglutide decreased the risk of CV events vs PBO in both subgroups regardless of heart rate increase <10 or ≥10 bpm.

Table: Arrhythmia adverse events (AEs) with frequency ≥0.2%

	Liraglutide N=4668				Placebo N=4672			
	N	%	E	R	N	%	E	R

Effect of liraglutide on cardiovascular outcomes in patients with or without prior heart failure history in LEADER

H.A. Saevereid[1], M. Husain[2], S.C. Bain[3], J.F.E. Mann[4], M.A. Nauck[5], N. Poulter[6], B. Goldman[1], A.B. Thomsen[1], S. Marso[7], LEADER Publication Committee on behalf of the LEADER Trial Investigators; [1]Novo Nordisk A/S, Søborg, Denmark, [2]Ted Rogers Centre for Heart Research, Toronto General Hospital Research Institute, Toronto, Canada, [3]Institute of Life Science, Swansea University, Swansea, UK, [4]Friedrich Alexander University of Erlangen, Erlangen, Germany, [5]Diabetes Center Bochum-Hattingen, St. Josef Hospital (Ruhr-University Bochum), Bochum, Germany, [6]Imperial College London, London, UK, [7]HCA Midwest Health Heart & Vascular Institute, Kansas City, USA.

Background and aims: Some type 2 diabetes (T2D) therapies are associated with an increased risk of heart failure (HF). In the LEADER trial, liraglutide significantly reduced the risk of major adverse cardiovascular (CV) events (MACE) by 13% vs placebo (PBO) when added to standard of care in people with T2D and high CV risk. Here, we report post hoc analyses conducted to assess the risk of CV events, including HF hospitalisation, in LEADER participants with or without a history of New York Heart Association (NYHA) class I-III HF.

Materials and methods: In LEADER, 9340 patients with T2D and high CV risk were randomised 1:1 to add liraglutide or PBO to standard of care, and followed for 3.5–5 years. Chronic NYHA IV HF was an exclusion criterion.

Results: At baseline, 18% of patients in both treatment arms had a history of HF (NYHA I-III); 14% had a history of NYHA II-III HF. Overall, fewer patients were hospitalised for HF with liraglutide vs PBO during the trial (HR [95% CI]: 0.87 [0.73–1.05], $p = 0.14$; Table). There was no interaction between treatment and history of NYHA I-III HF for the risk of the primary CV endpoint, an expanded CV endpoint or HF hospitalisation (Table).

Conclusion: No increased risk of MACE or hospitalisation due to HF was observed in patients either with or without a history of HF in the LEADER trial. The point estimates were in favour of liraglutide for MACE and expanded MACE, in patients both with and without a history of HF.

Table: Risk of CV events with liraglutide or placebo by NYHA I–III HF status at baseline

	Number of patients with an event (%)		HR (CI)	*p*-value
	Liraglutide	Placebo		
Primary composite MACE: first occurrence of CV death, non-fatal myocardial infarction, or non-fatal stroke				
Overall	608/4668 (13.0)	694/4672 (14.9)	0.87 (0.78–0.97)	0.01
Baseline NYHA I–III HF status				
Without	466/3833 (12.2)	524/3840 (13.6)	0.88 (0.78–1.00)	0.53
With	142/835 (17.0)	170/832 (20.4)	0.81 (0.65–1.02)	
Expanded composite MACE: CV death, non-fatal myocardial infarction, non-fatal stroke, coronary revascularisation, or hospitalisation for unstable angina pectoris or HF				
Overall	948/4668 (20.3)	1062/4672 (22.7)	0.88 (0.81–0.96)	0.005
Baseline NYHA I–III HF status				
Without	704/3833 (18.4)	786/3840 (20.5)	0.89 (0.80–0.98)	0.72
With	244/835 (29.2)	276/832 (33.2)	0.86 (0.72–1.02)	
Hospitalisation for HF				
Overall	218/4668 (4.7)	248/4672 (5.3)	0.87 (0.73–1.05)	0.14
Baseline NYHA I–III HF status				
Without	110/3833 (2.9)	140/3840 (3.6)	0.78 (0.61–1.00)	0.22
With	108/835 (12.9)	108/832 (13.0)	0.98 (0.75–1.28)	

HRs and *p*-values estimated using Cox proportional hazards model with treatment as a factor. For subgroups with or without NYHA I–III HF at baseline, *p*-values are for interaction between treatment and subgroup.

Alogliptin and pioglitazone prevent palmitate-induced apoptosis and autophagy in human cardiac progenitor cells from control but not from type 2 diabetic subjects

R. D'Oria[1], M. Incalza[1], C. Caccioppoli[1], A. Leonardini[1], R. Schipani[1], A. Cignarelli[1], A. Natalicchio[1], S. Perrini[1], V. Margari[2], D. Paparella[2,3], L. Laviola[1], F. Giorgino[1];
[1]Department of Emergency and Organ Transplantation, University of Bari, Bari, [2]Cardiac Surgery Santa Maria Hospital, Bari, [3]Cardiac Surgery, University of Bari, Bari, Italy.

Background and aims: Physiological tissue turnover in the heart requires proper activation and viability of multipotent cardiac progenitor cells (CPCs). A defective CPC compartment, in terms of CPC number and pro-angiogenic capacity, contributes to diabetes- and hyperglycemia-related heart failure in humans. GLP-1-based therapies have been shown to promote myocardial survival and improve endothelial dysfunction. On the other hand, pioglitazone has demonstrated pleiotropic anti-oxidant and anti-atherogenic effects. Thus, we investigated the effects of alogliptin and pioglitazone, alone or in combination, on the viability of human CPCs challenged with the saturated fatty acid palmitate.
Materials and methods: Human CPCs were obtained from control subjects and type 2 diabetic patients (T2DM) undergoing cardiac surgery for coronary artery bypass grafting and/or valve surgery. Human CPCs were exposed to 0.25 mM palmitate for 16 h after pre-treatment with 10 μM alogliptin and/or 10 μM pioglitazone for 1 h. Apoptosis was assessed by ELISA assay. Autophagy was evidenced by immunoblotting of LC3-II. Akt and Erk phosphorylation was studied by immunoblotting.
Results: Exposure of human CPCs isolated from control subjects to alogliptin and/or pioglitazone for 16 h resulted in Akt, but not Erk, activation ($p < 0.05$). By contrast, neither alogliptin nor pioglitazone, used alone or in combination, induced Akt or Erk phosphorylation in human CPCs from T2DM patients. Exposure to palmitate resulted in increased apoptosis and autophagy in CPC from both control subjects and T2DM patients ($p < 0.05$). Pretreatment with alogliptin, alone or in combination with pioglitazone before exposure to palmitate, reduced palmitate-induced apoptosis and autophagy in human CPCs isolated from control subjects ($p < 0.05$) but not in CPCs from T2DM patients.
Conclusion: Palmitate induces apoptosis and autophagy in human CPCs from control subjects and T2DM patients. Alogliptin and pioglitazone and their combination prevent the palmitate-induced abnormalities of human CPCs isolated from control subjects, likely through enhancement of pro-survival signaling pathways. CPCs obtained from T2DM patients appear to be resistant to the protective effects of alogliptin and/or pioglitazone. Hence, diabetes may affect the viability of the CPC compartment by impairing the activation of protective signaling pathways.

Platelet reactivity and clinical outcome on prasugrel and ticagrelor in type 2 diabetic patients with acute myocardial infarction: real world single centre experiences

M. Samos[1], T. Bolek[1], R. Simonova[2], I. Skornova[2], F. Kovar[1], P. Galajda[1], P. Kubisz[2], J. Stasko[2], M. Mokan[1];
[1]Department of Internal Medicine I, Jessenius Faculty of Medicine in Martin, Comenius University in Bratislava, Martin, [2]Department of Hematology and Blood Transfusion, Jessenius Faculty of Medicine in Martin, Comenius University in Bratislava, Martin, Slovakia.

Background and aims: Type 2 diabetes (T2D) is associated with high on-treatment platelet reactivity (HTPR) on clopidogrel, which might be overcome with prasugrel. Now, ticagrelor has been shown to be similarly effective as prasugrel in unselected population of acute coronary syndrome patients. The aim of this pilot study was to compare the on-treatment platelet reactivity and clinical outcome in prasugrel-treated and ticagrelor-treated T2D patients undergoing percutaneous coronary intervention (PCI) for acute myocardial infarction (AMI).
Materials and methods: A single centre, preliminary prospective study with observational design enrolling 23 T2D patients (11 prasugrel-treated, 12 ticagrelor treated) undergoing PCI was performed. On-treatment response was tested with vasodilator-stimulated phosphoprotein phosphorylation (VASP-P) flow cytometry analysis. Samples were taken prior coronary angiography (sample 1) and on the next day after this procedure (sample 2). Composite primary major cardiac events endpoint (cardiovascular death, AMI, need for repeated urgent myocardial revascularization and stent thrombosis) was recorded in a 6-month period of clinical follow-up.
Results: The time interval form ADPRB loading dosing to blood sampling did not differ significantly in prasugrel-treated and ticagrelor-treated T2D patients. Similarly, no significant differences in VASP-P were found between prasugrel-treated and ticagrelor-treated T2D patients (sample1: 52.7 ± 25.5 versus 50.5 ± 21.1, $p = 0.62$; sample2: 26.3 ± 10.3 versus 29.9 ± 12.7, $p = 0.45$). In addition, there were no significant differences in cardiovascular mortality and in the incidence of primary composite endpoint comparing ticagrelor- and prasugrel-treated patients.
Conclusion: Ticagrelor therapy reaches similar on-treatment platelet reactivity. In addition, no significant differences were found in clinical outcome between ticagrelor- and prasugrel-treated T2D patients with AMI.

Pyruvate dehydrogenase kinase 4 in the liver mediate hepatic gluconeogenesis by modulation of cAMP-PKA-CREB signal pathway

J.-B. Seo[1], B.-Y. Park[2], J.-H. Jeon[1], Y.-K. Choi[1], N.-Y. Kim[1], M.-J. Kim[1], J.-G. Kim[1], K.-G. Park[1], E.-H. Kim[3], I.-K. Lee[1];
[1]Department of Internal Medicine, School of medicine, Kyungpook National University, Daegu, [2]Department of Biomedical Science, Graduate School, Kyungpook National University, Daegu, [3]Department of Internal Medicine, Daegu Fatima Hospital, Daegu, Republic of Korea.

Background and aims: Hepatic gluconeogenesis is facilitated by glucagon, and it is mediated by cyclic AMP (cAMP)-protein kinase A (PKA)-cAMP response element binding (CREB) signaling pathway. In diabetic condition, it is well known that pyruvate dehydrogenase kinase 4 (PDK4) expression is increased in the muscle and liver. However, there are few studies on relationship between PDK4 and gluconeogenic signaling pathway in the liver.
Materials and methods: Primary mouse hepatocytes were used for quantitative real-time PCR, western blot and glucose production assay. Metabolic flux analysis was performed to determine the rate of fatty acid oxidation by using [U-$^{13}C_{16}$] palmitate. Ad-PDK4 and shPDK4 were delivered into diet-induced obesity mice to determine the role of PDK4 in hepatic gluconeogenesis.
Results: Knockdown of hepatic PDK4 in diet-induced obesity mice decreased hepatic glucose production. PDK inhibitor dichloroacetate also attenuated PKA-CREB signaling and gluconeogenesis. Mechanistically, inhibition of PDK4 decreased cAMP levels in hepatocytes. This correlated with lower ATP levels and an increase in phosphorylated AMP-activated protein kinase (AMPK), suggesting cAMP reduction was by the action of the AMPK-sensitive cyclic nucleotide phosphodiesterase 4B (PDE4B). Metabolic flux analysis showed that the reduction in ATP was a consequence of diminished rate of fatty acid oxidation (FAO). On the contrary, overexpression of PDK4 increased FAO and increased ATP which decreased phosphorylation of AMPK and allowed greater accumulation of cAMP. The latter were abrogated by the FAO inhibitor etomoxir, suggesting a critical role for PDK4 in FAO stimulation and the regulation of cAMP levels.
Conclusion: In this study, we suggest that PDK4 in the liver has a critical role in the regulation of hepatic gluconeogenesis by FAO stimulation and cAMP regulation.

The increased flux of pyruvate cycling coupled with Krebs cycle is responsible for the pathogenesis of non-alcoholic liver disease

M.-J. Kim[1], Y.-H. Go[1,2], J.-H. Jeon[1,2], Y.-K. Choi[1], N.-Y. Kim[1], J. Seo[1], J.-G. Kim[1], K.-G. Park[1], E.-H. Kim[3], I.-K. Lee[1,2];
[1]Kyungpook National University School of medicine, Daegu, [2]Leading-edge Research Center for Drug Discovery and Development for Diabetes and Metabolic Disease, Daegu, [3]Internal Medicine, Fatima hospital, Daegu, Republic of Korea.

Background and aims: Non-alcoholic liver disease (NAFLD) is one of the most important chronic liver disorders worldwide and closely associated with obesity and insulin resistance, so called metabolic syndrome. The relationship between hepatic mitochondrial dysfunction and the pathogenesis of NAFLD is widely being investigated. However, the exact mechanism by which mitochondrial dysfunction affects the occurrence of NAFLD is hardly known. Pyruvate dehydrogenase kinase (PDK) inhibits mitochondrial pyruvate dehydrogenase complex (PDC) activity by phosphorylation. Excessive suppression of PDC activity might play a crucial role in the development of metabolic disease. Indeed, increase of PDK is observed in the context of mitochondrial dysfunction, encompassing diabetes and obesity. Thus, here we investigated the role of PDKs with regard to its role in the regulation of pyruvate cycling and Krebs cycle flux in NAFLD.
Materials and methods: Briefly, wild-type (WT) and PDK2 knockout (KO) mice (8-week-old male) were fed high-fat diet (HFD; 20% of calories were carbohydrate and 60% from fat). PDC activity assay was measured spectrophotometrically. Western blotting for PDK1, PDK2, PDK3, PDK4, phospho-PDHE1α (Ser293, Ser300), and β-tubulin was performed from hepatocytes. The mRNA expression was also detected by quantitative real-time RT-PCR. Hepatic metabolites were prepared from tissues of overnight-fasted mice. Hepatic pyruvate, ß-hydroxybutyrate, oxaloacetate (OAA), and citrate were measured by enzymatic methods. Hepatic succinate was measured with Succinic Acid Assay kit. Statistical analysis was determined by the unpaired Student's t-test when two groups were compared.
Results: In diet-induced obesity mice, the expression of pyruvate dehydrogenase kinase 2 (PDK2) in the liver was increased. In metabolic flux analysis, it was found pyruvate cycling as well as TCA cycle flux was augmented by chronic high fat feeding. This was a consequence of decreased PDC flux and corresponding increase of anaplerotic pyruvate carboxylase flux. As a result, increased phosphoenolpyruvate level in the hepatocyte increased the rate of gluconeogenesis and glyceroneogenesis. When PDK2 was knocked down, however, a flux of pyruvate cycling and Krebs cycle was attenuated. Mechanistically, decreased pyruvate cycling flux by PDK2 deficiency resulted in decreased level of OAA. Decreased rate of conversion of OAA to acetyl-CoA, in turn, increased the rate of ketogenesis. This result contributed to increased rate of lipolysis, fatty acid oxidation and depletion of intrahepatic triglyceride content. The PDK2-deficient mice showed decreased gluconeogenesis and improved NAFLD upon HFD compared with wild-type challenged with HFD.
Conclusion: We report the pathophysiology of NAFLD is strongly associated with the flux of pyruvate cycling. It depends on PDK2 activity which inhibits the PDC and increase hepatic Krebs cycle flux. On the other hands, inhibition of PDK2 results in decreased pyruvate recycling flux, thereby increasing ketogenesis and ß-oxidation. Modulation of pyruvate cycling might be a key pathway to improve NAFLD.

Insulin resistance and farnesoid X receptor expression in patients with non-alcoholic fatty liver disease and various disorders of carbohydrate metabolism

E. Mishina[1], A. Mayorov[1], A. Bogolyubova[2], P. Bogomolov[3], M. Matsievich[3], K. Kokina[3];
[1]Endocrinology Research Centre, Moscow, [2]Engelhardt Institute of Molecular Biology of the Russian Academy of Sciences, Moscow, [3]Moscow Regional Research and Clinical Institute, Moscow, Russian Federation.

Background and aims: Aim of the study was to assess the insulin resistance (IR) and expression of the farnesoid X receptor (FXR) in patients with non-alcoholic fatty liver disease (NAFLD) and various disorders of carbohydrate metabolism.
Materials and methods: The study included 20 patients aged 18–60 years with a body mass index more than 27.5 kg/m^2. All participants underwent clinical and laboratory examination, determination of IR (calculation by mathematical models of glucose homeostasis and hyperinsulinemic euglycemic clamp test); a biopsy of the liver was performed under ultrasound control with further morphological study of the biopsy specimen. The severity of NAFLD was estimated by the percentage of steatosis, the activity scale of NAFLD (NAS). When a liver biopsy

was performed, a part of the tissue was frozen at a temperature of −80°C with a further molecular biological study. Frozen liver tissue samples were used to isolate RNA and proteins with subsequent quantitative PCR analysis, the Western blot method. Statistical analysis was carried out using nonparametric statistical methods.

Results: In hyperinsulinemic euglycemic clamp test, it was found that in patients without NAFLD, IR was less pronounced (M-index 5,1 [3.3; 7.0] mg/kg/min) compared with patients with steatosis (M-index 3.1 [2.4; 3.5] mg/kg/min) or *nonalcoholic steatohepatitis (NASH) (*M-index 2.1 [1.8; 2.7] mg/kg/min). There was a negative correlation between the degree of NAFLD and the M-index (rs = −0.554, $p < 0.05$). A negative correlation was found between the M-index and the degree of a disorder of carbohydrate metabolism (rs = −0.532, $p = 0.01$). In a real-time PCR, the expression of FXR in liver tissues in groups of patients without NAFLD and with steatosis did not differ. The group of patients with NASH is divided depending on FXR expression level into two parts: in 4 out of 8 patients the expression was at the same level, as in patients with steatosis and without NAFLD (subgroup "NASH FXR low"), while in other patients the level of expression of FXR is much higher (subgroup "NASH FXR high"). Lower levels of immunoreactive insulin (23 vs 46 μU/ml) and HOMA-index (7 vs 13.5) were noted in the "NASH FXR high" subgroup assessing IR. Also, the "NASH FXR high" subgroup showed a lower percentage of steatosis (30 vs 56), and lower scores on the NAS scale (3.2 vs 4.2). However, all the above differences were not statistically significant due to the small number of patients in every group.

Conclusion: There is a negative correlation between the degree of NAFLD and the M-index, as well as between the M-index and the degree of a disorder of carbohydrate metabolism. Increased expression of FXR is probably associated with less pronounced steatosis and IR.

Nitric oxide (NO) contributes to the control of hepatic insulin response by promoting mitochondrial-endoplasmic reticulum interactions

A. Bassot[1], Y. Gouriou[1], M.-A. Chauvin[1], G. Vial[2], N. Bendridi[1], C. Cottet[3], J. Rieusset[1], B. Morio[1];
[1]CarMeN Laboratory, INSERM U1060, Lyon, [2]HP2 Laboratory, INSERM U1042, Grenoble, [3]LBFA Laboratory, INSERM U1055, Grenoble, France.

Background and aims: Under physiological conditions, NO produced by the endothelial NO synthase (eNOS) participates in the control of hepatic response to insulin. In addition, recent evidences have shown that the contact points (MAMs) between mitochondria and the endoplasmic reticulum (ER) are functional domains necessary for insulin signaling in the liver. Since mitochondria are targets of NO, we hypothesized that they could participate in the regulation of the hepatic response to insulin by regulating mitochondrial-ER (MAMs) interactions.

Materials and methods: The study was carried out on HuH7 cells and confirmed on primary rat hepatocytes and in the liver of C57B16J mice. NO concentration was modulated using the eNOS substrate (arginine) and inhibitor (L-Name), as well as an NO donor (Nonoate). MAMs were quantified using in situ Proximity Ligation Assay by targeting the interactions (<40 nm) of two main proteins at the MAM interface, VDAC1 (mitochondrial) and IP3R1 (RE). Involvement of cGMP pathway was explored with activators of soluble guanylate cyclase (sGC) (BAY 41-2272) and cGMP dependent protein kinase (PKG) (8Br-cGMP) and the PKG inhibitor (KT-5823). Insulin response was explored by Western Blot. Finally, proteins at the MAM interface that may be targets of NO (cyclophylin D: cypD, GRP75) were tested using siRNA approaches.

Results: Arginine (1 mM) and Nonoate (1 mM) enhanced MAMs by 37 and 165% vs. control ($p < 0.05$), whereas L-Name (1 mM) decreased them by 49% ($p < 0.05$). Those effects were prevented by inhibiting PKG (KT-5823, 1 μM) and mimicked by activating PKG (8Br-cGMP, 0.5 mM) and sGC (BAY 41-2272, 2 μM). Mitochondrial fusion (Mitotracker green®) was improved concomitantly with NO-induced MAMs, whereas eNOS inhibition caused mitochondrial fission. Mitochondrial oxygen consumption (oxygraphy) was not improved by increasing NO concentration but was reduced by 33% following eNOS inhibition ($p < 0.05$). In agreement with the regulation of MAMs, increasing NO concentration improved the response to insulin (100 nM) (+33% vs. control, $p < 0.05$) whereas eNOS inhibition diminished this response (−25%, $p < 0.05$). Finally, the decrease of cypD expression induced by the siRNA was the only condition that significantly reduced the effect of NO on MAMs (−54%, $p < 0.001$) and insulin response (−50% , $p < 0.05$) vs. treated control.

Conclusion: Under physiological conditions, NO participates in the control of the hepatic response to insulin by regulating mitochondrial-RE (MAMs) interactions. NO effects are mediated through the sGC/cGMP/PKG pathway and involve cypD. The mechanisms may involve the control of calcium exchanges between the two organelles, via the VDAC-1/Grp75/IP3R-1 complex with which cypD can interact.

Adiponutrin (PNPLA3) rs738409 genotype influences the metabolic activity of non-alcoholic fatty liver disease

A. Nadasdi[1], V. Gál[2], K. Rosta[3], J. Harreiter[4], A. Kautzky-Willer[4], A. Somogyi[1], G. Firneisz[1,5];
[1]2nd Department of Internal Medicine, Semmelweis University, Budapest, Hungary, [2]Brain Imaging Centre, Research Centre for Natural Sciences, Hungarian Academy of Sciences, Budapest, Hungary, [3]Department of Obstetrics and Gynecology, Medical University of Vienna, Vienna, Austria, [4]Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria, [5]MTA-SE Molecular Medicine Research Group, Hungarian Academy of Sciences, Budapest, Hungary.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) and T2DM are prevalent and closely associated to each other and to obesity, dyslipidaemia, insulin resistance (IR). The *PNPLA3* rs738409 *G/G* genotype is a risk factor for NAFLD development and progression. We aimed to measure the intrahepatic (IHCL) and intrapancreatic lipid contents (IPCL) quantitatively and to assess the correlations with metabolic parameters according to *PNPLA3* genotypes in a middle aged female population.

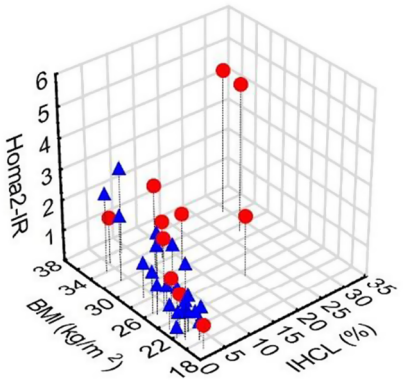
Materials and methods: IHCL and IPCL was measured with [1]HMRS and Cemical Shift Imaging in 34 non-pregnant women (mean: age = 37 yrs, BMI = 26.3 kg/m^2) with known *PNPLA3* rs738409 genotypes (*C/C* vs. *G/G*), pregnancy history (pGDM vs. pNGT) from our prior GDM genetic study. 75 g OGTT (0′–30′–120′), plasma glucose (PG), insulin, HbA_{1C} levels liver-tests were assessed and anthropometric data were recorded. Serum DPP4 activity (sDPP4) was measured in an enzyme-kinetic-assay using Gly-Pro-pNA as substrate. We analysed data according to prior GDM (pGDM/pNGT $n = 19/15$), *PNPLA3* rs738409 genotypes (*C/C*, *G/G* $n = 23$, 11), OGTT results (IFG+IGT+DM/NGT $n = 8/26$) and presence of NAFLD (IHCL >5.5%, $n = 9$). Statistics: T, MWU/Pearson, SRO correlation test and multiple regression.

Results: Women with *G/G* genotype (vs. *C/C*) had higher IHCL (median = 10.1 vs. 3.4%, $p = 0.01$), with pGDM (vs. pNGT) higher 120′PG (mean = 7.1 vs. 5.7 mmol/l, $p = 0.041$) levels and higher proportion of women had abnormal GT (abnGT/pGDM vs. abnGT/pNGT: $n = 6/19$ vs. 2/15, respectively). In the NAFLD group (vs. non-NAFLD) the 30′/120′ PG (mean = 10.1 vs. 7.5/8.1 vs. 5.8 mmol/l, $p = 2*10^{-5}/0.002$) levels were increased. There were different correlations among HOMA2-IR, IHCL and BMI according to the *PNPLA3* genotypes (Fig 1A). The correlation between the IHCL and 120′ PG (Fig 1B) was also influenced by the *PNPLA3* genotypes. Correlations between BMI-IHCL, IHCL-Uric

acid, IHCL-TG and IHCL-IPCL were also modified significantly by the *PNPLA3* genotype. We confirmed the correlation among seDPP4 activity and the liver tests (DPP4 vs. ASAT, ALAT and γGT: $p = 0.024$, 0.075 and 0.043, $r = 0.41$, 0.32 and 0.36 respectively).

Conclusion: Both the intrahepatic lipid deposition and the history of GDM had significant metabolic consequences. Although an increased HOMA-IR and the abnormal OGTT were associated with NAFLD, the track of correlations between the IHCL and metabolic parameters were significantly modified by the *PNPLA3* rs738409 genotype. The rs738409 gene variant influences the metabolic activity corresponding to a given degree of liver fat accumulation.

Fig 1A: Correlation among BMI, IHCL and HOMA2-IR - by *PNPLA3* rs738409 genotypes



PNPLA3 rs738409*C/C* R(z/xy) = 0.863; $p<10^{-5}$
PNPLA3 rs738409*G/G* R(z/xy) = 0.859; p=0.005

Effect of the hepatic extracellular vesicles in inflammation-associated insulin resistance in non-alcoholic fatty liver disease

I. Garcia-Martinez[1,2], R. Alén[1], M. Izquierdo[1], Á. Valverde[1,2];
[1]Instituto de Investigaciones Biomédicas Alberto Sols, Madrid, [2]Centro de Investigaciones Biomédicas En Red de Diabetes y Enfermedades Metabólicas (CIBERdem), Madrid, Spain.

Background and aims: Cell-cell communication by extracellular vesicles (EVs) is an emerging issue in the progression of non-alcoholic fatty liver disease (NAFLD). It has been shown that injured hepatocytes by lipotoxicity release EVs and, on the other hand, patients with NAFLD or non-alcoholic steatohepatitis (NASH) secrete increased levels of EVs. However, the role of EVs in cell-to-cell communications within liver cells remains uncertain. We previously analyzed the impact of the hepatocyte-macrophage cross-talk in inflammation-mediated insulin resistance in NAFLD. In order to better understand whether EVs may be novel non-invasive biomarkers to monitor liver damage in NAFLD we aimed to analyze first the EVs secretion profile in hepatocytes cultured under NAFLD conditions and, second, the impact of released EVs on the inflammatory responses triggered by macrophages and, ultimately, in insulin signaling in hepatocytes.

Materials and methods: Eight weeks old C57BL6j male mice were fed chow diet (control) or high fat diet (HFD, 60% kCal from fat) for 12 weeks. EVs were isolated from: hepatocytes from chow diet-fed mice stimulated with palmitic acid (PA) 1) or remained untreated as controls 2), hepatocytes from HFD-fed mice 3), and plasma from HFD-fed mice 4). EVs were characterized by detection of specific markers (CD81, Tsg101) by Western-blot and evaluation of size/concentration by Nanoparticle Tracking Analysis (NTA). Mouse peritoneal macrophages were stimulated for 8h with EVs isolated from Groups 1–4 and changes in iNOS, IL6, IL1b and TNFa levels were assessed by qPCR. In addition, hepatocytes were cultured for 24h with conditioned medium (CM) from these macrophages and insulin signaling was studied through the Akt (Serine 473) phosphorylation.

Results: EVs secretion was elevated by 3-4 fold in PA-stimulated hepatocytes or in hepatocytes isolated from HFD-fed mice compared to the levels of non-treated hepatocytes (controls). Likewise, EVs secretion was elevated in plasma from HFD-fed mice compared to those isolated from control mice fed a chow diet ($P < 0.05$). Addition of EVs isolated from both kinds of lipid overloaded hepatocytes (PA-stimulated or isolated from mice fed a HFD) to mouse peritoneal macrophages increased iNOS expression and proinflammatory cytokines levels ($p < 0.05$). Moreover, insulin resistance, manifested by decreased Akt (Serine 473) phosphorylation was induced in healthy hepatocytes pre-incubated with CM from macrophages stimulated with EVs released by lipid-overloaded hepatocytes.

Conclusion: Our results identified a novel hepatocyte-macrophage-hepatocyte cross-talk by which EVs secretion by hepatocytes under NAFLD conditions induced a pro-inflammatory response in macrophages which, in turn, generates insulin resistance in hepatocytes in a paracrine-manner. The study of the mechanisms of action of hepatocyte-derived EVs in hepatic and extra-hepatic insulin sensitive cells could provide new therapeutic targets against insulin resistance during NAFLD.

Molecular phenomics and metagenomics of hepatic steatosis in non-diabetic obese women

R. Burcelin, FLORINASH consortium FP7;
Inserm 1048 I2MC, Hopital Rangueil, Toulouse, France.

Background and aims: The role of molecular signals from the microbiome and their coordinated interactions with those from the host

in hepatic steatosis - notably in obese patients and as risk factors for insulin resistance and atherosclerosis - needs to be understood. Precisely, the early onset events triggering the hepatic lipid load have not be studied and could be linked to a specific gut microbiota profile characterized with a causal role.

Materials and methods: To this aim a cohort of 700 non diabetic obese women was recruited from Spain and Italy. 88 patients underwent a multi-omics analysis at baseline including metagenomics, liver transcriptomics, plasma and urine metabolomics and proteomics. Hundreds of clinical and biochemical parameters were recorded including NAFL scores (recorded by histological analyses), insulin resistance (as assessed by the hyperinsulinemic clamp), intima media thickness and oral glucose tolerance to cite a few. Through state of the art system biological analyses we here reveal molecular networks linking gut microbiome and host phenome to hepatic steatosis.

Results: We here show that steatotic patients have low microbial gene richness and increased genetic potential for processing of dietary lipids and endotoxin (LPS) biosynthesis (notably from Proteobacteria), hepatic inflammation and dysregulation of aromatic and branched-chain amino acid (AAA and BCAA) metabolism. We demonstrated that faecal microbiota transplants and chronic treatment with phenylacetic acid (PAA), a microbial product of AAA metabolism, successfully trigger steatosis and BCAA metabolism. Molecular phenomic signatures were predictive (AUC = 87%) and consistent with the gut microbiome making an impact on the steatosis phenome (>75% shared variation) and, therefore, actionable via microbiome-based therapies

Conclusion: Our data demonstrate that a specific fecal microbiota was causal of the early events triggering hepatic lipid accumulation. therefore, in addition to being a predictive biomarkers the molecular changes in gut microbiota metagenome could be considered as a putative targets for the control of NAFLD.

A porcine placental extract alleviates lipotoxicity-induced steatohepatitis by suppressing activation of hepatic macrophages and stellate cells

T. Ota[1,2], L. Xu[2], G. Chen[2], M. Nagashimada[2];
[1]Asahikawa Medical University, Asahikawa, [2]Kanazawa University, Kanazawa, Japan.

Background and aims: Excessive hepatic lipid accumulation causes aberrant activation of liver macrophages and hepatic stellate cells (HSCs), resulting in the exacerbation of hepatic insulin resistance and nonalcoholic steatohepatitis (NASH). We previously developed a cholesterol- and saturated fatty acid-induced mouse model of lipotoxic NASH and revealed that hepatic oxidative stress and insulin resistance promotes hepatic inflammation and fibrosis, replicating the pathophysiological features of human NASH. Placental extracts have been used to treat various chronic diseases due to their anti-oxidative effect. However, the effects of the placental extracts on the development of NASH have yet to be elucidated. In the present study, we investigated the effect of porcine placental extract (PPE) in a lipotoxicity-induced NASH model.

Materials and methods: Eight-week-old C57BL/6 mice were fed a high-cholesterol and high-fat (CL) diet or a CL diet containing 0.3% PPE (CL+PPE) for 15 weeks. The liver histology, insulin sensitivity, inflammatory/stress signal, and fibrogenesis were examined. Intrahepatic immune cell numbers were quantified by flow cytometry.

Results: After 15 weeks of feeding, histological examination revealed hepatic steatosis, inflammation and fibrosis in mice fed CL diet. They showed hyperinsulinemia even though weight and adiposity were similar. The PPE significantly attenuated hepatic steatosis, and the increase in liver triglyceride and TBARS levels caused by the CL diet. The PPE improved glucose intolerance and hyperinsulinemia in the CL group and enhanced the insulin signal, assessed by IRβ and Akt phosphorylation in the liver, which was associated with the attenuation of MAPK (ERK/p38MAPK) and NF-κB activation. To quantify the numbers of total ($CD45^+CD11b^+F4/80^+$), pro-inflammatory M1-like ($CD11c^+CD206^-$), and anti-inflammatory M2-like ($CD11c^-CD206^+$) macrophages in the liver, we analyzed hepatic immune cells by flow cytometry. Although the PPE did not alter the total number of liver macrophages markedly, it decreased the number of M1-like macrophages by 44.2% In contrast, the PPE increased the number of M2-like macrophages by 1.4-fold, resulting in a predominance of M2 over M1 macrophage populations in the liver of NASH mice. Accordingly, the PPE suppressed lipopolysaccharide-induced M1 marker (*Tnfa*, *Il1b* and *Mcp-1*) mRNA expression in isolated murine peritoneal macrophages, whereas it facilitated interleukin 4-induced M2 marker (*Mrc2*, *Cd206* and *Mgl1*) mRNA expression in a dose-dependent manner. Importantly, the PPE markedly attenuated hepatic fibrosis by decreasing hepatic hydroxyproline, a marker of collagen fiber content by 62% in the liver of CL group. Furthermore, the PPE decreased TGFβ-induced phosphorylation of Smad, and α-SMA protein levels in the liver of NASH mice and in RI-T cells, a HSC line. Consistently, the PPE reduced mRNA expression of TGFβ-induced fibrogenic genes (*Col1a1* and *fibronectin*). Moreover, the PPE decreased mRNA expression of *Nox4* and intracellular reactive oxygen species levels in TGFβ-stimulated RI-T cells.

Conclusion: The PPE attenuated lipid accumulation and peroxidation, insulin resistance, inflammatory and stress signaling, and fibrogenesis in the liver of NASH. Thus, PPE may be a potential approach to prevent NASH by limiting lipid peroxidation, promoting M2 macrophage polarization, and attenuating HSC activation.

PS 112 Unconventional aspects of cardiovascular disease in diabetes

1166

Insulin resistance and CVD risk: a time varying analysis in type 1 diabetes

T.J. Orchard, R.G. Miller, T. Costacou;
Epidemiology, University of Pittsburgh, Pittsburgh, USA.

Background and aims: We have previously demonstrated that baseline estimated glucose disposal rate (eGDR), an inverse measure of insulin resistance (IR) based on a prediction equation (waist hip ratio, hypertension and HbA1c) derived from hyperinsulinemic euglycemic clamp studies, is a strong predictor of coronary artery disease (CAD) in type 1 diabetes. Whether eGDR remains a strong independent predictor when risk factor assessments over time are accounted for, and whether it predicts total CVD including stroke, are unclear. We thus now report its role in predicting total cardiovascular disease (CVD) including stroke, in a time varying analysis.
Materials and methods: Data are from the Pittsburgh Epidemiology of Diabetes Complications (EDC) study an ongoing, prospective cohort study of childhood-onset (<17 yrs) T1D diagnosed in 1950–80 with 25 yrs of follow up ($n = 658$, 49% women, mean age 27, T1D duration 18 yrs at 1986–88 baseline). In addition to biennial surveys throughout, follow-up exams occurred biennially for the first 10 yrs and again at 18 and 25 yrs. CVD was defined as the first occurrence of fatal MI, CAD, or stroke; nonfatal MI or stroke; or coronary revascularization (all validated by review of death certificates and/or medical records); ischemic ECG (Minnesota Codes 1.3, 4.1, 4.3, 5.1, 5.3, and 7.1) or EDC physician diagnosed angina. Those experiencing any CVD were compared to participants not developing any CVD during follow up. Baseline (BL), time varying updated mean (UM) and time varying most recent (MR) risk factors were assessed in Cox models (HRs per unit).
Results: A first CVD event was documented in 236 of the 604 participants without prevalent CVD at baseline. The final model was constructed using the independent predictors that emerged from models based on blocks of related variables (demographic, behavioral, family history, blood pressure, lipids, and diabetes specific). Independent predictors in the final model were diabetes duration (HR 1.099, $p < 0.0001$); current log albumin excretion rate (1.20, $p < 0.001$); mean log triglycerides (1.86, $p = 0.0005$); current eGDR (0.9, $p = 0.003$); baseline LDLc (1.005, $p = 0.012$); current eGFR (0.99, $p = 0.030$). An alternate model without eGDR but with its predictors, showed similar prediction with HbA1c and hypertension replacing eGDR and eGFR, and a similar fit (Akaike Information Criterion 2272.8 v 2270.2). Further models with three different outcomes (Major Atherosclerotic Cardiovascular Events - MACE i.e. stroke, MI or fatal CVD, $n = 107$); revascularization ($n = 38$) and soft endpoints (Ischemic ECG or angina, $n = 91$) suggest eGDR is a particularly strong predictor of soft endpoints (HR 0.817, $p < 0.001$).
Conclusion: We conclude that IR (eGDR) is an independent predictor of CVD (particularly "soft" CVD endpoints) in fully adjusted, time varying, analyses. The similarity of fit of models with either eGDR, or with its components, however, is consistent with the hypothesis that most of the prediction of IR (eGDR) is explained by blood pressure and glycemia.

Role of atherogenic dyslipidaemia in silent coronary heart disease of type 2 diabetes patients with LDL-cholesterol at therapeutic goal

M. Hermans[1], M. Nguyen[2], A. Sultan[3], I. Banu[2], E. Cosson[2], A. Avignon[3], P. Valensi[2];
[1]Cliniques universitaires St-Luc, Brussels, Belgium, [2]Hôpital Jean Verdier, Bondy, France, [3]Centre Hospitalier Universitaire, Montpellier, France.

Background and aims: Several studies have identified the role of atherogenic dyslipidaemia (AD), defined by the combination of low HDL-C and high TG, as a cardiovascular risk factor. AD is a well-established residual risk factor even in type 2 diabetes (T2DM) patients whose LDL-C reaches therapeutic target. Our goal was to evaluate the respective role of AD and of an LDL-C remained excessive in silent coronary disease of asymptomatic T2DM patients.
Materials and methods: Among T2DM patients screened (since 1991) for silent myocardial ischemia (SMI; by myocardial stress scintigraphy) and for coronary artery stenosis (CAS; in case of positive scintigraphy), we retained 1398 with LDL-C <130 mg/dl (58% male, 59.7 ± 10.3 years, BMI 29.3 ± 5.9 kg/m², hypertension 73%, albuminuria 59%, smoking 25%, lower extremity arterial disease 11%, receiving statins 39% and/or fibrate 8%). Rest echocardiography was also performed in 399 of these patients. The total population was divided into 665 patients with LDL-C between 100 and 130 mg/dl (group 1) and 733 patients with LDL-C <100 mg/dl (group 2). AD was defined as triglyceride levels ≥200 mg/dl and HDL-C ≤40 mg/dl (males) or ≤50 mg/dl (females).
Results: SMI was present in 24% of the total population, and significant CAS in 8%. In group 2, the proportion of patients on statins was higher ($p < 0.0001$). AD was present in 73 patients of group 1 (11%) and 73 patients of group 2 (10%). Patients with AD had lower diabetes duration, and higher values of BMI, HbA1c, and 10-year coronary events' risk (UKPDS) ($p = 0.02$ to <0.0001). Comparisons were made for patients in group 1 (with or without AD) and those in group 2 (with or without AD). The prevalence of SMI was slightly higher in patients in groups 1 and 2 with AD than in those without AD ($p = 0.139$). The prevalence of CAS was significantly higher in patients of groups 1 and 2 with AD (17.4% and 14.3%) than in patients of groups 1 and 2 without AD (8.2% and 6.1%) ($p = 0.002$). In a multivariate analysis model including AD, gender, hypertension, diabetes duration, BMI, HbA1c, nephropathy, and statins, AD remained significantly associated with coronary stenosis. Between the 4 groups there was no significant difference in left ventricular mass or ejection fraction, hypertension or smoking.
Conclusion: These data show that in T2DM patients the prevalence of silent coronary stenoses is higher in patients with AD, and even higher in the presence of AD with an LDL-C <100 mg/dl than in the presence of an LDL-C between 100 and 130 mg/dl without AD. They suggest that in patients with very high cardiovascular risk, in addition to lowering LDL-C below 100 mg/dl, management of atherogenic dyslipidaemia is necessary to reduce the residual risk of macrovascular disease.

Effect of ADAMTS7 in left ventricular diastolic and systolic dysfunction in subjects with type 2 diabetes free of cardiovascular disease

A. Ganotopoulou[1], V. Lambadiari[2], A. Papazafiropoulou[1], A. Theodosis-Georgilas[3], A. Trikkalinou[1], N. Kassinos[3], V. Liossi[1], K. Anagnostopoulou[1], S. Iraklianou[1], G. Dimitriadis[2], A. Melidonis[1];
[1]Diabetes Center, Tzaneio General Hospital of Piraeus, Piraeus, [2]2nd Department of Internal Medicine-Propaedeutic, Research Institute and Diabetes Center, Attikon University Hospital, Medical School, National and Kapodistrian University of Athens, Athens, [3]Cardiology Department, Tzaneio General Hospital of Piraeus, Piraeus, Greece.

Background and aims: ADAMTS7 belong to the family of metalloproteinases and contribute to the tissue morphogenesis, regulate cell proliferation and are important regulators of tissue regeneration.Recent studies have shown a pathogenetic role of ADAMTS7 to vascular remodeling caused by coronary atherosclerosis.However, its role to diabetic cardiomyopathy is still unknown. Therefore, the aim of the present study was to estimate the effect of ADAMTS7 to cardiac remodeling, expressed in terms of established ultrasound indicators of cardiac function, in subjects with type 2 diabetes mellitus (T2D) free of cardiovascular disease.

Materials and methods: 65 patients with T2D [mean age (± standard deviation, SD) of 57.5 ± 10.7 years, HbA1c: 6.9 ± 0.7%, body mass index (BMI) 30.8 ± 3.8 kg/m^2] without known cardiovascular disease were examined. All study patients underwent fully clinical examination and a blood sample was taken at fasting state for the measurement of ADAMTS7 (Elisa method) at baseline. Also an ultrasound examination of the heart was performed at baseline and 12 months after subject's enrollment into the study. The following ultrasound indicators of cardiac function were calculated: LVIDd, LVIDs, LVEF, LVFS, LVMASS, A′, A, D, E, DT, S, LA, E′ and E/E′.
Results: At baseline levels of ADAMTS7 were 0.32 ± 0.12 pg/ml. The majority of study patients were on metformin treatment (90%), 38,7% on DPP-4 inhibitors, 25,8% on GLP-1 analogs, 12.9% on sulfonylureas, 9.7% on SGLT-2 inhibitors, 3.2% on glitazones and 25.8% on insulin. 80.6% had hypertension and 61.3% dyslipidemia. Multivariate regression analysis (backward), after adjustment for the established ultrasound indicators of cardiac function, showed that ADAMTS7 levels were positive correlated with LVIDs (inner diameter of the left ventricle) (beta = 0.570, $p = 0.05$) and A′ (atrial contraction) (beta = 0.326, $p = 0.05$).
Conclusion: The results of the present study show that ADAMTS7 might be an indicator of early left ventricular diastolic (A′) and systolic dysfunction (LVIDs) in subjects with T2D. The above findings add information to the role of ADAMTS7 as a newly biomarker of cardiac remodeling.

Subclinical ventricular dysfunction in young population with congenital generalised lipodystrophy detected by speckle-tracking echocardiography

V.O. Fernandes, C.B.R. Liberato, N.B.C. Olegario, A.D.R. Montenegro, G.E.C. Paiva, L.A.A. Batista, L.V. Martins, I.L.R. Liberato, A.B. Carvalho, C.B. d'Alva, R.M. Montenegro Junior;
Brazilian Group for the Study of Inherited and Acquired Lipodystrophies (BRAZLIPO), Universidade Federal do Ceara, Fortaleza, Brazil.

Background and aims: Congenital generalized lipodystrophy (CGL) is an autosomal recessive disorder characterized by absence of functional adipocytes and lipid stored in other tissues, including muscle and liver. Affected individuals develop severe insulin resistance (IR), dyslipidemia, hepatic steatosis and diabetes, usually with early cardiovascular mortality. Echocardiographic findings previously described in CGL used only the conventional technique. Thus, this study aimed to perform speckle-tracking echocardiography (STE), a recently developed technique for the characterization and quantification of myocardial deformation, in one of the largest casuistry of CGL in Brazil.
Materials and methods: A cross-sectional study with 22 CGL patients from 2013 to 2016. Clinical, biochemical and echocardiographic evaluation were conducted in CGL group and with 22 healthy subjects matched for sex and age. All patients undergone standard conventional transthoracic echocardiography and two-dimensional STE using Vivid 7 and 9 ultrasound system (GE Vingmed Ultrasound, Milwaukee, Wi, USA). This technique includes global longitudinal strain (GLS) measure, obtained by evaluating the mean of the strain value of the 18 segments of the left ventricle in the three standard apical incidences.
Results: The mean age was 14.6 ± 10.7 years old (yo): 40.9% (9) aged 0 to 9 years, 27.3% (6) aged 10 to 17 years and 31.8% (7) ≥18 years. There were 59% (13) females. All CGL patients had hypoleptinemia, 95.4% (21) low HDL-c, 86.36% (19) hypertriglyceridemia, 71.4% (15) severe insulin resistance, 50% (11) hepatic steatosis, 63.6% (14) diabetes, 40.9% (9) hyperinsulinemia, 41% (9) hypercholesterolemia and 18.2% (4) high blood pressure. When evaluated by conventional echocardiography, all CGL group presented normal systolic and diastolic function, 31.8% (7) left ventricular (LV) hypertrophy, 27.3% (6) left atrial diastolic volume increase, 18.2% (4) LV systolic diameter increase and 4.5% (1) LV diastolic diameter increase. Comparing CGL and control groups, the CGL subjects had higher LV volume, LV mass index and LV diastolic diameter. Although the normal ejection fraction (EF) in all sample, those with CGL under 18 yo had lower EF than control ($p < 0.05$). Evaluation by STE showed abnormal results of global longitudinal strain (GLS) in 68.2% (15) of CGL group ($p < 0.01$). The GLS was normal in all control group. CGL group also had worse results in the evaluation of global longitudinal strain and of all evaluated segments, except for the apical. In those with altered GLS, 93.3% (14) had hypertriglyceridemia, 93.3% (14) low HDL-c, 73.3% (11) diabetes, 60% (9) high HOMA-IR index, 53.3% (8) hyperinsulinemia and 46% (7) hypercholesterolemia. It was observed a positive correlation with GLS and insulin ($p = 0.007$), HbA1c ($p = 0.005$), blood glucose ($p = 0.018$) and HOMA-IR index ($p = 0.021$).
Conclusion: This young population with CGL presented subclinical ventricular dysfunction by speckle-tracking echocardiography, even with a normal conventional echocardiographic study.
Disclosure: **V.O. Fernandes:** None.

Extracellular matrix turnover influences myocardial contraction behaviour in diabetic cardiomyopathy assessed by speckle tracking echocardiography

K. Pappritz[1,2], J. Grune[2,3], O. Klein[1,2], F. Dong[1], M. El-Shafeey[1], J. Lin[1], U. Kintscher[4,2], C. Tschöpe[1,5], S. Van Linthout[1,2];
[1]Berlin – Brandenburger Center for Regenerative Therapies (BCRT), Charité – Universitätsmedizin Berlin, Berlin, [2]German Center for Cardiovascular Research (DZHK), partner site Berlin, Berlin, [3]Institute of Physiology, Charité – Universitätsmedizin Berlin, Berlin, [4]Center for Cardiovascular Research (CCR), Charité – Universitätsmedizin Berlin, Berlin, [5]Department of Cardiology, Charité – Universitätsmedizin Berlin, Berlin, Germany.

Background and aims: Diabetic cardiomyopathy is referred to be an own clinical entity in the context of diabetes mellitus (DM). Experimental streptozotocin (STZ)-induced Type I diabetic cardiomyopathy is associated with cardiac collagen I deposition resulting in left ventricular (LV) dysfunction. LV contraction is determined by the shortening and thickening of the longitudinal and circumferential fibres, which can be investigated by two-dimensional speckle-tracking echocardiography (STE). The present study aimed to investigate the impact of LV matrix composition on global deformation behaviour in the pathogenesis of STZ-induced diabetic cardiomyopathy.
Materials and methods: Eight-week-old male C57BL6/j mice were intraperitoneally injected with 50 mg/kg BW STZ, dissolved in 0.1 mol/L sodium citrate, during 5 consecutive days. 6, 9, and 12 weeks (w) post DM induction, echocardiographic measurements were performed on a Vevo 3100 using a 30-MHz linear-frequency transducer. Two-dimensional STE-based analyses were assessed from B-mode images using the VevoStrain software package. In an additional set, the LV was harvested to analyze gene and protein expression.
Results: Global longitudinal strain (GLS) was impaired in mice at 6w (co 6 w: −21 ± 1.0% vs. STZ 6 w: −15 ± 0.43%; $p < 0.0001$), 9 w (co 9 w: −21 ± 0.93% vs. STZ 9 w: −12 ± 0.63%; $p < 0.0001$), and 12 w (co 12 w: −19 ± 0.81% vs. STZ 12 w: −13% ± 0.90%; $p < 0.0001$) post STZ application. Furthermore, the 9 w STZ group displayed a 3% ($p = 0.0287$) worsened GLS compared to the 6 w STZ group. In parallel, an enhanced global circumferential strain (GCS) was observed in the 6w (co 6 w: −23 ± 0.93% vs. STZ 6 w: −27 ± 1.2%; $p = 0.0054$) and 12w (co 12w: −24 ± 0.98% vs. STZ 12 w: −27 ± 0.69%; $p = 0.0988$) STZ mice vs. controls. Furthermore, 9 w STZ animals displayed a 5% ($p = 0.0003$) and 5% ($p = 0.0006$) impaired GCS vs. 6 w and 12 w STZ mice, respectively. The impairment in GLS in 9w STZ mice vs. controls was associated with a 1.7-fold ($p = 0.0005$) enhanced collagen I expression accompanied by a 2.9-fold ($p = 0.0059$) increased collagen I/III protein ratio compared to controls. Interestingly, collagen I protein, lysyl oxidase (Lox) and Lox-like (LoxL)-2 mRNA expression was 2.4-fold ($p < 0.0001$), 1.4-fold ($p =$

0.0284), and 1.4-fold ($p = 0.0170$) lower in the STZ 12 w vs. the STZ 9 w group, respectively. Quantitative segmental analysis further indicated decreased myocardial deformation behaviour of the anterior and posterior base at 9 w after STZ treatment compared to controls. This observation was supported by changes in protein expression assessed by imaging mass spectrometry.
Conclusion: Type I DM influences cardiac collagen deposition in a time-dependent manner, which finally results in changes of the endomyocardial deformation capacity indicated by altered GLS.

Diabetes-like environment impairs differentiation and induces senescence of epicardial adipose tissue-derived mesenchymal stem cells
S. Cabaro[1,2], V. D'Esposito[1,2], V. Parisi[1], M. Lecce[1,2], D. Liguoro[1,2], A. Liotti[1,2], I. Cimmino[1,2], F. Oriente[1,2], D. Leosco[1], F. Beguinot[1,2], P. Formisano[1,2];
[1]University of Naples "Federico II", Department of Translational Medical Sciences, Naples, [2]National Council of Research (CNR), URT GDD-IEOS, Naples, Italy.

Background and aims: Excess of visceral fat is a major culprit in the development of type 2 diabetes (T2D) and related disorders. A growing body of evidence indicates that epicardial adipose tissue (EAT), the visceral fat of the heart, may play an active role in dysregulation of cardiac function. Indeed, EAT thickness positively correlates with the release of inflammatory molecules and with the severity of heart pathologies, including heart failure, aortic valve stenosis and coronary artery disease (CAD). Moreover, EAT thickness is inversely associated with insulin sensitivity and positively correlates with metabolic parameters including postprandial glucose, HbA1c level, and HOMA-IR. In patients with diabetes, prolonged hyperglycemia damages several organs, including heart. Diabetic hyperglycemic microenvironment could regulate the balance between self-renewal and differentiation of stem cells in adipose tissue, but the involved mechanisms have not been thoroughly investigated. Thus, potent pro-inflammatory activation of EAT suggests a direct involvement of cardiac visceral fat in inflammatory phenomena occurring in patients with cardiovascular diseases. This study aims at investigating whether different glucose concentrations may impact on EAT functions.
Materials and methods: EAT biopsies were collected from diabetic ($n = 7$) and non-diabetic ($n = 7$) individuals with CAD. EAT-derived mesenchymal stem cells (MSCs) were isolated ($n = 5$) and cultured in high glucose (HG 25 mmol/l) or normal glucose (NG 5.5 mmol/l) concentration, as control. Cell surface markers were assessed by FACS analysis and gene expression levels by real time RT-PCR.
Results: EAT-MSCs cultured in NG and HG exhibited similar proliferation rate. Additionally, the expression of cell surface markers, characteristic of adipose tissue-derived MSCs ($CD90^+$, $CD31^-$, $CD45^-$, $CD73^+$), was similar in both conditions. Interestingly, HG-treated EAT-MSCs displayed a 50% decreased expression of the multipotent markers Oct-4 and Nanog. Moreover, mRNA levels of the senescence marker $p21^{CIP1/WAF1}$ were significantly increased in HG-cultured cells. HG-treated EAT-MSCs maintained their adipogenic and osteogenic potential, after the application of appropriate induction media, however either lipid or calcium accumulation seemed to be lower compared with NG-cultured cells. Consistent with these data, in EAT biopsies from diabetic patients there was a 1.7- and 2.2-fold reduction of mRNA levels of PPARgamma and BMP1, respectively master gene regulators of adipogenic and osteogenic differentiation.
Conclusion: Collectively, these data indicate that a diabetic-like environment directly influences EAT-derived MSC features and significantly affects their stemness and differentiation potential, driving towards accelerated senescence.

Continued administration of the hydroxyl fatty acid 9-PAHSA alleviates diabetic-induced cardiac dysfunctions by enhancing autophagic flux in the heart of db/db mice
H. Jin, Q.-L. Guo, H.-G. Zhou, J.-C. Guo;
Fudan University, Shanghai, China.

Background and aims: Diabetic cardiomyopathy (DCM) is one of the most common complications of type 2 diabetes mellitus (T2DM), leading to high mortality in patients. However, effective interventions for DCM therapy are still lack so far. Recently, a novel branched palmitic acid esters of hydroxyl stearic acid 9-PAHSA has been proved to be bioactive in T2DM, but whether it could protect cardiomyocytes in DCM pathology remains unclear.
Materials and methods: Thirty- two-week-old male C57BLKS/J db/db mice were used as the T2DM model mice. Age-matched male littermates C57BLKS/J wild type mice were used as the non-diabetic control. All the animals were purchased from Nanjing University Biological Center (Nanjing, China), and housed in colony cages with free access to water and regular diet in a 12h light/dark cycle and temperature-controlled environment. By using the iTRAQ approach and 1.5-fold change cut-off value, we analyzed the effect of 9-PAHSA on the myocardial protein profile of db/db diabetic mice, and evaluated the efficacy of 9-PAHSA against myocardium dysfunction.
Results: A total of 432 proteins were identified among these three groups. Of these 432 proteins, 80 were found to be differentially expressed in db/db+9-PAHSA group with respect to db/db+ ventricular hypertrophy(veh)group. Among these 80 proteins, the level of 37 proteins was elevated in the db/db+ veh group when compared with the control + veh group, and decreased after 9-PAHSA treatment. Other 43 proteins levels were decreased in the db/db+veh group with respect to the control +veh group, and reversed after the treatment. These identified 80 proteins were further functionally classified to evaluate the underlying metabolic processes altered after 9-PAHSA intervention. A total of 20 proteins could be classified into four main functional classes including cardiac lipid metabolism-related, mitochondrial-related, cardiomyopathy-related, and autophagy-related proteins. The expression level of serum 9-PAHSA levels was reduced in diabetic db/db mice. Continued administration of 9-PAHSA for four weeks could significantly improves cardiac functions and structure. Moreover, by using iTRAQ proteomics analysis, we found that 9-PAHSA could induce the expression changes in series of proteins, including autophagy-related BAG3 and HspB8.
Conclusion: Our results demonstrate that 9-PAHSA enhances the cardiac autophagy in db/db mice, as evidenced by electron microscopy and by western blotting analysis of LC3, P62, BECN1, PI3K III, and mTOR. Continued administration of 9-PAHSA could improve diabetic-induced myocardial dysfunction by promoting autophagic flux and reducing myocardial hypertrophy in db/db mice. Our results also showed that chronic treatment of 9-PAHSA could improve db/db diabetic-induced cardiac dysfunctions, possibly via enhancing autophagic flux. Considering the fact that 9-PAHSA levels are reduced in db/db diabetic mice, the exogenous supplementation of 9-PAHSA might be an effective means for the T2DM-related DCM. 9-PAHSA could also be a candidate drug for the clinical therapy of DCM.

Retinal microvascular associations with blood pressure and arterial stiffness are modified by diabetes status: results from the UK Biobank
R.J. Tapp[1,2], C.G. Owen[1], S.A. Barman[3], D.P. Strachan[1], R.A. Welikala[3], P.J. Foster[4,5], P.H. Whincup[1], A.R. Rudnicka[1];
[1]Population Health Research Institute, St Georges, University of London, London, UK, [2]Melbourne School of Population and Global Health,

University of Melbourne, Melbourne, Australia, [3]Faculty of Science, Engineering and Computing, Kingston University, Surrey, UK, [4]Integrative Epidemiology Research Group, UCL Institute of Ophthalmology, London, UK, [5]NIHR Biomedical Research Centre at Moorfields Eye hospital, London, UK.

Background and aims: Retinal microvascular changes and arterial stiffness are both independent predictors of cardiovascular disease (CVD) and mortality. A growing body of evidence suggests an association between retinal microvascular changes and arterial stiffness. We examined the associations of retinal microvascular architecture with blood pressure (BP) and arterial stiffness, and examined whether associations were modified by diabetes.

Materials and methods: The UK Biobank eye study included 68,549 participants, aged 40–70 years, who underwent non-mydriatic retinal photography, BP and arterial stiffness measurement. Retinal vessel architecture was analyzed using the fully automated QUARTZ software, which measured vessel width and tortuosity. Blood pressure was measured using an Omron 705 IT BP monitor and the arterial stiffness index (ASI) was assessed using a photoplethysmography transducer. Diabetes status, blood pressure medication and previous CVD events were self-reported.

Results: A total of 53,094 participants were included in these analyses. Mean arteriolar and venular diameters were 10.0 pixels (SD 0.9) and 11.8 pixels (SD 1.6) and mean arteriolar and venular tortuosity were 4.4 (SD 1.6) and 3.2 (SD 1.4) respectively. Narrower arterioles were associated with higher systolic BP (beta coefficient (β)-0.09 per 10 mmHg, 95% CI −0.10 to −0.09, $p \leq 0.001$), mean arterial pressure (MAP) (β −0.16 per 10 mmHg, 95% CI −0.16 to −0.15, $p < 0.001$) mean pulse pressure (PP) (β −0.07 per 10 mmHg, 95% CI −0.07 to −0.06, $p < 0.001$) and ASI (β −0.06, 95% CI −0.08 to −0.05, $p < 0.001$). Increased arteriolar tortuosity was associated with higher systolic BP (β 1.14 per 10 mmHg, 95% CI 0.89 to 1.39, $p < 0.001$), MAP (β 1.22 per 10 mmHg, 95% CI 0.84 to 1.59, $p < 0.001$) and PP (β 1.81 per 10 mmHg, 95% CI 1.45 to 2.17, $p < 0.001$). Similar patterns of association were evident for venules (diameter and tortuosity). These associations were unaffected by adjustment for confounders and removal of participants with CVD events or on treatment for high BP. Furthermore, the presence of diabetes was strongly associated with arteriolar narrowing. However, the inverse association of arterial narrowing with systolic BP and MAP were significantly stronger in those without diabetes than in those with diabetes. Associations of venular tortuosity with MAP and ASI were also significantly modified by diabetes status.

Conclusion: This landmark study assessing the retinal microvasculature at scale, has shown clear associations between retinal microvascular architecture, BP and ASI. These observations may be useful in furthering our understanding of the interplay between microvascular and macrovascular disease at a population level.

Glycaemic control, cardiovascular disease and mortality in type 2 diabetes patients in a real life setting over time: population-based data from the Netherlands

E. Heintjes[1], E. Houben[1], S. Cremers[2], W. Beekman[2], F. Penning-van Beest[1], C. Stehouwer[3], R. Herings[1,4];
[1]PHARMO Institute for Drug Outcomes Research, Utrecht, [2]AstraZeneca BV, Den Haag, [3]Department of Internal Medicine and Cardiovascular Research Institute Maastricht (CARIM), Maastricht University Medical Centre, Maastricht, [4]Department of Epidemiology & Biostatistics, VU Medical Center, Amsterdam, Netherlands.

Background and aims: According to the EURO Diabetes Index 2014, the quality of Dutch diabetes care is very good in terms of glycaemic control. The main criticism of the EURO Diabetes Index was the lack of data on short- and long-term outcomes. Dutch GP guidelines (revised in 2013) state that the goal of diabetes treatment is the prevention and treatment of cardiovascular and microvascular complications. The aim of this study was to assess trends in HbA1c levels, risk of cardiovascular disease (CVD) and all-cause mortality (ACM) among T2D patients in the Netherlands.

Materials and methods: A series of cohort studies were conducted among annual samples of adult T2D patients treated with glucose-lowering drugs in both primary and secondary care (2008–2016), using records from the PHARMO Database Network. January 1st of each year served as index date and inclusion was restricted to patients without type 1 diabetes, gestational diabetes and polycystic ovary syndrome. Most recent HbA1c levels were assessed in the year prior to index date. Annual incidence of CVD (acute myocardial infarction, ischemic stroke, angina pectoris or congestive heart failure) and ACM was assessed. Rate ratios (RRs) were calculated by comparing age-standardised incidence rates with a diabetes-free population matched on age, sex and general practitioner. Life years lost (LYL) to T2D was determined by comparing the life expectancy of the T2D patients with the matched diabetes-free patients.

Results: In total, 53,602 T2D patients were included in annual cohorts (mean age range: 66–69 years; proportion male range: 51–55%). Mean HbA1c increased from 52 ± 11 mmol/mol in 2008 (proportion <53 mmol/mol: 58%) to 54 ± 12 mmol/mol in 2016 (proportion <53 mmol/mol: 52%). In 2016, the RR (95% CI) was 1.68 (1.35–2.08) for CVD and 1.78 (1.44–2.21) for ACM (Figure). On average, RRs showed an 80% increased risk of CVD and 86% for ACM over all years. No trend was observed in the RRs for ACM and CVD. Overall, the LYL to T2D was approximately four years at the age of 50 years and decreased to approximately one year at the age of 80 years. At the (overall mean) age of 66 years this was approximately 2.5 years.

Conclusion: HbA1c levels increased slightly over time, in line with the introduction of revised GP guidelines for individualised HbA1c targets in the Netherlands. No trend was observed for the increased risk of ACM and CVD among T2D patients from 2008–2016, despite the introduction of several changes in the guidelines on diabetes care. Overall, T2D patients at the age of 66 years are expected to have about 2.5 years shorter life expectancy than the general Dutch population.

Estimation of 4 year cardiovascular risk in Indian type 2 diabetic patients using the ADVANCE risk engine in daily clinical practice settings: results from DiaCRE study

G. Bantwal[1], A. Joshi[2];
[1]St. Johns Medical College and Hospital, Bengaluru, [2]Clinic, Mumbai, India.

Background and aims: Cardiovascular (CV) risk assessment is an imperative tool that directs clinical decision making on therapies and encourages patients for lifestyle changes and medication adherence. The ADVANCE (**A**ction in **D**iabetes and **V**ascular Disease: Pretar**A**x And Diamicro**N**Modified Release **C**ontrolled **E**valuation) risk engine is applicable in global real-world clinical settings owing to inclusion of participants from developing countries in the landmark ADVANCE study. The **DiaCRE** (**Dia**betes **C**ardiovascular **R**isk **E**valuation score card) study aimed at assessing the 4year CV risk using ADVANCE risk engine model in Indian type 2 diabetes (T2D) patients undergoing treatment in real-world clinical practice settings.
Materials and methods: DiaCRE was a prospective, non-interventional study that recruited T2D patients aged ≥18 years. General information and CV risk factors were collected at a single-visit. 4year CV risk was calculated using ADVANCE risk engine model. Data were analysed by bivariate and multiple logistic regression. Likelihood estimates corresponding to the impact of one unit change in each CV risk factor on 4 year CV risk score were calculated.
Results: 172 physicians enrolled 4648 patients at 69 cities across India. Mean age was 55.3 years, mean age at diagnosis of diabetes was 47 years and mean duration of diabetes was 8.3 years. The median 4 year CV risk score was 1.4% and a risk score ≥7% was estimated in 694 (14.9%) patients. The most common modifiable risk factor was HbA_{1c} ≥6% ($n = 4315$, 92.8%), followed by non-HDL cholesterol (≥116 mg/dL) ($n = 3556$, 76.5%), pulse pressure >50 mmHg ($n = 3277$, 70.5%), and hypertension ($n = 2742$, 59%) as defined in ADVANCE risk engine model. The estimated risk was significantly higher in male than female patients ($p < 0.0001$) and in obese than non-obese patients ($p = 0.0031$). The median 4-year CV risk score of patients with HbA_{1c} <6% was 0.5% which steadily increased to 1.4% and 4.3% in patients with HbA_{1c} 6–<9% and HbA_{1c} ≥9%, respectively. Presence of ≥2 risk factors in 3740 (80.4%) patients indicated high burden of risk factors in majority of Indian T2D patients in daily clinical practice settings. The percentage likelihood of 4 year CV risk increased with one unit change in all individual risk factors (as shown in table) ($p < 0.0001$). Multiple logistic regression analysis demonstrated that each CV risk factor significantly affected the 4 year CV risk independently ($p < 0.0001$).
Conclusion: The DiaCRE study using the ADVANCE risk engine model in daily clinical practice settings in India demonstrated high burden of risk factors. The estimated 4 year CV risk was significantly influenced by all risk factors and HbA_{1c} was the most common modifiable risk factor. These findings identify a need for measures (including modification of therapies) to control the risk factors. The ADVANCE CV risk engine may serve as a vital tool for patient awareness in addressing control of the risk factors in daily clinical practice.

Risk factor	Percentage likelihood of 4-year CV risk increase with one unit change in individual risk factors (95% CI)
HbA_{1c}	3.6 (3.1 - 4.1)
Age at diagnosis	1.1 (1.1 - 1.2)
Duration of diabetes	1.2 (1.2 - 1.3)
Gender (Male)	0.6 (0.5 - 0.7)
Atrial fibrillation	14.9 (8.7 - 25.5)
Retinopathy	15.0 (11.3 - 19.8)
Hypertension	9.3 (8.1 - 10.7)
Pulse pressure	4.7 (4.1 - 5.3)
Albuminuria	4.2 (3.8 - 4.6)
Non-HDL cholesterol	4.1 (3.6 - 4.6)

Disclosure: **G. Bantwal:** None.

Risk of cardiovascular disease in individuals with latent autoimmune diabetes of adults: results from the UKPDS

E. Maddaloni[1], R.L. Coleman[2], P. Pozzilli[1], R.R. Holman[2];
[1]Dept of Medicine, Unit of Endocrinology and Diabetes, Campus Bio-Medico University of Rome, Rome, Italy, [2]Diabetes Trial Unit, University of Oxford, Oxford, UK.

Background and aims: Diabetes autoantibodies (AAb) to islet-cell cytoplasm (ICA), to glutamic acid decarboxylase (GADA) or to islet antigen-2 (IA-2A), are detectable in up to 12% of adults with a clinical diagnosis of type 2 diabetes (T2D). The presence of AAb identifies subjects with adult-onset autoimmune diabetes, who are mostly affected by a slowly progressive form known as latent autoimmune diabetes of adults. Subjects with detectable AAb tend to be leaner and to have a healthier cardiovascular (CV) risk profile than AAb-negative subjects, but it remains uncertain whether the risk of CV events differ between these two groups. We examined the long-term risk of CV disease in the large population with a clinical diagnosis of new-onset T2D enrolled in the United Kingdom Prospective Diabetes Study (UKPDS), according to their AAb status.
Materials and methods: ICA, GADA and IA-2A were measured in 5096 UKPDS participants at or soon after diagnosis of T2D. The incidence of major adverse CV events, a composite of cardiovascular death, nonfatal myocardial infarction or nonfatal stroke (MACE3), was compared between those with no antibodies (AAb-) and those with ≥1 AAb positive tests (AAb+). Hazard ratios (HR) were adjusted for pre-specified potential confounders (age, race, sex, metabolic profile and smoking status) and for therapy allocation (diet, insulin, sulfonylureas, metformin, non-randomized). The interaction between CV risk factors (age, sex, lipid profile, body mass index [BMI], HbA1c, systolic blood pressure [SBP], smoking status) and AAb status was also examined.
Results: The 557 AAb+ UKPDS participants were younger, with higher mean HbA_{1c} and HDL-cholesterol values but lower BMI, total

cholesterol and SBP values than AAb- subjects (all $p < 0.01$). Over a mean ± SD follow-up period of 16.3 ± 6.0 years a total of 1071 MACE3 events occurred with incidence rates/1000 person-years (95% confidence interval [CI]) of 17.1 (14.6–20.0) in AAb+ and 23.5 (22.4–24.7) in AAb- participants (HR 0.71, CI 0.60–0.84, $p < 0.001$). Following adjustment for pre-specified confounders, there was no significant difference in MACE3 risk between AAb+ and AAb- participants (adj-HR 0.90, CI 0.76–1.07, $p = 0.22$). The 186 UKPDS participants with ≥2 positive AAb tests (double-AAb+) had the lowest MACE3 risk (HR 0.46, CI 0.33–0.65, $p < 0.001$), but this difference became non-significant following adjustment for potential confounders (adj-HR 0.75, CI 0.46–1.22, interaction $p = 0.25$) (See Figure). There were no significant interactions between CV risk factors and AAb status.

Conclusion: In adults with newly-diagnosed diabetes the long-term risk of MACE3 does not differ between those with and without detectable AAb after adjustment for confounders. This suggests measurement of diabetes AAb does not aid in the stratification of CV risk among adults with a clinical diagnosis of new-onset T2D.

Cardiovascular outcomes and mortality in type 2 diabetes with associated cardio-renal-metabolic comorbidities

D.Z.I. Cherney[1], D.C. Wheeler[2], M. Kosiborod[3], S.V. Arnold[3], S. MacLachlan[4], P.R. Hunt[5], H. Chen[6], E. Repetto[6], J. Vora[7];
[1]University Health Network, Toronto General Hospital, Toronto, Canada, [2]Centre for Nephrology, University College London, London, UK, [3]Saint Luke's Mid America Heart Institute, Kansas City, USA, [4]Evidera, London, UK, [5]Evidera, Waltham, USA, [6]AstraZeneca, Gaithersburg, USA, [7]University of Liverpool, Liverpool, UK.

Background and aims: Cardio-renal-metabolic comorbidities (CRMCs) in patients with type 2 diabetes (T2D) are associated with high morbidity and mortality rates. We evaluated the incremental contribution of various CRMCs to the risk of myocardial infarction, stroke, or cardiovascular death (MACE), heart failure (HF) and all-cause mortality in patients with newly diagnosed T2D.

Materials and methods: Using International Classification of Diseases (ICD)-9 codes and Read codes, CRMCs (hypertension [HTN], hyperlipidaemia [HPLD] and chronic kidney disease [CKD]) were identified at the time of T2D diagnosis using databases in the UK (Clinical Practice Research Datalink [CPRD]) and the US (Humedica/Optum). The CPRD database includes longitudinal primary care data from 714 real-life clinical practices and covers approximately 8% of the UK population while the Humedica/Optum databases are US electronic medical records that are claim based and derived mainly from hospitals and outpatient clinics. Humedica databases include approximately 18.5 million patients from 38 States. Both the UK and US (Humedica/Optum) databases are broadly representative of the demographic and geographic breakdown of their respective populations. Patients were followed post-diagnosis of T2D for the occurrence of MACE, HF and mortality and evaluated for the increase in relative risk due to CRMCs.

Results: Between 1 Jan 2011 and 31 Mar 2015, we identified 59,362 patients in the UK and 180,722 patients in the US with incident T2D (mean age [SD]: 61.8 [13.6] and 62.4 [13.5] years; 55.9% and 52% men, respectively). There were no significant differences in the effects of CRMCs on outcomes between countries. The risk of MACE, HF and mortality increased with the number of CRMCs (Table). CKD was associated with the highest incremental risk, with an HR (95% CI) of 2.23 (2.17, 2.49) for mortality compared with T2D alone.

Conclusion: In patients with a new diagnosis of T2D, the risk of MACE, HF and death increased with the number of CRMCs, with CKD being the largest driver of mortality. These results may have implications for risk stratification of patients with T2D, and highlight the importance of identifying novel renoprotection strategies among T2D patients with various CRMCs.

Table. Combined analyses of US and UK databases: MACE, HF and mortality rates in patients with incident T2D and cardio-renal-metabolic diseases

Outcomes	CRMCs at the time of T2D diagnosis	N	Events/100 PY (95% CI)	Incremental % increase in event rate	Adjusted HR (95% CI)
MACE	T2D only	31881	4.34 (4.21, 4.47)	Reference	Reference
	T2D + HTN + HPLD	73448	5.71 (5.61, 5.81)	31.57	1.18 (1.14, 1.23)
	T2D + HTN + HPLD + CKD	21570	8.30 (8.06, 8.54)	43.36	1.56 (1.47, 1.65)
HF	T2D only	31881	4.01 (3.88, 4.14)	Reference	Reference
	T2D + HTN + HPLD	73448	4.84 (4.75, 4.93)	20.70	1.11 (1.07, 1.16)
	T2D + HTN + HPLD + CKD	21570	7.34 (7.12, 7.57)	51.65	1.79 (1.69, 1.90)
Mortality	T2D only	31881	2.14 (2.05, 2.23)	Reference	Reference
	T2D + HTN + HPLD	73448	2.66 (2.60, 2.73)	24.30	1.0 (1.0, 1.1)
	T2D + HTN + HPLD + CKD	21570	5.44 (5.27, 5.62)	104.51	2.23 (2.17, 2.49)

1178

A contemporary Australian cardiovascular risk equation for type 2 diabetes: the Fremantle Diabetes Study Phase II

W.A. Davis[1], M. Hunter[2], T.M.E. Davis[1];
[1]Medical School, The University Of Western Australia, Fremantle, [2]Busselton Health Study, Busselton Population Medical Research Institute, Busselton, Australia.

Background and aims: Due to the lack of valid Australian cardiovascular disease (CVD) risk assessment for type 2 diabetes (T2D) we previously developed the Fremantle Diabetes Study (FDS) equation for 5-year risk of hospitalisation for myocardial infarction (MI)/stroke or CVD death. However, there have been substantial changes in the diagnosis, management and outcome of diabetes in the 20 years since the original FDS cohort was enrolled. When the equation was applied to the contemporary FDS Phase II (FDS2) T2D cohort, calibration was poor, while improved survival after acute CVD events has seen hospitalisation for heart failure (HF) become a key additional outcome. In light of these

considerations we have developed and validated a contemporary CVD risk equation.

Materials and methods: FDS2 is a community-based longitudinal observational study. 1551 participants with T2D were followed from baseline (2008–11) for 5 years or until a first CVD event (hospitalisation for MI/stroke/HF or CVD death) or death from other causes. Incident events were identified from hospital morbidity and death registries. Missing covariates were multiply imputed (x20), defining models that included the outcomes of CVD and competing risk of death. Competing risk regression modelling with backward elimination identified independent predictors of CVD within 5 years of study entry. The proportional subdistribution hazards assumption was checked using log-minus-log curves. Discrimination was assessed by the area under the receiver-operating characteristic curve (*c*-index), calibration using the Hosmer and Lemeshow test (Ĉ-statistic) and accuracy by the Brier score. Positive and negative predictive values (PPV, NPV), sensitivity and specificity were determined for a 10% 5-year CVD risk cut-off. The equation was validated in 174 adults with T2D from the Busselton Diabetes Study. StataIC 13 was used for statistical analyses.

Results: The average age of the cohort was 66 years, 52% were men and the median diabetes duration was 9 years. During 6,896 person-years' follow-up, 245 participants (15.8% (95% CI 14.0–17.7%)), had a CVD event. Variables in the final competing risk model comprised age, Australian Aboriginality, heart rate, diabetes duration, ln(gamma-GT), serum albumin, eGFR <45 ml/min/1.73 m^2, ln(urinary albumin:creatinine), left ventricular hypertrophy, anticoagulant use, peripheral arterial disease and history of CVD. The proportional hazards assumption was not violated. The mean 5-year predicted risk of CVD was 14.4%. Model discrimination was good (*c*-index: 0.81 (95% CI 0.78–0.84), $p < 0.001$, as were calibration (Ĉ-statistic = 0.12) and accuracy (Brier score (95% CI): 0.10 (0–0.83)). PPV, NPV, sensitivity and specificity for a 10% 5-year CVD risk cut-off were 31.5%, 95.3%, 82.4% and 66.2%, respectively. During 5-years' follow-up, 21.2% (37 cases) of the validation cohort had an incident CVD event compared with a mean predicted risk of 13.5% (24 cases). There was good discrimination (*c*-index: 0.80 (0.72–0.88), $p < 0.001$), calibration (Ĉ-test $p = 0.26$) and accuracy (Brier score: 0.14 (0–0.88)). At a 10% risk cut-off the sensitivity was 78.4%, specificity 65.0%, PPV 37.8% and NPV 91.8%.

Conclusion: A valid and more sophisticated 5-year CVD risk equation has been developed which includes HF as an outcome and reflects contemporary management and longer survival in Australians with T2D.

Socio-economic inequalities in hospital admissions for major cardiovascular events in people with diabetes in England

E. Vamos, Z. Shather, A. Laverty, A. Bottle, H. Watt, A. Majeed, C. Millett;
Imperial College, London, UK.

Background and aims: While extensively studied in the general population, little is known about how people with diabetes from different socioeconomic groups have benefited from reductions in CVD over the last decade. This nationwide study aims to determine changes in absolute and relative socio-economic inequalities in hospital admissions for major cardiovascular events and procedures among people with diabetes in England between 2004–2005 and 2014–2015.

Materials and methods: We identified all patients with diagnosed diabetes aged above 16 years admitted to hospital in England between 2004–2005 and 2014–2015 for acute myocardial infarction (AMI), stroke, percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG). Socio-economic status was measured using Index of Multiple Deprivation. Diabetes-specific admission rates were calculated for each year by deprivation quintile. We assessed temporal changes relative inequalities in admissions for each outcome using negative binomial regression models, and we used linear regression models to assess changes in absolute inequalities between deprivation groups.

Results: Admission rates rose steadily with increasing levels of deprivation throughout the study period. People with diabetes from the most deprived quintile had 2.17-fold increased risk of AMI (95% CI 1.98–2.37), 2.04-fold risk of stroke (95% CI 1.88–2.22), 1.79-fold risk of CABG (95% CI 1.65–1.94), and 2.03-fold risk of PCI (95% CI 1.89–2.18) ($P \leq 0.001$ for all) compared with the least deprived group. Socio-economic gradients did not significantly change over the study period for any of the study outcomes. Absolute differences in admission rates between the least and most deprived quintiles did not significantly change for AMI ($P = 0.342$) and reduced for stroke, PCI and CABG admissions (by 14, 134 and 46 per 100,000 people with diabetes, respectively, $P \leq 0.005$ for all). From 2004–2005 to 2014–2015, there was a reduction in in-patient mortality rates for all outcomes except for PCI. Trends in in-patient mortality did not statistically significantly differ between the most affluent and other deprivation groups for the study outcomes.

Conclusion: Socio-economic inequalities persisted in hospital admissions for major CVD events in England among people with diabetes throughout the study period. Besides improved risk stratification strategies considering socio-economically defined needs, wide-reaching population-based policy interventions are required to reduce inequalities in diabetes outcomes.

Disclosure: **E. Vamos:** None.

Ranking of cardiovascular impairments in impaired glucose tolerance

L. Lind;
Department of Medical Sciences, Uppsala, Sweden.

Background and aims: Impairments in several markers of the cardiovascular system have been described in impaired glucose tolerance, but the relative importance of those are not known. We aimed to investigate which cardiovascular markers that were most closely linked to an impaired glucose tolerance.

Materials and methods: In a population-based study of individuals all aged 50 years, the Prospective study of Obesity, Energy and Metabolism (POEM), 502 subjects were thoroughly investigated regarding endothelial function, arterial compliance, heart rate variability, arterial blood flow and atherosclerosis, performance at an exercise test with gas exchange (VO_2 and VCO_2), left ventricular structure and function, lung function and multiple measurements of blood pressure. Based on an oral glucose tolerance test (OGTT), the participants were grouped into: normal, impaired glucose tolerance and diabetes.

Results: Of all hemodynamic and structural variables analyzed, an impaired glucose tolerance was most closely related to resting heart rate (based on Chi^2-value at ANOVA). Heart rate was followed by maximal workload, VO_2-recovery 5 min following exercise, reflectance index at pulse wave analysis, manual systolic blood pressure, ambulatory pulse and pulse pressure, echolucency of carotid intima-media complex at ultrasound, and pulse wave velocity ($p < 0.0005$ for all variables).

Conclusion: Of multiple measured cardiovascular markers, resting heart rate was most closely related to an impaired glucose tolerance. Also exercise capacity and the recovery in VO_2 following exercise were amongst the top ranked cardiovascular impairments linked to an impaired glucose tolerance.

Does sex influence the tolerance to ischaemia-reperfusion injury in a metabolic syndrome model?

N. Fourny, C. Lan, M. Bernard, M. Desrois;
Aix Marseille Univ, CNRS, CRMBM, Marseille, France.

Background and aims: Worldwide prevalence of Metabolic Syndrome (MetS) keeps increasing and becomes a real public healthcare problem. MetS is based on the presence of at least 3 risk factors including abdominal obesity, glucose intolerance, dyslipidemia and hypertension. MetS is a well-known risk factor of type 2 diabetes and cardiovascular (CV) complications such as myocardial infarction. Epidemic studies showed a higher prevalence and CV risk in men. However, few studies explore sex differences in this context. Consequently, the aim of this study was to compare the effects of a high-fat high-sucrose diet (HFHSD) on the sensitivity to ischemia-reperfusion injury of male and female Wistar rat hearts.

Materials and methods: Male and female Wistar rats were subjected to HFHSD (12 MHFSD and 10 FHFSD) or Normal Diet (12 MND and 10 FND) for 5 months. Then, rats underwent an intraperitoneal glucose tolerance test (IPGTT) to determine glycemic status, and *ex vivo* experiments on the isolated perfused heart were performed to study the tolerance to ischemia-reperfusion injury. Isolated hearts were perfused with a physiological buffer containing 0.4 mM palmitate for 24 minutes before switching to 1.2 mM palmitate for 32 minutes low-flow (0.5 mL/min/g wet wt) ischemia. Next, flow was restored with 0.4 mM palmitate buffer for 32 minutes. High-energy phosphates and intracellular pH were measured during the experimental course by ^{31}P magnetic resonance spectroscopy with simultaneous measurement of contractile function. Coronary flow was measured before and after ischemia. At the end of experiments, hearts were freeze-clamped for biochemical assays.

Results: After 5 months of HFHSD, body weight was increased in males ($p < 0.001$ vs. MND) but not in females and fat percent was higher in both HFHSD groups (respectively $p < 0.01$ and $p < 0.05$ vs. controls). IPGTT showed a significant glucose intolerance in male and female HFHSD ($p < 0.001$ vs. controls) which was more pronounced in females ($p < 0.05$ vs. MHFSD at T15min). HFHSD increased fasting blood glucose in both males and females compared with controls ($p < 0.05$) but increased plasma free fatty acids only in females ($p < 0.05$ vs. FND). Heart weight to tibia length ratio was higher with HFHSD only in males ($p < 0.001$ vs. MND). Interestingly, in male and female HFHSD, we found impaired myocardial function (respectively $p < 0.001$ and $p < 0.05$ vs. controls) and coronary flow (respectively $p < 0.01$ and $p < 0.05$ vs. controls) during reperfusion, with no difference between males and females. Energy metabolism was significantly altered in male and female HFHSD compared with controls. ATP was decreased only in MHFSD during reperfusion ($p < 0.01$ vs. MND). PCr was impaired during reperfusion in male and female HFHSD groups compared with their respective controls ($p < 0.01$ and $p < 0.05$) and in FND compared with MND ($p < 0.05$). Finally, intracellular pH was similar between groups during the whole protocol.

Conclusion: Five months of HFHSD induced metabolic syndrome in both male and female with sex differences in tolerance to glucose, body weight and heart weight to tibia length ratio. HFHSD also decreased the tolerance to ischemia-reperfusion in both sex, characterized by impaired energy metabolism, cardiac and endothelial function during reperfusion. In conclusion we found no effect of sex on the tolerance to ischemia-reperfusion in our model of MetS.

Prolongation of the QTc interval is associated with an increased risk of cardiovascular diseases: the Hoorn study

S. Welten[1], A.A. van der Heijden[2], G. Nijpels[2], J.W.J. Beulens[1], P. Elders[2], J. Dekker[1];
[1]Epidemiology and Biostatistics, VU University Medical Center, Amsterdam, [2]Department of General Practice and Elderly care Medicine, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: Prolongation of the heart rate-corrected QT interval (QT/√heart-rate frequency=QTc), i.e. time from ventricular depolarization to complete repolarization, may predict cardiovascular diseases (CVD). There are several hypotheses about the underlying mechanisms, including a role for impaired glucose metabolism. We investigated whether prolongation of the QTc interval is associated with CVD in the general population, and whether this association is different within the glucose metabolism groups.

Materials and methods: We analyzed an age-, sex- and glucose tolerance-stratified sample from the Hoorn Study, a population-based cohort study which started in 1989. After exclusions, 447 participants aged 50–74 years, who had duplicate oral glucose tolerance tests (except for those using glucose lowering medication) and 12-lead electrocardiography (ECG) at baseline were eligible for analysis. Cox regression was used to investigate the association between sex-specific QTc quartiles and CVD incidence. All analyses were adjusted for age, sex, smoking status, systolic blood pressure, glucose tolerance status, hypertension and total cholesterol. Stratified analyses were conducted for glucose tolerance status. Sensitivity analyses were performed in participants without medication.

Results: During a mean follow-up of 10 years, 305 CVD events were observed. The age and sex adjusted hazard ratios (95% CI) of participants in the second (males; 370–388 ms, females; 386–401 ms), third (males; 389–408 ms, females; 402–420 ms) and fourth (males; >408 ms, females; >420 ms) sex-specific QTc quartiles were 1.17 (0.83–1.65), 1.41 (1.01–1.97), 1.70 (1.23–2.36) with the first quartile (males; <370 ms, females; <386 ms) as reference category. The multivariable adjusted hazard ratios for participants in the fourth sex-specific QTc quartile were 1.54 (1.10–2.14) compared with participants with a QTc interval in the first quartile. The same analyses in people without medication resulted in even stronger associations (HR: 1.75, 95% CI: 1.05–2.93). Stratified analyses showed that the association was stronger for participants with impaired glucose status (HR: 2.45, 95% CI: 1.13–5.30) and diabetes (HR: 2.19, 95% CI: 1.12 to 4.28).

Conclusion: Prolongation of the QTc interval on the ECG was significantly associated with increased risk of CVD in the general population. This association was stronger in participants with impaired glucose metabolism or type 2 diabetes. QTc duration may contribute to improved CVD risk stratification.

Soluble urokinase plasminogen activator receptor predicts cardiovascular events, mortality and kidney function decline in patients with type 1 diabetes

V. Rotbain Curovic[1], S. Theilade[1], S.A. Winther[1], N. Tofte[1], J. Eugen-Olsen[2], F. Persson[1], T.W. Hansen[1], J. Jeppesen[3,4], P. Rossing[1,4];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]Clinical Research Centre, Hvidovre Hospital, Hvidovre, [3]Department of Medicine, Amager Hvidovre Hospital, Glostrup, [4]University of Copenhagen, Copenhagen, Denmark.

Background and aims: Soluble urokinase plasminogen activator receptor (suPAR) is an important inflammatory biomarker. The predictive qualities of suPAR in relation to complications in patients with type 1 diabetes (T1D) have not been determined. We investigated the prognostic ability of suPAR for the development of cardiovascular events (CVE), mortality and decline in renal function in T1D.

Materials and methods: 667 patients with T1D and various degrees of diabetic kidney disease were included in a prospective study. suPAR was measured with commercially available ELISA kits (suPARnostic kit). In 2016, patients were traced through the National Death Register and the National Health Register, from which data for CVE and mortality was gathered. Data for estimated GFR (eGFR) measurements, obtained at outpatient visits, were traced through electronic laboratory records. Endpoints were classified as: CVE (cardiovascular death, non-fatal myocardial infarction, non-fatal stroke and coronary or peripheral arterial interventions), mortality, and eGFR-decline of ≥30%. Median follow-up ranged from 5.2 to 6.2 years. Results were adjusted for known risk factors and confounders: sex, age, LDL cholesterol, HbA_{1c}, systolic blood pressure, BMI, smoking status, urinary albumin excretion rate, eGFR, prescribed renin-angiotensin-aldosterone system inhibitors, and c-reactive protein. Hazard ratios (HR) were calculated per doubling of suPAR and are presented with 95% confidence interval (CI). Furthermore, the relative integrated discrimination (rIDI) was calculated to assess the added predictive contribution of suPAR to the above described risk factors.

Results: Of the 667 participants, 368 (55%) were male; mean±SD age was 55 ± 13 years and eGFR 88 ± 25 ml/min/1.73 m^2. Median (interquartile range) of suPAR was 3.4 (2.7–4.5) ng/ml. There were 94 (14.2%) cases of CVE, 58 (8.7%) deaths and 93 (14.0%) cases of eGFR-decline ≥30%. The adjusted HR (95% CI) for the respective endpoints were 3.50 (2.09–5.87), 4.42 (2.15–9.07) and 2.91 (1.71–4.97). rIDI analysis showed discrimination slope contribution of 32.4% for CVE, 39.7% for mortality, and 14.8% for eGFR-decline. All presented results were highly significant ($p \leq 0.001$).

Conclusion: Higher suPAR level is consistently associated with an increased risk of CVE, mortality and eGFR-decline in patients with T1D, independent of classical risk factors. In addition, it is a sizeable and significant contributor in the risk stratification of the described complications based on rIDI. Our results suggest that suPAR may have an important role in identifying T1D patients at risk of severe complications at an early stage.

Coronary CT angiography improve discriminative performance of cardiovascular risk predictor in asymptomatic patient with type 2 diabetes

J. Ahn[1], K. Hur[1,2], Y. Choe[3], S.-A. Chang[4], J.-H. Choi[4,5], M.-K. Lee[1,2]; [1]Division of Endocrinology and Metabolism, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, [2]Samsung Advanced Institute for Health Sciences & Technology, Seoul, [3]Department of Radiology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, [4]Division of Cardiology, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, [5]Department of Emergency Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea.

Background and aims: Predicting cardiovascular risk in asymptomatic diabetic patients is unsatisfactory. Clinical guidelines advocate clinical risk predictors with various criteria and different approaches to predicting algorithms, which show poor calibration each other and typically overestimate the true risk. Considering the progressive nature of atherosclerosis, detection of subclinical atherosclerosis by non-invasive modalities such as coronary computed tomography angiography (CCTA) or carotid intima-media thickness measurement (CIMT) may improve risk stratification. We investigated whether non-invasive modalities could improve the prediction of cardiovascular event of asymptomatic patients with type 2 diabetes.

Materials and methods: In this prospective single center study, a total of 306 asymptomatic patients with type 2 diabetes without history of coronary artery disease were enrolled. Patients underwent coronary computed tomography angiography (CCTA), coronary calcium score, and carotid intima-media thickness (CIMT) measurement. Clinical risk predictors were calculated by Framingham, ASCVD, UKPDS, DECODE, and QRISK3 scores. The primary outcome was major adverse cardiac and cerebrovascular event (MACCE) consisting cardiovascular death, nonfatal myocardial infarction, stroke, and revascularization.

Results: A total of 12 MACCE developed during median follow-up time of 3.8 years. Clinical risk predictors was moderate in overall (c-statistics = 0.534 to 0.729) and overestimated the MACCE risk by 2- to 9-fold. The MACCE risk increased proportionally to the severity and extent of coronary atherosclerosis measured by CCTA ($p < 0.01$, all), but did not to coronary calcium score or CIMT. In time-dependent receiver operating characteristics, reclassification, and survival analyses, the performance of all clinical risk predictors improved by addition of the severity of stenosis measured by CCTA ($p < 0.05$, all). Subgroup analysis of survival data by maximal diameter stenosis ≥50% enables further discrimination of high- and low-risk subgroups ($p < 0.01$, all) (Figure).

Conclusion: CCTA could improve the predictive performance of the clinical risk predictors in asymptomatic type 2 diabetes patients, whereas coronary calcium score or CIMT did not.

Specific short and long term prognostic value of admission HbA_{1c} and plasma glucose in non-diabetic patients with acute myocardial infarction: data from the RICO survey

B. Vergès[1], B. Mouhat[1], M. Zeller[2], F. Chagué[1], J.-C. Beer[1], M. Maza[1], Y. Cottin[1];
[1]Hopital du Bocage, Dijon, [2]Université de Bourgogne Franche Comté, Dijon, France.

Background and aims: In non-diabetic patients with acute myocardial infarction (MI), acute hyperglycemia is associated with high risk of cardiovascular (CV) mortality. However, the prognostic value of HbA1c as a marker of chronically elevated plasma glucose remains unclear. From the large observational RICO survey, we aimed to identify the specific prognostic values of HbA1c and plasma glucose measured on admission for acute MI in non-diabetic patients regarding in-hospital and one year CV mortality.
Materials and methods: From the RICO survey database all the consecutive non-diabetic patients with acute MI ($n = 6884$) admitted in the cardiology intensive care unit of the university hospital of Dijon from January 2001 to June 2016 were included. Patients with diabetes were excluded. Cut off levels (high/low) were determined by ROC curve analysis for the prediction of CV death (HbA1c: 5.9% and glucose: 156 mg/dL). Patients were divided into 4 groups, based on levels of both HbA1c and plasma glucose: low HbA1c/low glucose (n = 3849), low HbA1c/high glucose ($n = 734$), high HbA1c/low glucose ($n = 1802$) and high HbA1c/high glucose ($n = 499$).
Results: Elevation of either glucose or HbA1c was associated with elevated risk of hospital mortality, when compared to group with low HbA1c and glucose levels (Figure). However, by multivariate logistic regression analysis, only high glucose remained a prognostic factor of hospital death (OR(95%CI): 1.59 (1.16–2.17) after adjustment for covariates (age, sex, risk factors, prior MI, creatinine clearance, chronic and acute treatments). In survivors at discharge, a marked increased risk of one-year CV mortality was found in the group with elevated levels of both glucose and HbA1c, when compared to all other groups ($p < 0.001$). Moreover, high HbA1c was an independent predictive factor of one year CV mortality, beyond high glucose (OR(95%CI): 1.75(1.35–2.27) and 1.98(1.49–2.61), respectively) and covariates (age, sex, risk factors, creatinine clearance, CRP, LVEF, acute and discharge treatments).
Conclusion: In our large population-based study, high levels of both HbA1c and glucose are in non-diabetic patients with acute MI, associated with increased risk of mortality at short or long term. Elevated admission plasma glucose, reflecting acute hyperglycemia and high HbA1c, reflecting chronic hyperglycemia, appear to give different prognostic information. Early mortality risk was mainly driven by acute hyperglycemia, and HbA1c was a strong predictive factor for one year mortality, independently of acute plasma glucose. Our findings may help identifying high risk patients to target for aggressive secondary prevention after MI.

Association between serum cystatin C and vascular complications in type 2 diabetes without nephropathy

H. Park, J. Lee, H. Kim, D. Byun, K. Suh, M. Yoo;
Internal Medicine, Soonchunhyang University Hospital, Seoul, Republic of Korea.

Background and aims: Recent studies have shown associations between serum cystatin C levels and vascular complications; however, few have investigated these associations in diabetes without nephropathy. We evaluated the relationship between serum cystatin C and vascular complications in type 2 diabetes patients with normal renal function or mild renal impairment.
Materials and methods: A total of 806 consecutive patients with type 2 diabetes who were admitted to the diabetes center of Soonchunhyang University Hospital for blood glucose control were retrospectively reviewed. Patients with nephropathy were excluded. Subjects were categorized into quartiles of serum cystatin C levels (Q1, ≤0.65 mg/L; Q2, 0.66~0.79 mg/L; Q3, 0.80~0.94 mg/L; and Q4, ≥0.95 mg/L). Multivariate logistic regression was conducted for the risk of vascular complications.
Results: The proportion of patients with diabetic retinopathy (DR), coronary heart disease (CHD) and stroke increased across the serum cystatin C quartiles (p for trend <0.001). After adjustment for confounding factors, the highest serum cystatin C level remained a significant risk factor for DR (odds ratio [OR] 1.929, 95% confidence interval [CI] 1.030–3.614, $p = 0.040$). Compared with Q1, a significant positive association was observed between serum cystatin C and CHD in Q2 (OR 7.321, 95% CI 1.560–34.361, $p = 0.012$), Q3 (OR 6.027, 95% CI 1.324–27.435, $p = 0.020$) and Q4 (OR 8.122, 95% CI 1.755–37.577, $p = 0.007$). No associations were observed between cystatin C and stroke after additional adjustment for confounding variables.
Conclusion: Serum cystatin C levels are independently associated with DR and CHD, suggesting that cystatin C may be useful for identifying type 2 diabetes patients without nephropathy who are at high risk for vascular complications.

Relationship between albuminuria and total mortality among insulin treated patients with type 2 diabetes and nephropathy: analysis of a large UK primary care cohort

I. Idris, R. Donnelly, U. Anyanwagu;
Royal Derby Hospital Centre, University of Nottingham, Derby, UK.

Background and aims: Overt proteinuria (urinary albumin-creatinine ratio (ACR) >300 mg/g) is an established risk factor for progression of nephropathy and total mortality. However, whether, among insulin-treated patients with Type 2 diabetes in routine practice, a reduction in ACR translates into a mortality reduction remains far from clear.
Materials and methods: We obtained data on a large cohort of insulin users with T2D and nephropathy (baseline ACR ≥300 mg/g) from UK general practices between 2007–2014. Their corresponding ACR values after one year of follow up were thereafter categorised into: (1) <300 mg/g (i.e. proteinuria reduction) or (2) >300 mg/g (i.e. persistent or progressive proteinuria), and the cohort was followed up for 5 years for all-cause mortality. Cox proportional hazard models were fitted to estimate the risk of all-cause death.
Results: A total of 11,074 patients with insulin treated T2D met the inclusion criteria. Their mean age was 62.3(13.6) years; mean HbA1c: 8.7(1.8) %; and 53% were male. 682 deaths occurred after a follow-up period of 43,393 person-time with a mortality rate of 16 per 1000 person-

years. 5-year survival was markedly reduced in the group whose proteinuria persisted or progressed (91 vs 95%; log-rank p value <0.001). Compared to patients whose ACR levels remained above 300 mg/g, all-cause mortality was 27% lower compared with those whose proteinuria regressed to <300 g/g (aHR: 0.73; 95%CI: 0.56 to 0.97; $p = 0.028$) (Figure 1)

Conclusion: In patients with insulin treated T2D and nephropathy in routine practice, a reduction in proteinuria (e.g. via better BP or glycaemic control) is associated with a significant reduction in all-cause mortality. Thus, proteinuria is not simply a risk marker of renal and cardiovascular disease, but also an important target for therapy. Proteinuria reduction should be viewed as a goal for renal and cardiovascular protection.

Role of glycaemic variability in increased cardiac output in the obese patients with impaired glucose tolerance

A. Rezki, M. Fysekidis, S. Chiheb, I. Banu, E. Cosson, P. Valensi;
AP HP Jean Verdier Hospital, Department of Endocrinology-Diabetology-Nutrition, CRNH-IdF, CINFO, Bondy, France.

Background and aims: In obese patients, cardiac output is increased and cardiac autonomic function often altered. This study examined the change in cardiac contractility and its determinants in obese patients with impaired glucose tolerance (IGT) compared with those with a normal glucose tolerance (NGT) and the influence of glycemic variability.

Materials and methods: We included 66 obese patients with normal blood pressure (BP) and without cardio-vascular history, separated according to OGTT: 38 NGTs and 28 IGTs, who were well matched for sex, age and BMI (38.4 ± 4.1 and 37.4 ± 4.3 kg/m²). Peripheral and central BP and carotid-to-femoral pulse wave velocity (PWV) were measured by applanation tonometry (SphygmoCor®), cardiac vagal and sympathetic control (HF-HR, LF-HR) by spectral analysis (Task Force Monitor® finger plethysmography), stroke volume (SV), indexed cardiac output (iCO) and thoracic fluid content (TFC) by thoracic impedance, cutaneous blood flow (CBF) and CBF response to acetylcholine (endothelial function) by laser doppler flowmetry (Periflux®). Glycemic variability was evaluated in IGTs by calculating standard deviation (SD-glucose), CONGA and J index from 24-h continuous glucose monitoring.

Results: IGTs had similar BP, PWV and sympatho-vagal activity but higher SV, iCO and TFC ($p < 0.04$ to < 0.002) than NGTs. In IGTs, SV and iCO correlated positively with CONGA, systolic BP ($p < 0.03$ to $p < 0.05$) and negatively with age and PWV ($p < 0.001$ and $p < 0.03$), and iCO also correlated negatively with HbA1c ($p = 0.04$). In multivariate analysis, SV and iCO remained correlated with CONGA independently of HbA1c, age, PWV and systolic BP. In IGTs TFC correlated negatively with mean basal CBF and CBF response to acetylcholine ($p < 0.03$ and < 0.04).

Conclusion: Among obese patients, IGTs exhibit higher left ventricle contractility and higher central blood volume than NGTs. Higher glycemic variability could contribute to increase cardiac work by increasing central blood volume secondarily to a reduction of peripheral microcirculation.

Prediction of liver fat in people with and without type 2 diabetes: an IMI DIRECT study

N. Atabaki Pasdar[1], M. Ohlsson[2], A. Viñuela[3], F. Frau[4], R. Koivula[5,1], J. Fernandez[5], E. Thomas[6], A. Mari[7], R. Gupta[8], A. Kurbasic[1], E. Pearson[9], I. Pavo[10], J. Bell[11], P.W. Franks[1];
[1]Department of Clinical Sciences, Genetic and Molecular Epidemiology Unit, Lund University, Lund, Sweden, [2]Department of Astronomy and Theoretical Physics, Computational Biology and Biological Physics Unit, Lund University, Lund, Sweden, [3]Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland, [4]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, [5]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK, [6]Department of Life Sciences, University of Westminster, London, UK, [7]Institute of Biomedical Engineering, National Research Council, Padova, Italy, [8]Department of Bio and Health Informatics, Technical University of Denmark, Kongens Lyngby, Denmark, [9]Division of Molecular and Clinical Medicine, University of Dundee, Dundee, UK, [10]Eli Lilly, Vienna, Austria, [11]Metabolic and Molecular Imaging Group, MRC Clinical Science Centre, Imperial College Hammersmith Campus, London, UK.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is highly prevalent and causes serious health complications in type 2 diabetes (T2D) and beyond. In NAFLD, triglycerides accumulate in hepatocytes, promoting hepatic gluconeogenesis, and thereby raising risk of T2D or exacerbating the disease pathology. Liver biopsy, MRI scans, ultrasounds and liver enzyme tests are often used for NAFLD diagnosis, but the invasive nature of biopsies, the high costs of the MRI scans and ultrasounds and the low accuracy of liver enzyme tests are significant limitations. Here, we aim to derive a prediction tool for NAFLD by applying machine learning approaches to the extensive phenotypic data obtained in participants with pre-diabetes or diabetes cohorts from IMI DIRECT.
Materials and methods: Multi-omics (genetic, transcriptomic, proteomic, metabolomic) and clinical data including plasma biomarkers and measures of beta-cell function, insulin sensitivity, anthropometry and lifestyle comprised the key input variables. The outcome variable was MRI image-derived liver fat content (categorized into fatty ($\geq$5%) or normal (<5%) for 1514 participants. Random forest analysis with 5 × 5-fold cross-validation was used to develop the algorithms (2/3 of the data for training and the rest for validation). Feature selection of different layers of omics data was done using LASSO (least absolute shrinkage and selection operator). 'Advanced' (all available input variables) and 'pragmatic' (20 clinically accessible variables) prediction algorithms were developed.
Results: The 'pragmatic' algorithm yielded a cross-validated predicative accuracy (ROCAUC) of 81.4% in both cohorts combined (predictive accuracy was similar in the pre-diabetes and diabetes cohorts). For the 'advanced' algorithm, the ROCAUC was 86.7% in both cohorts combined. In the latter algorithm, measures of beta-cell function were amongst the highest-ranked input variables.
Conclusion: We have developed a new prediction tool for NAFLD as a safer and potentially more cost-effective alternative to MRI scans or biopsies in at-risk populations. In patients predicted by our algorithm to exceed the liver fat threshold, scans or biopsies would likely be performed for conformational diagnosis. Our analysis also highlights the important role of insulin sensitivity and beta cell function in liver fat accumulation, which are not features of conventional NAFLD risk algorithms.

Pooled cohort analysis of non-alcoholic fatty liver disease in patients with type 2 diabetes and the associated diagnostic performance of FibroScan

S. Czernichow[1], S.A. Harrison[2], M. Allison[3], E. Tsochatzis[4], Q.M. Anstee[5], D. Sheridan[6], I.N. Guha[7], J. Cobbold[8], V. Paradis[9], P. Bedossa[9], C. Barsamian[1], A.H. Paredes[10], P.N. Newsome[11];
[1]Department of nutrition, Hopital Européen Georges Pompidou, Paris, France, [2]Radcliffe Department of Medicine, Oxford, UK, [3]Addenbrookes Hospital, Cambridge, UK, [4]Royal Free Hospital, London, UK, [5]Institute of cellular medicine, Newcastle upon Tyne, UK, [6]Institute of Translational and Stratified Medicine, Plymouth, UK, [7]NIHR Nottingham Biomedical Research Centre, Nottingham, UK, [8]John Radcliffe Hospital, Oxford, UK, [9]Department of Pathology, Beaujon Hospital, Clichy, France, [10]Brooke Army Medical Center, Fort Sam Houston, USA, [11]NIHR Liver Biomedical Research Unit, Birmingham, UK.

Background and aims: We set out to establish the prevalence of non-alcoholic fatty liver disease (NAFLD) in patients with type 2 diabetes mellitus (T2DM) and then to evaluate the associated performance characteristics of FibroScan in determining the histological severity of NAFLD.
Materials and methods: Three cohorts were pooled for this analysis. *Screening cohort:* Patients referred for routine colon cancer screening in a single American centre were screened for evidence of NAFLD using FibroScan, Liver MultiScan (magnetic resonance imaging proton density fat fraction (PDFF), liver inflammation and fibrosis (LIF) score) and magnetic resonance elastography (MRE). Patients with PDFF ≥5% or LIF ≥2 or LSM ≥7 kPa on FibroScan or ≥3 kPa on MRE were offered a liver biopsy (LB). *Bariatric surgery cohort:* Patients with severe obesity defined as a BMI >35 kg/m² prospectively underwent a FibroScan examination before bariatric surgery in a single French centre. LB samples were collected during surgery. *NAFLD cohort:* Patients with suspected NAFLD prospectively underwent FibroScan and LB at seven British centres. All LB were scored by the same expert pathologists in a blinded manner using the NASH CRN system, and consensus achieved. All patients underwent a FibroScan examination which measured both liver stiffness and controlled attenuation parameter (CAP). The association between T2DM and prevalence of NAFLD-associated liver lesions assessed using risk ratio (95% CI). FibroScan diagnostic performance was assessed using AUC.
Results: 684 patients (186 in the screening cohort, 116 in the bariatric surgery cohort and 370 in the NAFLD cohort) had an interpretable LB and valid FibroScan examination. 38% had T2DM, 48% were female, and their median BMI was 34.5 [30.1–39.6] kg.m^{-2}. Prevalence of NAFLD and related histological features is presented in Table 1 with their associated risk ratios for T2DM. In patients with T2DM, the diagnostic performance (AUC) of FibroScan for identifying fibrosis ≥2, fibrosis = 4 and steatosis ≥1 was 0.77 [0.71–0.82], 0.89 [0.83–0.94] and 0.85 [0.73–0.96] respectively.
Conclusion: T2DM is a significant risk factor for all aspects of NAFLD-related liver pathology. FibroScan has good diagnostic accuracy to discern the presence of fibrosis and steatosis in patients with T2DM.

	All patients	Non-diabetic patients	T2DM patients	Risk ratio *[95% CI]*
N	684	423	261	-

CcK18 detection as a reliable marker for NAFLD/NASH detection in type 2 diabetes

M. Hauber, B. Stratmann, D. Tschoepe;
Diabeteszentrum, Herz- und Diabeteszentrum NRW, Ruhr Universitaet Bochum, Bad Oeynhausen, Germany.

Background and aims: Liver disease (non-alcoholic fatty liver disease (NAFLD), non-alcoholic steatosis hepatis (NASH) or liver fibrosis) are commonly detected in patients with type 2 diabetes mellitus (T2DM). We evaluated the laboratory marker Kreatin18Asp396 (ccK18) with respect to correctly identify non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatosis hepatis (NASH), determined by elevation in Alaninaminotransferase (ALAT>ULN).
Materials and methods: 603 consecutive non-selected patients with type 2 Diabetes mellitus were available for analysis; Kreatin18Asp396 (ccK18) (M30 Apoptosense-ELISA (VLVbio, Schweden) was analysed in EDTA-Plasma. Current diagnosis is made considering ALAT (women: ALAT >35 U/l, men: ALAT >50 U/L) activity.
Results: Patients (414m/189f, age 61.9 ± 12.3 years, average duration of T2DM 13.0 ± 9.5 years). HbA1c was 8.9 ± 2.0%, ASAT 35.7 ± 20.6 U/l, ALAT 42.0 ± 30.3 U/l, γGT 98.4 ± 161.8 U/l. CcK18 was 396.2 ± 530.7 U/l. Correlations of ccK18 to ALAT was 0.613, and to ASAT 0.629 (Pearson Correlation) for the whole cohort ($p < 0.0001$ for all). Weaker, but significant correlation were detected to HbA1c 0.162, BMI 0.118, Diabetes duration −0.190, ferritin 0.329 and γGT 0.346.
Separation by laboratory diagnosis of liver disease according to existing ALAT ULN: **Men ($N = 291$): ALAT ≤ ULN:** ccK18 = 242.1 ± 306.1 U/l. **Men ($N = 123$): ALAT > ULN:** ccK18 = 823.4 ± 815.6 U/l. **Women ($N = 118$): ALAT ≤ ULN:** ccK18 = 231.3 ± 243.4 U/l. **Women ($N = 71$): ALAT > ULN:** ccK18 = 563.1 ± 532.1 U/l. In a subgroup of 29 patients liver biopsy results were available and indicated an increased level of ccK18 correlating with NAFLD-Score: **NAS = 3 ($N = 7$):** ccK18 = 645.4 ± 686.1 U/l, ALAT = 53.0 ± 17.1 U/l, ASAT = 62.0 ± 22.6 U/l, HbA1c = 9.7 ± 1.4% **NAS = 4 ($N = 4$):** ccK18 = 453.2 ± 270.8 U/l, ALAT = 86.0 ± 26.0 U/l, ASAT = 93.5 ± 44.3 U/l, HbA1c = 9.3 ± 1.8% **NAS = 5 ($N = 8$):** ccK18 = 704.0 ± 411.7 U/l, ALAT = 50.0 ± 17.8 U/l, ASAT = 59.0 ± 16.3 U/l, HbA1c = 9.8 ± 1.6% **NAS = 6 ($N = 7$):** ccK18 = 836.7 ± 632.3 U/l, ALAT = 43.1 ± 17.7 U/l, ASAT = 56.1 ± 29.5 U/l, HbA1c = 9.2 ± 1.4% **NAS = 7 ($N = 1$):** ccK18 = 820.7 U/l, ALAT = 159 U/l, ASAT = 181 U/l, HbA1c = 10.4%
Conclusion: ccK18 might be useful tool to identify further patients being at risk for liver damage even after normalization of ALAT as results of liver biopsies indicate an increase in ccK18 with higher NAFLD-Score. CcK18 identifies further patients being at risk of liver disease presenting with ALAT-values within normal ranges. Dynamic course of ccK18 allows procedural observation of cellular liver regeneration after Intervention.

Frequency of fibrosis estimated by noninvasive scores in type 2 diabetic patients with nonalcoholic fatty liver disease

M. García Domínguez[1], I. Martin Timon[2], I. Moreno Ruiz[2], B. Ugalde Abiega[2], D. Varillas Delgado[3], F.J. del Cañizo Gómez[2];
[1]Sureste University Hospital, Madrid, [2]Infanta Leonor University Hospital, Madrid, [3]Francisco de Vitoria University, Madrid, Spain.

Background and aims: The prevalence of nonalcoholic fatty liver disease (NAFLD) is >70% in type 2 diabetes mellitus (T2DM). These patients are particularly susceptible to more severe forms of NAFLD, progression to esteatohepatitis and development of hepatocellular carcinoma. Moreover, the coexistence of NAFLD and T2DM results in worse metabolic profile and higher cardiovascular risk. Our aims were: 1) to study frequency of abnormal aminotransferase (AT) levels and fibrosis [by NAFLD Fibrosis Score (NFS) and Fibrosis 4 Calculator (FIB4)]; 2) to investigate variables associated with higher score, excluding those directly included in formulae.
Materials and methods: Patients with T2DM and NAFLD diagnosed by ultrasound attending our clinic were identified consulting diagnosis database in I. Leonor Hospital.
Results: 66 subjects; mean ± SD: 64.6 ± 13.9 y; 47% women; BMI 31.1 ± 6.8 kg/m^2; HbA1c 6.9 ± 1.1%. 77.3% had high AT. NFS score: −0.31 ± 1.30. 83.3% had intermediate or high probability of fibrosis (NFS ≥−1.5). FIB4 1.40 ± 0.70. 4.5% had FIB4 >3.25, meaning high probability of advanced fibrosis. Subset with normal AT: 84.3% had NFS ≥−1.5. No patients had FIB4 >3.25; and 43.1% had FIB4 1.45–3.25. Subset with high AT: 80% had NFS ≥−1.5. 20% had FIB4>3.25, and 13.3% had FIB4 1.45–3.25. Patients with high AT had lower IMC than those with normal AT (31.0 ± 5.0 vs 34.2 ± 6.9; $p = 0.05$); whereas glycemic control was worse in high-AT patients (A1c 7.6 ± 1.5 vs 6.7 ± 0.9; $p = 0.008$). Patients with hypercholesterolemia had higher NFS (−0.21 ± 1.31 vs −1.313 ± 0.69; $p < 0.05$). There was no significant association with BMI, fasting glucose, A1c, HDL, LDL, TG. Morbid obesity was associated with lower FIB4 (0.61 ± 0.15; grade 1 obesity 1.26 ± 0.65; overweight 1.62 ± 0.60; $p < 0.05$. This was explained because in our sample, older people had significantly lower BMI. Glycemic control was significantly worse in patients with higher FIB4 (low FIB4: mean A1c 7.1%; medium FIB 4: 6.5%; high FIB4: 8.5%; $p < 0.05$).
Conclusion: Our results confirm that patients with T2DM and NAFLD have high probability of fibrosis (estimated by noninvasive scores). The scores are as high in patients with normal AT levels as in normal-AT ones. NAFLD must be actively sought by ultrasound in every T2DM patient.

Glutamate dehydrogenase and the hyperammonaemia in HI/HA syndrome: study on the contribution by the liver

K. Luczkowska, P. Maechler;
Department of Cell Physiology and Metabolism, University of Geneva, Geneva, Switzerland.

Background and aims: The hyperinsulinism/hyperammonemia syndrome (HI/HA) is the second most common cause of congenital hyperinsulinism. Clinically, the phenotype shows severe hypoglycemia with neonatal and early infancy-onset, accompanied by elevated plasma ammonia levels. It is a rare genetic disease caused by gain-of-function mutations in *GLUD1*, a gene encoding for the enzyme glutamate dehydrogenase (GDH). Mammalian GDH is catalysing the reversible reaction of glutamate to alpha ketoglutarate plus ammonia. HI/HA syndrome gives rise to increased (3–5 times) plasma ammonia levels, presumably due to systemic expression of mutant GDH. This study aims to elucidate the contribution of the liver in the elevated circulating ammonia. Hepatocytes emerged as a main candidate playing a central role in amino acid catabolism and ammonia detoxification through urea cycle.
Materials and methods: To recapitulate the genetic background of the patients suffering from HI/HA (mostly heterozygous) we transduced primary mouse hepatocytes with adenoviruses carrying either human wild type hGDHwt or mutant $hGDH_{S445L}$ expressed along with the endogenous GDH. Mouse hepatocytes were isolated by liberase digestion and cultured in 6-well plates. After adenoviral transduction, hepatocytes were further cultured for 48 h. Then, cells were starved for 6 h and stimulated for 1 h with glucose-free KRBH containing either no substrate (non-

stimulated control) or 5 mM glutamine alone or combined with 5 mM alanine (mix). The supernatants were collected, ammonia and urea measurements were performed.

Results: The efficiency of transductions was controlled by immunoblotting in all the investigated conditions showing similar expression of the transgenes. Both alanine and glutamine are important substrates for gluconeogenesis. The ammonia production from glutamine is contributed by both deamidation by glutaminase, producing glutamate, and then its deamination by GDH generating alpha ketoglutarate. However, alanine solely relies on GDH for ammonia production. Upon amino acid challenge, both wild type and mutant hepatocytes increased ammonia production in comparison to endogenous GDH. When stimulated with the mix, ammonia generation was higher in the hepatocytes expressing $hGDH_{S445L}$ *vs.* hGDHwt (107 ± 8 *vs.* 88 ± 9 nmol/h per 10^6 cells, $n = 12$, $p < 0.0001$). In the liver, GDH provides ammonia to the first enzyme of the urea cycle, namely carbamoyl phosphate synthetase. Upon the mix challenge, the $hGDH_{S445L}$ higher activity was reflected by the increased urea production (334 ± 33 *vs.* 297 ± 32 nmol/h per 10^6 cells, $n = 12$, $p < 0.05$). Overall, the differences between $hGDH_{S445L}$ *vs.* hGDHwt were more pronounced in ammonia production hinting limited capacity of the urea cycle to compensate for pathological ammonia generation. In ongoing experiments, human wild type and mutant GDH are expressed by adenoviral intravenous delivery to mice before assessment of *in vivo* ammonia generation. Preliminary data show efficient expression of the respective transgenes in the liver.

Conclusion: Hepatocytes carrying mutant GDH produced significantly more ammonia upon amino acid exposure, which underscores hyperammonemia present in patients suffering from HI/HA syndrome.

Plasmatic expression of miR-34a in non alcoholic fatty liver disease in a Mexican population

M. Velazquez[1], M.L. Lazo de la Vega[1], Y. Ruiz[1], L. Ibarra[1], M. Preciado[2], B. Jordan[3], S. Garnelo[3];
[1]Department of Medical Sciences, University of Guanajuato, Leon, Guanajuato, [2]Department of Medicine and Nutrition, University of Guanajuato, Leon, Guanajuato, [3]General surgery, Regional Genral Hospital of Leon, Leon, Guanajuato, Mexico.

Background and aims: Non alcoholic fatty liver disease (NAFLD) is caused by excessive accumulation of fatty acids (steatosis) in form of triglycerides in the liver, and it is one of the main causes of death by liver diseases in the world. There are several diagnostic methods for NAFLD. However, most of them are not sufficiently sensitive nor specific, and liver biopsy, the current gold standard, is invasive. Consequently, several molecules such as microRNAs (miRNAs) have been studied as potential biomarkers for diagnosing NAFLD. miRNAs participate in the post-transcriptional regulation of several biological processes, and can be found in most biological fluids. miR-34a participates in lipid metabolism, and it has been found to be upregulated in NAFLD. However, its expression appears to be dependent on the NAFLD studied population, and the diagnostic method used, with contradictory results between the studies. Prevalence of NAFLD has increased in the Mexican population, and there has been an increase in the incidence of the disease by 60%. The aim of the present study is to analyze whether plasmatic expression levels of miR-34a are associated with the presence or absence of NAFLD in a Mexican population.

Materials and methods: Seventy one subjects were recruited and classified in two groups: 30 subjects with NAFLD (NAFLD group) and 41 without NAFLD (Control group), diagnosed by histopathology. Anthropometric measurements were obtained: weight, height, body mass index (BMI), diastolic and systolic pressure, waist, hip, waist-hip ratio. Plasma and serum was used for lipid profile determination: total cholesterol (TC), triglycerides (TG), LDL, HDL, VLDL), and hepatic function tests: ALT, AST, GGT. Total RNA was isolated from plasma, using a spike-in of *C. elegans* miR-39 as extraction control. A histopathological analysis (Kleiner's index) was performed in which the diagnosis and degree of severity of NAFLD was subclassified by scoring from 0 to 6, taking 6 as the highest severity. Expression of miR-34a was determined by real time PCR using a specific Taqman MicroRNA Assay. Student's T test and U-Mann-Withney were used to analyze biochemical and anthropometric variables as well as for the comparison of miR-34a plasmatic expression between NAFLD group and control group.

Results: miR-34a expression was found five-fold higher in NAFLD compared to control group ($p = 0.009$).Similarly, when subclassifying by the degree of severity of the NASH, significant differences were observed between subgroup 3 *vs* subgroup 0 ($p = 0.009$) and *vs* group 2 ($p = 0.009$); between subgroup 4 *vs* 0 ($p = 0.03$) and *vs* subgroup 2 ($p = 0.03$); and between subgroup 4 *vs* 0 and *vs* subgroup 2. Differences were obtained when comparing NAFLD group *vs* control group in BMI ($p = 0.010$), diastolic pressure ($p = 0.047$), glucose ($p = 0.018$), TC ($p = 0.000$), LDL ($p = 0.044$), VLDL ($p = 0.047$), TG ($p = 0.002$), ALT ($p = 0.000$), AST (0.000) y GGT ($p = 0.012$).

Conclusion: In addition to the metabolic alterations demonstrated in the comparison of both groups, the expression levels of miR-34a were elevated in NAFLD group. This result supports the potential use of miR-34a as NAFLD biomarker in our population. More research must be done in order to elucidate the role of miR-34a in the molecular mechanisms of NAFLD.

The combination of Barberis Aristata, Elaeis Guineensis and Coffea Canephora extracts ameliorates the metabolic profile and hepatic miR-122 levels in a mouse model of NAFLD

C. Nigro[1], P. Mirra[1], V. Lembo[2], G. Mazzone[2], A. Rossi[2], G. D'Argenio[2], V. Cossiga[2], A. Leone[1], F. Beguinot[1], N. Caporaso[2], C. Miele[1], F. Morisco[2];
[1]URT-GDD of the IEOS-CNR & DiSMeT, University of Naples "Federico II", Naples, [2]Gastroenterology Unit, Department of Clinical Medicine and Surgery, University of Naples "Federico II", Naples, Italy.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) is one of the most common chronic liver disease affecting a large part of the world population. It is well documented that NAFLD is associated to metabolic syndrome. NAFLD and metabolic syndrome seem to have insulin resistance as a common pathophysiological mechanism. Recently, a number of studies have described microRNAs (miRNAs) as mediators in the pathogenesis of both insulin resistance and NAFLD. Therefore, the aim of this study is to evaluate whether and how a mixture of plant extracts consisting of Berberis Aristata, Elaeis Guineensis and Coffea Canephora may affect the development of obesity, hepatic steatosis and insulin resistance, conceivably associated to the modulation of miRNAs levels, in an animal model of NAFLD induced by a high fat diet.

Materials and methods: Three groups of C57BL/6 mice ($n = 8$ each) were randomized into one of the following 24 week diets: 1) standard diet (SD); 2) high fat diet (HFD, 60% fat); 3) HFD enriched with plant extract (HFD+E) (140 mg/Kg/die). Body weight was monitored during the diet protocol. At the end of the treatment all mice were fasted for 4 hours and intraperitoneally injected with a bolus of insulin (0.75 U/kg) to test the insulin tolerance by ipITT. Blood samples were used to measure glycaemia by a portable glucometer, insulinemia by ELISA assay, transaminases and lipid profile by a clinical chemistry benchtop analyzer. After sacrifice, liver biopsies were collected to examine the hepatic histology by H&E staining and to isolate total RNA and measure miRNA expression by q-PCR.

Results: The HFD+E mice show lower body weight (40 ± 3.6 vs 47.4 ± 6 g, HFD+E vs HFD, $p = 0.008$), the amelioration of insulin sensitivity (10138 ± 1620 vs 7529 ± 1469 mg/dl*120 min, iAUC of HFD+E vs HFD, $p = 0.008$) together with the reduction of insulinemia (725.8 ± 270 vs 1156.3 ± 307.4 pg/ml, HFD+E vs HFD, $p = 0.04$), total cholesterol (178 ± 17 vs 209 ± 19 mg/dl, HFD+E vs HFD, $p = 0.007$), low density lipoproteins (10.7 ± 3.2 vs 19.3 ± 1.6 mg/dl, HFD+E vs HFD, $p < 0.001$), triglycerides (86.3 ± 11 vs 130.3 ± 22 mg/dl, HFD+E vs HFD, $p < 0.001$) and alanine-aminotrasferase (38.7 ± 24 vs 81.3 ± 47 mg/dl, HFD+E vs HFD, $p = 0.03$) compared to HFD mice. H&E staining show macro- and microvesicular steatosis with ballooning degeneration in mice fed with HFD, which is improved in mice fed with HFD+E. Moreover, a down-regulation of miR-122 hepatic levels is observed in HFD mice compared to SD mice (0.95 ± 0.6 vs 2.17 ± 1.5 REU, HFD vs SD, $p = 0.03$). Interestingly, this effect on the miRNA levels is prevented by the combination of plant extracts with HFD (2.13 ± 1.39 vs 0.95 ± 0.6 REU, HFD+E vs HFD, $p = 0.03$).
Conclusion: In conclusion, the combination of Berberis Aristata, Elaeis Guineensis and Coffea Canephora added to HFD is able to ameliorate obesity, insulin resistance and hepatic steatosis, which are developed by C57BL/6 mice fed with a HFD. Moreover, this metabolic profile associates to the modulation of hepatic miR-122 levels, which are down-regulated in HFD mice and remain unchanged in mice fed with HFD+E compared to SD mice. These data suggest a possible role of miR-122 in the beneficial effects of plant extracts combination on metabolic syndrome.

The characteristics of non-alcoholic fatty liver disease related hepatocellular carcinoma in a Chinese population: a retrospective study
H. Chen[1], X. Li[1], X. Gao[1,2];
[1]Zhongshan Hospital, Fudan University, Shanghai, [2]Institute of chronic metabolic disease, Fudan University, Shanghai, China.

Background and aims: The prevalence of hepatocellular carcinoma (HCC) among patients with non-alcoholic fatty liver disease (NAFLD) is increasing in recent years. The aim of this retrospective study was to evaluate the incidence and characteristics of patients with NAFLD-HCC compared with viral hepatitis B (HBV)-HCC in a Chinese population.
Materials and methods: Patients with newly diagnosed HCC at liver surgery department Zhongshan hospital from January 2011 to December 2015 were investigated in this study. They were divided into either HBV or NAFLD group based on underlying etiologies. Patients with other HCC etiologies, alcohol consumption history, or missing data were excluded. Demographic information, laboratory results, metabolic data and tumor behavior were assessed.
Results: Total 6402 patients were finally included in this study. The ratio of NAFLD related HCC were annually growing from 2011 (3.8%) to 2015 (6.4%). Male gender accounted for the majority part in both group. Patients with NAFLD-HCC were usually diagnosed at older age (63.7 ± 10.4 years) compared to HBV-HCC (53.6 ± 10.5 years, $p < 0.01$). Patients with NAFLD-HCC were observed as having significant higher BMI (24.6 ± 3.26 kg/m^2 in NAFLD-HCC vs. 23.3 ± 2.98 kg/m^2 in HBV-HCC, $p < 0.01$), total cholesterol (4.5 ± 0.97 mmol/L vs. 4.12 ± 0.92 mmol/L), triglycerides (1.69 ± 1.2 mmol/L vs. 1.09 ± 0.56 mmol/L), and HDL-C (1.13 ± 0.34 mmol/L vs. 1.2 ± 0.37 mmol/L). While fasting plasma glucose seemed to be no significant difference. As a key biomarker, alpha-fetoprotein was significantly higher in HBV group. The ratio of cirrhosis was a little higher in HBV-HCC (59.8% in HBV-HCC vs. 45.0% in NAFLD-HCC). Nodule size was larger in NAFLD-HCC (5.32 ± 0.14 cm vs. 4.61 ± 0.05 cm, $p < 0.01$).
Conclusion: This study indicates that the annual incidence rate of NAFLD related HCC is steady growing. These patients should be monitored carefully due to elder age at diagnosis, disorders of lipid metabolism, and worse tumor behavior.
Disclosure: **H. Chen:** None.

PS 116 Clinical aspects of NAFLD

1197

Influence of gender on progression of liver metabolic diseases in response to different nutritional challenges
S. Smati[1,2], A. Polizzi[1], M. Régnier[1], A. Marrot[1], C. Luzowicz[1], S. Ellero-Simatos[1], F. Lasserre[1], N. Loiseau[1], T. Al Saati[3], A. Montagner[2], P. Gourdy[2], H. Guillou[1];
[1]INRA, Toulouse, [2]INSERM, Toulouse, France, [3]Inserm, Toulouse, France.

Background and aims: Non Alcoholic Fatty Liver Disease (NAFLD) currently affects 30% of the population and is a pathology for which there is sexual dimorphism. Indeed, several epidemiological studies show protection against NAFLD in premenopausal women. The establishment of reliable animal models is essential for the study of this protection. The aim of our study was to evaluate the influence of gender in different mice models of steatosis and NASH and to identify a model that replicates at best the sexual dimorphism observed in humans.
Materials and methods: One hundred and twenty males and females C57BL/6J received different hypercaloric diets: High Fat Diet (HFD), Choline Deficient (CDHFD), enriched with cholesterol (Western Diet) and co-administered with drinking water containing glucose and fructose (Western Diet & sugar). These diets were given ad libitum for 15 weeks ($n = 12$ per group). The mice were sacrificed at the end of the follow-up, at the age of 6 months. This study was conducted under the EU guidelines for the use and care of laboratory animals and was approved by an independent ethics committee.
Results: The cholesterol enriched Western Diet (4.5 kcal/gram, lipids 42%, carbohydrates 42.7%, proteins 15.2%, cholesterol 0.2%) induces a strongly dimorphic phenotype for the onset of the NASH. Males have a major steatosis associated with severe inflammation and fibrosis. Females show much less steatosis (intrahepatic triglycerides measured at 305 versus 893 μg/mg in males, $p < 0.0001$). Both sexes develop obesity and have impaired glucose tolerance. In contrast, insulin resistance is more severe in males than in females (respectively HOMA-IR at 51.0 versus 13.1, $p = 0.0041$). Cytolysis in males is significantly higher than in females (ALAT at 115 versus 51 U/L, $p = 0.002$). Finally, the transcriptomic approach shows that the transcriptional responses induced by the diet are very contrasted between males and females.
Conclusion: The Western Diet induces NASH associated with more fibrosis only in males. These results suggest a possible effect of dietary cholesterol in the etiology of NASH. Obtaining this phenotype will allow to study the mechanisms involved in the protection of females and in particular the role of estrogen.
Disclosure: **S. Smati:** None.

Neck circumference to height ratio is a reliable predictor of liver stiffness and nonalcoholic fatty liver disease in prediabetes
D. Dutta[1], M. Kumar[2], S.A. Mondal[3], S. Mukhopadhyay[2];
[1]Diabetes, Endocrinology & Metabolism, Venkateshwar Hospital, Dwarka, New Delhi, New Delhi, [2]Endocrinology & Metabolism, IPGMER & SSKM Hospital, Kolkata, [3]Biochemistry, IPGMER & SSKM Hospital, Kolkata, India.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) and dysglycemia are public health challenges. There is urgent need for anthropometric surrogates for NAFLD screening. This study evaluated role of neck circumference (NC) and neck-height ratio (NHtR) as predictors of liver stiffness measure (LSM) in individuals with prediabetes (IPD).
Materials and methods: In a cross-sectional study, 188 IPD from 1130 screened individuals underwent anthropometry, ultrasonography,

Fibroscan® for liver stiffness (LSM), dyslipidemia, insulin resistance (IR) and fetuin-A assessment.
Results: Hypertension, hypertriglyceridemia, low HDL-C, metabolic syndrome (MetS), NAFLD and significant liver stiffness (SLS) (LSM >8.5 kPa) were observed in 53.7%, 31.4%, 71.3%, 73.9%, 24.5% and 11.2% prediabetes individuals respectively. Of the 46-prediabetes individuals with NAFLD, 21 had significant liver stiffness on fibroscan. Prediabetes with NAFLD had significantly higher BMI, NC, NHtR, glycated haemoglobin, triglycerides, fatty liver index (FLI) and LSM. The median [25th–75th percentile] for NC was 36.5 cm [36–38] in males and 34 cm [32–36.75] in females ($P < 0.001$); the corresponding NHtR was 22.09 [21.32–22.96] and 21.70 [21.03–23.62] cm/m respectively ($P = 0.272$). Prediabetes in highest NHtR quartile had significantly higher BMI, hypertension, MetS, fasting glucose, glycated hemoglobin, HOMA-IR, NAFLD, LSM, SLS, and lower HDL-C. Stepwise forward linear regression revealed that NHtR, FLI and LDL-C were best predictors of LSM, at baseline (Model-1), after adjusting for age and sex (Model-2) and adjusting model-2 plus systolic and diastolic blood pressure (Model-3). Logistic regression, using presence of significant liver stiffness (LSM >8.5 kPa) as the dependent variable, showed relationship between NHtR and liver stiffness after adjusting for sex was statistically significant (odds ratio 1.421 [95% CI 1.111 −1.817]; $P = 0.005$). A similar logistic regression showed relation between NC and liver stiffness approached statistical significance (odds ratio 1.158 [95% CI 0.997–1.345]; $P = 0.056$). NHtR and NC (in females), and NHtR and BMI (in males) had largest AUCs for predicting LSM, NAFLD and MetS. NHtR (AUC: 0.816; $P = 0.001$) and NC (AUC: 0.744; $P = 0.014$) were best predictors of liver fibrosis in females. BMI (AUC: 0.695; $P = 0.025$) and NHtR (AUC: 0.619; $P = 0.061$) were the best predictor of liver fibrosis in males. NHtR ≥21.54 cm/m (sensitivity: 90%; specificity: 52.5%; females) and ≥21.62 cm/m (sensitivity: 80%; specificity: 49.4%; males) was best predictor of SLS. Nine out of the 10 females with SLS in this study had NHtR ≥21.54 cm/m. Nine out of 11 males with SLS in this study had NHtR of 21.62 cm/m. The occurrence of NAFLD in quartile-1 ($n = 47$) and quartile-4 ($n = 44$) of NC was 14.89% and 43.18% respectively. This evaluation achieved a power of 98%, keeping α (Type I error) at 0.05.
Conclusion: NHtR can be a good screening tool [good sensitivity (80–90%) with a relatively poor specificity (around 50%)] for detecting liver stiffness in prediabetes. The high sensitivity ensures we will not miss cases in community during screening. Patients thus detected can undergo confirmatory tests for NAFLD.

Cardiorespiratory fitness is associated with markers of hepatic steatosis in patients with type 2 diabetes

J. Sokolovska[1], L. Sviklāne[1], K. Ostrovska[2], A. Kļaviņa[2], J. Stefanovičs[1], L. Selavo[1];
[1]University of Latvia, Riga, [2]Latvian Academy of Sport Education, Riga, Latvia.

Background and aims: several studies have shown that physical activity is effective for reduction of liver fat in patients with insulin resistance and type 2 diabetes. However, few studies address the question whether level of cardiorespiratory fitness (CF) is associated with the risk of liver steatosis. Fatty liver index (FLI), hepatic steatosis index (HSI), nonalcoholic fatty liver disease liver fat score (NAFLD-LFS) have been validated for evaluation of risk of hepatic steatosis in healthy subjects and patients with type 2 diabetes. The aim of this work was to study differences in the levels of hepatic steatosis markers FLI, HSI and NAFLD-LFS between groups of type 2 diabetic patients with different level CF.
Materials and methods: 63 previously untrained patients with type 2 diabetes aged 35–75 have been enrolled. The patients have been divided in two groups according to relative VO2 max status (low CF group: VO2 max males <29 ml/min/kg, females <25 ml/min/kg; high CF group: VO2max males ≥29 ml/kg/min, females ≥25 ml/min/kg). FLI, HSI, NAFLD-LFS were calculated by formulas, which are based on clinical features and blood biochemistry as previously published. Leisure time physical activity of participants was evaluated via Minnesota leisure time activity questionnaire and expressed in metabolic equivalent (MET).
Results: Clinical characteristics of the group were: mean age 58.6 ± 9.5 years, mean duration of diabetes 8.0 ± 9.7 years, mean BMI 33.5 ± 5.5 kg/m^2, mean HbA1c 6.9 ± 1.3%, mean FLI 79.8 ± 25.9, mean HSI 37.7 ± 5.6, mean NAFLD-LFS 1.73 ± 1.8, mean VO2 max 24.0 ± 95.1 ml/kg/min, mean leisure time physical activity 33.7 ± 25.2 (corresponds to moderate activity). HSI, FLI and NAFLD-LFS were higher in patients with low CF (FLI: Low CF group 82.0 ± 21.3 versus high CF group 66.5 ± 31.1, $p = 0.023$; HSI: Low CF group 39.1 ± 5.1 versus high CF group 34.9 ± 5.4, $p = 0.004$; NAFLD-LFS: Low CF group 2.2 ± 1.7 versus high CF group 0.9 ± 1.8, $p = 0.009$). Serum insulin concentration was higher in low CF group compared to high CF group (versus 11.7 ± 8.5 μV/ml versus 6.3 ± 8.6 μV/ml ($p = 0.045$). However, we did not observe differences between VO2 max groups in HbA1c, duration of diabetes, MET, microalbuminuria as well as cytokines associated with risk of diabetic complications (VEGF-A, Angiopoietin-2, MMP7, MMP2). There was a significant correlation between VO2 max and indices (VO2max and FLI $p = 0.029$, VO2max and HSI $p = 0.000$, VO2max and NAFLD-LFS $p = 0.005$) as well as insulin ($p = 0.012$) and waist ($p = 0.004$).
Conclusion: markers of hepatic steatosis HSI, FLI and NAFLD-LFS are associated with cardiorespiratory fitness in previously untrained subjects with type 2 diabetes. These results provide new data on association between hepatic steatosis and cardiac complications of diabetes

Association of serum vitamin D and insulin resistance with noninvasive markers among prediabetic individuals with nonalcoholic fatty liver disease

R. Zinnat, I.A. Hossain, L. Ali;
Biochemistry & Cell Biology, Bangladesh University of Health Sciences, Dhaka, Bangladesh.

Background and aims: Prediabetes and nonalcoholic fatty liver disease (NAFLD) both are independently known to be an insulin resistant condition. A number of noninvasive markers have been evaluated for the diagnosis of NAFLD where vitamin D deficiency due to impaired insulin action is a hallmark feature of the disorder. Data examining the association of serum vitamin D and insulin resistance with noninvasive markers are scare. In this context, the present study was assessed to investigate the association of serum vitamin D with noninvasive markers and to explore whether this association is mediated by insulin resistance among prediabetic individuals.
Materials and methods: We studied 277 prediabetic subjects (M/F, 167/110; age in years, 39.7 ± 9.3; BMI in kg/m^2, 25.4 ± 3.9; M ± SD) confirmed by OGTT following WHO Group Study criteria. NAFLD was diagnosed by upper abdomen ultrasonography comprising into 192 non NAFLD (120/72; 38.3 ± 8.9; 24.3 ± 4.1) and 85 NAFLD (47/38; 39.1 ± 9.6; 26.5 ± 3.3) groups. The noninvasive markers include the fatty liver index (FLI), hepatic steatosis index (HSI), NAFLD fibrosis score (NFS), fibrosis4 (FIB4) score, BARD score and BAAT score respectively. Serum insulin and vitamin D levels reflecting 25 hydroxyvitamin D [25(OH)D] were measured by ELISA techniques. Insulin resistance (HOMA-IR) was calculated by homeostasis model assessment (HOMA).

Results: In NAFLD subjects, the FLI index (>60), HSI (>36), NFS (−1.455–0.675), FIB4 index (>2.67), BARD score (2–4 points) and BAAT score (4 risk parameters) was 46.2% (66), 95.1% (136), 6.3% (9), 9.1% (13), 21% (30) and 40.6% (58) respectively. Compared to non NAFLD subjects, NAFLD subjects had significantly lower levels of [25(OH)D] (26.58 ± 6.46 vs. 35.89 ± 14.27 nmol/L, $p < 0.001$) while, significantly higher levels of HOMA-IR (2.37 ± 1.24 vs. 1.75 ± 0.55, $p < 0.001$). Pearson's correlation analysis showed a significant negative correlation of [25(OH)D] with HOMA-IR ($r = -0.289$, $p = 0.032$), fasting serum insulin ($r = -0.278$, p=0.046), postprandial serum insulin ($r = -0.210$, $p = 0.048$), FLI ($r = -0..342$, $p < 0.001$), HSI ($r = -0.214$, $p = 0.022$) and BAAT score ($r = -0.272$, $p = 0.026$) respectively in NAFLD subjects. Multiple linear regression analysis showed a significant negative association of HOMA-IR with [25(OH)D] ($\beta = -0.299$, $p = 0.035$) as well as significant positive association with FLI ($\beta = 0.525$, $p = 0.025$), BAAT score ($\beta = 0.279$, $p = 0.047$), NFS ($\beta = 0.458$, $p = 0.013$) and FIB4 score ($\beta = 0.396$, $p = 0.048$) after adjusting the effects of confounding variables of BMI and triglyceride respectively. On binary logistic regression analysis, [25(OH)D] (OR = 0.870, 95% CI: 0.821–0.921, $p < 0.001$), HOMA-IR (OR = 1.822, 95% CI: 0.901–3.684, $p = 0.034$), FLI (OR = 1.049, 95% CI: 1.007–1.094, $p = 0.023$), BAAT score (OR = 0.480, 95% CI: 0.242–0.951, $p = 0.035$) and FIB4 score (OR = 6.638, 95% CI: 1.322–33.321, $p = 0.021$) were found to be significant determinants of NAFLD when adjusted the effects of major confounders of BMI, triglyceride, HSI, BARD score and NFS respectively.

Conclusion: NAFLD subjects seem to have an association with [25(OH)D] deficiency and noninvasive markers and this relationship is mediated by insulin resistance which is considered the pathophysiological determinant of prediabetes.

Gamma-glutamyltransferase levels reflect glycaemic status in type 2 diabetic people treated with an SGLT2 inhibitor tofogliflozin

T. Takamura[1], K. Kaku[2], A. Yoshida[3], H. Kusakabe[3], H. Suganami[4]; [1]Department of Endocrinology and Metabolism, Kanazawa University Graduate School of Medical Sciences, Kanazawa, [2]Department of Internal Medicine, Kawasaki Medical School, kurashiki, [3]Medical Information and Product Advancement Department, Kowa Pharmaceutical Co., Ltd., Tokyo, [4]Clinical Data Science Department, Kowa Pharmaceutical Co., Ltd., Tokyo, Japan.

Background and aims: The circulating levels of gamma-glutamyltransferase (GGT) and alanine aminotransferase (ALT) are used clinically as indices of fatty liver diseases and predictors of type 2 diabetes (T2D). However, contributions of hyperglycemia and obesity to levels of GGT and ALT have not been demonstrated clinically. Thus, we examined relationships between various clinical parameters and GGT and ALT levels during intervention for hyperglycemia and obesity with the SGLT2 inhibitor tofogliflozin in people with T2D.

Materials and methods: The pooled analysis included four tofogliflozin phase 2 and 3 trials (Supplemental Table 1), with durations of at least 24 weeks, that included 1046 participants with T2D who received either tofogliflozin (10, 20, or 40 mg) or placebo, either as a monotherapy or as an add-on to other antidiabetic agents. Differences in various parameters between tofogliflozin and placebo groups were analyzed by ANCOVA. Clinical parameters related to baseline and percent changes in hepatic enzymes were clarified using multivariate analysis.

Results: Study-group baseline characteristics were 67% men; mean age, 58 years; HbA1c, 8.1%; BMI, 26 kg/m^2; GGT, 48 IU/L; and ALT, 29 IU/L. In multivariate analyses, baseline GGT levels were positively correlated with FPG levels, but not body mass index (BMI). ALT levels were positively correlated with both HbA1c levels and BMI, but not FPG. Decreases in GGT and ALT levels during tofogliflozin therapy were distinct. GGT levels rapidly and significantly decreased as early as week 4 and plateaued after week 8, which was maintained until week 24, with a similar decrease in FPG. Conversely, ALT levels decreased gradually for 24 weeks, without a plateau, with a similar decrease in body weight. At weeks 4 and 24, overall GGT level reduction was significantly correlated with FPG and body weight reduction, whereas overall ALT reduction was correlated only with body weight reduction. Because the patterns of the decreases in GGT and ALT levels were distinct at the early and late phases; we analyzed the factors influencing the reduction in GGT and ALT levels individually at week 4 ($\Delta_{0\text{-}4}$) and week 24 ($\Delta_{0\text{-}24}$) by using a multivariate stepwise method. At both week 4 and 24, the overall reduction in GGT was significantly correlated with the reductions in FPG and body weight, whereas the overall reduction in ALT was correlated only with the reduction in body weight, and not FPG.

Conclusion: Our results indicate that GGT and ALT levels reflect two distinct pathologies of T2D, glycemic status and obesity, respectively, which may help understand mechanisms underlying liver enzyme elevation and establish GGT and ALT as surrogate markers for hyperglycemia and obesity, respectively, in clinical and epidemiological studies.

Hepatocellular carcinoma as a independent risk factor for post transplant diabetes in liver recipients

S. M. Bernardes[1], T. Gonçalez Bovi[2], F. Colitti Lemos[1], C. Minatel Righetto[2], A. Russo Fiore[2], L. Teixeira Lot[3], A. Moura Neto[2], I. de Fátima Ferreira Santana Boin[3]; [1]São Leopoldo Mandic Faculty of Medicine, Campinas, São Paulo, Brazil, Campinas, [2]Discipline of Endocrinology, Internal Medicine Department, Faculty of Medical Sciences, University of Campinas, Campinas, São Paulo, Brazil, Campinas, [3]Department of Surgery, Faculty of Medical Sciences, University of Campinas, Campinas, São Paulo, Brazil, Campinas, Brazil.

Background and aims: Non-alcoholic steatohepatitis (NASH), a condition tightly related to type 2 diabetes mellitus, is becoming increasingly common as a cause for end stage liverdisease and hepatocellular carcinoma (HCC). There are few data related specifically to theidentification of risk factors for post transplant Diabetes Mellitus (PTDM) in liverrecipients. The aims of this study were to investigate the risk factors for PTDM and therelation of HCC and PTDM in patients submitted to liver transplantation.

Materials and methods: Revision of medical records of adult patients submitted to liver transplantation. A total of 152 consecutive patients seen at the post transplantation clinic from February to June 2017 were included.

Results: Of all patients, 76.5% were men. The median (interquartile range) age was 59 (52.7–65) years, transplant time 6 (2.3–9) years, BMI 27.5 (24.4–29.8) kg/m^2 and diagnosis of DMPT was made at a median of 2 (1–6) years after thetransplant. Among the 152 patients, 43.2% had diagnosis of DM and 27% were classifiedas PTDM. As for comorbidities, 48.3% presented hypertension, 32.2%hypercholesterolemia and 31.5% hypertriglyceridemia. The major cause oftransplantation was hepatitis C virus (55%), followed by alcohol abuse (32.9%). Additionally, 40.3% were diagnosed with HCC before liver transplantation. The mostcommonly used immunosuppressants after liver transplantation were tacrolimus (78.4%), mycophenolate (62.8%), everolimus (24.5%) and prednisone (PDN) (23.8%).Comparisons using the Chi-Square test showed a predominance of males in patients withPTDM compared to those without PTDM (87.5% vs 72.2%, $p = 0.05$) and higher a frequencyof HepC (72.5% vs 42.1%, $p = 0.001$) and of tacrolimus use (92.5% vs 72.9%, $p = 0.01$) inthose with PTDM. There was no significant difference in rejection occurrence. The independent risk factors for PTDM according to multivariate logistic regression were HepC (OR =

3.8, 95% CI 1.3–10.9, $p = 0.013$), presence of HCC (OR = 3.7, 95% CI, 1.2–11 5, $p = 0.025$), the use of tacrolimus (OR = 6.3, 95% CI 1.2–32.5, $p = 0.029$) and PDN (OR = 7.2, 95% CI 2.4–21, 8, $p < 0.001$).

Conclusion: HCC is an independent risk factor for PTDM inliver recipients. Patients with NASH prior to liver transplantation could be more predisposed to both HCC and DM, thus possibly explaining this association. Patients with HepC and those exposed to tacrolimus and prednisone are other groups of high risk for PTDM. Liver recipients with history of HepC and/or HCC should be carefully evaluated for PTDM and more diabetogenic drugs avoided in these groups of patients, if possible.

	Without DM or Pre transplantation	PTDM	p

L-Carnitine supplementation effects on kidney damage in mice with nonalcoholic steatohepatitis

I. Terruzzi[1], F. Vacante[2], A. Montesano[3], P. Senesi[2], G. Mollica[2], R. Codella[3,2], L. Luzi[3,2];
[1]Diabetes Research Institute, Metabolism, Nutrigenomics and Cellular Differentiation Unit, San Raffaele Scientific Institute, Milan, [2]Metabolism Research Center, IRCCS Policlinico San Donato, Milan, [3]Department of Biomedical Sciences for Health, University of Milan, Milan, Italy.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is caused by an accumulation of fat in the liver, ranging from fatty infiltration plus inflammation (non-alcoholic steatohepatitis - NASH), to advanced fibrosis and, finally, to cirrhosis that can progress to hepatocellular carcinoma. It is now increasingly clear that NAFLD not only affects the liver but can also increase the risk of developing extra-hepatic diseases, including diabetes, cardiovascular disease and chronic kidney disease (CKD). An overabundance of common factors and pathways are implicated in the pathogenesis of NAFLD and CKD. Several studies, including our previous work, have examined the effectiveness of L-Carnitine (LC) in liver and heart function. If LC is properly prescribed, it is recognized to improve kidney function. The effects of LC administration on NAFLD development and kidney histological-functional failure association were investigated in mouse model of steatohepatitis, induced by a methionine-choline deficient diet (MCD).

Materials and methods: C57BL/6 male mice ($n = 18$, age: 12 weeks) were divided in three different groups and studied for 6 weeks: control group (CONTR) was fed normal diet while both MCD and LC groups received MCD diet. In LC group, from week 3 to week 6 MCD diet was enriched with 200 mg/kg/die LC (drinking water). To study if LC attenuates fat deposition, inflammatory infiltration tissue fibrosis and kidney histopathology were assessed by histochemical staining, western blot assay and immunofluorescence.

Results: There were no significant differences in body weight between MCD and LC, while, as described in literature, there was a significant weight loss in MCD and LC groups in respect with CONTR. MCD is strictly associated with inflammation and oxidative stress (ROS) onset: ROS production was significantly reduced and Ca^{2+}/calmodulin-dependent kinases II protein levels increased in LC group in respect to MCD group. This evidence seem to show that LC antioxidant action was linked to mitochondrial function and calcium signaling. Moreover, alpha smooth muscle actin protein content increased in MCD mice while decreased in LC mice. The trend of this fibrotic marker advocates for a LC anti-fibrotic action in kidney, further confirmed by Cytokeratin 18 (CK18) protein content decrease after LC supplementation. CK18 is also recently recognized as a marker of cellular stress and its decrease suggests an LC protective effect in renal tubular injury.

Conclusion: Taken together, these results suggest that LC preserves renal function probably by reducing ROS production and modulating Ca^{2+} homeostasis. Although the association between NAFLD and CKD is strong and consistent across different patient populations, the progression and the treatment of associated CKD-NAFLD remains an issue of intense debate. Our preliminary data could represent a new nutraceutical field of investigation.

Disclosure: **I. Terruzzi:** None.

PS 117 Treating NAFLD

Modified mesenchymal stromal cells: a novel and safe therapy in type 2 diabetes and its complications

S. Sen, N. Kundu, Y. Kropotova, N. Ahmadi, C. Domingues;
George Washington University, Washington, USA.

Background and aims: Mesenchymal stromal cells (MSCs) are multipotent cells that can home-in to the sites of inflammation and may coalesce with the host tissue. Though systemic antioxidant delivery has been unsuccessful, delivery of antioxidants locally at the site of inflammation using antioxidant upregulated fat derived MSCs, delivered intraperitoneally, may reduce inflammation and improve glucose homeostasis and diabetes associated complications in diet-induced obese diabetic mouse model.
Materials and methods: GFP-containing adenoviral constructs were used to upregulate antioxidants Sod2 (mitochondrial), Catalase (cytosolic) or Null (control) individually, in adipose-derived MSCs, ex-vivo. Modified MSCs were delivered intraperitoneally (IP) into mice that received 45% and 60% high-fat diet for 8–16 weeks, $n = 4$ in each group
Results: Glucose tolerance was improved at week 4 in the antioxidant upregulated MSC-receiving groups with concomitant reduction in hyperplasia in omental fat. A reduction in plasma levels of TNFa, an well-known inflammatory marker, was noted in all treated animal groups in comparison to null-MSCs. RT-PCR analysis of omental and pericardial fat showed significant up-regulation in mRNA expression of brown fat marker, Ucp1 (~1000-fold and 10-100-fold, respectively) which was associated with PGC1A upregulation. Browning was confirmed by Ucp1-staining. Remarkably, the treatment showed a significant reduction in liver fat content (by histology) and triglyceride content measurement.
Conclusion: Delivery of Sod2 and Catalase upregulated MSCs improved glycemic control by reducing systemic inflammation, promotes browning of white adipose tissue in the peritoneum and reverses hepatic lipid accumulation. These results indicate that antioxidant upregulated MSCs can help to improve glucose homeostasis, improve adipocyte energetics and prevents development of fatty liver disease. Modified MSC therapy can be a promising therapy for type 2 diabetes, obesity and its complication such as fatty liver disease.

Long term effects of liraglutide in type 2 diabetic patients with vs without steatosis at baseline: 5 years prospective real-world study

G. Castellino[1], A. Rizvi[2], D. Nikolic[1], R. Chianetta[1], A. Patti[1], R. Giglio[1], S. Speciale[1], C. Mannina[1], R. Citarrella[1], G. Montalto[1], N. Papanas[3], M. Rizzo[1];
[1]DIBIMIS, University of Palermo, Italy, Palermo, Italy, [2]Endocrinology, Diabetes and Metabolism, University of South Carolina, Columbia, USA, [3]Diabetes Centre, Second Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis, Greece.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) is frequently seen in type 2 diabetes subjects (T2DM) and associated with increased cardio-metabolic risk. Several studies showed that liraglutide is safe, well tolerated, and has a certain benefit on NAFLD. We assessed if, after long-term treatment, the effects of liraglutide on glyco-metabolic parameters, including a marker of subclinical atherosclerosis, cIMT, could differ in T2DM subjects with steatosis versus those without steatosis at baseline.
Materials and methods: This prospective 5 years real-world study included 31 T2DM subjects (19 men and 12 women; mean age: 60 ± 17 years), naïve to incretin-based therapies, without prior history of a major CV event and treated with metformin only. Liraglutide (1.2 mg/day) was given as add-on to stabile dose of metformin (1500–3000 mg/day). cIMT was measured by B-mode real-time ultrasound, while the presence of steatosis was assessed by ultrasound. The cohort of patients was subdivided in those with steatosis ($n = 17$) and those without steatosis ($n = 14$).
Results: Paired t-test and ANOVA were performed. After 5 years of liraglutide treatment, anthropometric and glycemic parameters improved, as well as a good metabolic control was achieved in both groups (Table), although statistical significance was not reached for all parameters. On the other hand, cIMT reduced significantly in both groups.
Conclusion: The improvements of assessed glyco-metabolic parameters was seen in both groups with and without steatosis at baseline, including significantly reduced cIMT. However, no significant differences were found for all parameters in the inter-group analysis. These data indicate on an effective CV prevention by liraglutide treatment in T2DM subjects regardless of the presence of diabetic complications. Although it remains to be established by larger studies, these findings support the potential use of liraglutide in populations at increased CV risk and without diabetes.

Effects of a carbohydrate-reduced high-protein diet on liver, pancreas and muscle triglyceride content in patients with type 2 diabetes

A. Samkani[1], M.J. Skytte[1], A.D. Petersen[1], M.N. Thomsen[1], A. Astrup[2], E. Chabanova[3], J. Frystyk[4], J.J. Holst[5], H. Thomsen[3], S. Madsbad[6], T.M. Larsen[2], S.B. Haugaard[1], T. Krarup[1];
[1]Dept. of Endocrinology, Copenhagen University Hospital Bispebjerg, Copenhagen, [2]Dept. of Nutrition, Exercise and Sports, University of Copenhagen, Copenhagen, [3]Dept. of Radiology, Copenhagen University Hospital Herlev, Herlev, [4]Dept. of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, [5]Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, [6]Dept. of Endocrinology, Copenhagen University Hospital Hvidovre, Hvidovre, Denmark.

Background and aims: Nonalcoholic Fatty Liver Disease (NAFLD) is associated with obesity and insulin resistance and the prevalence of NAFLD is up to three times higher in individuals with type 2 diabetes (T2D) compared with the general population. We hypothesized that an iso-energetic carbohydrate-reduced high-protein diet (CRHP) reduces the liver triglyceride content within 6 weeks in T2D compared with a conventional diabetes diet (CD).
Materials and methods: An iso-energetic CRHP diet was compared with a CD diet (30/50 E% carbohydrate, 30/17 E% protein and 40/33 E% fat, respectively) in a randomized open label crossover trial with 12 weeks of continuous food provision. Each diet was consumed 6 weeks. Energy intake was adjusted continuously to reinforce weight stability. Twenty-eight participants with T2D treated with only oral glucose lowering medication were included in the trial; (mean±SD) age 64 ± 8 years, body mass index 30 ± 5 kg/m^2, daily caloric need 10.5 ± 1.6 MJ, HbA_{1c} 59.6 ± 8.4 mmol/mol, T2D duration 7.0 ± 5.4 years. Liver and psoas muscle fat were measured by Magnetic Resonance (MR) spectroscopy. Pancreas fat was measured by MR imaging. Subcutaneous and visceral

adipose tissue volumes were measured in a 1 cm axial slice through mid L3. All MR data were analyzed blinded to treatment. Differences from baseline and after 6 weeks on each diet were assessed using Wilcoxon signed rank tests, while differences between diets were assessed by employing a linear mixed model on logarithmized data to meet model assumptions.

Results: Six weeks of CRHP diet significantly reduced the liver fat content from 5.8 (2.1–13) % (median; IQR) to 1.0 (1–3.6) % ($p < 0.001$), while no change was found after 6 weeks of CD diet (from 3.3 (1.4–8.7) % to 2.6 (1.0–8.3) %, $p = 0.46$). The difference in liver fat content reduction between diets was significant ($p < 0.001$). Furthermore, 6 weeks of CRHP diet significantly reduced the pancreas fat content from 6.1 (4.5–13) % (median; IQR) to 5.1 (3.1–13.4) % ($p = 0.019$), while no change was found after 6 weeks of CD diet (from 4.5 (3.1–13) % to 6.3 (4.1–11) %, $p = 0.20$). The difference in pancreas fat content change between diets was significant ($p = 0.042$). Psoas muscle fat content, subcutaneous and visceral fat volumes and waist circumference did not change significantly on either diet.

Conclusion: The present findings are promising for the dietary management of nonalcoholic fatty liver disease in T2D as a CRHP diet significantly reduces liver and pancreas fat content within 6 weeks of treatment compared with a CD diet in weight stable subjects.

The effect of semaglutide on liver enzymes in subjects with obesity and elevated alanine aminotransferase: data from a randomised phase 2 trial

T. Monk-Hansen[1], L. Van Gaal[2], S. Harrison[3], S. Rasmussen[1], P.N. Newsome[4];
[1]Novo Nordisk A/S, Søborg, Denmark, [2]Antwerp University Hospital, Edegem, Belgium, [3]University of Oxford, Oxford, UK, [4]Queen Elizabeth Hospital, Birmingham, UK.

Background and aims: The glucagon-like peptide 1 analogues semaglutide and liraglutide improve glycaemic control and reduce elevated liver enzymes in subjects with type 2 diabetes (T2D), and reduce body weight in subjects with or without T2D. Histological resolution of nonalcoholic steatohepatitis has also been seen for liraglutide in subjects with or without T2D. A randomised, placebo-controlled phase 2 trial of once-daily subcutaneous semaglutide (0.05, 0.1, 0.2, 0.3, or 0.4 mg following escalation every 4 weeks) in subjects with obesity without T2D, showed mean weight losses of −6.0% (0.05 mg) to −13.8% (0.4 mg) with semaglutide vs −2.3% with placebo at week 52. The effect of semaglutide on liver enzymes in subjects with elevated baseline alanine aminotransferase (ALT) was evaluated in a *post hoc* sub-analysis from this trial.

Materials and methods: Baseline fibrosis was categorised by the nonalcoholic fatty liver disease (NAFLD) fibrosis score (NFS) and Fibrosis-4 (FIB-4) score. Changes in ALT were estimated at week 52 (mixed model on log-transformed data) and semaglutide-to-placebo group ratios and 95% confidence intervals (95%CI) calculated from this model for subjects with high baseline ALT (>30 U/L [male]; >19 U/L [female]).

Results: Mean (range) baseline characteristics of the 957 treated subjects (35% male) were: age 47 (18–86) years, weight 111 (70–244) kg, body mass index 39 (30–80) kg/m^2, mean NFS −0.49 (−4.70–4.66) and mean FIB-4 0.72 (0.14–3.31); 52% ($n = 499$) had high ALT, 18% a high NFS (>0.676), and <1% a high FIB-4 (>3.25) at baseline. Semaglutide-to-placebo ALT ratios (95%CI) at week 52 in those with high baseline ALT were: 0.88 (0.76–1.01; 0.05 mg); 0.94 (0.82–1.08; 0.1 mg); 0.82 (0.71–0.95; 0.2 mg); 0.79 (0.68–0.91; 0.3 mg), and 0.82 (0.70–0.95; 0.4 mg). *P* values were <0.01 at doses >0.1 mg, unadjusted for multiple testing. Normalization of high baseline ALT was seen at week 52 in 29% (17/58; 0.05 mg), 25% (15/59; 0.1 mg), 38% (19/50; 0.2 mg), 43% (23/54; 0.3 mg), and 46% (21/46; 0.4 mg) of subjects on semaglutide, versus 18% (14/76) of subjects on placebo.

Conclusion: In this obese population 52% had elevated liver enzymes at baseline and 18% had a high NFS score. In subjects with obesity and high ALT, semaglutide 0.2–0.4 mg daily reduced ALT as compared to placebo and resulted in dose-related ALT normalization in up to 46% of subjects after 52 weeks. These data support a potential role for semaglutide in the treatment of NAFLD with elevated liver enzymes.

Dual chemokine receptor CCR2/CCR5 antagonist cenicriviroc prevents and reverses lipotoxicity-induced insulin resistance, steatohepatitis, and liver fibrosis in mice

G. Chen[1], M. Nagashimada[1], T. Ota[1,2];
[1]Kanazawa University, Kanazawa, [2]Asahikawa Medical University, Asahikawa, Japan.

Background and aims: Hepatic lipid accumulation drives innate immunity with recruitment of bone marrow-derived macrophages and activation of liver-resident Kupffer cells, leading to the development of insulin resistance and NASH. However, treatment options that target macrophage/Kupffer cells recruitment or activation with the aim of halting the insulin resistance and NASH remain limited. A C-C chemokine receptor 2 (CCR2) and its ligand, MCP-1, plays a central role in macrophage recruitment. In addition, we reported that a different C-C chemokine receptor, CCR5, promotes obesity-induced insulin resistance and hepatic steatosis by regulating macrophage M1/M2 polarization. Cenicriviroc (CVC), a dual CCR2 and CCR5 receptor antagonist, has been reported for its anti-fibrotic activity in a murine model of NASH and is currently evaluated in clinical trial in patients with NASH. In the present study, we investigated the effect of CVC in a lipotoxic model of NASH with hepatic fibrosis and insulin resistance, replicating the pathophysiological features of human NASH.

Materials and methods: Eight-week-old C57BL/6 mice were fed a high-cholesterol, high-fat (CL) diet or a CL diet containing 0.015% CVC (CL+CVC) for 12 weeks. The liver histology, insulin sensitivity, and fibrogenesis were examined. We next quantified intrahepatic immune cell numbers by flow cytometry.

Results: After 12 weeks of feeding, histological examination showed steatohepatitis with fibrosis in mice fed CL diet. They showed hyperinsulinemia without significant change in weight and adiposity. The CVC administration decreased the increase in plasma ALT levels as well as liver triglyceride, cholesterol, and TBARS levels caused by the CL diet. In addition, CVC improved glucose intolerance and hyperinsulinemia in the CL group and augmented the insulin signal, assessed by IRβ and Akt phosphorylation in the liver. Flow cytometry analysis revealed that the numbers of CD45$^+$CD11b$^+$F4/80$^+$ total macrophages were significantly reduced in CL+CVC group by 54%. Moreover, mice fed CL+CVC had 72% fewer CD11c$^+$CD206$^-$ M1-like macrophages, but 94% more CD11c$^-$CD206$^+$ M2-like macrophages than CL group. The hepatic total numbers of CD3$^+$, CD4$^+$, and CD8$^+$ T cells were lower in CL+CVC group than in CL group by 41%, 51%, and 48%, respectively (all $P < 0.05$), indicating that CVC caused an M2-dominant shift in macrophages/Kupffer cells and a subsequent reduction in CD4$^+$ and CD8$^+$ T cell recruitment in the liver. In parallel experiments *in vitro*, CVC decreased LPS-induced M1 marker (*Tnfa*, *F4/80* and *Il1β*) mRNA expression but enhanced IL-4-induced M2 marker (*Chi3l3*, *Mgl1* and *Mgl2*) mRNA expression dose-dependently in isolated murine peritoneal macrophages. Furthermore, CVC attenuated hepatic fibrosis by repressing the activation of hepatic stellate cells (HSCs) and decreasing hydroxyproline content by 32%. Accordingly, CVC suppressed mRNA

expression of TGFβ-induced fibrogenic genes (*a-SMA*, *Col1a1* and *fibronectin*) in RI-T cells, a HSC line. Importantly, CVC reversed insulin resistance, as well as hepatic steatosis, inflammation and fibrosis, in pre-existing advanced NASH.

Conclusion: The dual chemokine receptor CCR2/CCR5 antagonist, CVC prevented and reversed lipid accumulation and peroxidation, insulin resistance, inflammation and fibrogenesis in the liver of NASH by polarizing M2 macrophage and attenuating HSC activation.

The effect of the combination of dapagliflozin and liraglutide in non alcoholic fatty liver disease in patients with type 2 diabetes compared to sitagliptin and pioglitazone

A. Koutsovasilis, A. Sotiropoulos, D. Papadaki, M. Pappa, V. Kordinas, S. Bousboulas, T. Peppas;
3rd Internal Medicine Department & Diabetes Center, General Hospital of Nikaia-Piraeus, Athens, Greece.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is now the most frequent chronic liver disease that occurs across all age groups and is associated with the presence and morphology of subclinical coronary atherosclerosis. Pioglitazone has several clinical evidence in the treatment of NAFLD in Type 2 Diabetes Mellitus (T2DM) patients. Since lifestyle modifications and weight loss remain difficult to achieve by most people, an effective pharmacologic treatment for NAFLD is sorely needed. Dapagliflozin and Liraglutide are agents which lower blood glucose, significantly reduce body weight and blood pressure. The aim of the study was to examine the effectiveness of the combination of dapagliflozin and liraglutide in NAFLD patients with T2DM compared with dapagliflozin, liraglutide, sitagliptin, and pioglitazone.

Materials and methods: 421 T2DM patients with NAFLD were included in the study. 85 patients under treatment with dapagliflozin and liraglutide, 89 patients were under treatment with dapagliflozin, 82 patients under treatment with liraglutide, 71 under treatment with pioglitazone and 94 under treatment with sitagliptin. All patients also received metformin. Mean follow up period was 52 weeks ± 2 weeks. The evaluation of liver fibrosis depended on the calculation of aspartase aminotransferase (AST) to platelet counts ratio (APRI) index. APRI over 1.5 was considered as bridging fibrosis and over 2.0 as liver cirrhosis. All patients went through an ultrasonography before being included in the study and after the end of the study.

Results: There was no difference in patients age (58.8 ± 9.6, $p = 0.288$), duration of T2DM (6.4 ± 2.9, $p = 0.312$), Body Mass Index (30.24 ± 2.98, $p = 0.362$) and HbA1c (8.05 ± 0.93%, $p = 0.196$) between study's groups. HbA1c values improved in all five groups with most patients maintain the therapeutic goal in the first group ($p < 0.001$) group after 52 weeks of treatment. APRI index's improvement was significant in the group with the combination of dapagliflozin and liraglutide (1.14 (0.52–1.24) vs 0.74 (0.41–0.95), $p = 0.001$), in the dapagliflozin group (1.10 (0.56–1.20) vs 0.96 (0.33–1.03), $p = 0.022$), in the liraglutide group (1.16 (0.52–1.24) vs 0.86 (0.45–1.05), $p = 0.010$) and in the pioglitazone group (1.18 (0.48–1.27) vs 0.88 (0.42–1.10), $p = 0.012$). There was no improvement in the sitagliptin group (1.08 (0.43–1.25) vs 1.06 (0.49–1.22) $p = 0.493$). APRI index's improvement was accompanied by a significant change of fatty liver in ultrasonography. Most of the patients (67) in the dapagliflozin and liraglutide group achieved a >5 kg decrease ($p < 0.001$).

Conclusion: Administration of dapagliflozin and liraglutide in combination led not only to good control of T2DM but also in significant improvement of liver inflammation, alteration of liver fibrosis, and reduction of body weight, particularly important factors in patients with T2DM. As far as we know, this study is the first to be carried out on the long-term effect of dapagliflozin and liraglutide in combination on liver fibrosis which indicates their positive impact in T2DM with NAFLD. Particularly, body weight reduction was a favorable outcome of applying dapagliflozin and liraglutide in NAFLD patients with T2DM.

MEDI0382, a GLP-1/glucagon receptor dual agonist, improves NASH and reduces liver fibrosis in mice

J.L. Trevaskis[1], M.L. Boland[1], J. Conway[2], S. Guionaud[3], J. Grimsby[1], L. Jermutus[4], C.J. Rhodes[1];
[1]Cardiovascular, Renal and Metabolic Diseases, MedImmune, Gaithersburg, USA, [2]Translational Sciences, MedImmune, Gaithersburg, USA, [3]Global Pathology, AstraZeneca, Cambridge, UK, [4]Cardiovascular, Renal and Metabolic Diseases, MedImmune, Cambridge, UK.

Background and aims: Effective treatment of non-alcoholic steatohepatitis (NASH), characterized by hepatic steatosis, inflammation and fibrosis is an unmet medical need. MEDI0382, a balanced GLP-1/glucagon dual receptor agonist, is under development for the treatment of T2DM and NASH. Here we examined the effects of MEDI0382 on metabolic and NASH-related endpoints compared to liraglutide, a GLP-1 receptor agonist.

Materials and methods: Leptin-deficient *ob/ob* mice were maintained on low-fat (LFD) or high *trans*-fat, fructose and cholesterol diet for 8 weeks to induce NASH then randomized to four 6-week treatment groups: vehicle, MEDI0382 (30 nmol/kg), liraglutide (40 nmol/kg) or vehicle-treated and switched to LFD. Terminal liver sections were evaluated for NASH activity score (NAS), reflecting steatosis, lobular inflammation and ballooning. Fibrosis was assessed by pathologist score and collagen immunoreactivity. Gene expression was performed via RNAseq and qPCR. Mitochondrial function was assessed in primary mouse hepatocytes isolated from lean or *ob/ob* NASH mice.

Results: MEDI0382 and liraglutide reduced body weight and improved glucose tolerance to a similar extent relative to vehicle, with diet-switching having minimal impact. Hepatic lipid was reduced by 40% with MEDI0382 treatment ($p < 0.001$ vs. vehicle), which was more effective than liraglutide (20%) or switch to LFD (20%, both $p < 0.05$ vs. MEDI0382). The NAS was reduced by MEDI0382, more so than liraglutide or switch to LFD. Hepatic collagen increased 2.4-fold with NASH and was reduced by 40% in MEDI0382-treated mice ($p < 0.05$), but was not altered by liraglutide or diet-switch. Consistent with histopathology improvements, fibrotic (*Col1a1*, *Col3a1*, *Col4a1*) and inflammatory (*Tnf*, *Tgfb1*, *Il1b*, *Ccl2*) genes were increased with NASH and reduced with MEDI0382 treatment. An analysis of gene signatures demonstrated a NASH-related decrease in metabolic signaling which was reversed by MEDI0382. Conversely, inflammatory signatures increased with NASH were reduced by MEDI0382. Studies in primary hepatocytes revealed reduced mitochondrial function in *ob/ob* NASH mice that was significantly increased by MEDI0382, whereas liraglutide had no effect. Furthermore, MEDI0382, but not liraglutide, increased expression of *Ppargc1a* mRNA which could be blocked with an inhibitor of protein kinase A, but concomitantly increased the number of lysosomal-associated mitochondria.

Conclusion: MEDI0382 exerted similar metabolic control relative to liraglutide, but exhibited superior effects on primary NASH endpoints including improved NAS and reduced fibrosis. Increased mitochondrial biogenesis and degradation, leading to restored mitochondrial function, may underlie some of the observed improvement in NASH with MEDI0382.

Cancer incidence and mortality among 457,473 persons with type 2 diabetes compared to 2,287,365 matched controls in Sweden: an observational study

H.H. Bjornsdottir[1,2], S. Franzén[1], A. Rawshani[3,1], A. Rawshani[3,1], N. Sattar[4], A.-M. Svensson[1], S. Gudbjornsdottir[3,1];
[1]Swedish National Diabetes Register, Center of Registers in Region, Gothenburg, Sweden, [2]Faculty of Medicine, University of Iceland, Reykjavik, Iceland, [3]Department of Molecular and Clinical Medicine, Institute of Medicine, University of Gothenburg, Gothenburg, Sweden, [4]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, UK.

Background and aims: Studies suggest an increased risk for certain cancer types for type 2 diabetes (T2DM) and that these patients have an increased mortality from cancer. However, many of the studies in this area are limited by potential bias. Therefore, we set out to evaluate the incidence of all cancer and site-specific cancer, along with time-trends in cancer incidence as well as post-cancer mortality, among patients with T2DM compared to matched controls.
Materials and methods: We included patients defined by the epidemiological definition as T2DM in the Swedish National Diabetes Register (NDR) between 1998 through 2012 and followed them through 2014. Each diabetic person was matched to 5 controls based on age, sex and county. The cohort included 457,473 persons with diabetes and 2,287,365 matched controls. All individuals were followed until the first site-specific cancer occurrence, death or end of follow-up, whichever came first. Incidence, trends in incidence and post-cancer mortality for cancer were estimated with cox regression and standardised incidence rates.
Results: T2DM had a slightly increased risk for all cancer, HR 1.1 (95% CI, 1.09 to 1.12). For the most common cancer sites we observed the following for incidence rates: Increased risk for breast cancer, HR 1.05 (95% CI, 1.01 to 1.09) and colorectal cancer, HR 1.20 (95% CI, 1.16 to 1.23), decreased risk for prostate cancer, HR 0.82 (95% CI, 0.80 to 0.83), and risk of lung cancer, HR 1.01 (95% CI, 0.97 to 1.05) for T2DM compared to controls. Of these four cancer sites only lung cancer showed a significant difference in change of risk over time, with a 30% greater increase in incidence over a 10 year period for T2DM compared to controls. For post-cancer mortality we observed the following: Increased mortality after diagnosis of prostate cancer, HR 1.29 (95% CI, 1.25 to 1.35), breast cancer, HR 1.25 (95% CI, 1.18 to 1.33) and colorectal cancer HR 1.09 (95% CI, 1.05 to 1.13). in T2DM compared to controls. There was not a significant difference in post-cancer mortality between the groups for lung cancer, HR 1.02 (95% CI, 0.98 to 1.06). The cancer types that T2DM was most associated with increase in risk were the following: Liver (HR 3.31), corpus uterus (HR 1.78), penis (HR 1.56), kidney (HR 1.45), gallbladder and bile ducts (HR 1.32), stomach (HR 1.21) and bladder (HR 1.20). Of these sites, pancreas cancer and corpus uterus cancer showed a significant difference in change of risk over time, with a 38% greater increase in incidence over a 10 year period for pancreas cancer and a 26% greater decrease for corpus uterus cancer for T2DM compared to controls.
Conclusion: All cancer incidence was slightly elevated in patients with T2DM compared to controls. Patients with T2DM have an increased risk of certain cancers as well as lower post-cancer survival. Changes in cancer incidence over time were virtually the same in patients with diabetes compared to controls, with the exception of pancreas-, corpus uterus- and lung cancer. With rising incidence of diabetes these observations may be of importance and a challenge to improve future diabetes care.

Prospective cohort study of type 2 diabetes and the risk of cancer in Japan: 5-year interim report

K. Tsuneda[1], A. Yoshikawa[1], K. Okita[1], Y. Inui[1], S. Fujita[2], M. Takahara[2], H. Iwahashi[2], S. Kurebayashi[3], H. Konya[3], A. Otsuka[3], N. Handa[3], T. Fukui[3], H. Matsushima[3], N. Watanabe[3], S. Kawata[1];
[1]Hyogo Prefectural Nishinomiya Hospital, Nishinomiya City, Hyogo, [2]Osaka University Hospital, Suita City, Osaka, [3]Nishinomiya Study Group, Nishinomiya City, Hyogo, Japan.

Background and aims: It is reported that type 2 diabetes is associated with the increased risk of malignant neoplasms, mainly digestive organ cancer. Some clinical studies have also reported the association between antidiabetic medicines and the risk of malignant neoplasms, nevertheless sufficient conclusions have not been made yet. To investigate the association between diabetes and the risk of cancer, we initiated "Nishinomiya Study" in October 2012. As part of the study, we've followed up all cases including baseline characteristics and antidiabetic medicines taken before the onset of malignant neoplasms. The aim of the present study is to clarify the relation between the risk of cancer and type 2 diabetes including antidiabetic medicines.
Materials and methods: The subjects were recruited from currently registered type 2 diabetic patients receiving outpatient treatment at 51 clinical units. Participants consisted of 4516 cases (2711 male and 1805 female, aged 65.6 ± 11.7 years, body mass index (BMI) 25.1 ± 4.4 kg/m^2, glycated hemoglobin (HbA1c) 7.2 ± 1.0%, waist circumference 89.4 ± 10.9 cm). We prospectively investigated the association of baseline characteristics and the antidiabetic medicines with the risk of cancer. The Kaplan-Meier method with differences analyzed by the generalized Wilcoxon test and Cox proportional hazards models were used to evaluate the impact of the baseline characteristics and the antidiabetic medicines on cancer risk. The study protocol was approved by the ethics committee of Hyogo Prefectural Nishinomiya Hospital and registered with the University hospitalMedical Information Network.
Results: 168 cases (123 male and 45 female, aged 69.5% ± 9.0 years, BMI 24.9 ± 3.9 kg/m^2, HbA1c 7.2 ± 0.9%, waist circumference 89.2 ± 10.8 cm) were newly diagnosed with cancer. The majority of the malignant neoplasms were digestive tract cancers (35 cases of colon cancer and 30 cases of gastric cancer). As treatments for diabetes, the patients suffering from cancer were treated with sulfonylureas ($n = 70$, 41.7%), dipeptidyl peptidase-4 inhibitors ($n = 79$, 47.0%), insulin ($n = 36$, 21.4%), biguanides ($n = 56$, 33.3%), alpha-glucosidase inhibitors ($n = 27$, 16.1%), glinides ($n = 16$, 9.5%), thiazolidines ($n = 20$, 11.9%) or only diet ($n = 9$, 5.4%). Primary outcome is the onset of malignant neoplasm. Male's onset was significantly higher ($p < 0.01$) than female's with Kaplan-Meier analysis. Cox proportional hazards regression analysis including age, sex, sulfonylureas, dipeptidyl peptidase-4 inhibitors, insulin, biguanides, alpha-glucosidase inhibitors, glinides and thiazolidines showed that elder age (95% CI, 1.03 to 1.07; $p < 0.01$) and male (95% CI, 1.47 to 3.01; $p < 0.01$) significantly increase the risk of cancer. Furthermore restricted to digestive tract cancer or colon cancer, Kaplan-Meier analysis revealed that more subjects who take sulfonylureas, glinides or insulin suffered from colon cancer than subjects who take none of these medicines ($p < 0.05$).
Conclusion: Sex, age and some antidiabetic medicines may have a significant influence on the risk of cancer.

Insulin sensitivity in diabetes associated with pancreatic cancer

P. Skrha[1], P. Fric[2], J. Uhrova[3], M. Andel[1], J. Skrha[4];
[1]2nd Department of Internal Medicine, 3rd Faculty of Medicine, Charles University, Prague, [2]Department of Gastroenterology, General Military Hospital, Charles University, Prague, [3]Department of Medical

Biochemistry, Charles University, Prague, [4]3rd Department of Internal Medicine, 1st Faculty of Medicine, Charles University, Prague, Czech Republic.

Background and aims: Nearly 80% of patients with pancreatic ductal adenocarcinoma (PAC) have diabetes mellitus or prediabetes (DM). The insulin resistance and β-cell dysfunction were reported in the PAC patients previously. Lower leptin and higher adiponectin levels are associated with higher peripheral insulin sensitivity, whereas HOMA-IR reflects more the liver insulin resistance. Our aim was to compare adiponectin, leptin, leptin/adiponectin ratio and HOMA index (HOMA-IR) as markers of insulin sensitivity/resistance among patients with PAC, type 2 diabetes mellitus (T2DM) and healthy control persons and then in patients within the PAC group itself.
Materials and methods: Seventy seven patients with PAC, 34 T2DM patients without the cancer and 24 healthy control persons were enrolled in our study. The PAC group was subdivided according to the presence of diabetes. In 43 patients the new-onset diabetes was confirmed less than 1 year before the cancer diagnosis and this diabetes was evaluated as pancreatogenic caused by the cancer (PAC T3cDM). 17 PAC patients had long-term type 2 diabetes (PAC T2DM) and 17 patients had normal glucose tolerance (PAC NDM). Fasting plasma concentrations of adiponectin, leptin, insulin and glucose were measured in every subject. Leptin/adiponectin ratio and HOMA-IR were calculated, Kruskal-Wallis ANOVA test and Pearson's correlation were used for statistical evaluation.
Results: Basic results in the whole group of PAC patients were compared with T2DM and control groups (Table).In the PAC T3cDM group, the lowest leptin concentration (7.8 ± 2.3 ng/l) and the highest adiponectin concentration (14.7 ± 3.6 ng/ml) were observed. In the PAC patients a significant difference of the leptin/adiponectin ratio was found only between PAC T3cDM and T2DM or controls (0.8 ± 0.3 vs 2.4 ± 1.2 or 1.5 ± 0.5, $p = 0.0003$ and 0.02, respectively). In the PAC subgroups, HOMA-IR in the PAC T2DM (5.1 ± 2.3) corresponded to that in T2DM, and in the PAC NDM (2.1 ± 0.9) to controls. HOMA-IR in the PAC T3cDM (3.1 ± 0.9) was not significantly different from controls. Significant positive correlation between leptin/adiponectin ratio and HOMA-IR was observed only in T2DM and PAC T2DM ($r = 0.38$ and 0.63, respectively), but not in T3cDM.
Conclusion: Patients with pancreatic ductal adenocarcinoma-associated new-onset diabetes (T3cDM) are significantly more insulin sensitive than patients with long-term T2DM with or without pancreatic cancer. We conclude that there exists a significant heterogeneity of insulin sensitivity/resistance in patients with pancreatic cancer.

	PAC	T2DM	Controls	p-values
Adiponectin (ng/l)	12.8±1.3	9.6±2.5	10.3±4.3	NS
Leptin (ng/l)	8.2±1.7*	12.3±2.5*	10.6±2.5	*0.0006
Leptin/adiponectin	0.9±0.2*⁻	2.4±1.2*	1.5±0.5⁻	*0.0005, ⁻0.02
HOMA-IR	3.4±0.7*	4.6±1.1*°	2.5±0.9°	*0.009, °0.02

Insulin resistance and colon epithelial proliferation

L. Kedenko[1], J. Mayböck[1], C. Kronberger[2], T. Kiesslich[1], I. Kedenko[1], B. Paulweber[1], G. Wolkersdörfer[1];
[1]University Clinic for Internal Medicine I, Regional Hospital of Salzburg/PMU, [2]Institute of Pathology, Regional Hospital of Salzburg/PMU, Austria.

Background and aims: Epidemiologic data showed an increased risk of colorectal cancer in subjects with type 2 diabetes and insulin resistance. Little is known about the actual effect of insulinemia and insulin resistance on proliferation and the underlying signaling in the intestinal mucosa. Therefore, the first objective of our work was to clarify the relation between hyperinsulinemia, a metabolic condition caused by insulin resistance, and its effect on colon epithelial proliferation. The second objective was to confirm the role of insulin signaling pathway in colon epithelial proliferation by conducting gene expression analysis of selected candidate genes from the insulin signaling pathway.
Materials and methods: Colonoscopy with mucosa biopsies was performed in 56 participants with high and low levels of insulin sensitivity based on the highest and lowest quartile of insulin sensitivity/resistance from short Insulin Tolerance Test (KITT). Evaluation of proliferative activity in various colonic subsites was performed immunohistochemically using Ki-67 as proliferation marker. Total RNA was isolated from the colon biopsies and was used for further gene expression analyses of the 84 genes using RT^2 Profiler PCR Array Human Insulin Signaling Pathway (Qiagen, Germany).
Results: Polypoid lesions were found in 29 subjects - 23 adenomas and 6 hyperplastic polyps. In 27 subjects no polypoid lesions were detected, resulting in a polyp detection rate of 0.52 and an adenoma detection rate of 0.41 in our cohort. Proliferation indices equally decreased from the right to the left colonic subsites in the insulin resistant as well as in the sensitive group. Surprisingly, insulin sensitive individuals showed generally higher proliferation activity than resistant ones in all examined localizations, though differences in mean proliferation indices between two groups were not significantly different between different colonic subsites. Independent Student's t-test revealed 6 out of 84 analyzed genes that showed significant difference ($p \leq 0.05$) in gene expression between insulin resistance and insulin sensitive groups. Most of these genes were overexpressed in insulin sensitive group compared to insulin resistance group. These genes showed also a negative relationship with proliferation index in correlation analysis with Pearson's correlation coefficient: −0.32 for *IGF2R*, −0.14 for *MAP2K1* and *PPARG*, −0.12 for *ANG* and *MAPK3*. Only expression levels of *NCK1* correlated positively with proliferation index (Pearson's correlation coefficient +0.24).
Conclusion: We demonstrated for the first time that in the insulin sensitive individuals proliferation indices and expression of the key genes from the insulin signaling pathway were lower in comparison with insulin sensitive individuals in all colon localizations. The general assumption, that hyperinsulinemia is a direct promotor of enhanced proliferative activity in colon epithelium of insulin resistant individuals can not be confirmed by our results. Rather, our results suggest a resistance of the intestinal mucosa towards insulin in insulin-resistant individuals.

Obesity, glucose abnormalities and metabolic syndrome are hallmarks of well differentiated nets

A.P. Santos[1], C. Castro[2], I. Torres[1], R. Henrique[3,4], M.H. Cardoso[5,4], M.P. Monteiro[6,7];
[1]Endocrinology, IPO Porto, Porto, [2]Epidemiology, IPO Porto, Porto, [3]Pathology, IPO Porto, Porto, [4]ICBAS, Porto, [5]Endocrinology, CHP-UP, Porto, [6]Anatomy Department, ICBAS, Porto, [7]UMIB, Porto, Portugal.

Background and aims: Metabolic syndrome (MetS) and hypercholesterolemia had been previously described as risk factors for rectal NETs. An association between well-differentiated (WD) GEP-NETs and MetS has been described before by our group in a case control study**.** The aim of the present work was to compare different WD GEP-NETs focusing obesity and metabolic abnormalities characteristic of MetS, in a cohort of patients followed in a Portuguese tertiary centre.
Materials and methods: 135 patients (pts.) with WD (G1 and G2) GEP-NETs were recruited from the Endocrine Tumours Clinic of IPO Porto and were classified according to primary tumour localization (L),

hormonal secretion (F), extension of disease (Ext) and WHO 2010 grading (G). These different types of GEP-NETs were analysed according to BMI, obesity grade, waist circumference (WC), lipid and fasting glucose (FG) profile and MetS and MetS individual criteria, determined before treatment.

Results: Mean age and age at diagnosis was 62.1 y (30–85) and 58.6 y (29–85) respectively; 58.4% were male; 74.2% Gastrointestinal (GI) NETs; 69.5% G1; 55.4% non-functioning (NF) and 46.3% disseminated. Family history of type 2 DM (47.7%), excess weight and obesity (62.6%), abdominal obesity (52%); high blood pressure (HBP) (64%), metabolic abnormalities (MA) including FG abnormalities (41.5%) and MetS (57.1%) were frequent in the whole group. We found no differences between GI-NETs vs. pancreatic (pan) NETs; NF vs functioning (F); G1 vs G2 and localised vs loco-regional vs disseminated disease, concerning BMI: $p = 0.175$(L) , 0.308(F), 0.647(G) and 0.756(Ext); obesity grade: $p = 0.168$ (L), 0.281(F), 0.621(G) and 0.269(Ext); HBP: $p = 0.229$(L), 0.292(F), 0.427(G) and 1.0(Ext); dyslipidaemia: $p = 0.435$(L), 0.143(F) and 0.524(E), FG abnormalities: $p = 0.215$(L), 0.281(F), 0.575(G), 0.295(Ext) and MetS: $p = 0.838$ (L), 0.187(F) and 0.113(Ext). Concerning WHO grading, dyslipidaemia was significantly more frequent in G1 vs. G2 tumors ($p = 0.034$) and there was a trend for a higher association of G1 vs. G2 NETs with MetS ($p = 0.056$).

Conclusion: Although the association of GEP-NETs and metabolic risk factors was seldom described, it is traditionally stated that glucose abnormalities are associated with NF and some rare functioning pan-NETs. Our findings suggest that besides pancreatic and rectal NETs, metabolic abnormalities and MetS may be an hallmark of all WD-GEP-NETs, with a tendency to be more frequent in G1 tumours. These results reinforce the need of more studies exploring the association between obesity, metabolism and NETs in order to explain the recent burden of the disease, as it has already been described in other cancers.

Glucose enhances breast cancer cell aggressiveness via adipose-derived mesenchymal stem cells

V. D'Esposito[1], G. Mosca[1], M. Ambrosio[1], T. Migliaccio[1], S. Cabaro[1], N. Prevete[2], G. Piccolo[3], A. Maione[1], L. Albano[1], F. D'Andrea[3], F. Beguinot[1], P. Formisano[1];

Background and aims: Diabetes and cancer have been closely linked to each other both epidemiologically and biologically. Several studies indicate that hyperglycaemia increases breast cancer incidence and progression. However, the molecular mechanisms are still unclear. Glucose may exert its effects on both cancer cells and tumour microenvironment, including resident adipose-derived mesenchymal stem cells (MSCs). Both cancer cells and MSCs respond to metabolic insults changing their secretory pattern. Here, we analysed whether glucose could interfere on the crosstalk between mammary adipose tissue derived-MSCs (MAT-MSCs) and oestrogen positive-MCF7 breast cancer cells, thereby modifying MSC phenotype and affecting tumour progression.

Materials and methods: MSCs were isolated from mammary adipose tissue ($n = 6$) and characterized for mesenchymal stem cell markers ($CD90^+$, $CD29^+$, $CD106^-$, $CD45^-$) by FACS analysis. Adipocyte differentiation was tested by Oil Red O staining. MAT-MSCs were co-cultured with MCF7 in 25 mM glucose (high glucose, HG) or in 5.5 mM glucose (low glucose, LG) by using transwell systems. Upon 4 days, gene expression levels were analysed by real time RT-PCR. 3D co-cultures (spheroids) of MSC -MCF7 (1:5 ratio) were established in ultra-low attachment plates in HG or LG. Upon 10 days, spheroids were counted, collected and dissociated. Levels of specific proteins were determined by FACS analysis.

Results: MAT-MSCs stained positive for CD90 and CD29 (99.2% and 99.9% of cells respectively) and negative for CD106 and CD45 markers (99.9% and 98.1% of cells). Moreover, they were able to differentiate through the adipogenic lineage. When treated with HG for 4 days, the cells did not modify the expression of the multipotency gene OCT4 and of the fibrosis marker a-SMA, as compared with LG. However, when co-cultured with MCF7 in HG, MAT-MSCs displayed a 1.4 fold down-regulation of OCT4 and a 1.4-fold increase of a-SMA. No changes in the expression of genes involved in adipogenic commitment (ZNF423 and WNT10b) were detected. In HG 3D co-cultures, MAT-MSCs significantly increased the number of MCF7-derived spheroids either compared to MCF7 alone either to MCF7 - MSC co-cultured in LG. Spheroid dissociation showed a reduction of OCT4 and an increase of a-SMA proteins in MAT-MSCs and, interestingly, an increase of OCT4 protein in MCF7. This occurred more markedly in HG compared to LG.

Conclusion: Glucose modifies the complex relationship between cancer cells and MSCs contributing to loss of multipotency and acquisition of fibroblast-like features in MSCs (cancer associated fibroblasts). Interestingly, by acting through MSCs, glucose increases the stemness potential of breast cancer cells, thus suggesting a reduction of drug sensitivity and an increase of metastatic potential. These findings underline that hyperglycemia may contribute to cancer progression also acting on breast cancer surrounding MAT-MSCs.

The phosphorylation of Akt through mTORC2 a possible link between dietary AGEs, diabetes and colorectal cancer

A.I. Serban[1], O.I. Geicu[2], L. Stanca[1], A. Dinischiotu[2];
[1]Preclinical Sciences, University of Agronomic Sciences and Veterinary Medicine Bucharest, Faculty of Veterinary Medicine, Bucuresti sector 5, [2]Biochemistry and Molecular Biology, University of Bucharest, Faculty of Biology, Bucuresti sector 5, Romania.

Background and aims: Recent evidence suggested in type 2 diabetes the negative feedback from S6K is reduced, thus Akt-S473P by mTORC2 is enhanced. Activated Akt is associated with cell survival and proliferation, as well as angiogenesis. We explored the hypothesis that high dietary intake of advanced glycation end products (AGEs) may have a role in the correlation between type 2 diabetes and colorectal cancer risk.

Materials and methods: Total casein was glycated *in vitro* in the same conditions as those used in the production of sweetened UHT milk drinks (30 min 70°C, 4 sec at 140°C in the presence of 116 mM lactose and 55 mM glucose-fructose). C2BBe1 colorectal carcinoma cells with enterocyte morphology were treated with 200 μg/ml glycated or control casein for 3, 6, 9 and 24 h. Concurrently with AGEs treatment, TNF-α, RAGE (receptor of AGEs) and IL-1β were blocked using 1 μg/ml specific antibodies. The phosphorylation status of signaling proteins was assessed using Bio-Plex Pro Cell Signaling MAPK 9-plex panel and Akt 8-plex panel. IL-8 levels and matrix metalloproteinase (MMP) activity were evaluated from cell medium using the Bio-Plex Pro Human Cytokine 8-Plex Immunoassay and gelatin zymography.

Results: After 3 h, mTOR-S2448 and PTEN-S380 phosphorilation increased by 6.5 and 3-fold, followed by Akt (Ser473) (increasd by 4.4 fold), GSK-3α/β (Ser21/Ser9) and ATF-2 (Thr71) (both increased by about 3-fold) at the 6 h interval. Akt (Ser473) and ATF-2 (Thr71) were the only ones still phosphorilated at the 9 h interval, and ATF-2 (Thr71) persisted after 24 h. Although phosphorilation levels remained higher than controls, antibody blockade of RAGE was most efficient in diminishing AGEs induced phosphorilations, reducing them by almost half, while IL-1β blockade also had a significant effect, especially towards reducing mTOR-S2448 and PTEN-S380 phosphorilation. MMP-

2 and MMP-9 activity was induced by AGEs exposure in a time-dependent manner. MMP activation by AGEs exposure was diminished by both RAGE and IL-1β blockade. Our data show that AGEs exposure can mediate via RAGE, the phosphorylation of mTOR-S2448 and the formation of active mTORC2, thus increasing Akt-S473 phosphorylation and activation. The fact that p70 S6 kinase and IRS1were unphosphorylated indicated that the mTORC1 was probably inactive. The unphosphorylated form of IRS1 and the phosphorylated PTEN induced the stabilization of active Akt, suggesting that PI3K/Akt signaling pathway is active. In addition, Akt seems to phosphorylate Ser-136 inducing BAD inhibition, an anti-apoptotic mechanism. The activation of PI3K/Akt phosphorylated GSK-3β, leading to its ubiquitination and degradation; thus its inhibitory role in epithelial-mesenchymal transition, cell invasion and migration is diminished. The accumulation of IL-8 in a time dependent manner can be a consequence of both NF-κB and Akt activation inducing MMPs activation and cancer progression. MAPK 9-plex revealed that only ATF-2 is phosphorilated (Thr71) and activated by AGEs exposure. RAGE blockade effectively decreased ATF-2 activation by AGEs.

Conclusion: AGEs exposure may stimulate cancer cell survival by activating Akt signaling. Pro-metastatic conditions may also be encouraged, by sustained proliferation and MMP activation.

Endogenous insulin hypersecretion links diet-induced obesity to pancreatic cancer development in Ptf1a^{CreER};LSL-Kras^{G12D} mice

A. Zhang, X. Hu, J. Magrill, J.L. Kopp, J.D. Johnson;
Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada.

Background and aims: Obesity and type 2 diabetes (T2D) are risk factors for pancreatic ductal adenocarcinoma (PDAC), a cancer with a 5-year survival rate of only 6%. However, the mechanisms linking obesity and T2D to cancer remain unclear. Elucidating these mechanisms may help us target pathways that cause early lesions in at-risk patients before the disease progresses. Hyperinsulinemia is a cardinal feature of obesity and early-stage T2D. Elevated insulin is also strongly linked with many cancer types, and, even for non-obese people, cancer mortality is significantly higher in those with elevated insulin. However, although many epidemiological and clinical studies show the association between hyperinsulinemia and PDAC, no *in vivo* study has directly demonstrated a causal link between PDAC and insulin itself. Therefore, the aim of our study is to determine whether excess insulin contributes significantly to PDAC initiation and/or progression in the context of a high-fat diet (HFD).

Materials and methods: We have previously shown that partial knockout of the *Ins1* gene (*Ins1*$^{+/-}$) on a genetically stable *Ins2* null background can be used to reduce insulin production and circulating insulin in mice in the context of a HFD, when compared to mice with two alleles of *Ins1* gene (*Ins1*$^{+/+}$). To test our hypothesis that endogenous insulin production could modulate PDAC initiation, we employed a conditional mutant *Kras* allele, LSL-*Kras*^{G12D}, driven by a tamoxifen-inducible, acinar cell-specific *Ptf1a*^{CreER} knock-in allele. Thus, *Ins1*$^{+/-}$;*Ins2*$^{-/-}$;*Ptf1a*^{CreER};LSL-Kras^{G12D}(PK-*Ins1*$^{+/-}$;*Ins2*$^{-/-}$) mice, which are genetically incapable of sustained hyperinsulinemia on a HFD, were compared to littermate control *Ins1*$^{+/+}$;*Ins2*$^{-/-}$;Ptf1a^{CreER};LSL-*Kras*^{G12D} (PK-*Ins1*$^{+/+}$;*Ins2*$^{-/-}$) mice fed the same diet. After 1 year of HFD and tracking the body weight, fasting blood glucose (FBG), and insulin levels, we performed blind quantitative histopathological analysis of Hematoxylin & Eosin (H&E) stained pancreas sections to determine whether reducing insulin can limit HFD-promotion of *Kras*^{G12D}-driven PDAC via measuring the pre-neoplastic lesion pancreatic intraepithelial neoplasia (PanIN) and tumour area.

Results: PK-*Ins1*$^{+/-}$;*Ins2*$^{-/-}$ mice had modestly lower fasting insulin levels when compared with control PK-*Ins1*$^{+/+}$;*Ins2*$^{-/-}$ mice. Importantly, the modest reduction in circulating insulin did not affect glucose homeostasis. Blind quantification of the ratio of PanIN plus tumor area to the total pancreas area showed that PK-*Ins1*$^{+/-}$;*Ins2*$^{-/-}$ mice ($n = 9$) had a statistically significant ($p = 0.018$) reduction in PanIN area when compared with PK-*Ins1*$^{+/+}$;*Ins2*$^{-/-}$ controls ($n = 13$). Striking differences in histopathology were evident using H&E and Alcian blue staining. Quantitatively, reducing insulin production by limiting *Ins1* gene dosage reduced the percent PanIN by ~50% in average, an effect that was not significantly correlated with the difference in body weight or FBG.

Conclusion: Our data show that, in the context of a hyperinsulinemia-inducing HFD, modestly reducing endogenous insulin production by limiting *Ins1* gene dosage is sufficient to reduce the incidence of PanIN lesions without affecting glucose homeostasis. This suggests hyperinsulinemia is a causal factor linking obesity and T2D to PDAC. Lifestyle interventions or therapeutics with mild insulin suppressing actions may be useful in the prevention of some cancers.
