PS 047 SGLT2 inhibitors around the world: evidence from clinical trials and registries
PS 048 Glycaemic and metabolic effects of SGLT2 inhibitors
PS 049 Novel aspects of SGLT2 inhibitors
PS 050 SGLT2 inhibitors: What do the CVOTs tell us?
PS 051 Tackling glucose and fat with novel agents
PS 052 Quality of nutrients and meals: How important are they?
PS 053 Dietary supplements: Which is best?
PS 054 All what you need to know for a healthy diet
PS 055 New clues on metformin, sulfonylureas and insulin
PS 056 Metabolic effects of novel, dual and triple incretin agonists
PS 057 Lipids and fatty liver: What GLP1 receptor agonists can do
PS 058 More on GLP1 receptor agonists and diabetes complications
PS 059 On the efficacy of GLP1 receptor agonists
PS 060 GLP1 receptor agonists: How good are they in real practice?
PS 061 GLP1 receptor agonists: Do age and ethnicity matter?
PS 062 Incretin-based therapies: adherence and tolerability
PS 063 DPP4 inhibitors: new regiments and new comparisons
PS 064 Incretin-based therapies: new mechanistic insights
PS 065 Beta cell function and response to incretin-based therapies
PS 066 Multiple facets of continuous glucose monitoring
PS 067 Artificial insulin delivery and insulin pump therapy
PS 068 Faster acting insulins: state of the art
PS 069 Approaches to insulin titration
PS 070 Clinical outcomes in insulin treated patients
PS 071 Combination therapy with ultra-long-acting insulin
PS 072 Clinical and patient reported outcomes
PS 073 Diabetes control around the world
PS 074 Cost effectiveness in diabetes therapies
PS 075 Psychosocial aspects in diabetes
PS 076 Education and patient/provider perceptions
PS 077 Therapeutic adherence and satisfaction
PS 078 Hypoglycaemia rates with basal insulin
PS 079 Clinical pathophysiology of insulin and hypoglycaemia
PS 080 Causes and consequences of hypoglycaemia
PS 081 Sweet mothers - big babies
PS 082 From pregnancy to breastfeeding
PS 083 Diabetic pregnancy: experimental work
PS 084 Neuropathy: prevalence and clinical impact
PS 085 Neuropathy: markers and remedies
PS 086 Autonomic neuropathy
PS 087 Foot ulcers: morbidity and mortality
PS 088 Diabetic foot ulcers: How to prevent and how to treat
PS 089 The impact of retinopathy
PS 090 Retinopathy: there is more than hits the eye
PS 091 Biomarkers of nephropathy
PS 092 Diabetic nephropathy: Predictions are hard to make
PS 093 Nephropathy: from markers to real life
PS 094 Animal studies on nephropathy
PS 095 Diabetic nephropathy: on the bench
PS 096 Of drugs and kidneys
PS 097 Unexpected comorbidities
PS 098 Factors affecting cardiovascular outcome
PS 099 Don't forget!
PS 100 Brain functionalities
PS 101 Understanding vascular complications
PS 102 The pump and the barrier
PS 103 Diabetes from childhood to adults
PS 104 Complications and treatment
PS 105 Bones and muscles
PS 106 From metabolism to vascular function
PS 107 Big vessels
PS 108 Adverse cardiovascular disease events
PS 109 Dyslipidaemia and diabetes
PS 110 Treating cardiovascular disease in diabetes
PS 111 Metabolism, inflammation in metabolic liver disease
PS 112 Unconventional aspects of cardiovascular disease in diabetes
PS 113 Epidemiology of cardiovascular disease and diabetes
PS 114 Vascular complications
PS 115 Novel diagnostic tool for NAFLD
PS 116 Clinical aspects of NAFLD
PS 117 Treating NAFLD
PS 118 Cancer and diabetes

OP 01 Inflammatory events in type 2 diabetes

1

Metabolic reprogramming of CD8$^+$ T cells regulates systemic glucose metabolism

H.-S. Yi[1], Y. Lee[1], B. Ku[2];
[1]Chungnam National University Hospital, Daejeon, [2]Chungnam National University School of Medicine, Daejeon, Republic of Korea.

Background and aims: Chronic inflammation induced by proinflammatory cytokines is closely related to metabolic diseases. However, the functional characteristics of T cells in the development of diabetes are not yet fully understood.
Materials and methods: We studied the patients visiting a hospital for routine health check-ups, who were divided into two groups: normal controls, and people with prediabetes. Gene expression profiling of peripheral blood mononuclear cells (PBMCs) from normal controls and drug-naïve patients with type 2 diabetes was undertaken using microarray analysis. We also studied the immunological characteristics and metabolic signatures of senescent T cells in the normal subject and patients with prediabetes. Moreover, liver tissues from 10 subjects who underwent hepatectomy at Chungnam National University Hospital due to hepatocellular carcinoma or metastatic liver cancer were used to isolate hepatic resident T cells, which were investigated using FACS analysis. We also investigated senescent T cells in the liver of normal or mice with metabolic deterioration caused by aging or diet-induced obesity.
Results: Patients with diabetes or prediabetes exhibit a proinflammatory response. Gene annotation enrichment analysis showed that most of the upregulated genes in the diabetes group are implicated in T cell activation, phagocytosis, and the inflammatory response. Proinflammatory cytokines and cytotoxic molecules are also highly expressed in senescent ($CD8^+CD28^-CD57^+$) T cells from patients with prediabetes. Patients with prediabetes have higher concentrations of reactive oxygen species (ROS) in their senescent $CD8^+$ T cells. the larger quantity of ROS produced by metabolically reprogrammed senescent T cells contributes to impaired glucose homeostasis. Addtionally, senescent $CD8^+$ T cells impair hepatic insulin sensitivity via production of proinflammatory cytokines. On the other hand, murine senescent ($CD153^+CD279^+$) T cells with features of inflammation are also present in larger numbers in the livers of aged compared to young mice. Feeding a high fat diet increased senescent ($CD153^+CD279^+$) T cells in the liver of mice, leading to impairment of hepatic glucose homeostasis.
Conclusion: In summary, this study defines a new clinically relevant concept of a T cell senescence-mediated inflammatory response in the pathophysiology of type 2 diabetes. We also found that T cell senescence promotes systemic inflammation and alters hepatic glucose homeostasis. The rational modulation of $CD8^+$ T cell senescence would be a promising avenue for the treatment or prevention of type 2 diabetes.

Methylglyoxal induces microglial polarisation to pro-inflammatory state

J. Lin[1], J. Wang[1], A. Schlotterer[1], M. Kolibabka[1], N. Dietrich[1], T. Fleming[2], H. Hammes[1];
[1]Medical Faculty Mannheim, Mannheim, [2]Medical Faculty Heidelberg, Heidelberg, Germany.

Background and aims: Diabetic retinopathy induces vasoregression and neurodegeneration and finally leads to blindness. Microglial activation is involved in diabetic retinopathy. Recently our study showed that exogenous AGE precursor methylglyoxal activates and recruits microglia in normoglycemic retina. Different functional properties of microglia are dependent on the state of polarization. Classical activation of M1 phenotype is pro-inflammation and alternative activation of M2 phenotype is anti-inflammation. However, the role of methylglyoxal in microglial polarization remains unclear. Hence, this study aims to investigate the role of methylglyoxal in microglial polarization.
Materials and methods: 6 week old C57Bl6 mice were intravitreally injected MG (1 μl per eye), in a dose of 10mM/L. Two days later eyes were enucleated. Retinal RNA were isolated and PCRs were performed. Microglial quantification was using retinal whole mount immunofluorescence staining. Mouse microglial cells line (BV2 cell) were incubated with 1 μM, 10 μM and 100 μM of MG for 1, 2 and 3 days. We detected the effects of MG on microglial M1/M2 phenotype markers using gene expression and immunofluorescence, *in vivo* and *in vitro* experiments, respectively.
Results: Exogenous MG increased microglial recruitment and induced pro-inflammatory gene expression of TNF-α and Galectin3 with 2 fold, 5 fold for MCP-1, Iba1 2.9 fold, ICAM1 1.7 fold in mouse retina. In vitro, MG induced RAGE translocation into nucleus in microglial cells. Immunofluorescence signals of CD74 and Galectin3 were elevated after MG treatment. MG inhibited Arginase1 and Mrc1, and the former with dose dependent manner. Oppositely, MG promoted the gene expression of CD74 at 24 hour MG treatment; RAGE, IL-1ß and MCP-1 in BV2 cells at 72 h MG treatment; TNF-α, MIP-1α in 48 h.
Conclusion: MG-induced pro-inflammation is mediated by microglia. MG induces microglial to M1 polarization state and MG shows the pro-inflammatory role *in vivo* and *in vitro*.

Metformin alleviates the negative effects of the proinflammatory environment in brown adipocytes

N. Pescador[1,2], V. Francisco[1], C. Escalona[1], L. Ruiz[1], M. Valdecantos[1], A. Calle[2], M. Obregón[1], Á. Valverde[1,2];
[1]Instituto de Investigaciones Biomédicas Alberto Sols, Madrid, [2]CIBERDEM, Madrid, Spain.

Background and aims: Obesity-induced chronic inflammation is critical in the pathogenesis of insulin resistance and type 2 diabetes mellitus (T2DM) due to recruitment as well as activation of macrophages in adipose tissues. The pathophysiology of inflammation-induced metabolic dysfunction has been extensively documented in white adipose tissue (WAT) depots. However, little is known of the relevance of inflammation in brown adipose tissue (BAT) during T2DM linked to obesity. We have examined the impact of M1 proinflammatory signaling pathways, on insulin signaling and thermogenic gene expression in brown adipocytes and the effect of metformin in these processes.
Materials and methods: RAW264.7 macrophages were stimulated with lipopolysaccharide (LPS) (100 ng/ml) for 6 h in the absence or presence of metformin (10mM). Conditioned medium (CM) was collected and added to brown adipocytes to explore the effects on inflammation and insulin signaling pathways as well as thermogenic gene expression. Eight week-old male C57 Bl/6 mice were fed HFD for 10 weeks. Metformin (500 mg/kg) was administered daily by oral gavage for 4 weeks. Then, mice were maintained at thermoneutrality (28°C) for one week and one group was exposure to cold (4°C) for 16 h.
Results: Treatment of brown adipocytes with LPS-CM significantly decreased insulin-mediated protein kinase B (Akt) phosphorylation ($p < 0.05$). Consequently, both insulin-induced glucose transporter 4 (GLUT4) translocation to the plasma membrane and glucose uptake were decreased ($p < 0.05$). Under these conditions, early activation of the N-terminal Janus activated kinase (JNK) ($p < 0.05$), signal transducer and activator of transcription 3 (STAT3) ($p < 0.05$) and p38 mitogen-activated protein kinase (p38 MAPK) ($p < 0.05$) was also observed together with degradation of the inhibitor of nuclear factor kappa B (IκBα). ($p < 0.05$) Furthermore, LPS-CM inhibited the effect of the beta3 agonist CL316243

in lipolysis ($p < 0.05$) and uncoupling protein (UCP)-1 expression ($p < 0.05$). All these effects were prevented by the treatment of brown adipocytes with LPS-CM supplemented with metformin. In vivo administration of metformin increased *Ucp1* mRNA levels upon cold exposure.
Conclusion: Our data demonstrate that the proinflammatory environment triggers signaling cascades that interfere with insulin and CL316243 effects in brown adipocytes. Furthermore, metformin improves insulin and beta adrenergic responses by targeting the inflammatory pathways. Our results suggest the importance of brown adipocytes as sensitive cells to proinflammatory mediators released by macrophages suggesting that inflammation in BAT might play a major role in insulin resistance associated to obesity.

Hyperglycaemia epigenetically primes pro-inflammatory RELA/p65 gene in cord blood-derived CD34$^+$stem cells

V. Vigorelli, J. Resta, S. Genovese, G. Pompilio, M. Vinci;
Centro Cardiologico Monzino - IRCCS, Milan, Italy.

Background and aims: Diabetes profoundly affects multiple signaling pathways and key transcription factors that account for the systemic pro-inflammatory state and increased propensity for the patients to develop atherosclerosis. In addition, as a consequence of hyperglycemia, diabetic patients have decreased number and dysfunctional circulating CD34$^+$ cells that under normal physiological conditions contribute to the maintenance of vascular homeostasis and regeneration. Emerging evidence suggests that epigenetic mechanisms, such as DNA methylation and histone modifications, are involved in the regulation of inflammatory genes in vascular cells under diabetic conditions. Since CD34$^+$ cells are also important precursors of immune cells, we hypothesized that uncontrolled hyperglycemia might epigenetically skew CD34$^+$ cells towards inflammatory cells. We sought to evaluate epigenetic priming of inflammatory response genes by high glucose conditions in CD34$^+$ stem cells.
Materials and methods: CD34$^+$ cells were purified from cord blood of healthy donors and expanded in normal-glucose (NG; with 30 mM mannitol for osmotic control) or high-glucose (HG; 30 mM) serum-free medium plus cytokines (FLT3, SCF, IL3 and IL6) for up to 20 days. The expression of RELA/p65, KAT2B/PCAF, IL6 and TNFα genes was assessed by qPCR. Western Blot was used to evaluate acetylation of NF*k*B p65 at lysine-310. H3K9me3 and RNA polymerase II recruitment to the RELA/p65 gene promoter were evaluated by ChIP-qPCR assay.
Results: Increasing evidence links glucose metabolism to changes in chromatin. We therefore examined H3K9me3 status of RELA gene promoter encoding for the p65 subunit of inflammatory transcription factor NFκB in CD34$^+$ cells after high glucose exposure. ChIP-qPCR data showed significant reduction of H3K9me3 levels in HG-CD34$^+$ cells ($n = 5$; FC 1 ± 0.16 SE *vs* 0.4 ± 0.1 SE; $p = 0.0327$). The lowering of this repressive epigenetic modification coincided with increased recruitment of RNA polymerase II to the RELA/p65 gene promoter and a significant up-regulation of p65 gene expression ($n = 8$; FC 1 ± 0.27 SE *vs* 1.41 ± 0.3 SE; $p = 0.0034$). Interestingly, KAT2B/PCAF gene, a histone acetyltransferase implicated in NF*k*B p65 acetylation and co-activation was also overexpressed ($n = 12$; FC 1 ± 0.14 SE *vs* 1.4 ± 0.19 SE; $p = 0.0225$). This post-translational modification is critical for nuclear stabilization and full transcriptional activity of NFκB, responsible for the expression of inflammatory genes. Hence, we assessed the acetylation of NFκB p65 at lysine-310 and the expression of NFκB p65 target genes such as TNFα and IL6. The analysis revealed an increased acetylation at lysine-310 in HG-CD34$^+$ cells and significant up-regulation of TNFα ($n = 9$; FC 1 ± 0.15 SE vs 1.38 ± 0.28 SE; $p = 0.0408$) and IL6 ($n = 10$; FC 1 ± 1.25 SE vs 1.86 ± 1.09 SE; $p = 0.05$) gene expression.
Conclusion: These results suggest that elevated glucose exposure might epigenetically prime CD34$^+$ cells for a pro-inflammatory response and/or skew CD34$^+$ cell differentiation into cell lineages with deleterious properties.

Crosstalk between gut and pancreas in the context of metabolic syndrome: study in a rodent model of nutritional programming

A. Sanchez-Roncero[1], P. Martínez-Oca[1], F. Escrivá[1,2], E. Fernández-Millán[1,2], C. Álvarez[1,2];
[1]Bioq y Biol Mol., Fac. Farmacia, UCM, Madrid, [2]CIBER, ISCIII, Madrid, Spain.

Background and aims: Nutritional restriction during critical periods of development has been associated with the later appearance of metabolic pathologies during adulthood, such as obesity and type 2 diabetes. The relationship between low birth weight and the appearance of these pathologies is encompassed within the thrifty phenotype hypothesis. Experimental animal models, including ours, based on perinatal nutrient restriction have supported the role of altered endocrine pancreas development during early life and insulin sensitivity as key factors for the later occurrence of dysregulated glucose homeostasis. However, the underlying mechanisms leading to this condition remain unclear. In this regard, the intestinal microbiota is an emerging factor involved in the regulation of energy metabolism by modifying intestinal permeability and, consequently glucose, lipid and immune system homeostasis. Specifically we have studied the effect of nutritional restriction-rehabilitation on the morphology and integrity of the intestinal barrier and its role on pancreas inflammation.
Materials and methods: To this end, offspring of Wistar rat dams fed ad libitum (control [C]) or 65% food-restricted during pregnancy and suckling time (undernourished [U]) were weaned onto a high-fat (HF) diet (CHF and UHF, respectively) to drive catch-up growth. The experiments were carried out in female rats aged 18 and 25 weeks (prior to or after overt metabolic syndrome establishment, respectively). Morphometric studies of gut were performed by using haematoxylin and PAS staining. Localization of tight junction proteins (occludin, ZO-1) were visualized by immunofluorescence. Circulating proinflammatory cytokines and blood lipopolysaccharides (LPS) levels were measured by ELISA and the limulus test, respectively. The inflammatory phenotype of pancreatic islets was determined by CD68$^+$-cell staining and by the in vitro response of isolated islets to LPS.
Results: Nutritional restriction altered the number and size of epithelial cells from ileum, as well as mucin-producer Goblet cells compared with C animals. Our results also indicated that both, early food-restriction (U rats) and later rehabilitation with high-fat diet (UHF and CHF rats) increased intestinal permeability causing disorganization on the tight-junction proteins of the intestinal epithelium, mainly ZO-1 and occludin. This event was correlated with increased circulating levels of bacterial LPS in female U rats even prior to high-fat feeding, enhanced levels of *Tlr4* expression and macrophage infiltration into pancreatic β-cells. Incubation of isolated islets from 25-week old CHF and UHF rats with different doses of LPS (0.1, 1 and 5 μg/ml) for 24 hours significantly induced cytokine production in both populations but with less intensity in UHF islets suggesting development of LPS resistance.
Conclusion: These data suggest that intestinal barrier dysfunction induced by inappropriate maternal nutrition contributes to the early appearance of endotoxemia in the offspring before the development of overt metabolic syndrome, therefore emerging as a causal factor.

Glucagon induces the expression of inflammatory markers in the liver through NLRP3 inflammasome

C. Di Fatta, R. Spiga, E. Mancuso, A. Fuoco, C. Averta, G.C. Mannino, F. Andreozzi, G. Sesti;
Department of Medical and Surgical Sciences, University Magna Graecia of Catanzaro, Catanzaro, Italy.

Background and aims: Hyperglucagonemia promotes an inappropriately high rate of hepatic glucose production that is the predominant cause of fasting hyperglycemia and a major contributor to the etiopathogenesis of type 2 diabetes mellitus (T2DM). T2DM and insulin-resistance are strongly associated with an increase in the production of pro-inflammatory molecules, which, in turn, nurture the onset of several invalidating complications. In this contest, the inflammasome plays a key role in the inflammatory response. It has been implicated in a broad range of common inflammatory diseases, such as T2DM. The aim of our study was to assess whether hyperglucagonemia affects the expression of inflammatory markers in the liver and to analyze the molecular mechanism underlying the synthesis of inflammatory molecules in presence of glucagon.
Materials and methods: We analyzed a cohort of 132 Italian non-diabetic subjects enrolled in the CATAnzaro MEtabolic RIsk factors (CATAMERI) study, who underwent an oral glucose tolerance test. In addition, starved HepG2 cells were treated with different concentrations of glucagon (0.05, 0.5, 1, 10, 100 nM) for 24h, in order to mimic chronic exposure. To confirm glucagon pivotal role, a specific inhibitor of the glucagon receptor was employed. Changes in FGG, C3 and CRP mRNA expression were detected through real-time RT-PCR. We evaluated the cleavage of procaspase-1 to caspase-1 by Western Blot as a marker of NLRP3 inflammasome-mediated inflammation activation.
Results: In vivo, we observed a significant ($p < 0.01$) correlation between circulating levels of glucagon and inflammatory markers, such as complement component 3 (C3, $r = 0.227$), fibrinogen (FGG, $r = 0.193$) and C-reactive protein (hsPCR, $r = 0.230$), after correction for age and sex. In vitro, glucagon induced a significant ($p < 0.05$) increase in the gene expression of C3 (~4 fold), FGG (~2.5 fold) and CRP (~2 fold) in a dose-dependent manner with a maximum effect at the concentration of 10nM. Glucagon treatment induced a significant increase in the cleavage of procaspase-1 to caspase-1 (up to 2.5 fold) in a dose-dependent manner. Pre-treatment with a specific glucagon receptor inhibitor was able to block the pro-inflammatory stimulatory effects of glucagon at both transcriptional and protein levels.
Conclusion: These data suggest that hyperglucagonemia may induce an inflammatory state stimulating directly the synthesis of inflammatory molecules (C3, FGG and CRP) in the liver via the activation of NLRP3 inflammasome pathway.

Novel plantar pressure-sensing smart insoles reduce foot ulcer incidence in 'high-risk' diabetic patients: a longitudinal study

C.A. Abbott[1], K.E. Chatwin[1], A.N.B. Hasan[1], S.M. Rajbhandari[2], C. Sange[2], N. Musa[2], P. Foden[3], K. Stocking[3], L. Vileikyte[4], F.L. Bowling[4], A.J.M. Boulton[4], N.D. Reeves[1];
[1]Manchester Metropolitan University, Manchester, [2]Lancashire Teaching Hospitals NHS Foundation Trust, Chorley, [3]Wythenshawe Hospital, Manchester, UK, [4]University of Manchester, Manchester, UK.

Background and aims: The lifetime risk of diabetic, neuropathic, plantar first foot ulceration is 25%, whereas ulcer recurrence rates for patients with ulcer history are 50–70% within 5 years. To date, effective ulcer prevention strategies remain elusive. Foot ulcer development in the insensate foot is intimately linked to high peak plantar pressures and high pressure-time integrals during gait as patients with diabetic neuropathy cannot detect aberrant pressures and do not adjust their walking strategy appropriately. We hypothesize that an intervention providing plantar pressure feedback would reduce aberrant high pressures developed during daily activities. We aimed to test efficacy of a novel plantar pressure-sensing smart insole system, the SurroSense Rx® (Orpyx Medical Technologies Inc., Canada) in reducing DFU occurrence in 'high risk' diabetic patients. This system comprises pressure-sensing inserts worn inside patients' footwear, recording continuous plantar pressure at eight sensor locations, during day-to-day life. When critical pressure thresholds are detected, a smartwatch feeds back to the patient via an alert and encourages off-loading, to modify aberrant plantar pressures developed during daily activities.
Materials and methods: In this randomised controlled trial, patients with recent history of DFU, peripheral neuropathy, no peripheral vascular disease, and no current DFU were recruited from two hospital sites within Greater Manchester, UK. Ninety participants were consented, 58 were randomized, all being set-up with the pressure-sensing inserts and smartwatch. Intervention group (IG) received feedback alerts from the smartwatch when pressures were 'high', whereas Control group (CG) did not receive alerts. At baseline, participants received device training and a detailed foot check. Patients were reviewed monthly for a foot check and system calibration. Follow-up was for 18 months or until plantar ulceration occurred.
Results: At follow-up, there were 10 ulcers from 8,638 person-days in CG and 4 ulcers from 11,835 person-days in IG. A Poisson regression model compared the two groups on incidence of ulceration with log exposure days as offset and showed a 71% reduction in ulcer incidence in IG (Incidence Rate Ratio = 0.29, 95% CI: 0.09–0.93) relative to the CG ($p = 0.037$). Characteristics of CG ($n = 26$) vs. IG ($n = 32$) were: age, 67.1(9.6) vs. 59.1(8.5) [mean (SD)]; Type 1 diabetes, $n = 4$ (15.4%) vs. $n = 9$ (28.1%); duration diabetes, 21.2 (10.7) vs. 22.2 (14.3) years; HbA1c, 58 (41–83) vs. 65.5 (38–122) [median (range)] mmol/mol. In survival analysis, the Kaplan-Meier graph and log-rank test suggested no significant difference in treatment groups in time to ulceration (18 month ulcer-free proportion: CG - 68.4%, IG - 77.5%; $p = 0.30$). Self-reported hours of wearing the device were: CG, 4.6 (2.9) vs. IG, 5.1 (3.0) hours/day, $p = 0.63$.
Conclusion: Plantar pressure feedback and encouragement to offload throughout daily life via smartwatch alerts resulted in 71% lower DFU incidence after 18 months follow-up. We conclude that there has been a significant, positive impact of this plantar pressure feedback intervention on reducing DFU incidence in 'high risk' diabetic patients.

Ultrasound versus sharp wound debridement in healing of recalcitrant neuropathic diabetic foot ulcers: clinical and pathological study

F. Kyrillos[1], A. Albehairy[1], M. Roshdi[1], W. Elkashef[2], M. Tarshoby[1];
[1]Diabetes and Endocrinology department, Mansoura University, Mansoura, [2]Pathology department, Mansoura University, Mansoura, Egypt.

Background and aims: Debridement is the consistent mainstay for the standard care of diabetic foot ulcer. Non surgical sharp debridement is the gold standard method used with some known limitations. Researchers proposed advantages for low frequency ultrasound (LFU) debridement for healing of chronic ulcers. The aim of this study is to compare clinical outcome, pathological and immuno-histochemical effect of LFU debridement versus sharp debridement on recalcitrant neuropathic diabetic foot ulcers.
Materials and methods: 21 diabetic patients of matched age and sex with recalcitrant neuropathic foot ulcers (duration ≥6 months with standard therapy, sharp debridement and proper offloading), were recruited from Mansoura Diabetic Foot Clinic (Specialized Medical Hospital- Mansoura university). Only grade 1A and 2A ulcer (University of Texas) were included in the study. All patients continued on same ulcer management with randomization into 2 groups according to method of debridement: Sharp group; continued using scalpel (11 patients) and Ultrasound (US) group; using LFU (12 patients). Patients received 1 debridement session every 2 weeks for 2 months. Tissue biopsies were taken from the base and edge of ulcers at the first session and after 2 months of debridement. Clinical outcome was assessed by reduction of ulcers surface area after 2 months. Pathological parameters for healing were assessed blindly by the pathologist. Pathological scoring included cellularity, vascular proliferation, type of collagen, inflammatory cells and fibrosis. Immunoreactivity of Matrix metalloproteinase-1 (MMP-1) was also assessed.
Results: Greater reduction in ulcers surface area in US group (43%) versus sharp group (24.24%) ($p = 0.001$). Improvement in total ulcer pathology score was evident after each type of debridement with more improvement in US group versus sharp group (23.21% vs.6.67%, respectively) ($p = 0.004$). Significant increase in cellularity in base and edge of the ulcers, vascular proliferation of ulcer base and inflammation of the ulcer edge after 2 months of US debridement ($p = 0.04, 0.03, 0.04, 0.03$ respectively), while sharp debridement decreased the cellularity in the base of ulcers ($p = 0.04$) with no significant change in other pathological parameters. MMP-1 expression decreased significantly in both base and edge of ulcers treated by sharp debridement ($p = 0.03, 0.02$ respectively), while increased significantly in the base of ulcers after US debridement ($p = 0.037$).
Conclusion: LFU debridement is superior to sharp debridement regarding healing of recalcitrant neuropathic diabetic foot ulcers. In contrast to sharp debridement, LFU debridement increases expression of MMP-1, cellularity, vascular proliferation and inflammation in the ulcers improving the total pathology score and indicating better opportunity for ulcer healing.

The LeucoPatch® system in the management of hard-to-heal diabetic foot ulcers: a multicentre, multinational, observer-blinded, randomised controlled trial

F. Game[1], W. Jeffcoate[2], L. Tarnow[3], J. Jacobsen[4], D. Whitham[5], E. Harrison[5], S. Ellender[5], M. Löndahl[6];
[1]Derby Teaching Hospitals NHS Foundation Trust, Derby, UK, [2]Nottingham University Hospitals NHS Trust, Nottingham, UK, [3]Holbaek Sygehus, Holbaek, Denmark, [4]Statcon ApS, Kokkedal, Denmark, [5]University of Nottingham, Nottingham, UK, [6]Skåne University Hospital, Lund, Sweden.

Background and aims: The LeucoPatch® device uses bedside centrifugation without additional reagents to generate a disc comprising autologous platelet-rich fibrin and leucocytes which is applied to the surface of the wound. The aim of the study was to test the effectiveness of LeucoPatch® on the healing of hard-to-heal foot ulcers in people with diabetes.
Materials and methods: 595 people with diabetes and a foot ulcer consented to participate. After a 4 week run-in-period those with a reduction in ulcer area of <50% were randomised to either pre-specified good standard care alone or care supplemented by weekly application of LeucoPatch®. The primary outcome was percentage of ulcers healed within 20 weeks, defined as complete epithelialisation confirmed by an observer blind to randomisation group and maintained for four weeks.
Results: 269 people were randomised; mean age 62 years, 82% male, 82% Type 2 diabetes. In the intervention group 34.1% ($n = 45/132$) of ulcers healed within 20 weeks vs 21.6% ($n = 29/134$) of the controls (OR 1.58, 95% CI 1.06–2.35; $p = 0.02$) by intention-to-treat analysis. Time to healing was shorter in the intervention group ($p = 0.0246$) (Figure 1). No difference in adverse events was seen between groups.
Conclusion: The use of LeucoPatch® is associated with significant enhancement of healing of hard-to heal foot ulcers in people with diabetes.

Platelet-rich plasma plays an anti-inflammatory and cell proliferation-promoting role through miR-21/PDCD4/NF-kB pathway in vitro of a diabetic wound model

W. Deng[1], T. Li[1], D. Armstrong[2];
[1]Department of Endocrinology and Nephrology, Diabetic Foot Center, Affiliated Central Hospital of Chongqing University, Chongqing Emergency Medical Hospital, Chongqing, China, [2]Department of Surgery, Keck School of Medicine of the University of Southern California, Los Angeles, USA.

Background and aims: Infection and inflammatory disorders are two of contributing factors for non-healing diabetic foot ulcers (DFUs). Platelet-rich plasma (PRP) has an antibacterial and wound repair accelerating effect in DFUs healing. The MicroRNAs relate to wound healing are high abundance expression in platelet. MicroRNA-21(miR-21)plays a key role

in antibacterial and inflammatory through regulation of nuclear transcription factor(NF-κB) activity, but the mechanism remains unclear. This study aimed to determine the potential antibacterial, anti-inflammatory and cell proliferation-promoting mechanism of PRP on DFUs healing.
Materials and methods: Considering the common infection of DFUs caused by Staphylococcus aureus (S. aureus), HaCaT cells and S. aureus were co-cultured under high glucose conditions to serve as an in vitro model for infected cells in DFUs. Platelet-rich gel (PRG) or extract liquid of platelet-rich gel(EPG)was used to interfere with the model to observe the growth of HaCaT cells and S. aureus, and the effect of miR-21 changes in HaCaT cells on PDCD4, NF-κB and related inflammatory factors.
Results: Incubation of HaCaT cells with increasing concentrations of S. aureus induced to a dose-dependent decline of cell proliferation. Protein level of PDCD4 elevated and NF-κB activity enhanced in cells with increased IL-6, TNF-α and decreased IL-10, TGF-β1 under this condition. As an effective component of PRG, EPG had a specific anti-S. aureus activity. EPG dose-dependently protected HaCaT cells from bacterial damage and promoted cell proliferation. Meanwhile, EPG could increase intracellular miR-21, reduce PDCD4 expression and inhibit NF-κB activity to alleviate inflammation of infected HaCaT cells. Furthermore, anti-inflammatory effects to HaCaT cells were also observed in the absence of S. aureus infection.
Conclusion: In conclusion, the in vitro model we built provides a valuable tool for study of DFUs healing mechanism. MiR-21 regulates NF-κB through PDCD4 plays an anti-inflammatory and pro-cell proliferation role in the process of wound healing promoted by PRG. The results support the favorable function of PRG in treating DFUs and may provide novel therapeutic target for refractory wounds.

Autologous mononuclear versus mesenchymal stem cells in healing of recalcitrant neuropathic diabetic foot ulcers

A. Albehairy[1], F. Kyrillos[1], H. Gawish[1], O. State[1], H. Abdelghaffar[2], O. Elbaz[2], A.H. El-Sebaie[2], A.A. Emam[3], M. Tarshoby[1];
[1]Internal Medicine, Mansoura University, Mansoura, [2]Clinical Pathology, Mansoura University, Mansoura, [3]Mansoura University, Mansoura, Egypt.

Background and aims: Most human studies involved bone marrow mononuclear stem cells (BM-MNCs) and bone marrow mesenchymal stem cell (BM-MSCs) safety and efficacy involved treatment of ischemic wounds and critical limb ischemia, with less specific studies on neuropathic diabetic foot ulcers. Recent pilot clinical study suggested that autologous BM-MSCs is safe and promising in treatment of recalcitrant diabetic foot ulcer. **Aim of the work:** To compare the therapeutic effect of autologous BM-MNCs and BM-MSCs on the healing process in patients with recalcitrant neuropathic diabetic foot ulcers
Materials and methods: Eighteen patients with type 2 diabetes mellitus with neuropathic foot ulcer grade 2 New Texas classification were selected from Diabetic Foot Clinic, Mansoura University, Egypt from May 2016 to August 2017. Only patients who failed to respond to 12 weeks of weekly sharp debridement and proper offloading were included in the study. Patients were randomly assigned to MSCs, MNCs or control group. The study was conducted in Mansoura Regenerative Medicine Centre, Egypt. After aspiration of 20 ml of patients' own bone marrow under good aseptic technique either mononuclear stem cells (MNCs) were separated or Mesenchymal stem cells (MSCs) were cultured. The bone marrow sample was diluted with phosphate buffer saline then separation using Ficoll hybaqe harvesting the layer of MNCs then washed twice using the complete media. This process revealed $5x10^6$ to $6x10^6$ of MNCs. Mesenchymal stem cells (MSCs) were characterized by adherence, trans-differentiation and CD characterization. Cultured cells were subjected to microbiological and karyotyping testing. MSCs number ranged from $1x10^6$ to $2x10^6$. The revealed MNCs or MSCs were dissolved in 2cm saline to be used for injection in the edges of the wound at eight points once. All patients continued on same offloading and dressing and were followed for 12 weeks for the change in ulcer surface area and the presence of any local reactions
Results: Percentage reduction of Ulcer surface area was higher in both (MSC) and (MNC) groups 68% and 59% respectively compared to only 6.25% in control group after 12 weeks of follow up. (P value <0.05), However, there was no statistical significant difference between the healing rate of (MSC) and (MNC) groups. Complete healing was achieved in one patient in MSC group and in another patient in MNC group.
Conclusion: Local injection of both autologous bone marrow derived MSCs and MNCs augmented healing of recalcitrant neuropathic diabetic foot ulcers. Using both cells was well tolerated by the patients with no short term complications. The small non significant better healing associated with the use of MSCs should be weighed against the fact that MNCs separation is easier and achieved by less manipulation

Association of diuretics use and amputations in patients with type 2 diabetes: A hypothesis driven from CANVAS warning?

L. Potier[1], R. Roussel[1], G. Velho[2], P.-J. Saulnier[3], A. Bumbu[1], O. Matar[1], M. Marre[1], K. Mohammedi[4], S. Hadjadj[5];
[1]Department of Diabetology, Endocrinology and Nutrition, Assistance Publique – Hôpitaux de Paris (AP-HP), Paris, [2]Team 2, INSERM U1138, Paris, [3]INSERM CIC1402, Poitiers, [4]Département d'Endocrinologie, Diabétologie, Nutrition, Hôpital Haut-Lévêque, Paris, [5]Department of Endocrinology and Diabetology, Centre Hospitalier Universitaire de Poitiers, Poitiers, France.

Background and aims: Recently, safety data signaled an increased risk of amputations in patients with type 2 diabetes taking SGLT2 inhibitors. If this side effect is due to drug-induced hypovolemia, the use of diuretics should also increase that risk. The aims were to analyze the association between the use of diuretics and the risk of lower limb events (LLE) in patients with type 2 diabetes.
Materials and methods: SURDIAGENE is a French prospective observational cohort including type 2 diabetes patients enrolled from 2002 to 2012. Participants were followed-up until onset of LLE, death, or December 31, 2015, whichever came first. Participants: 1459 patients with type 2 diabetes, with information on use of diuretics at baseline and available data on primary outcomes during follow-up. Exposure: Use of diuretics at baseline (thiazides, loop and/or potassium-sparing diuretics). Main Outcomes: LLE, a composite of lower-extremity amputations (LEA) (amputation at or above the metatarsophalangeal joint) and lower limb revascularizations (LLR) (angioplasty or bypass).
Results: At baseline, of the 1459 studied participants, 670 were taking diuretics (in patients with and without diuretics, mean age was 67.1 and 62.9; 55.8% and 59.8% were men, respectively). During a median follow-up of 7.2 years, LLE occurred in 85 (12.7%) and 57 (7.2%) of the users and non-users, respectively ($p = 0.001$). The hazard ratio for LLE in users vs. non-users was 2.08 (95%CI, 1.49–2.93; $p < 0.0001$). This association remained significant in multi-adjusted model (1.83 (1.27–2.67; $p = 0.0013$) and after considering death as a competing risk (subhazard ratio 1.89 (1.35–2.64; $p = 0.0002$)). When separated, LEA but not LLR were associated with the use of diuretics (2.61 (1.55–4.50; $p = 0.0013$) and 1.30 (0.84–2.02; $p = 0.24$), respectively).

Conclusion: Among patients with type 2 diabetes treated with diuretics, there was a significant and independent increase in the risk of LLE, predominantly LEA. Diuretics should be used cautiously in patients with type 2 diabetes at risk of amputations. Further studies are needed to explore the role of drug-induced hypovolemia in the association between the use of diuretics and LLE. The hypovolemia hypothesis could provide an explanation for the increased risk of LEA observed with SGLT2 inhibitors.

Linagliptin reduced renal injury and proteinuria in a rat model of crescentic nephritis

A.-L. Mayer[1], K. Amann[1], T. Klein[2], C. Daniel[1];
[1]Department of Nephropathology, University of Erlangen-Nürnberg, Erlangen, [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

Background and aims: Dipeptidyl peptidase 4 (DPP-4) inhibitors are a class of oral glucose lowering drugs, used in the treatment of type 2 diabetes. In human kidney biopsies we observed high DPP-4 expression in early crescent formation. This glomerular lesion occurs in various kidney diseases and is a pathogenic hallmark of renal dysfunction. Therefore, we investigated the potential involvement of DPP-4 in the pathogenesis of nephritis induced by anti-GBM (glomerular basement membrane antibody) in Wistar rats.

Materials and methods: Linagliptin (3 mg/kg/bw, $n = 11$) and vehicle ($n = 11$) were used to treat anti-GBM nephritis in 8-week regimens: either preventive or therapeutic (treatment started 4 weeks after model induction). Kidney function, morphologic changes, inflammation and fibrosis were monitored.

Results: Disease prevention with linagliptin in anti-GBM nephritic rats significantly ($p < 0.01$) reduced the number of crescents (51 ± 3% vs 65 ± 3%), glomerulosclerosis (score 1.2 ± 0.07 vs 1.6 ± 0.1), tubule-interstitial injury (score 1.2 ± 0.1 vs 1.8 ± 0.2), renal fibrosis (score 1.3 ± 0.13 vs 1.9 ± 0.14) and proteinuria (265 ± 29 vs 363 ± 22 mg/24h) compared with untreated nephritic rats. Furthermore, the preventive linagliptin regimen significantly reduced the number of $Pax8^+$ cells on the glomerular tuft by 17 ± 5% at day 14 ($p < 0.05$) and 60 ± 5% at week 8 ($p < 0.001$), indicating accelerated resolution of the cellular crescents. Therapeutic intervention with linagliptin resulted in weaker amelioration of renal disease at week 8, but significantly ($p < 0.05$) reduced renal fibrosis (score 1.4 ± 0.13 vs. 1.9 ± 0.14), crescent formation (52 ± 4% vs. 65 ± 3%) and $Pax8^+$ cells on glomerular tuft (65 ± 5.2% reduction) compared with vehicle. Proteinuria was also reduced, but this result did not reach significance.

Conclusion: DPP-4 inhibition with linagliptin ameliorates renal injury in a severe rat model with anti-GBM induced nephritis as shown by reduced crescents, proteinuria and fibrosis, and resolution of crescents. Therapeutic intervention with linagliptin showed weaker effects compared with preventive intervention.

Non-esterified free fatty acids (NEFA) can enhance the inflammatory response in renal tubules by inducing ATP release

H. Sun[1], Z. Sun[2], X. Ruan[3];
[1]Department of Endocrinology and Metabolism, the First Affiliated Hospital of Soochow University, Suzhou, China, [2]Department of Endocrinology and Metabolism, Zhongda Hospital, Nanjing, China, [3]John Moorhead Research Laboratory, Centre for Nephrology, University College London (UCL) Medical School, London, UK.

Background and aims: Diabetes mellitus is the leading cause of chronic kidney disease (CKD) in both developed and developing countries. The global widespread of CKD is rapidly becoming a worldwide health problem. The severity of tubulointerstitial inflammation has long been considered as a crucial determinant of progressive CKD. Although the pathogenesis of tubulointerstitial inflammation is poorly understood, one common association and likely pathogenic factor is proteinuria. However, excessive plasma non-esterified free fatty acids (NEFA) load in proteinuria can leak across the damaged glomeruli to be reabsorbed by

renal proximal tubular cells, and cause inflammatory tubular cells damage by as yet unknown mechanisms. The present study was designed to investigate these mechanisms induced by NEFA overload.

Materials and methods: HK-2 cells were incubated with palmitic acid (PA). THP-1 cells were differentiated into macrophages by phorbol-12-myristate-13-acetate (PMA). Mitochondrial reactive oxygen species (mtROS) production was determined using dihydroethidium, and extracellular ATP (eATP) was detected by an ATP Assay Kit. Caspase-3/7 activity was tested by Caspase-3/7 Green ReadyProbes Reagent, and YoPro-1 fluorescence has been used to quantify pannexin-1 (Panx1) activation. Transwell filter migration assay were used for the chemotaxis assay, and the monocyte chemoattractant protein-1 (MCP-1) in the supernatants was detected by MCP-1 ELISA kit. Expression of mRNA and protein were examined by quantitative RT-PCR and western blot, respectively.

Results: 1. NEFA induces mtROS-dependent caspase-3/7 activation in renal tubular cells, and then, the activated caspase-3/7 opens the Panx1 channel, leading to pathophysiological ATP release. 2. Both eATP and NEFA increase the secretion of MCP-1 from renal tubular cells, which induce monocyte infiltration. 3. NEFA stimulates interleukin-1β (IL-1β) release from both macrophages renal tubular cells. 4. eATP stimulates IL-1β release from both macrophages renal tubular cells via the P2X7R-mTOR-FOXO1-TXNIP/NLRP3 inflammasome pathway.

Conclusion: NEFA increase mtROS production and inflammatory stress, causing 'the first hit.' The first hit stimulates ATP release from Panx1 channel on renal tubules by activation of caspase-3/7. Then, playing as 'the second hit', eATP aggravates the tubular inflammatory response by increasing monocyte infiltration and stimulating inflammatory cytokine release from both macrophage and renal tubular cells via the P2X7R-mTOR-FOXO1-TXNIP/NLRP3 inflammasome pathway. This may cause a severe renal inflammatory response and renal dysfunction. Therefore, inhibition of the ATP release may be a potential point to alleviate renal inflammation and improve renal function.

Overexpression of CD38 (NADase) in diabetic kidney disease results in renal mitochondrial oxidative stress and pathologies via NAD^+-dependent Sirt3 inactivation

Y. Ogura, M. Kitada, I. Monno, D. Koya;
Kanazawa Medical University, Kahokugun, Japan.

Background and aims: Diabetic kidney disease (DKD) is a leading cause of end-stage renal disease (ESRD) worldwide. Although the detailed pathogenesis of DKD is not elucidated yet, aging is recognized as one of the risk factors for the progression of ESRD. Therefore, aging-related mechanism by which DKD could aggravate would be a novel therapeutic target for DKD. Nicotinamide adenine dinucleotide (NAD) levels decrease during aging, and are involved in age-related metabolic unhealth. Previous report demonstrated that expression and activity of the CD38 (NADase) increased with aging, and that CD38 is required for the age-related NAD decline and mitochondrial dysfunction via a pathway mediated at least in part by regulation of Sirt3 activity. However, the role of CD38 in the pathogenesis for DKD has not elucidated yet.

Materials and methods: In this study, we evaluated the role of CD38 in modulation of mitochondrial oxidative stress which is related to altered Sirt3 activity, in the kidney of Zucker Diabetic Fatty rats (ZDFRs) and in cultured human renal tubular epithelial cells (HK2 cells) exposed high-glucose condition.

Results: At 28 weeks of age, the ZDFRs exhibited elevated HbA1c levels, heavier kidney weight, increase in urinary albumin, urinary liver type fatty acid binding protein (L-FABP) and urinary 8-hydroxy-2′-deoxyguanosine (8-OHdG) excretion, histological tubulo-interstitial fibrosis and glomerulomegaly, and inflammation, compared to non-diabetic Zucker Lean rats. Additionally, in renal mitochondria, the NAD^+/NADH ratio was reduced, and acetylation levels of mitochondrial antioxidant enzymes, isocitrate dehydrogenase 2 (IDH2) and superoxide dismutase (SOD2), which are regulated by Sirt3, were increased in ZDFRs. Similarly, in cultured HK2 cells exposed to high-glucose condition, CD38 expression was increased, compared to cells under low-glucose condition, resulting in the reduction of NAD^+/NADH ratio and Sirt3 activity, which increased in acetylation levels of IDH2 and SOD2. Administration of the CD38 inhibitor, apigenin, to ZDFRs and HK2 cells, restored the NAD^+/NADH ratio, decreased the levels of IDH2 and SOD2 acetylation and renal mitochondrial oxidative stress.

Conclusion: Therefore, restoring Sirt3 activation by suppression of CD38 could be a novel therapeutic target for DKD.

Soluble Nogo-B overexpression inhibits diabetes-mediated endothelial cell proliferation in a murine model of early diabetic glomerulopathy

I.P. Hernandez-Diaz[1], G. Fouli[1], C. Ricciardi[1], A. Hayward[1], D.E. Long[2], L. Gnudi[1];
[1]School of Cardiovascular Medicine & Sciences, King's College London, London, [2]Developmental Biology and Cancer, University College London, London, UK.

Background and aims: Impaired angiogenesis, as seen in early diabetic glomerulopathy (DG), is characterised by thin wall capillaries and increased vascular permeability and is paralleled by an increase in endothelial cells (ECs) number, mainly driven by cell proliferation. Nogo-B is expressed in the glomerular endothelium and podocytes, and is mainly localised in the endoplasmic reticulum; previous works has implicated Nogo-B in vascular remodelling where it promotes vascular integrity. Nogo-B expression is downregulated in the diabetic glomeruli and soluble Nogo-B (sNogo-B, a circulating 200AA N-terminus fragment of Nogo-B) has been shown to correct diabetes-mediated Nogo-B downregulation and albuminuria. In this work, we have studied the effects and putative cellular mechanisms of sNogo-B overexpression on ECs proliferation/impaired glomerular angiogenesis in a murine model of diabetes.

Materials and methods: 5–8 weeks old DBA2J male mice were injected i.p. with streptozotocin (40 mg/kg/day) for 5 days, sNogo-B overexpression in the circulation was induced by tail injection of adeno-associated vector (AAV) driving the expression sNogo-B (AAV driving the expression of green fluorescent protein [GFP] was utilised as control). Animals with glycaemia >22 mM were considered diabetic. Animals were killed after 12-weeks of diabetes and the right kidney was frozen in Optimal Cutting Temperature (OCT) compound for sectioning and histology with immunofluorescence with the ECs marker (CD31) and the proliferation marker (KI67). In parallel renal cortex cell lysate was utilised for the study of VEGFA levels with ELISA, and AKT, eNOS and GSK3β total and phosphorylated levels with western immunoblotting.

Results: Diabetes (D) resulted in a significant increase in glomerular ECs proliferation when compared to non-diabetic (ND) status (ND-GFP *vs* D-GFP, $p = 0.0001$); diabetes-mediated glomerular ECs proliferation was partially prevented by sNogo-B overexpression (D-GFP *vs* D-sNogo-B, $p = 0.005$). In ND mice, sNogo-B overexpression had no effect on ECs proliferation. VEGFA, AKT^{ser473} and $eNOS^{ser1177}$ phosphorylation (molecules/pathways involved in ECs proliferation) were upregulated in D mice (ND-GFP *vs* D-GFP, $p < 0.04$); sNogo-B overexpression partially inhibited diabetes-mediated VEGFA expression, and AKT^{ser473} and $eNOS^{ser1177}$ phosphorylation (D-GFP *vs* D-sNogo-B, $p < 0.03$). $GSK3\beta^{ser9}$ phosphorylation was unchanged in D-GFP animals when compared to ND-GFP ones; sNogo-B overexpression was paralleled by a significant upregulation of $GSK3\beta^{ser9}$ phosphorylation in ND mice (ND-GFP *vs* ND-sNogo-B, $p = 0.001$), while, in D mice, sNogo-B

overexpression was paralleled by a significant downregulation of GSK3β^{ser9} phosphorylation (D-GFP *vs* D-sNogo-B, $p = 0.03$).
Conclusion: sNogo-B overexpression prevents diabetes-mediated glomerular ECs proliferation, an event that seems to be related to sNogo-B-mediated inhibition of the pro-angiogenesis and permeability VEGFA/AKT^{ser473}/eNOS^{ser1177} phosphorylation pathway, and by GSK3β activation (reduced GSK3β^{ser9} phosphorylation) known to favor capillary formation/stability over ECs proliferation/angiogenesis. sNogo-B appears to ameliorate endothelial dysfunction in early DG and studies are ongoing to better dissect its role in the pathophysiology of DG.

FoxO1 inhibits autophagosome-lysosome fusion leading to endothelial autophagic-apoptosis in diabetes

X. Wu[1], H. Zhang[1], K. He[2], X. Zhao[1], Y. Wu[1], S. Ge[3], Y. Shao[2];
[1]Endocrinology, the First Affiliated Hospital with Nanjing Medical University, Nanjing, [2]Thoracic surgery, the First Affiliated Hospital with Nanjing Medical University, Nanjing, [3]Neurology, the First Affiliated Hospital with Nanjing Medical University, Nanjing, China.

Background and aims: Endothelial dysfunction in response to various insults such as hyperglycemia, dyslipidemia and altered homeostasis is critical in the genesis of diabetic angiopathy. Recent data found that inadequate autophagy contributed to endothelial dysfunction in patients with diabetes. However, whether inadequate autophagy leads to endothelial cells (ECs) apoptosis remains unknown. The aim of this study is to investigate the relationship between inadequate autophagy and ECs apoptosis in diabetes and its underlying mechanism.
Materials and methods: Aortic vascular ECs were freshly isolated from the discarded vascular tissue of diabetic patients undergoing artery vascular replacement surgery. Cultured human aortic vascular ECs (HAECs) were stimulated with AGEs-bovine serum albumin or BSA. The expression levels of LC3-II, P-62, Rab7, Atg14, STX17, LAMP2, cleaved-caspase-3, Bcl-2, FoxO1, Ac-FoxO1, and p-FoxO1 were determined by western blotting. Autophagosomes were observed by electron microscopy. The apoptosis rate was evaluated by flow cytometry. The fusion of autophagosome and lysosomes was detected by immunofluorescence.
Results: Compared with non-diabetic subjects, the levels of LC3-II and p-62 were increased in ECs from diabetes. Western Blotting and immunofluorescence showed that the expressions of Atg14 and STX17 were decreased, and the co-localization of autophagosomes marker (LC3-II) with lysosomes marker (LAMP2), and Atg14 with STX17 were declined, suggesting inadequate autophagy with impaired autophagosome-lysosomal fusion in ECs from diabetic patients. AGEs induced HAECs autophagy in a time-dependent manner. For 24h, the expressions of LC3-II, Atg14, STX17 and Rab7 and the number of autophagosomes were gradually increased with no change of P-62, LAMP2 expression and apoptosis rates. For 48h, AGEs markedly upregulated LC3-II and p62 expression and the number of autophagosomes with decreased level of Atg14, STX17, Rab7 and co-localization of LC3-II with LAMP2, and Atg14 with STX17 which indicated the reduced autophagic flux with impaired autophagosome-lysosomal fusion. The apoptosis rates were significantly increased with elevated cleaved-caspase-3 level and declined Bcl-2 expression. Inhibition of autophagy with 3-MA could reduce AGEs-induced HAECs apoptosis, suggesting that activated autophagy contributes to ECs apoptosis. Higher levels of FoxO1, Ac-FoxO1 and Ac-FoxO1 binding to Atg7 were detected in AGEs-treated HAECs. Knockout FoxO1 by siFoxO1 reduced AGEs-induced autophagy, and increased the expression of Atg14, suggesting that FoxO1 regulates the expression of Atg14. Immunofluorescent staining showed that FoxO1 knockdown promoted the co-localization of LC3-II with LAMP2, and Atg14 with STX17 in HAECs exposed to AGEs, indicating that FoxO1 is crucial signaling molecular mediating ECs autophagy in diabetes.
Conclusion: Inadequate autophagy with impaired autophagosome-lysosomal fusion exists in ECs from diabetic patients. FoxO1 mediates AGEs-induced ECs autophagic apoptosis through impairing autophagosome-lysosomes fusion by inhibiting Atg14 expression, which may be a target for therapy of diabetic vascular complications.

Empagliflozin suppresses atherosclerotic lesion formation in apolipoprotein E deficient mice by inhibiting macrophage activation

T. Matsumura, S.M. Nishida, T. Senokuchi, N. Ishii, S. Nishida, T. Kondo, H. Motoshima, E. Araki;
Department of Metabolic Medicine, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan.

Background and aims: Cardiovascular disease (CVD) is one of the major causes of death in patients with type 2 diabetes (T2D). Recent studies suggest that SGLT2 inhibitors, which are novel class of glucose-lowering agents, reduce cardiovascular events in T2D patients with high risk of CVD. However, it remains uncertain whether the cardiovascular benefits merely depend on glucose-lowering effects or some other mechanism(s). Therefore, we examined whether empagliflozin suppressed the progression of atherosclerosis in diabetic and non-diabetic Apolipoprotein E-deficient (*Apoe*$^{-/-}$) mice, and whether it had direct anti-atherogenic effects in macrophages.
Materials and methods: *Apoe*$^{-/-}$ mice (12 weeks age) were fed normal chow (NC) or a high fat diet (HFD), or treated with streptozotocin (120 mg/kg), and further treated with a placebo or empagliflozin (5 mg/kg/day) for 8 weeks. Mouse peritoneal macrophages from C57BL/6 mice were used for in vitro experiments. Atherosclerotic lesion size of aortic sinus and en face of aorta were estimated by oil-reo-O staining. Expression of 4-HNE, F4/80, Ki67 and Iba1 were visualized by fluorescence immunohistochemistry. Expression of SGLT2, MCP-1 and TNF-α were performed by Real-time RT-PCR and/or Western blot analysis. Intracellular ROS generation was measured by H_2DCF-DA. Cell proliferation was estimated by a CCK-8 assay kit and direct counting of the live cell number. Membrane currents of macrophages were performed by patch clump measurements.
Results: In all mouse models, there were no significant differences on dietary intake and lipid profile between placebo and empagliflozin-treated groups. However, body weight was lower in the empagliflozin group than the placebo group in NC-fed mice. Glucose levels during a food load test were lower in the empagliflozin group than the placebo group in all mouse models. Treatment with empagliflozin suppressed the progression of atherosclerotic lesions in the aortic sinus and en face of the whole aorta in all mouse models. The 4-HNE-positive area and number of proliferating macrophages in plaques, and mRNA expression of MCP-1 and TNF-α in the aorta were lower in empagliflozin groups than in control groups. Expression of SGLT2 mRNA and protein were confirmed in mouse peritoneal macrophages. Empagliflozin inhibited LPS-induced ROS generation, MCP-1 and TNF-α mRNA expression, and GM-CSF-induced cell proliferation, as well as suppressed glucose-sensitive inward current and glucose uptake in macrophages. Moreover, a pan-glucose transporter inhibitor or sodium channel blocker suppressed macrophage proliferation, suggesting the involvement of SGLT2 for macrophage activation.
Conclusion: We revealed that treatment with empagliflozin suppresses the progression of atherosclerosis in normoglycemic and hyperglycemic *Apoe*$^{-/-}$ mice. Moreover, we revealed for the first time that macrophages express functional SGLT2, and empagliflozin directly suppresses ROS generation, inflammatory responses, and cell growth of macrophages. These actions of empagliflozin may indicate that SGLT2 inhibitors may be beneficial for the treatment of diabetic macrovascular complications, and SGLT2 in macrophages may be a therapeutic target in normoglycemic patients with atherosclerotic diseases.

OP 04 The adipose tissue: from biology to intervention studies

19

Insulin sensitising effects of vitamin D mediated through reduced adipose tissue inflammation and fibrosis

E. Lontchi-Yimagou[1], S. Kang[2], K. Zhang[1], A. Goyal[1], J. You[1], P. Kishore[1], E. Rosen[3], M. Hawkins[1];
[1]Albert Einstein College of Medicine, Bronx, [2]University of California, Berkeley, Berkeley, [3]Beth Israel Deaconess Medical Center, Boston, USA.

Background and aims: Despite epidemiologic evidence linking vitamin D deficiency with insulin resistance and type 2 diabetes, much controversy exists regarding whether vitamin D repletion has beneficial metabolic effects. Since vitamin D (25(OH)D) has anti-inflammatory and anti-fibrotic effects, expression of its receptor in adipocytes and macrophages suggests that 25(OH)D signaling could mediate paracrine effects within adipose tissue and improve insulin resistance. We designed parallel studies in humans and rodents to define the effects of vitamin D on adipose tissue inflammation and fibrosis, and on systemic insulin resistance.
Materials and methods: We performed a randomized, double-blinded placebo-controlled trial to examine the effects of repleting vitamin D levels to >30 ng/ml in 25(OH)D-deficient (<20 ng/ml), insulin resistant, overweight-to-obese humans ($n = 19$). A comprehensive study of whole-body insulin action was undertaken with stepped euglycemic (~90 mg/dL) hyperinsulinemic clamp studies, both before (1st visit) and after administration of vitamin D or placebo (2nd visit). Adipose tissue fibrosis and inflammation were quantified by 'real-time' rt-PCR and immunofluorescence in subcutaneous abdominal adipose tissue. To determine whether vitamin D's effects are mediated through adipocytes, we performed hyperinsulinemic clamp studies (4 mU/kg/min) and adipose tissue analysis in an adipocyte-specific vitamin D receptor knockout (VDR KO) mouse model (Adiponectin-Cre+VDR+/fl) following high fat diet feeding for 12 weeks.
Results: 25(OH)D repletion was associated with reductions in adipose tissue gene expression of inflammatory (0.6–0.7-fold decreased expression of *TNF-α, IL-6, iNOS and PAI-1*) and pro-fibrotic (0.4–0.8-fold decreased expression of *TGF-β1, HiF1α, Collagen I, V, VI and MMP7*) factors, decreased collagen VI immunofluorescence (19% reduction, $p = 0.02$) and improved hepatic insulin sensitivity in humans, with heightened suppression of endogenous glucose production (EGP) during hyperinsulinemic clamp studies (1.28 ± 0.20 *vs* 0.88 ± 0.18 mg/kg/min, $p = 0.03$). Despite no differences in body weight or adiposity, compared to wild type (WT), adipose-specific VDR KO mice exhibited increased adipose tissue expression of several pro-inflammatory (*Tnf-α*, *iNos*, *Pai-1*, *Mcp*-1 and *F4/80*; 4–10 fold) and pro-fibrotic genes (*Tgf-β1*, *Collagen VI*, and *Tsp1*; 2–4 fold), in concert with hepatic insulin resistance (EGP 10 ± 3 *vs* 3 ± 2 mg/kg/min in WT, $p = 0.021$). There were no changes in insulin-mediated glucose uptake in either humans or mice.
Conclusion: These complementary human and rodent studies establish a beneficial role of vitamin D to improve hepatic insulin resistance, likely by restraining adipose tissue inflammation and fibrosis. Thus, normalizing 25(OH)D levels could have metabolic benefits in targeted individuals.

FKBP51 ablation using CRISPR/Cas-9 impairs adipocyte differentiation

C. Castillejo-López[1], X.M. Abalo[2], C.O. Sidibeh[2], M.J. Pereira[2], P.G. Kamble[2], J.W. Eriksson[2];
[1]Immunology, Genetics and Pathology, Uppsala University, Uppsala, [2]Medical Sciences, Uppsala University, Uppsala, Sweden.

Background and aims: Prolonged exposure to high levels of endogenous or exogenous glucocorticoids (GC) has adverse effects on critical metabolic processes that can lead to insulin resistance, diabetes, central obesity and dyslipidemia. GC action depends on its binding to the cytosolic GC receptor, which act as a transcription factor tightly regulated by a chaperone protein complex that includes FKBP51 (FK506-binding protein 51). FKBP51 is implicated in stress-related psychiatric disorders. Recently, in a microarray study, we reported that the expression of the corresponing gene, *FKBP5*, was highly upregulated in human adipose tissue after 24 h treatment with a synthetic glucocorticoid, dexamethasone. Moreover, *FKBP5* SNPs were found to be associated with type 2 diabetes. In this study, we aimed to investigate the consequences of FKBP51 ablation in human adipocyte differentiation.
Materials and methods: We used CRISPR/Cas-9 methodology to generate two independent *FKBP5* knockouts in two different cell models: human preadipocytes isolated from stromal vascular cells obtained from human adipose tissue biopsies (non-diabetic healthy volunteers) and the preadipocyte SGBS cell line (Simpson-Golabi-Behmel Syndrome). The phenotype was analyzed in preadipocytes and in differentiated adipocytes by Western blot, RT-qPCR, and immunohistochemistry capacity of differentiated adipocytes.
Results: Gene editing in different cell cultures displayed a prevalence of at least 50% of null allelic mutations and on average of 75% protein reduction. Adipogenesis assays showed that *FKBP5*-KO preadipocytes had reduced ability to differentiate into mature adipocyte. The gene expression of adipogenic markers at different time points during differentiation was assessed, and *PPARG*, *FABP4*, *CD36,* and *ADIPOQ* expression was reduced by a ~60%, ~95%, ~95% and 90% ($p < 0.01$), respectively, compared to wild-type (WT) control cells. In addition, the degree of differentiation assessed by quantifying the amount of lipid accumulation on the 14th day of differentiation also showed a reduced accumulation of lipid in *FKBP5*-KO cells by about 30% ($p < 0.01$) compared to WT. Studies are ongoing to investigate the effect of dexamethasone on cell differentiation and glucose uptake capacity in differentiated *FKBP51*- KO and WT adipocytes.
Conclusion: We show proof-of-concept for CRISPR/Cas-9 gene editing and ablation in human adipose precursor cells of FKBP51, a chaperone protein modulating GC-receptor activity. The resulting phenotype includes a markedly impaired adipogenesis. This implies a critical role of FKBP51 in human adipose tissue that may influence insulin action and other metabolic functions.

Insulin regulates lipolysis and fat mass by upregulating growth/differentiation factor 3 in adipose tissue macrophages

T. Izumi, Y. Bu, K. Okunishi;
Gunma University, Maebeshi, Gunma, Japan.

Background and aims: Previous genetic studies in mice have shown that functional loss of activin receptor-like kinase 7 (ALK7), a type I transforming growth factor-β receptor, increases lipolysis to resist fat accumulation in adipocytes. Although growth/differentiation factor 3 (GDF3) has been suggested to function as a ligand of ALK7, it is unknown how GDF3 production is regulated under nutrient-excess conditions.
Materials and methods: We identified the cell source of GDF3 by biochemical and FACS fractionation of mouse white adipose tissue (WAT). We examined the effects of insulin on GDF3 expression in adipose tissue macrophages (ATMs) ex vivo and on body and WAT weights and serum nonesterified fatty acid levels in vivo in both ALK7-intact and ALK7-deficient obese mouse strains. To examine the involvement of ATMs and GDF3 in the insulin activity toward lipolysis and adiposity, we performed experiments of clodronate treatment and transplantation of bone marrow from GDF3-knockout mice to deplete macrophages and their GDF3, respectively.
Results: A physiologically low level of insulin converted $CD11c^-$ adipose tissue macrophages into GDF3-producing, $CD11c^+$ macrophages ex vivo, and directs ALK7-dependent accumulation of fat in vivo. Depletion of ATMs by clodronate upregulated adipose lipases and reduced fat mass in ALK7-intact obese mice, but not in their ALK7-deficient counterparts. Furthermore, depletion of ATMs or transplantation of GDF3-deficient bone marrow negated the in vivo effects of insulin on both lipolysis and fat accumulation in ALK7-intact obese mice.
Conclusion: Insulin efficiently inhibits lipolysis and accumulates fat primarily through the upregulation of GDF3 in ATMs, but not through its direct activities on adipocytes. The GDF3-ALK7 axis between ATMs and adipocytes represents a previously unrecognized mechanism by which insulin regulates both fat metabolism and mass.

The diabetes risk gene TCF7L2 regulates human adipose progenitor cell biology

M. Verma, N. Loh, M. Todorčević, K. Pinnick, A.V. Dam, M. Neville, F. Karpe, C. Christodoulides;
Oxford Centre for Diabetes Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, Oxford, UK.

Background and aims: Dysfunctional adipose tissue *e.g.* as seen in obesity or lipodystrophy is associated with insulin resistance (IR) which predisposes to type 2 diabetes (T2D) and cardiovascular disease (CVD). Nonetheless, the risk of T2D and CVD is not uniform in similarly obese subjects. The adipose tissue (AT) response to chronic caloric overload (hypertrophy *vs.* hyperplasia) is a major determinant of susceptibility to IR. TCF7L2 is a key transcription factor involved in WNT signalling, a developmental pathway, which has a central role in AT biology. A common SNP in TCF7L2 (rs7903146) is the strongest genetic determinant of T2D risk in humans with the risk being higher in lean *vs.* obese subjects. We hypothesised that TCF7L2 modulates T2D risk partly *via* effects on AT biology.
Materials and methods: *In vitro* functional studies in primary and immortalised human adipose progenitor cells (APCs) and AT phenotyping in rs7903146 risk variant carriers.
Results: *Ex vivo TCF7L2* expression was higher in APCs compared to mature adipocytes (mADs) ($p < 0.001$, $n = 35–49$) and adipose endothelial cells ($p < 0.01$, $n = 5–6$) in both abdominal and gluteal depots. *Ex vivo TCF7L2* expression corelated positively with BMI in abdominal ($p = 0.001$, $R^2 = 0.28$, $n = 35–50$) and gluteal ($p = 0.04$, $R^2 = 0.12$, $n = 35–50$) APCs but not in mADs. Stable TCF7L2 knockdown (KD) with two independent shRNAs (low and high efficiency) in immortalised human abdominal APCs led to impaired proliferation ($p < 0.01$) and a dose-dependent increase in WNT signalling ($p < 0.001$) both basally and following WNT3a treatment. Notably, adipogenesis was enhanced ($p < 0.001$) with low efficiency TCF7L2 KD whilst being impaired ($p < 0.001$) with high efficiency TCF7L2 KD in both immortalized and primary human abdominal APCs. AT phenotyping showed reduced *ex vivo* TCF7L2 mRNA ($p = 0.015$, $n = 15–29$) and protein ($p = 0.04$, $n = 5–10$) levels *selectively* in abdominal APCs of T2D risk allele (T) carriers. Accordingly, *in vitro* reporter assays for *cis*-regulatory activity at rs7903146 revealed that the T2D risk allele (T) abrogates a weak enhancer in abdominal APCs (C *vs.* T, $p < 0.001$). Lastly, compared with homozygous carriers of the C allele, individuals homozygous for the T2D risk allele (T) displayed altered adipocyte size distribution in abdominal AT ($p < 0.001$, $n = 9–25$).
Conclusion: These results implicate TCF7L2 in human adipose progenitor biology, AT plasticity and susceptibility to T2D.

Pros and cons of gastric bypass surgery in obese individuals with type 2 diabetes: nationwide, matched, observational cohort study

V. Liakopoulos, S. Franzén, A.-M. Svensson, M. Miftaraj, J. Ottosson, I. Näslund, S. Gudbjörnsdottir, B. Eliasson;
Department of Molecular and Clinical Medicine, University of Gothenburg, Gothenburg, Sweden.

Background and aims: Long-term effects of gastric bypass (GBP) surgery have been presented in observational and randomized studies, but there is still only limited data for obese persons with type 2 diabetes (T2DM), in particular regarding postoperative complications. We investigated postoperative outcomes after GBP in a nation-wide cohort.
Materials and methods: In this observational study, we merged data from the Scandinavian Obesity Surgery Registry, the National Diabetes Register and national databases. We matched persons with type 2 diabetes who had undergone GBP with persons not surgically treated for obesity, based on sex, age, BMI and propensity score. The risks of postoperative outcomes were assessed using Cox regression model adjusted for sex, age, BMI and socioeconomic status.
Results: 5321 T2DM patients who had undergone GBP and 5321 control persons were followed for up to 9 years. We confirm lower risks of all-cause mortality (49%) and cardiovascular disease (34%), found positive effects on severe kidney disease, but also demonstrate significantly increased risks (2 to 9-fold) of several short-term complications after GBP. There were higher rates of abdominal pain and gastrointestinal conditions frequently requiring additional surgical procedures, apart from reconstructive plastic surgery. Long-term, the risk of anemia was 92% higher, malnutrition appeared approximately 3-fold more often, while psychiatric diagnoses were 33% increased, and alcohol abuse was 3-fold higher than in the control group.
Conclusion: This nation-wide study confirms the benefits but also describes the panorama of adverse events after bariatric surgery in obese persons with T2DM. In order to maximize the benefit and minimize the risk of unfavorable results after bariatric surgery, a thorough and long-term follow-up and support of these patients seems paramount. Better selection of patients for such treatment could probably also improve results.

Differing gut hormone responses drive weight loss after Roux-en-Y gastric bypass and sleeve gastrectomy, with similar effects on glucose dynamics and insulin sensitivity

C. Liaskos[1,2], C. Koliaki[1], K. Alexiadou[1], I. Mourouzis[3], C. Pantos[3], G. Argyrakopoulou[1], A. Alexandrou[4], N. Katsilambros[1], T. Diamantis[4], N. Tentolouris[1], A. Kokkinos[1];
[1]First Department of Propaedeutic Medicine, School of Medicine, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece, [2]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich-Heine University, Düsseldorf, Germany, [3]Department of Pharmacology, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece, [4]First Department of Surgery, School of Medicine, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece.

Background and aims: Bariatric surgery, the most effective method for the long-term treatment of class III obesity, exerts beneficial effects on glucose metabolism. Possible underlying mechanisms include massive loss of fat mass, restricted caloric intake and changes in gut hormones. Aim of our study was to compare the effects of Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy (SG) on glucose, insulin, ghrelin, PYY and GLP-1 levels.
Materials and methods: We recruited 28 obese patients, of which 11 underwent RYGB (age: 38.6 ± 8.2 years; BMI: 48 ± 6 kg/m^2) and 17 SG (age: 41.3.6 ± 8.1 years; BMI: 50.7 ± 7.3 kg/m^2, p = NS vs RYGB)]. They were examined preoperatively, as well as 3, 6, and 12 months after surgery. Blood samples were drawn before, and 30, 60, 90, 120, 150 and 180 min after consumption of a mixed meal for the measurement of glucose, insulin, ghrelin, PYY and GLP-1. Insulin resistance was estimated with the HOMA-IR index. Postprandial responses were expressed as area under the curve (AUC).
Results: There were no preoperative differences between groups in any of the parameters. Both experienced significant and comparable weight loss (BMI 12 months RYGB: 30.8 ± 5.2 vs SG: 34.4 ± 6.7 kg/m^2, p = NS). Glucose AUCs were reduced 6 ($p \leq 0.007$) and 12 months ($p \leq 0.002$) after both procedures, with no difference between groups (Glucose AUC 12 months RYGB: 15858.3 ± 1700 vs SG: 16750 ± 2660.3 mg min/dl, p = NS). Both operations led to significantly and comparably lower fasting insulin levels at all time points. HOMA-IR was profoundly decreased for both groups at all postoperative time points (HOMA-IR preop RYGB: 6.7 ± 5.6 vs SG: 8.2 ± 6.2, p = NS, and HOMA-IR 12 months RYGB: 1.6 ± 1.3 vs SG: 1.9 ± 0.9, p = NS). Fasting ghrelin decreased after SG (Ghrelin preop SG: 223.2 ± 77 vs 3 months: 129.3 ± 20.9, 6 months: 106.4 ± 15.8, 12 months: 128 ± 19.8 pg/ml, all $p \leq 0.02$ vs preop), while was increased at 12 months ($p = 0.04$ vs preop) after RYGB. Ghrelin AUC decreased at 3 months after SG ($p = 0.015$), with nonsignificant changes after RYGB. PYY AUC increased at 3, 6, and 12 months after RYGB (PYY AUC preop RYGB: 11406.7 ± 4593.9 vs 3 months: 19187.4 ± 5617.5, 6 months: 22405.8 ± 8259.2, 12 months: 24940.6 ± 9399.1 pg min/ml, all $p \leq 0.02$), and only at 3 months after SG ($p = 0.016$). GLP-1 AUC was significantly higher in the RYGB group compared to that after SG at 6 months (GLP-1 AUC 6 months RYGB: 9966 ± 2137.9 vs SG: 7507.7 ± 3011.1 pM min, $p = 0.046$).
Conclusion: RYGB and SG induce distinctly differing gut hormone responses, the first leading to a pronounced increase in PYY, and the second to a decrease in ghrelin. However, the satiety-inducing effects of both lead to comparable effects on weight loss, glucose dynamics and insulin sensitivity. It seems that weight loss *per se* is the primary driving force behind these metabolic improvements, while gut hormones play a secondary role.

Finerenone improves the cardiovascular benefits after a return to a normal diet in the mouse model of high fat diet-induced obesity

M. Pieronne-Deperrois[1], L. Nicol[1], S. Messaoudi[2], A. Marouchtchak[1], V. Richard[1], P. Kolkhof[3], F. Jaisser[2], P. Mulder[1], A. Ouvrard-Pascaud[1];
[1]Inserm U1096, Medical school of Rouen-Normandy University, Rouen, France, [2]Inserm U1138, Cordeliers Institute, Paris 6 University, Paris, France, [3]Bayer Pharma AG, Wuppertal, Germany.

Background and aims: Patients with obesity exhibit high prevalence of left ventricular (LV) diastolic dysfunction. In a mouse model of high fat diet (HFD)-induced obesity, we assessed the benefit of a normalization of the diet in obese mice, and we hypothesized that the non-steroidal mineralocorticoid receptor (MR) antagonist Finerenone further improves heart function.

Materials and methods: Nine weeks old B6D2 male mice were fed a HFD (60% fat) or maintained on normal diet (CTL). After 16 weeks, obese mice were divided in 3 groups for 8 more weeks with either: *i)* HFD; *ii)* normal diet (HFD-STOP); *iii)* normal diet plus Finerenone 1 $mg.kg^{-1}.day^{-1}$mixed in the food (HFD-STOP+FINE).

Results: After 24 weeks of HFD in mice, blood pressure remained normal. However, compared to CTL after 16 weeks of HFD, mice showed 1) overweight and insulin resistance, 2) decreased Stroke Volume (SV) assessed by echocardiography, 3) reduced cardiac filling pressure (LV-End-Diastolic-Pressure, LVEDP: CTL 2.73 ± 0.1, HFD 4.73 ± 0.34 mmHg; $P < 0.001$) and impaired LV compliance (LV-End-Diastolic-Pressure-Volume-Relation, LVEDPVR: CTL 1.19 ± 0.26, HFD 4.77 ± 0.31 mmHg/RVU; $P < 0.001$) assessed by invasive hemodynamics, 4) reduced Coronary Reserve (CR: CTL 4.24 ± 0.71, HFD 1.27 ± 0.41 ml mg^{-1} min^{-1}; $P < 0.01$) assessed by MRI perfusion measurements and 5) reduced exercise ability in a stress-test on treadmill. After 24 weeks, HFD fed mice compared to CTL still had increased LV filling pressure, impaired LV compliance, reduced Coronary Reserve and limited exercise ability, plus worsened heart function including decreased LV fractional shortening and decreased cardiac output (CO). Switching HFD to normal diet in the HFD-STOP group from weeks 16 to 24, body weight decreased down to CTL values. In both HFD-STOP and HFD-STOP+FINE groups compared to HFD alone, diet normalization allowed improving insulin resistance, SV,CO and LV compliance, the latest being further improved by FINE (LVEDPVR: HFD-STOP 3.44 ± 0.39, HFD-STOP+FINE 2.28 ± 0.23 mmHg/RVU; $P < 0.05$). Interestingly, after diet normalization, there were raises of kidney weight and of albumin over creatinine urine ratio that were prevented by FINE (alb/creat/24hours: CTL 43.8 ± 4.5, HFD 43.5 ± 6.7, HFD-STOP 69.1 ± 7.3, HFD-STOP+FINE 44.3 ± 5.2; $P < 0.05$). Moreover, only the FINE treatment on top of diet normalization allowed improving LV filling pressure (LVEDP: CTL 2.73 ± 0.16, HFD 4.73 ± 0.34, HFD-STOP 4.53 ± 0.33, HFD-STOP+FINE 3.18 ± 0.26 mmHg; $P < 0.05$), Coronary Reserve (CR: CTL 3.76 ± 0.72, HFD 1.00 ± 0.33, HFD-STOP 1.19 ± 0.25, HFD-STOP+FINE 2.78 ± 0.67 ml mg^{-1} min^{-1}; $P < 0.05$) and total distance during the stress-test on treadmill.

Conclusion: When administered on top of diet normalization after HFD-induced obesity in mice, Finerenone improved albuminuria, led to further improvement of LV compliance and led to specific improvements of LV filling pressure and Coronary Reserve, likely contributing to improved performance in the running stress-test.

Characterisation of an animal model of type 2 diabetes with potential application in the evaluation of new therapies for diabetic neuropathy

F. Ezquer[1], C. De Gregorio[1], D. Contador[1], D. Santapau[1], M. Campero[2], M. Ezquer[1];
[1]Center for Regenerative Medicine, School of Medicine, Universidad del Desarrollo, Santiago, [2]Department of Neurology and Neurosurgery, Hospital Clínico José Joaquín Aguirre, Universidad de Chile, Santiago, Chile.

Background and aims: Diabetic Neuropathy (DN) is one of the most common clinical complications of diabetes affecting up to 60% of diabetic patients. DN is characterized by progressive, distal-to-proximal degeneration of peripheral nerves, affecting both sensory and motor fibers. Evidences from diabetic patients suggest that reduced availability of neuroprotective factors in the nerves in combination with a chronic pro-inflammatory microenvironment contribute to the pathogenesis of DN. Nowadays, there is no effective clinical treatment for DN. Therefore; the generation of new therapeutic alternatives is highly desirable. Different animal models of Type 2 Diabetes Mellitus (T2DM) have been used to study the progression of nerve dysfunction in DN. However, a complete characterization of all functional and structural alterations present in these models and the kinetics of their appearance are lacking. The aim of this work was to characterize the main functional, structural and electrophysiological alterations present in one of the most commonly used animal model of T2DM

Materials and methods: Leptin receptor deficient mice (BKS.Cg^{m}+/+ $Lepr^{db}$/J) (BKS *db/db*) spontaneously develop severe obesity and chronic hyperglycemia at 4 weeks of age. Diabetic (*db/db*) and non-diabetic (*db/+*) mice were analyzed from 4 to 32 weeks of age to evaluate the progression of DN. To identify potential peripheral neurologic defects, we measured functional parameters including sciatic nerve conduction velocity and the responses to mechanical stimuli and noxious radiant heating in the hind paws. We correlated these functional measurements with previously described structural alterations in other DN models, including intraepidermal nerve fiber density (IENF) in the plantar surface of the hind paws, the presence of apoptotic Schwann cells in sciatic nerve and the presence of lymphocyte infiltration in sciatic nerve. The study was carried out along the principles of laboratory animal care

Results: Diabetic mice showed progressive impairments at functional level beginning at 8 weeks in withdrawal latency in plantar test and at 16 weeks in nociceptive threshold in Von Frey test. Furthermore, diabetic mice displayed decreased conduction velocity in sciatic nerve at 26 weeks of age. Based on the severity of these physiological parameters, we defined an early (18 weeks), mid (26 weeks) and late (32 weeks) phase of disease to analyze some structural parameters. Diabetic mice showed a significant reduction of IENF beginning at 18 weeks of age, an increased number of TUNEL positive Schwann cells in the sciatic nerves beginning at 26 weeks of age and a significant increase in the number of infiltrating T lymphocytes in sciatic nerves beginning at 26 weeks of age.

Conclusion: We produced a complete description of the behavioral, histological and electrophysiological parameters of an animal model of T2DM at an early, mid and late phase of the disease. We found a progressive correlation between physiological parameters with the structural defects. This animal model recapitulates many of the alterations associated to DN in humans, and these defects worsened as diabetic time increased. Therefore, it could be used at preclinical level to evaluate new therapeutic outcomes for DN patients.

Cardiac metabolism of a lipodystrophic mouse model studied using hyperpolarised [1-^{13}C] pyruvate magnetic resonance spectroscopy

X. Teo, B. Bai, W. Chan, Y. Fu, W. Han, P. Lee;
Singapore Bioimaging Consortium, Singapore, Singapore.

Background and aims: Berardinelli-Seip congenital lipodystrophy is a rare form of autosomal recessive disorder caused by loss-of-function mutation in BSCL2 gene that codes for *Seipin*. The phenotypes include severe insulin resistance, hypertriglyceridemia, and almost complete loss of adipose tissue. These overlap with the characteristics of type-2 diabetes. Hence, it is plausible that there would be underlying alteration in cardiac metabolism. *Seipin* knockout (SKO) mice, as a mouse model of lipodystrophy, have recently been shown to exhibit cardiac hypertrophy and dysfunction. Here, we investigated the *in vivo* cardiac pyruvate metabolism of SKO mice using hyperpolarized [1-^{13}C] pyruvate magnetic resonance spectroscopy (MRS).
Materials and methods: Twenty four weeks old SKO mice ($n = 5$) and their heterozygous or wildtype littermates as controls ($n = 5$) underwent ^{13}C MRS. The MRS experiments were performed on a 9.4 T MR scanner (Bruker Biospec), with the heart positioned on a dual ^{1}H/^{13}C a Butterfly 20 mm butterfly surface coil (Doty). [1-^{13}C] pyruvic acid was polarized in a preclinical hyperpolarizer (Hypersense, Oxford Instruments) and was neutralized with Tris/NaOH buffer for dissolution. The dissolution was injected (0.56 mmol/kg, *i.v.*) into the animals under isoflurane anaesthesia, followed by simultaneous acquisition of cardiac ^{13}C MR spectra for 2 minutes immediately after injection. A typical *in vivo* hyperpolarized cardiac ^{13}C MR spectra shows [1-^{13}C] pyruvate (170.8 ppm) and [1-^{13}C] pyruvate hydrate (179.1 ppm), and the downstream metabolites: lactate (183.0 ppm), [1-^{13}C] alanine (176.4 ppm), and [1-^{13}C] bicarbonate (160.8 ppm). To assess the diabetic status of the animals, a handheld glucose meter was used to measure blood glucose concentrations immediately after blood sampling. Blood insulin levels were measured from collected serum using ELISA. Data are means ± SEM.
Results: The SKO mice had higher blood glucose than their age-matched littermates at 24 weeks old (22.4 ± 3.0 mmol/L vs 9.4 ± 0.5 mmol/L, $p = 0.0038$).The SKO mice also exhibited higher insulin levels compared with the littermate controls (93.0 ± 41.7 ng/mL vs 1.7 ± 0.4 ng/mL, $p = 0.047$). Upon injection of hyperpolarized [1-^{13}C] pyruvate, the ^{13}C label incorporation from [1-^{13}C] pyruvate into [1-^{13}C] lactate was similar in SKO mice and controls ([1-^{13}C] lactate/total carbon: 0.105 ± 0.022 vs. 0.100 ± 0.010, $p = 0.90$). The ^{13}C label incorporation into [1-^{13}C] alanine was also not different between SKO mice and controls ([1-^{13}C] alanine/total carbon: 0.030 ± 0.008 vs. 0.032 ± 0.006, $p = 0.79$). However, the ^{13}C label incorporation into [1-^{13}C] bicarbonate was 2 times higher in SKO mice than in controls ([1-^{13}C] bicarbonate/total carbon: 0.0053 ± 0.0015 vs. 0.0024 ± 0.0005, $p = 0.008$), which reveals a higher PDH activity in the SKO mice.
Conclusion: The SKO mice exhibited increased cardiac PDH flux, which is a characteristic of heart failure development. Hyperpolarized ^{13}C MRS allows measurements of enzymatic flux *in vivo*, thus making a longitudinal study with lipodystrophic SKO mice possible.

Role of amylin oligomer in transmission of type 2 diabetes between mother and offspring

C.-L. Chuang, S. Zhang, G. Amarsingh, G. Cooper;
University of Auckland, Auckland, New Zealand.

Background and aims: Pregnancy in diabetic women is associated with an increased risk of short- and long-term adverse consequences for the fetus and mother, the most significant of which is a predisposition to the development of metabolic syndrome and Type 2 diabetes mellitus (T2DM). There is substantive evidence for deposition of aggregated human amylin (hA) in organs of T2DM patients, including pancreas, heart, kidney and brain, consistent with haematogenous spread of aggregated hA from the islet. We aim to characterise a novel mechanism potentially responsible for the transmission of T2DM between the mother and offspring.
Materials and methods: hA over-expression transgenic (TG) and non-transgenic (NT) female mice as control were mated with NT male mice. NT male offspring from both TG and NT mother were subjected to more in-depth phenotypic characterization. Biochemical and physiological methods including measurements of litter-weights, litter-sizes, growth curves, blood glucose, intraperitoneal insulin tolerance test, intraperitoneal glucose tolerance test, and serum hormone (insulin, leptin, adiponectin) levels.
Results: NT male offspring from TG mother displayed several characteristics of T2DM. NT male offspring from TG mother weigh significantly more than NT male offspring from NT mother by 137 days of age. NT male offspring from TG mother also developed hyperinsulinaemia with insulin resistance, hyperleptinaemia with leptin resistance, and glucose intolerance between 120–240 days of age. More importantly, 70% of NT male offspring from TG mother developed diabetes, whereas none of NT male offspring from NT mother did. Moreover, they acquire this syndrome before their mothers become hyperglycaemic.
Conclusion: Non-diabetic hA over-expression TG mothers transmit T2DM to their NT offspring with high penetrance, whereas NT mothers do not, indicating amylin oligomer could potentially play a role in the transmission. The mechanism of inter-generational transmission of T2DM is vital to understand its familial clustering and increasing prevalence.

Pdx1-deficient zebrafish exhibit diabetes-induced altered function and structure of the pronephros and increased retinal sprouting angiogenesis

L.M. Wiggenhauser, S.J. Stoll, J. Kroll;
Department of Vascular Biology and Tumor Angiogenesis, European Center for Angioscience (ECAS), Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany.

Background and aims: Diabetic microvascular complications, e.g. nephropathy, retinopathy and neuropathy, are a major cause of morbidity and quality of life decrease in the rising number of diabetes patients worldwide and therapy options are limited. Pdx1 is a transcription factor responsible for MODY 4 diabetes and necessary for pancreatic ß-cell maturation and insulin production. To enhance the available set of screening organisms for new interventions and uncover possible new mechanisms of mentioned complications, we established a new genetic animal

model in embryonic and adult zebrafish to study microvascular complications in a pathophysiological setting of type 1 diabetes mellitus by gene knockdown of *pdx1*.

Materials and methods: Pdx1-deficient zebrafish were generated using CRISPR/Cas9 mediated genome editing, targeting exon 1 of the zebrafish *pdx1* gene in the ABTL strain. Through selective breeding homozygous $pdx1^{-/-}$ mutants were generated and validated in different reporter lines via sequencing and western blot for Pdx1. To examine the effect of the *pdx1* gene knockdown transgenic fluorescent zebrafish embryos were studied by fluorescence and confocal laser scanning microscopy. The constructs Tg(hb9:GFP), Tg(fli1:EGFP) and Tg(wt1b:GFP) were utilised to investigate pancreatic, vascular and nephric changes respectively. To assess ultrafiltration fluorescence-labelled 70 kDa dextran was intracardially injected. The dextran was chosen to resemble the size of human albumin. Adult zebrafish were sacrificed for blood sugar measurements, histology and retinal preparations.

Results: $pdx1^{-/-}$ embryos show reduced pancreatic size and adult specimen have increased blood sugar values 2 hours after feeding ($P < 0.05$). Homozygous $pdx1^{-/-}$ knockdown in zebrafish leads to morphological changes of the developing pronephros and is accompanied by increased loss of dextran through the filtration barrier ($P < 0.05$). The embryonic trunk vasculature did not exhibit susceptibility to the genotypical influence. The adult retinal vasculature analysis uncovered increased sprouting angiogenesis in both heterozygous $pdx1^{+/-}$ and homozygous $pdx1^{-/-}$ zebrafish and changes in the vascular architecture ($P < 0.05$).

Conclusion: *pdx1* knockdown successfully impaired pancreas development and function in zebrafish and lead to changes in organs, which are vulnerable to microvascular complications. Increased loss of dextran in injected $pdx1^{-/-}$ zebrafish and increased retinal vascular sprouting are indicating of pathophysiological mechanisms similar to the human condition. These findings suggest that zebrafish are susceptible to *pdx1* knockdown-mediated diabetic complications in both kidney and retina and should be further evaluated as a potential research model.

Downregulation of FKBPL influences metabolic and vascular function in experimental model of diabetes

A. Alqudah[1], R. McNally[1], N. Todd[1], K. Edgar[1], A. Short[1], D. Grieve[1], T. Robson[2], L. McClements[1];
[1]Queen's University Belfast, Belfast, UK, [2]Royal College of Surgons in Ireland, Dublin, Ireland.

Background and aims: There are currently over 400 million people living with diabetes in the world. Cardiovascular disease (CVD) is the leading cause of death globally and people with diabetes have a three-fold higher incidence of CVD. The underlying mechanisms implicated in the development of CVD in association with diabetes are linked to aberrant angiogenesis and endothelial dysfunction. FKBPL is a novel anti-angiogenic protein which has a critical role in physiological and pathological angiogenesis. While *Fkbpl* homozygous knockout mice resulted in embryonic lethality, $Fkbpl^{+/-}$ embryos were viable and developed normally but showed signs of early vascular dysfunction and leakiness. Based on these findings, we now investigate the effect of FKBPL downregulation on metabolic and vascular function in a streptozotocin (STZ)-induced diabetic mouse model.

Materials and methods: Both wild-type (WT, C57BL/6N) $Fkbpl^{+/+}$ and $Fkbpl^{+/-}$ mice were randomized between 10 and 12 weeks of age to either STZ treatment (5 consecutive STZ injections at 50 mg/kg/day) or vehicle control treatment with citrate buffer. Metabolic parameters were measured weekly. Insulin tolerance (ITT) and echocardiography tests were performed at 12 weeks of diabetes. Following 13 weeks of diabetes, organs were excised for immunofluorescent *ex-vivo* analysis. Comparisons were analyzed using one-way ANOVA.

Results: Blood glucose levels were higher in $Fkbpl^{+/-}$ diabetic mice compared to $Fkbpl^{+/+}$ diabetic controls during a period of 8 to 12 weeks of diabetes ($p < 0.05$, $n \geq 6$). Glycated haemoglobin (HbA1c) was higher in both non-diabetic and diabetic $Fkbpl^{+/-}$ mice compared to $Fkbpl^{+/+}$ controls (non-diabetic, 31 ± 0.9 mmol/mol vs. 27.25 ± 0.8 mmol/mol, $p < 0.05$, $n \geq 6$; diabetic, 88.7 ± 3.1 mmol/mol vs. 69.8 ± 3.5 mmol/mol, $p < 0.001$, $n \geq 6$). Notably, $Fkbpl^{+/-}$ non-diabetic mice gained more weight compared to $Fkbpl^{+/+}$ non-diabetic controls on a normal diet (10.92 ± 0.51 g vs. 7.05 ± 1.02 g, $p < 0.05$, $n \geq 6$). However, no differences in blood glucose levels were observed between these two groups of mice. The results of ITT at 12 weeks of diabetes showed a trend towards higher blood glucose levels in diabetic $Fkbpl^{+/-}$ mice compared to $Fkbpl^{+/+}$ diabetic controls (at 0 min, 33.3 ± 0 mmol/l vs. 29.12 ± 0.56 mmol/l, $p < 0.05$; at 120 min, 20.3 ± 3.02 mmol/l vs. 15.6 ± 1.61 mmol/l, $p = 0.09$, $n \geq 6$). This was associated with significant cardiac diastolic dysfunction, as indicated by reduced E/A ratio in both $Fkbpl^{+/+}$ and $Fkbpl^{+/-}$ diabetic mice compared to their respective controls ($p < 0.001$, $n \geq 6$), whilst E/A tended to be elevated in the non-diabetic $Fkbpl^{+/-}$ mice compared to $Fkbpl^{+/+}$ controls ($p = 0.08$, $n \geq 6$). Immunofluorescence staining of the hearts showed lower FKBPL protein expression in $Fkbpl^{+/+}$ diabetic mice compared to non-diabetic controls (mean fluorescence intensity: 0.12 ± 0.03 vs. 1 ± 0.17, $p < 0.01$, $n \geq 4$). Cardiac protein expression of intercellular adhesion molecule 1 (ICAM-1), a marker of endothelial dysfunction, was higher in diabetic animals as well as in $Fkbpl^{+/-}$ non-diabetic mice compared to $Fkbpl^{+/+}$ controls (mean fluorescence intensity: 1.37 ± 0.13 vs. 1 ± 0.04, $p < 0.01$, $n \geq 4$).

Conclusion: Our results suggest that FKBPL may play a key regulatory role in fat and glucose metabolism as well as irregular cardiac angiogenesis associated with diabetes. As such, FKBPL could be explored as a potential therapeutic target for prevention of cardiovascular complications of diabetes

Imaging Ins2 gene activity and single-cell RNA sequencing reveal heterogeneous beta cell states

H. Modi[1], H. Cen[1], S. Skovsø[1], X. Hu[1], N. Krentz[2], D. Dionne[1], S. Xuan[3], M. Huising[4], F. Lynn[1], J. Johnson[1];
[1]University of British Columbia, Vancouver, Canada, [2]University of Oxford, Oxford, UK, [3]University of Columbia, New York, USA, [4]University of California, Davis, USA.

Background and aims: Functional b-cell heterogeneity is well established and studied. Previous work from our group identified dynamic states marked by fluorescent proteins driven by the promoters of insulin and Pdx1. In order to study b-cell heterogeneity of insulin production with more accuracy, we turned to an *Ins2*^{GFP} knock-in/knockout mouse line, and other knock-in alleles. Here, our aims were to characterize heterogeneous b-cell states using mice and cells expressing the *Ins2*^{GFP} knock-in allele over time using live-cell imaging and single-cell RNA sequencing technology.
Materials and methods: Based on our preliminary data showing heterogeneity of GFP expression in the *Ins2*^{GFP} knock-in islets, we crossed this line with Ins1-mCherry transgenic mice that are known to show relatively stable mCherry expression. We conducted immunofluorescence of intact pancreatic sections and FACS analysis of dispersed islets to characterize GFP abundance. Dispersed islet cells from the resulting double-mutant *Ins2*$^{GFP/wt}$:Ins1-mCherry were studied over ~3 days using ImageXpress^{MICRO} live-cell imaging systems. Single-cell RNA sequencing, using the 10X Genomics platform, was performed on FACS purified GFP (+) and GFP- (-) b-cells from younger as well as older *Ins2*^{GFP} knock-in/knockout mice.
Results: Analysis of pancreatic tissue sections from *Ins2*^{GFP} knock-in mice showed that, at any given time, only about half of all b-cells were robustly GFP-positive, suggesting that not all b-cells have active transcription at the *Ins2* locus *in vivo*. FACS analysis confirmed *Ins2* mRNA and pre-mRNA were increased in GFP-positive cells compared to negative cells (861.9 ± 110.5 vs 97.2 ± 16.3, 2.06 ± 0.45 vs 1.01 ± 0.04 respectively). *In vitro* perifusion of islets isolated from *Ins2*$^{GFP/GFP}$ knock-in/knockout mice showed reduced insulin secretion at 20 mM glucose (AUC = 44.63 ± 4.7) compared to heterozygous *Ins2*$^{GFP/Wt}$ knock-in/knockout mice (AUC = 82.5 ± 6.3) and control *Ins2*$^{Wt/Wt}$ mice (AUC = 71.7 ± 10.2). Live-cell imaging of dispersed cells from *Ins1*^{mCherry}:*Ins2*$^{GFP/wt}$ mice revealed that GFP fluorescence flashed on and off in a sub-set of cells, suggesting bursts of transcription at the *Ins2* gene locus rather than stable heterogeneity. Using Cell Profiler software and custom R scripts, we tracked individual cell GFP activity and found that 153 out of 547 cells show flickering GFP activity. Principal component analysis identified 3 distinct clusters of *Ins2* gene activity cell behaviors. Single-cell RNA sequencing on FACS purified GFP-positive and GFP-negative population from islets isolated from young as well as old homozygous *Ins2*$^{GFP/GFP}$ and heterozygous *Ins2*$^{GFP/Wt}$ knock-in/knockout mice identified significantly up-regulated (Dapl1, Npy, Pgk1) and down-regulated (Xist, Nupr1, Rbp4) genes between low-GFP and high-GFP β-cells, which further gives insight about molecular features of this b-cell state.
Conclusion: Our results demonstrate the *Ins2*^{GFP} knock-in mice are a useful tool for studying b-cell heterogeneity, state transitions and plasticity. To the best of our knowledge, our observations are the first to find a previously uncharacterized form of b-cell plasticity and/or heterogeneity. Understanding the dynamics of insulin production has relevance for understanding the pathobiology of diabetes and for regenerative therapy research.

Loss of beta cell heterogeneity disrupts normal islet function

D. Nasteska[1], G.A. Rutter[2], Q. Zhou[3], D.J. Hodson[1];
[1]University of Birmingham, Birmingham, UK, [2]Department of Medicine, Imperial College London, London, UK, [3]Department of Stem Cell and Regenerative Biology, Harvard University, Cambridge, USA.

Background and aims: Immature β-cell subpopulations such as hubs give rise to heterogeneity in the islet, although it is still unclear how this may impact function *in situ*. To explore the contribution of heterogeneity to stimulus-secretion coupling and insulin release in the intact islet, we generated a loss of heterogeneity model using a viral strategy to upregulate β-cell maturity.
Materials and methods: Islets from wild-type mice (WT) were infected with an adenoviral vector carrying the polycistronic construct for *Pdx1, MafA, Ngn3* and *mCherry* (Ad3-NPM). Control islets (CT) were non-infected or treated with control virus (Ad-PATagRFP). Short hairpin RNA (shRNA) and corresponding scrambled control was used for knock-down of *Pdx1*. Gene expression was confirmed by qPCR and proteins detected by immunohistochemistry (IHC). High-speed spinning disk microscopy, coupled with biosensors/organic dye application was used for measuring Ca^{2+} fluxes, cAMP and ATP/ADP. HTRF assay was used to measure insulin secretion after stimulation with glucose and incretin mimetic.
Results: Forty eight hours post-infection (Ad3-NPM), *Pdx1* and *MafA* expression levels were increased (*Pdx1:* 9.9-fold *vs* CT, $p < 0.01$; *MafA:* 2.2-fold *vs* CT, $p < 0.01$), while *Ngn3* showed no change. *Pdx1* overexpression, as assessed by IHC, was largely restricted to Pdx1^{low} β-cells, inducing homogeneity across the β-cell population. The balance of the islet endocrine populations was unaffected, as concluded by normal α/β and δ/β ratios and normal α-specific gene expression (*Arx* and *Pax6*). Loss of heterogeneity impaired both glucose-stimulated (8.7 *vs* 5.2% content, CT *vs* Ad3-NPM; $p < 0.01$) and incretin-stimulated insulin secretion (56 *vs* 29% content, CT *vs* Ad3-NPM; $p < 0.01$). Ca^{2+} fluxes were blunted, both during high glucose ($\Delta F = 1.34$ *vs* 0.6 AU, CT *vs* Ad3-NPM; $p < 0.01$) and incretin stimulation ($\Delta F = 0.46$ *vs* 0.28 AU, CT *vs* Ad3-NPM; $p < 0.05$). cAMP levels but not ATP/ADP ratios were significantly decreased in Ad3-NPM islets (% forskolin max = 127 vs 71.5, CT *vs* Ad3-NPM; $p < 0.05$). The proportion of hubs (12 *vs* 8% hubs, CT *vs* Ad3-NPM; $p < 0.05$) and β-cell-β-cell connectivity (12.6 *vs* 6.0%; CT *vs* Ad3-NPM; $p < 0.05$) (i.e. coordination) were reduced, accompanied by decreased gene expression of *Gjd2*, encoding the gap junction protein connexin 36 (0.75-fold *vs* CT; $p < 0.05$). A reduction of expression was also seen in *Cacn1d* and *Cacnb2* subunits of the voltage-gated Ca^{2+} channels (0.75-fold and 0.67-fold *vs* CT; $p < 0.05$). Experiments in *Pdx1*-silenced islets (aiming to increase the Pdx1^{low} population) showed similarities to many of the above-listed results. *Pdx1* expression in the islet was reduced (0.7-fold vs CT), mainly due to a reduction in the Pdx1^{high} β-cell population, and this was associated with the absence of glucose-stimulated insulin secretion. Ca^{2+} amplitude in response to high glucose showed a significant drop ($\Delta F = 0.38$ *vs* 0.21 AU, CT *vs* shRNA treatment; $p < 0.01$), together with a decrease in hub proportion (12 *vs* 6% hubs, CT *vs* shRNA treatment; $p < 0.05$) and cell-cell connectivity (13.8 *vs* 8.9%; CT *vs*shRNA treatment; $p < 0.05$).
Conclusion: Loss of β-cell heterogeneity caused by changes in β-cell maturity prevents islets from mounting appropriate responses to stimuli. Cellular diversity within the beta complement thus appears to be an essential part of islet physiology.

Differential beta cell coupling patterns drive biphasic activity

M. Jaffredo[1], A. Pirog[2], É. Bertin[1], B. Catargi[3], S. Renaud[2], J. Lang[1], M. Raoux[1];

[1]CBMN, CNRS UMR 5248, Univ. Bordeaux, Bordeaux, [2]IMS, CNRS UMR 5218, Bordeaux INP, Univ. Bordeaux, Bordeaux, [3]CHU de Bordeaux, Hôpital Saint-André, Bordeaux, France.

Background and aims: After food intake, pancreatic islets secrete insulin with a biphasic pattern, which is impaired in type 2 diabetic patients. The mechanisms underlying this pattern have not been fully elucidated and the presence of distinct vesicle pools has been proposed as explanation. Electrical activity of islets consists of individual β cell activity (action potentials, APs) and the multicellular electrical response due to coupling between β cells (slow potentials, SPs). We addressed here the contribution of these two distinct activities to the 1st and the 2nd phase of β cell activity, and their modulation by physiological concentrations of GLP-1.
Materials and methods: Electrical activity (SPs and APs) of entire mice (C57Bl6/J, age 10–14 weeks) or human islets have been recorded on polymer-coated microelectrode arrays (MEA). These new electrodes allow simultaneous detection of APs (of very low amplitude) and SPs at a high time resolution (10'000 points/s x60 electrodes) for a prolonged period mimicking physiological digestion (2 h). Specific filters differentially detect SPs and APs and 3 parameters were analyzed at the same time: SP frequencies, SP amplitudes and AP frequencies. To investigate synchrony of SPs between different regions of the same islet, we used high density MEAs with an inter-electrode distance of 30 instead of 200 μm followed by analysis *via* Matlab.
Results: Islets were stimulated with glucose concentrations in the physiological range (5.5–8.2 mM). Electrical responses were biphasic for both SPs and APs. APs were mainly present during the 1st phase while the transition between the 1st and the 2nd phase is driven by SPs. In 2nd phase, the SP amplitude and synchronisation increased significantly (1st phase: 18.1 ± 2.3 μV; 2nd phase: 47.4 ± 5.5 μV, $p < 0.0001$), reflecting further electrical coupling and synchronisation of β cells. The intra-islet synchronisation was also further correlate using high density MEAs. The incretin GLP-1, at a physiological postprandial concentration (50 pM), did not change the individual activity of cells (APs) but increased specifically coupling (SPs) and only in the 2nd phase (37.7 ± 3.0 μV *vs* 47.0 ± 4.2 μV with GLP-1, $p < 0.0001$). Furthermore, when GLP-1 was applied in the presence of a subthreshold glucose concentration (5.5 mM), the hormone triggered only a 2nd phase. The biphasic electric profile was confirmed in human islets. Their exposure to a glucotoxic medium (20 mM glucose, 65 h) considerably increased basal activity and abolished the biphasic response as well as the discrimination between glucose concentrations. These glucotoxic effects were partially reversible.
Conclusion: Our data show that (i) electrical activity pattern shape the biphasic secretion and (ii) the transition period between the 1st and the 2nd phase results from increasing electrical synchronisation. Thus biphasic secretion is primarily dictated by changes in electrical activity rather than vesicle pools. The effects of GLP-1 on only coupling SP signals and only during the 2nd phase explain its clinical effects.

Glucose regulates pancreatic islet beta cell calcium dynamics and intercellular connectivity in vivo

V. Salem[1], L. Delgadillo Silva[2], K. Suba[1], N. Akhtar[3], N. Mousavy[1], A. Martin-Alonso[1], E. Georgiadou[1], D.C.A. Gaboriau[4], S.M. Rothery[4], T. Stylianides[3], D.J. Hodson[5], P. Marchetti[6], L. Briant[7], N. Ninov[2], G.A. Rutter[1];
[1]Department of Medicine, Imperial College London, London, UK, [2]DFG-Center for Regenerative Therapies, Technische Universität Dresden, Dresden, Germany, [3]Loughborough University, Loughborough, UK, [4]Imperial College London, London, UK, [5]University of Birmingham, Birmingham, UK, [6]University of Pisa, Pisa, Italy, [7]Radcliffe Department of Medicine, University of Oxford, Oxford, UK.

Background and aims: The coordinated function of pancreatic islet β cells is believed to be essential for the efficient release of insulin in response to elevated glucose concentrations. Whilst this behaviour has been demonstrated *in vitro* in isolated islets, its existence *in vivo*, where the islet is perfused and receives neural inputs, has not previously been examined. Here, we use the recombinant Ca^{2+} sensor GCaMP6 to explore connectivity in three living animal models: the zebrafish *D. rario*; in murine islets transplanted into the anterior chamber of the C57BL6 mouse eye (ACE), and in human islets engrafted in the ACE of immunodeficient *nu/nu* mice.
Materials and methods: *D. rario* bearing GCaMP6s and nuclear mCherry transgenes under the insulin promoter were immobilized and imaged on a Zeiss 780 laser-scanning confocal microscope (40x dipping objective, 488 nm illumination; 0.1 Hz data acquisition). Glucose manipulations were made through the bath or via direct intracardiac injection. Mouse (C57Bl6, Ins1Cre:GCaM6m$^{f/f}$) or human islets infected with adenovirus expressing GCaMP6m, were injected into the ACE then imaged 3–4 weeks later under isofluorane anaesthesia. Insulin or glucose were infused either via tail vein or IP to achieve "low glucose" concentrations (<6 mmol/l) or "high glucose" concentrations (>20 mmol/l). Data were collected on a modified Nikon Ti-E spinning disc confocal microscope (20x, 0.75 NA water immersion objective; 1–3 Hz). Corrections for movement, using nuclei as landmarks, were performed off-line using Fiji, and Ca^{2+} traces analyzed in manually-defined cytosolic regions with Image J and Igor.
Results: In each of the three systems, significant β cell Ca^{2+} dynamics existed under basal conditions. In zebrafish, these were rapidly abrogated upon glucose lowering via insulin injection or following the temporal inhibition of blood flow. The amplitude of the observed oscillations, and the degree of connectivity between individual β cells, were both increased in response to increases in circulating glucose concentrations. Examined in larger (>200 μm) mouse islets, Ca^{2+} waves often began at sites remote from capillaries, consistent with the existence of hub/pacemaker cells which serve as initiators of the waves. Increasing glucose concentrations augmented the proportion of connected β cells in zebrafish islets from <10 to 75 ± 9% ($p < 0.001$) of all cells, and correlation strength (R) from 0.15 ± 0.03 to 0.74 ± 0.1 ($p < 0.001$; $n = 6$ animals). Equivalent values for mouse islets were 65 to 86% ($n = 5$; $p = 0.02$) and R-values 0.34 ± 0.07 to 0.46 ± 0.08 ($n = 5$; $p = 0.05$). For human islets, elevated blood glucose increased connectivity from 58.3% to 63.9% ($n =$ 1 female, age 54, BMI 24.5).
Conclusion: These studies demonstrate glucose-regulated intercellular connectivity between β cells *in vivo*, and provide evidence for important hierarchical β cell behavior involving "hubs" and "followers" in initiating and sustaining Ca^{2+} dynamics and insulin secretion.

Beta-screen: non-invasive, easy to use MEA-based parallelised screening system for intact islets of Langerhans

S. Schönecker[1], K.-H. Boven[1], U. Kraushaar[2];
[1]Multi Channel Systems, Reutlingen, [2]Natural and Medical Sciences Institute at the University of Tübingen, Reutlingen, Germany.

Background and aims: Increase in blood glucose concentration leads to glucose-induced electrical activity of pancreatic beta cells resulting in insulin secretion. This electrical activity manifests in glucose concentration-dependent oscillations which can easily be recorded by microelectrode arrays (MEA). To increase the throughput of the measurements to be suitable for drug development we engineered a MEA-based parallelized recording system for primary rodent, human or stem cell derived islets of Langerhans called Beta-Screen.
Materials and methods: The recording chip consisting of five electrodes allows to record electrical oscillations from intact islets of Langerhans.

Eight chips can be connected to the device which enables recording from 40 islets simultaneously. Positioning is realized by suction and 8 chambers can be perfused independently. Intact murine Islets of Langerhans or islets isolated from human biopsies were used for recording. Electrical activity was recorded at 37°C as field potentials and quantified as fraction of plateau Phase (FOPP) or as number of single spike activity (spikes/5min).

Results: The glucose concentration response curve recorded with murine islets plotted as FOPP revealed a half-maximal activity of 12.26 ± 2 mM (n = 12) which is in line with traditional methods e.g. intracellular electrodes. The application of 150 μM diazoxide inhibited (n = 13) while 300 μM tolbutamide restored electrical activity (n = 13). Human islets of Langerhans displayed typical glucose-induced activity (10 mM, n = 10). Validation studies with tolbutamide and diazoxide showed the existence of functional K_{ATP} channels. Diazoxide reduced the mean spike activity from 833 ± 339 Spikes/5 min (10 mM glucose) to 8 ± 4 spikes/5 min. The additional application of tolbutamide restored spike activity up to 876 ± 310 spikes/5 min. TTX reduced spike activity from 1047 ± 314 to 199 ± 90 spikes/5 min after the application of 300 nM TTX (n = 11). The washout led to an increase of spike activity to 779 ± 301 spikes/min (n = 11). The glucose concentration response curve of the spike activity revealed an EC50 value of 8.66 ± 3.02 mM glucose.The glucose responsiveness in human islets recorded with the Beta-Screen is in line with other reports showing that the EC50 value of human beta-cells (~6 mM) is lower than in mouse beta-cells.

Conclusion: This study shows the successful development of a parallelized MEA chip, which allows to simultaneously record electrical oscillations from up to 40 intact islets of Langerhans. Previous attempts to use electrophysiological features as readout for a higher throughput screening failed due to technical limitations. The Beta-Screen device enables for the first time acute electrophysiological medium throughput recordings of intact islets. The validation of the Beta-Screen device revealed properties of electrical activity which are comparable to literature as well as to the acute recordings obtained with the classical MEA chips. This improvement of throughput will facilitate future studies with murine, human or stem cell derived islets of Langerhans. Moreover, it will facilitate basic research, e.g. in combination with knockout mice. Importantly, the capability to also record human islets opens numerous new possibilities for this approach, e.g. the system could be used as a quality control system prior to transplantation of human islets into patients with type 1 diabetes.

Role of the very long chain fatty acid elongase 2 (Elovl2) in the control of beta cell Ca^{2+} dynamics and connectivity

E. Georgiadou;
Medicine, Section of Cell Biology and Functional Genomics, London, UK.

Background and aims: ELOVL2 is an enzyme that synthesizes ω3-polyunsaturated fatty acids (PUFAs) including DHA (docosahexaenoic acid). Recent comparisons of multiple mouse strains have implicated *Elovl2* in the control of insulin secretion. Correspondingly, mice deleted for *Elovl2*selectively in the β-cell display impaired glucose homeostasis. In order to understand the molecular mechanisms involved, we have explored the role of a) altered Ca^{2+} dynamics and b) β-cell communication in these changes.

Materials and methods: C57Bl/6N male mice bearing floxed *Elovl2* alleles were bred to Ins1Cre animals to achieve highly selective deletion in β-cells. Animals were fed with regular chow (RC) or high fat diet (HFD, 36% fat) for 3 months. Ca^{2+} imaging of whole isolated islets was performed after loading with Fluo-8 (Stratech;10 μM), and perifusion in modified Krebs-Ringer buffer (mM: 130 NaCl, 3.6 KCl, 0.5 NaH_2PO_4, 24 $NaHCO_3$, 24 $NaHCO_3$, 1.5 $CaCl_2$, 0.5 $MgSO_4$, 10 HEPES) containing 3 mM glucose previously equilibrated with 95% O_2 and 5% CO_2 at 34–36°C. Images were captured at 0.5 Hz on a Zeiss Axiovert microscope equipped with a 10X 0.3–0.5 NA oil immersion objective, coupled to a Nipkow spinning-disk head (Yokogawa CSU-10) and illuminated at 491 nm. Connected cell numbers were determined using in house software (Igor) and the strength of correlation (R) with a Matlab (Mathworks) script.

Results: An elevation in glucose concentration from 3 to 17 mM prompted biphasic, oscillatory increases in intracellular Ca^{2+} dynamics in islets isolated from wild type (WT) animals fed on a RC diet. Conversely, both phases were reduced in islets deleted for *Elovl2*. Ca^{2+} dynamics were also reduced in islets from WT mice maintained on HFD, and loss of *Elovl2* further suppressed the response to high glucose (p < 0.01, n = 15–17 islets RC vs HFD p < 0.05, n = 24–27 islets). Responses to depolarisation with 20 mM KCl were also reduced in islets from *Elovl2* KO mice vs WT controls maintained on either diet. The number of connected cell pairs was reduced by deletion of *Elovl2* by 15% (p > 0.05, n = 27 islets) when examined at 3 mM, but not in 17mM (p > 0.05, n = 27 islets) glucose in islets isolated from mice fed on HFD. The increase in R between cell pairs at 17mM vs 3mM Glucose was reduced by *Elovl2* deletion (20% on RC and 10% on HFD).

Conclusion: These data demonstrate that *Elovl2* is required for glucose and depolarisation induced islet-wide Ca^{2+} dynamics and intercellular connectivity. This may suggest that very long chain fatty acids, including DHA, influence β-cell membrane potential or Ca^{2+} channel activity. Our observations also demonstrate that maintenance of mice on HFD reduces Ca^{2+} dynamics and connectivity and therefore, that altered ratios of unsaturated:saturated fatty acids may be an important determinant of glucose-induced insulin secretion.

DURATION-8 randomised controlled trial 104-week results: efficacy and safety of once-weekly exenatide (ExQW) plus once-daily dapagliflozin (DAPA) vs ExQW or DAPA alone

E. Hardy[1], S.A. Jabbour[2], C. Guja[3], S. Bhattacharya[1], P.K. Öhman[1], J.P. Frías[4];
[1]AstraZeneca, Gaithersburg, USA, [2]Thomas Jefferson University, Philadelphia, USA, [3]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania, [4]National Research Institute, Los Angeles, USA.

Background and aims: In patients with type 2 diabetes mellitus (T2DM) uncontrolled on metformin alone, exenatide once weekly (ExQW) + dapagliflozin (DAPA) significantly reduced glycaemia, body weight and systolic blood pressure compared to ExQW + placebo (PBO) or DAPA + PBO at 28 weeks (DURATION-8 trial). Here, we examined the efficacy and safety of this combination after 104 weeks of double-blind therapy.
Materials and methods: In DURATION-8, adults with T2DM and inadequate glycaemic control despite stable metformin monotherapy (≥1500 mg/day) were randomly assigned to receive ExQW (2 mg s.c. injection) + DAPA (10 mg oral tablet), ExQW + PBO or DAPA + PBO for 28 weeks. Patients entered 52- and 104-week controlled extension periods where they continued to receive active treatment. HbA_{1c}, body weight and systolic blood pressure along with safety were evaluated after 104 weeks.
Results: Of 695 patients randomised, 431 (62%) completed 104 weeks; 4.3% patients withdrew due to adverse events (AEs). Absolute reductions and between-group differences in HbA_{1c} were achieved at week 28 and maintained over weeks -52 and -104 (Figure). ExQW + DAPA significantly reduced fasting plasma glucose (FPG; mg/dL) at week 28 compared with ExQW alone (least-square [LS] mean [SEM]; −20.1 [4.0]; $P \leq 0.001$) or DAPA alone (LS mean [SEM]; −16.6 [3.9]; $P \leq 0.001$), with clinically relevant results observed at week-52 and -104 (change in FPG from baseline for ExQW + DAPA vs ExQW alone and DAPA alone at weeks 52 and 104 [LS mean {SEM}]: −17.6 [4.1], −19.2 [5.9] and − 23.3 [4.0], −27.1 [6.0]; $P \leq 0.001$, respectively). Clinically relevant changes versus baseline in other efficacy endpoints (postprandial glucose, body weight and systolic blood pressure) were also observed for the ExQW + DAPA group at week 104. All evaluations at 104 weeks were exploratory. AEs and serious AEs (SAEs) were balanced across treatment groups. SAEs were reported in 7.4%, 7.8% and 7.7% of patients in the ExQW + DAPA, ExQW + PBO and DAPA + PBO groups, respectively. Hypoglycaemia incidence was low. None of the patients experienced major hypoglycaemia. Minor hypoglycaemia and other hypoglycaemic events were more frequent with ExQW + DAPA vs ExQW + PBO and DAPA + PBO (1.7% and 6.9% vs 0.0% and 3.5% vs 0.4% and 3.4%, respectively).
Conclusion: ExQW + DAPA maintained efficacy over 104 weeks with no unexpected safety concerns.

Effect and safety of oral semaglutide monotherapy in type 2 diabetes: PIONEER 1 trial

M. Haluzik[1], J. Rosenstock[2], Y. Terauchi[3], O. Jeppesen[4], E. Christiansen[4], C.L. Hertz[4], V.R. Aroda[5,6];
[1]Institute for Clinical and Experimental Medicine, Prague, Czech Republic, [2]Dallas Diabetes Research Center at Medical City, Dallas, USA, [3]Yokohama City University, Yokohama, Japan, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Brigham and Women's Hospital, Boston, USA, [6]MedStar Health Research Institute Hyattsville, Hyattsville, USA.

Background and aims: Oral semaglutide, the first glucagon-like peptide-1 (GLP-1) receptor agonist in a tablet formulation, is in late-stage development for the treatment of type 2 diabetes (T2D).
Materials and methods: The effect and safety of oral semaglutide (3, 7, or 14 mg once daily) was assessed in this randomised, double-blind, placebo-controlled phase 3a trial in drug-naïve patients with T2D uncontrolled on diet and exercise ($n = 703$). The primary endpoint was change from baseline in HbA_{1c} at week 26. The primary estimand (treatment policy) evaluated the effectiveness regardless of trial product discontinuation or rescue medication use. A secondary estimand (hypothetical) evaluated the efficacy of trial product while on treatment without rescue medication using a mixed model for repeated measures (MMRM), and is the conventional statistical method used in many previous T2D studies.
Results: Baseline characteristics were balanced between treatment groups: approximately 49% of patients were female, mean age was 55 years and mean duration of diabetes was 3.5 years. Oral semaglutide resulted in clinically meaningful reductions in both HbA_{1c} (all doses)

and body weight (higher doses) at week 26 (Table). Adverse events (AEs) occurred in 58%, 53% and 57% for 3, 7, and 14 mg oral semaglutide, respectively, and 56% with placebo. The most common AE with oral semaglutide was transient mild or moderate nausea. Nausea occurred in 5–16% of patients with oral semaglutide vs 6% with placebo.

Conclusion: This trial represents the first phase 3 demonstration of the effect and safety of an orally administered GLP-1 receptor agonist. In conclusion, oral semaglutide demonstrated superiority vs placebo in reducing HbA_{1c} (all dose levels) and body weight (14 mg) and, consistent with the GLP-1 receptor agonist class, it was well tolerated in T2D uncontrolled on diet and exercise.

Common variants in the GLP-1 receptor are associated with glycaemic response to GLP-1 receptor agonists in observational and large RCT data: an IMI-DIRECT study

A.Y. Dawed[1], A. Mari[2], T.J. McDonald[3], N.R. Robertson[4], A. Mahajan[5], M. Walker[6], S. Gough[7], K. Zhou[1], I. Forgie[1], H. Ruetten[8], I. Pavo[9], S.G. Pillai[9], A.G. Jones[3], E.R. Pearson[1], for the DIRECT consortium;
[1]Molecular and Clinical Medicine, University of Dundee, Dundee, UK, [2]CNR Institute of Neuroscience, Padua, Italy, [3]NIHR Exeter Clinical Research Facility, University of Exeter and Royal Devon and Exeter Hospital, Exeter, UK, [4]Molecular and Clinical Medicine, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK, [5]Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK, [6]Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK, [7]Oxford Centre for Diabetes Endocrinology and Metabolism, NIHR Oxford Biomedical Research Centre, Oxford, UK, [8]Sanofi-Aventis Deutschland GmbH, TMED, Frankfurt, Germany, [9]Eli Lilly Research Laboratories, Indianapolis, USA.

Background and aims: Glycaemic response to GLP-1 Receptor Agonist (GLP-1RA) treatment varies markedly among patients with Type 2 Diabetes (T2D) yet the mechanism for this variation is uncertain. Common missense variants in the *GLP-1R* have previously been reported to alter GLP-1 mediated insulin secretion. We aimed to investigate how variants in the *GLP-1R* alter glycaemic response to the GLP-1RA in a locus wide meta-analysis.

Materials and methods: We performed a meta-analysis using data from four observational cohorts (DIRECT, PRIBA, GoDARTS and PROMASTER) in 1,238 subjects on liraglutide or exenatide and two randomized clinical trial cohorts from the AWARD (1,554 subjects from 5 trials on dulaglutide, liraglutide or exenatide) and the HARMONY (1,771 subjects from 7 trials on albiglutide or liraglutide) studies. In total, 4,563 T2D subjects were followed-up for 6 months after initiation of GLP-1RA. The association of variants in the *GLP-1R* region with reduction in glycated haemoglobin (HbA1c) after treatment were assessed using multiple linear regression assuming additive mode of inheritance.

Results: Gly168Ser (rs6923761) and rs2268640 were independently associated with reduction of GLP-1RA to lower HbA1c (Gly168Ser β (HbA1c change per allele) = −0.09%, $p = 3.59e^{-05}$, rs2268640 β per G allele = −0.10%, $p = 2.52e^{-07}$). The allele frequency for Gly168Ser and rs2268640 in a Caucasian population was 0.33 and 0.34, respectively. We then derived a genetic risk score, summing up these two variants from the HARMONY trials. The 43% of the population of HARMONY who carry no risk allele in either of the variants had a mean (SEM) HbA1c reduction of 0.99% (0.03) in response to GLP-1RA. In contrast, 53% of the population who carry 3 or more risk alleles had a mean (SEM) HbA1c reduction of 0.84% (0.03), a difference of 0.15% ($p < 0.001$). There was no significant impact of these SNPs on weight change in response to GLP-1RA. The Gly168Ser variant was previously shown to be associated with lower β-cell surface expression of *GLP-1R* and reduced intracellular calcium mobilization. The rs2268640 variant is a *cis*-eQTL, with carriers of the G allele having reduced expression of *GLP-1R* in the pancreas.

Conclusion: We observed significant associations between common variants in *GLP-1R* gene and GLP-1RA-induced HbA1c reduction with a large multi-ethnic cohort-collection. In HARMONY, the genetically determined effect on glycaemic response explains about $1/5^{th}$ of the overall response to GLP-1RA. This suggests that genetic variants in *GLP-1R* might explain part of the variability observed in the therapeutic response to GLP-1RA.

Potential impact of differential drop-in of open-label diabetes medications in EXSCEL

J.B. Buse[1], M.A. Bethel[2], R.A. Patel[2], S.R. Stevens[3], S.M. Gustavson[4], Y. Lokhnygina[3], A.F. Hernandez[3], R.R. Holman[2], for the EXSCEL Study Group;
[1]UNC School of Medicine, Chapel Hill, USA, [2]Diabetes Trials Unit, Oxford, UK, [3]Duke Clinical Research Institute, Durham, USA, [4]AstraZeneca, Gaithersburg, USA.

Background and aims: Greater drop-in of open label diabetes (DM) medications occurred during the EXenatide Study of Cardiovascular Event Lowering (EXSCEL) with placebo (P) than exenatide (E). As some DM medication classes reduced cardiovascular (CV) events in other outcome trials, we evaluated whether imbalanced use of concomitant DM medications during follow up may have impacted time to event analyses for major adverse CV events (MACE3; CV death, nonfatal myocardial infarction, or nonfatal stroke) or all-cause mortality (ACM).

Materials and methods: DM medication use was recorded by drug class at each study visit. Once initiated, new medications were assumed to continue for the study duration. For medication classes where drop-in occurred in >5% of participants and for open label glucagon-like peptide-1 receptor agonists [GLP-1 RA; 3% overall), Cox hazard models were performed by randomized treatment with right censoring at the drop-in visit. Cox hazard models for MACE3 were also recalculated by modelling the impact of drop-in medication by applying effect sizes derived from published trials: HR 1.02 for insulin, 0.99 for dipeptidyl peptidase-4 inhibitors (DPP-4i), 0.88 for GLP-1 RA, and 0.85 for sodium glucose transporter 2 inhibitors (SGLT2i). E vs P HRs for MACE3 and ACM were also recalculated using inverse probability weighting (IPW), preferentially weighting accumulated outcome data for participants who did not experience drop-in of DM medications.

Results: Concomitant DM medication use did not differ between groups at baseline, but during follow-up, drop-in use was more frequent in P for

biguanide (6.1 vs 4.8%), sulfonylurea (SU; 8.8 vs 6.9%), DPP-4i (10.6 vs 7.5%), insulin (13.8 vs 9.4%), SGLT2i (5.4 vs 3.7%), and GLP-1 RA (3.6 vs 2.5%). Using censoring analyses, E vs P HRs for MACE3 were minimally altered with drop-in medication (Table) but became nominally statistically significant with SU, SGLT2i or any DM medication. For ACM, neither the HR (95% CI) nor the *p* value were altered meaningfully. Modelled E vs P HRs for MACE3 dependent on published effect sizes were 0.92 (0.84, 1.01) for DPP-4i, 0.92 (0.84, 1.01) for GLP-1 RA, 0.92 (0.84, 1.01) for SGLT2i, and 0.92 (0.84, 1.01) for insulin. After IPW, E v. P HRs were 0.89 (0.78, 1.02), $p = 0.10$ for MACE3 and 0.82 (0.64, 1.04), $p = 0.104$ for ACM.

Conclusion: Observed MACE3 and ACM E vs P effect sizes in EXSCEL were robust to several methods of adjusting for the greater drop-in of open-label DM medications in P. Lower *p* values ($p < 0.05$) were observed for MACE3 after censoring for SU, SGLT2i, or any medication, suggesting drop-in medications can influence study outcomes. *P* values were consistently <0.05 for ACM. In summary, greater drop-in of cardioprotective medications with placebo can blunt signal detection and should be considered in the design and analysis of future trials.

Near-normoglycaemia, with meaningful discontinuations of prandial insulin, by adding weekly albiglutide to uncontrolled basal/bolus insulin-treated type 2 diabetes

J. Rosenstock[1], A. Nino[2], J. Soffer[2], J. Mallory[2], L. Erskine[2], A. Acusta[2], J. Dole[2], M.C. Carr[2], P. Home[3];
[1]Dallas Diabetes Research Center at Medical City, Dallas, USA, [2]GlaxoSmithKline, Collegeville, USA, [3]Newcastle University, Newcastle upon Tyrne, UK.

Background and aims: The glycemic efficacy of a weekly GLP-1 RA, albiglutide (Albi) 50 mg to replace prandial insulin lispro (Lis) was evaluated in type-2 diabetes mellitus (T2DM) inadequately controlled on a multiple daily insulin regimen (≥3 injections/day).
Materials and methods: Basal/bolus insulin was optimized during a 4-week run-in phase before randomization to: 1) Albi + optimized insulin glargine (Gla), with prandial Lis subsequently discontinued by week 4 ($n = 402$) or 2) optimized Lis + optimized Gla ($n = 412$).
Results: At week 26, the LS mean ± SE change from baseline in HbA1c was −34.9 ± 0.04 mmol/mol (−1.04% ± 0.04%) vs −35.5 ± 0.04 mmol/mol (−1.10% ± 0.04%) (treatment difference 0.7 [95% confidence interval (CI), −0.5, 1.9] mmol/mol or 0.06% [95% CI, −0.05, 0.17]%; non-inferiority $p < 0.0001$) (Table). In the Albi + Gla group, 218 subjects (54%) replaced all prandial insulin without reintroducing Lis through to week 26, resulting in a total daily insulin dose reduction of 61 U. Mean number of injections was reduced from 29 to 13 (mean change ± SD: −16 ± 8) per week. GI adverse events were higher in the Albi group (26% vs 13%). Albi + Gla was favorable for severe or documented symptomatic hypoglycemia (*n*: 230 [57%] vs 309 [75%]) and weight change (LS mean ± SE: −2.0 ± 0.2 vs +2.4 ± 0.2 kg; $p < 0.0001$) vs Lis + Gla.
Conclusion: Albi meaningfully improved glucose control; prandial insulin was stopped in 54% of participants, allowing substantial reductions in insulin dose and number of injections, less hypoglycemia, and body weight loss.

Diabetes prevention with lifestyle, linagliptin and metformin in patients with prediabetes: the PRELLIM project

R. Guardado-Mendoza[1,2], L. Jimenez-Ceja[1], D. Farfan[1], M. Alvarez-Canales[1], S. Salazar-Lopez[1], M. Montes de Oca[1], F. Angulo-Romero[1], M. Reyes-Escogido[1], E. Durán-Pérez[2], A. Aguilar-García[2];
[1]Metabolic Research Laboratory, University of Guanajuato, Leon, Guanajuato, [2]Hospital Regional de Alta Especialidad del Bajío, Leon, Guanajuato, Mexico.

Background and aims: Patients with impaired fasting glucose (IFG) + impaired glucose tolerance (IGT) have a high risk to develop T2DM. Lifestyle modifications and metformin are therapeutic options in these patients. The goal of this work was to evaluate the effect of linagliptin + metformin plus a lifestyle program on glucose metabolism, insulin secretion and beta cell function in patients with newly diagnosed IFG + IGT during 12 months.
Materials and methods: Patients had a basal metabolic evaluation including oral glucose tolerance test (OGTT) with insulin measurements, body composition, lipid profile and HbA1c. Patients with IFG+IGT, age 18–65 y were randomly assigned to: *i) lifestyle program plus linagliptin 2.5 mg/metformin 850 mg twice daily (**LM group**, n = 62)*, or *ii) lifestyle program plus metformin 850 mg twice daily* (***M group***, *n* = 58), with monthly follow-up and a 6 and 12 month metabolic evaluation. Insulin sensitivity, insulin secretion and beta cell function were calculated from the OGTT. The protocol was approved by the Ethical Committee. Intergroup differences were analyzed with a T test.
Results: There were not basal differences in age (48 vs 47 y), body composition (Weight 83 vs 83 kg, visceral fat 11.8 vs 11.6 AU), glucose metabolism (fasting glucose 108 vs 105 mg/dl, 30 minutes glucose 177 vs 170 mg/dl, 60 minutes glucose 200 vs 190 mg/dl, 90 minutes glucose 185 vs 181 mg/dl, and 120 minutes glucose 170 vs 165 mg/dl), insulin sensitivity and insulin secretion between LM and M group, respectively. At 12 months both groups had an improvement in weight (−5.4 vs −3.5 kg) visceral fat (−0.87 vs −0.44 AU) and insulin sensitivity (1.1 vs 1.18), all *p* = NS; however, LM group showed a better improvement in glucose at 0′ (−16 vs −6 mg/dl, *p* 0.001), 30′(−30 vs −11 mg/dl, p 0.007), 60′(−41 vs −14 mg/dl, *p* 0.008), 90′(−36 vs −18 mg/dl, *p* 0.061) and 120 minutes (−33 vs −19 mg/dl, *p* 0.118) during the OGTT (AUCglucose_OGTT −4008 vs −1639 mg/dl/120 min, *p* 0.005), insulin secretion (AUCins/AUCgluc_OGTT 0.14 vs −0.01, *p* 0.013), acute insulin response (0.50 vs −0.01, *p* 0.003), disposition index (1.1 vs 0.43, *p* 0.007), oral disposition index (0.10 vs 0.007, *p* 0.023), and HbA1c (−0.14 vs 0.23, *p* 0.007). Adherence to medications was 92 and 91% in the LM and M group, respectively.
Conclusion: Combination of linagliptin + metformin together with a lifestyle program improved better glucose metabolism, insulin secretion and beta cell function after 12 months in patients with IFG+IGT. This could be a useful preventive strategy in patients with prediabetes and a high risk of T2DM

Sex hormone binding globulin and development of insulin resistance: a longitudinal study

K. Ottarsdottir[1], A.G. Nilsson[2], M. Hellgren[1], U. Lindblad[1], B. Daka[1]; [1]Department of Public Health and Community Medicine, University of Gothenburg, Gothenburg, [2]Department of Internal Medicine and Clinical Nutrition, University of Gothenburg, Gothenburg, Sweden.

Background and aims: Previous cross-sectional studies and genetic studies using Mendelian randomization principle, have shown that low sex hormone binding globulin (SHBG) concentrations are associated to the risk of developing type 2 diabetes mellitus in both men and women. However, there is a lack of prospective studies investigating the association between SHBG and insulin resistance, and therefore we aim to investigate this association in a longitudinal study in men, premenopausal women, and postmenopausal women in a Swedish cohort.
Materials and methods: In this longitudinal observational study, a sample of 2816 subjects (*M* = 1400) were randomly selected from a Swedish population between 2002 and 2005 for a cohort study with the goal to detect risk factors for cardiovascular disease at an early stage. The cohort was followed up in 2012–2014. The mean follow-up time was 9.7 ± 1.4 years and the protocol was completed in a subset of 1327 (*M* = 657) individuals.Fasting blood samples were collected at both visits. Immunoassay technique was used for measurements of SHBG. The homeostatic model assessment of insulin resistance (HOMA-Ir) was used to define insulin resistance, and the variable was log-transformed in all statistical analyses due to distribution skewness. Analyses were stratified for sex and menopausal state as reported by the participants in a questionnaire at follow-up. As there was no self-report regarding menopause at baseline, 50 years of age was used as time of menopause at baseline and stratified analyses for age ≤50 or >50 were computed. Linear regressions were computed to investigate the association between SHBG and insulin resistance both in cross-sectional and longitudinal analyses.
Results: At baseline, concentrations of SHBG were significantly inversely associated with log transformed HOMA-Ir in men ($N = 1299$, $\beta = -0.213$, $p < 0.001$), premenopausal women ($N = 852$, $\beta = -0.087$ $p = 0.003$) and postmenopausal women ($N = 427$, $\beta = -0.246$ $p < 0.001$) in a model adjusting for age, lifestyle habits, hypertension, diabetes and waist-hip ratio. Similar results were found at follow-up; in men ($N = 546$, $\beta = -0.197$ $p < 0.001$), premenopausal women ($N = 152$, $\beta = -0.292$, $p < 0.001$) and in postmenopausal women ($N = 317$, $\beta = -0.237$ $p < 0.001$). In the longitudinal analysis in men, SHBG concentration at baseline was significantly inversely associated with log transformed HOMA-Ir at the follow-up in a multivariate model including age, lifestyle habits, hypertension, diabetes and waist-hip ratio, and log transformed HOMA-Ir at baseline ($N = 585$, $\beta = -0.087$ $p = 0.028$). Furthermore, there was a significant inverse association between SHBG levels at baseline and log transformed HOMA-Ir at follow-up in premenopausal ($N = 360$, $\beta = -0.092$ $p = 0.039$) and in postmenopausal women ($N = 215$, $\beta = -0.131$ $p = 0.012$) in the fully adjusted model.
Conclusion: In this study, SHBG levels could predict the deterioration of insulin resistance in both men and women, regardless of menopausal state. This might explain the previously shown association between SHBG level and type 2 diabetes.

Broad changes in body mass index between age 10 and adulthood are associated with type 2 diabetes risk independently of adult body mass index

J. Tyrrell, H. Yaghootkar, S.E. Jones, R. Beaumont, A.R. Wood, M.A. Tuke, K.S. Ruth, R.C. Andrews, T.M. Frayling;
University of Exeter, Exeter, UK.

Background and aims: Obesity is a strong risk factor for type 2 diabetes, but the condition occurs across the body mass index (BMI) range. Age, sex, ethnic differences, varying body fat distribution and genetic factors all contribute to differences in type 2 diabetes risk independently of BMI. Here, we used the UK Biobank to test the hypothesis that an additional factor, approximate change in BMI between childhood and adulthood, would contribute to type 2 diabetes risk.
Materials and methods: We used data from 371,903 individuals of European ancestry in the UK Biobank, with a measure of adult BMI, self-reported perceived relative body size at age 10 and genetic data available. First, we validated the perceived body size at age 10 by investigating the association with a BMI genetic risk score. We then stratified individuals based on their adulthood BMI into overweight and obese. Logistic regression models were used to calculate the odds of type 2 diabetes for individuals who were thin at age 10 and were either now overweight or obese in comparison to overweight or obese individuals who perceived themselves to be average or plump at age 10.
Results: Individuals in the overweight BMI range (25–30 kg/m^2) but who reported being thin, average and plump at age 10 had an average BMI of 27.2, 27.3 and 27.5 kg/m^2 respectively. Despite these very similar current BMIs, individuals who on average had moved up these broad BMI centiles were at 1.53 [95%CI: 1.44, 1.62] higher odds of diabetes than someone who had remained in an average BMI centile. Obese individuals (≥30 kg/m^2) who reported being thin, average and plump at age 10 had an average BMI of 33.6, 33.5 and 34.9 kg/m^2 respectively. Despite slightly lower current BMI, the prevalence of type 2 diabetes was highest in those people, who on average had moved up the broad BMI centiles, with individuals who were thin at age 10, average at age 10 and plump at age 10 having a type 2 diabetes prevalence of 14.6%, 11.0% and 12.3% respectively. This equated to an odds ratio of type 2 diabetes of 1.07 [95%CI: 1.01, 1.13] for the group of people moving up these broad BMI centiles compared to those staying at the same broad centile. These findings were independent of an individuals birthweight and current BMI.
Conclusion: These findings suggest that individuals who remain in higher BMI centiles throughout life may adapt to excess weight in ways that lower the risk of type 2 diabetes in comparison to individuals of similar adult BMI that have moved up the BMI centiles since childhood.

GWAS study on susceptibility to bacterial infections in patients with diabetes

J.R. Simonsen[1,2], A. Käräjämäki[3], I. Toppila[1,2], E. Ahlqvist[4], V. Harjutsalo[1,2], C. Forsblom[1,2], D.M. Aly[4], T. Tuomi[1], M. Lehto[1,2], L. Groop[4], P.-H. Groop[1,2], N. Sandholm[1,2];
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, University of Helsinki, Finland, Helsinki, Finland, [2]Abdominal Center of Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland, Helsinki, Finland, [3]Department of Primary Health Care, Vaasa Central Hospital, Vaasa, Finland, Vaasa, Finland, [4]Department of Clinical Sciences, Lund University Diabetes Centre, Lund University, Skåne University Hospital, Malmö, Sweden, Lund, Sweden.

Background and aims: Diabetes increases the risk of infectious diseases. In addition to classical autoimmune disorders, genetic variations in the human leukocyte antigen (HLA) region have been associated with increased susceptibility to specific bacterial and viral infections e.g. malaria, HIV, tuberculosis, and hepatitis. Finland - being one of the best-documented genetic isolates - is an excellent ground for genetic studies of infection related diseases. The aim of the present genome-wide association study (GWAS) is to identify genetic risk factors, which increase susceptibility to bacterial infections in patients with diabetes.
Materials and methods: For patients with type 1 diabetes (the FinnDiane Study; $n = 5{,}092$) and type 2 diabetes (Diabetes Registry Vaasa Direva; $n = 3{,}499$), nationwide register data on antibiotic drug prescription purchases (The Social Insurance Institution of Finland-KELA; www.kela.fi) and bacterial infections treated at hospital (Hospital Discharge Register; www.stakes.fi) were collected between 1995 and 2014. Each antibiotic purchase and hospitalization was counted as one infection event. The total number of infection events was counted over the follow-up period for each patient. Follow-up years prior to the onset of diabetes as well as years after the diagnosis of end-stage renal disease were excluded. DNA samples were genotyped using HumanCoreExome BeadChips in both the FinnDiane and Direva cohorts. Genotype imputation with 1000 Genomes reference panel resulted in $8.4\text{x}10^6$ and $8.6\text{x}10^6$ SNPs in FinnDiane and Direva, respectively. GWAS analyses were performed with RvTests software using score test, adjusted for mean HbA1c, duration of diabetes, and relatedness matrix, and the results from the two cohorts were combined with fixed effects meta-analysis with METAL software.
Results: Based on the FinnDiane cohort, the narrow sense heritability of this infection risk related phenotype (annual infection rate adjusted for long-term glycemic control) was estimated to be ~26%. Meta-analysis revealed a low-frequency variant (minor allele frequency 1%) associated significantly genome-wide with infection frequency ($p = 2.97 \times 10^{-9}$) at chromosome 5 near the genes *SGCD* and *TIMD4*, with altogether eight SNPs with p value $<10^{-6}$ in the locus. Furthermore, 48 SNPs from 12 loci reached a suggestive p value $<1 \times 10^{-5}$.
Conclusion: Genetic variants at chromosome 5 are associated with an increased risk of bacterial infections in patients with diabetes.

Trial data show the proposed 5 diabetes subgroups from cluster analysis do predict drug response and diabetes progression but simple clinical measures are stronger predictors

J.M. Dennis, B.M. Shields, W.E. Henley, A.G. Jones, A.T. Hattersley;
University of Exeter Medical School, Exeter, UK.

Background and aims: A recent cluster analysis of clinical and biochemical data close to diagnosis in Scandinavian patients (Ahlqvist et al) proposed 5 novel diabetes subgroups (1 autoimmune and 4 non-autoimmune). If these novel subgroups have clinical utility they should help predict the disease progression and drug response of an individual patient. We aimed to use individual data close to diagnosis from a large randomised trial to see if we could replicate the subgroups derived from the cluster analysis. We then went on to evaluate whether the cluster subgroups outperformed simple clinical characteristics in predicting drug response, disease progression and complications in the protocol driven conditions of the clinical trial.
Materials and methods: We evaluated 4,351 participants aged 30–75 with newly diagnosed type 2 diabetes in the ADOPT drug efficacy trial who were randomised to metformin, sulfonylureas or thiazolidinediones

for up to 5 years. We replicated the K-means clustering analysis of Ahlqvist et al to derive 5 patient clusters based on baseline measures of age at diagnosis, HbA1c, BMI, HOMA-IR, HOMA-B and GAD autoantibody status. We compared cluster prevalence and characteristics obtained with those previously reported by Ahlqvist et al. We then tested the predictive ability of the clusters for key patient outcomes (HbA1c response over 1 year, HbA1c progression from year 1 to 5, and 5 year risk of chronic kidney disease stage 3 (CKD, defined as 2 consecutive GFR <60 measures)), and compared results with regression models using 3 continuous routine clinical measures (age of diagnosis, baseline HbA1c and BMI).

Results: The 5 cluster derived subgroups in ADOPT replicated closely those previously reported by Ahlqvist et al as the subgroups were similar in size and had similar baseline characteristics. HbA1c response up to 1 year did vary by cluster subgroups for each drug, however the model incorporating continuous measures of age at diagnosis, baseline HbA1c and BMI had far greater predictive ability (Metformin R^2 0.24 for clusters versus 0.41 for continuous measures ($p < 0.001$), sulfonylureas R^2 0.27 vs. 0.41 ($p < 0.001$), thiazolidinediones R^2 0.17 vs 0.35 ($p < 0.001$)). There was some evidence of differential HbA1c progression by cluster ($R^2 = 0.08$) but continuous measures predicted progression similarly ($R^2 = 0.09$), with older participants progressing more slowly ($p < 0.001$). CKD occurred in 5% of participants and there were differences in risk by cluster ($p < 0.001$), but we found much better CKD risk prediction using continuous measures (C-statistic (equivalent to the area under a ROC curve) 0.63 for clusters versus 0.79 for continuous measures ($p < 0.001$)).

Conclusion: We used cluster analysis of individual data from the ADOPT trial to replicate in both prevalence and clinical characteristics the 5 diabetes subgroups reported by Ahlqvist et al. We show that in a trial setting these cluster derived subgroups do predict drug-specific response, glycaemic progression and complications, to a modest degree. However, the simple clinical measures of age at diagnosis, baseline HbA1c and BMI had much greater predictive ability. These results suggest the best guide to defining a patient's progression and drug response will be to use simple and easily obtained clinical measures and not cluster derived subgroups.

Excess mortality and cardiovascular disease in type 1 diabetes in relation to age at disease onset: a study of 27,195 patients with diabetes

A. Rawshani[1], N. Sattar[2], S. Franzén[3], B. Eliasson[1], A.-M. Svensson[3], S. Gudbjörnsdottir[3];
[1]Institute of Medicine, Gothenburg, Sweden, [2]Institute of Cardiovascular and Medical Sciences, Glasgow, UK, [3]Swedish National Diabetes Register, Gothenburg, Sweden.

Background and aims: Age at diagnosis has emerged as an important risk marker in diabetes. This simple variable may carry valuable information on clinically important factors, pathophysiological mechanisms, age-related variations in clinical care, age-dependent differences in ability to cope with the disease *etc*. Recent studies have demonstrated that age at diagnosis can contribute to identifying subtypes of diabetes in adults, as well as predict risk factor trajectories. No study has examined how age at diagnosis relates to excess risk of death and cardiovascular (CV) outcomes, while accounting for duration of diabetes. To answer this question, we compared individuals with type 1 diabetes (T1D) to matched controls from the general population.

Materials and methods: We estimated the excess risk of all-cause mortality, CV mortality, non-CV mortality, acute myocardial infarction (AMI), stroke, CVD (composite of AMI and stroke), coronary heart disease (CHD), heart failure (HF) and atrial fibrillation (AF). Individuals with diabetes were categorized into five groups, according to age at diagnosis: 0 to 9 years, 10 to 14 years, 15 to 19 years, 20 to 24 years and 25 to 30 years. Analyses were performed using Cox regression, with adjustment for socioeconomic, demographic variables, comorbidities and duration of diabetes.

Results: A total of 27,195 persons with T1D and 135,178 matched controls were included. Median follow-up was 5.1 years; 924 patients with T1D and 1,405 controls died. We observed a remarkable association between age at diabetes onset and excess risk of death and all cardiovascular outcomes. For patients who developed type 1 diabetes before 10 years of age hazard ratio (95% CI) was 4.11 (3.24–5.22) for death, 7.38 (3.65–14.94) for CV death, 11.44 (7.95–16.44) for CVD, 30.50 (19.98–46.57) for CHD, 30.95 (17.59–54.45) for AMI, 6.45 (4.04–10.31) for stroke, 12.90 (7.30–22.51) for HF and 1.17 (0.62–2.20) for AF. Risks of these outcomes declined gradually with increasing age at onset of T1D. With the exception of AF, no hazard ratio fell below 2.0. Risk of non-CV mortality was also greatest among those with early onset of type 1 diabetes. Considering risk factor control, increasing age at diagnosis was associated with better glycemic control, higher blood pressure, higher prevalence of smoking, more physical activity, and higher socioeconomic status. Refer to Figure 1.

Conclusion: Age at onset of type 1 diabetes is a fundamental predictor of survival, as well as all cardiovascular outcomes with the exception of atrial fibrillation. Early onset type 1 diabetes is associated with up to 30 times increased risk of serious cardiovascular outcomes..

Determinants of progression of type 2 diabetes, a cross sectional analysis of UK BioBank

X. Wang[1,2], M. Lonergan[1], L. Donnelly[1], K. Zhou[1], E.R. Pearson[1];
[1]Molecular and Clinical Medicine, Dundee University, Dundee, UK, [2]Science for Life Laboratory, Medical Cell Biology, Uppsala University, Uppsala, Sweden.

Background and aims: The progression after a diagnosis of Type 2 Diabetes (T2D) is highly variable between individuals. We aimed to identify the factors which are associated with the progression of T2D using UK BioBank data.

Materials and methods: 25290 patients in UK Biobank have prevalent diabetes. Diabetes diagnosis type is self-reported in UK biobank so to ensure that we excluded Type 1 Diabetes (T1D) all of the participants had a T1D genetic risk score <0.2132, a robust cut off value to allow only 1% 'contamination' with T1D. We studied 6215 white European patients with T2D with duration <10 years. From these we identified 2 groups, each of 429 patients, matched for duration of diabetes. For each fast progressor (on insulin within 10 years) we identified an individual with the same duration of diabetes but who was diet treated (slow progressor). We investigated the association of clinical and biochemical factors with the risk of progression of T2D in these two groups using multiple logistic regression including enter covariates used here.

Results: When comparing the fast and slow progression groups, the fast progression group was associated with younger age at diagnosis, higher BMI, higher waist to hip ratio, more common usage of statin and fibrate. Interestingly, when we compared the family history of diabetes between the fast and slow progression groups, we observed that a maternal family history of diabetes was associated with greater odds of fast progression (OR = 1.47 [95% CI 1.01–2.12 $P = 0.033$]). There was no association with sibling or paternal family history of diabetes with progression.

Conclusion: Younger age at diagnosis, higher BMI, higher waist to hip ratio, and greater usage of statin and fibrate are associated with increased rate of progression of T2D. The higher prevalence of maternal history of diabetes in the fast progression group suggests an impact of maternal intrauterine environment on offspring diabetes progression which warrants further investigation.

OP 09 Pregnancy and gestational diabetes

49

Increasing prevalence of gestational diabetes according to the results of a population-based screening programme in Hungary between 2009–2017

A. Kun[1], E. Szabó[2,3], J. Tornoczky[4], Z. Kerenyi[5], Á.G. Tabák[3,6];
[1]Department Obstetrics and Gynecology, Tolna County Balassa Janos Hospital, Szekszard, Hungary, [2]Szent Imre Teaching Hospital, Budapest, Hungary, [3]1st Department of Medicine, Semmelweis University Faculty of Medicine, Budapest, Hungary, [4]Diabetes Care Outpatient Unit, Tolna County Balassa Janos Hospital, Szekszard, Hungary, [5]Diabetes Outpatient Clinic, Tóth Ilona Health Service, Budapest, Hungary, [6]Department of Epidemiology and Public Health, University College London, London, UK.

Background and aims: Increasing prevalence of gestational diabetes (GDM) was reported from several countries in the last decade believed to be related to the increasing age and level of obesity of pregnant women. Using data from a population-based screening from a Western county in Hungary, we investigated changes (unadjusted and adjusted for known GDM risk factors) in fasting, 1-hour and 2-hour glucose and the risk of gestational diabetes based on the WHO-2013 diagnostic criteria between 2009 and 2017.

Materials and methods: During a universal screening program in a Western Hungarian region 9,469 of 10,076 pregnant women (age 29.5 ± 5.6 years; mean ± SD) had a 75 g OGTT with the determination of fasting, 1-hour and 2-hour glucose between 16/JAN/2009 and 02/OCT/2017. Based on these OGTTs $n = 1{,}505$ (14.9%) women were diagnosed with GDM. Maternal pre-pregnancy (lifestyle, socioeconomic status, obstetrical, medical and family history) and early pregnancy risk factors (anthropometrics, blood pressure) were collected according to standardized protocols. Time trends in OGTT glucose values were investigated by multiple linear regression, GDM risk by logistic regression with adjustments for calendar time and known risk factors.

Results: Prevalence of GDM increased from 11.6% in 2009 to 15.1% in 2017. Among pre-pregnancy risk factors, maternal age, maternal smoking, positive family history of diabetes, living in a relationship and living in the county capital; among early pregnancy risk factors, body weight and systolic blood pressure were related to both the risk of gestational diabetes and showed an association with the date of the OGTT during the observation period according to univariate analysis (all $p < 0.05$) and thus were deemed potentially explanatory of the time trend in GDM prevalence. Fasting glucose showed a yearly increase of 0.019 (SE 0.002) mmol/l per year in a model adjusted for GDM risk factors without a time trend (model 1), while the addition of all potential explanatory variables except BMI (model 2) decreased this trend to 0.015 (SE 0.002), and further adjustment for BMI (model 3) to 0.008 (SE 0.002) mmol/l. The yearly increase in 1-hour and 2-hour glucose was larger (0.11 SE 0.01 and 0.053 SE 0.006 mmol/l, respectively - model 1) but the attenuation of the coefficients was much smaller in further adjustment (0.08 SE 0.01 and 0.036 SE 0.006 mmol/l, respectively - model 3) although body weight remained the most important explanatory variable. The risk of GDM increased by 9% per year (OR 1.09 95%CI 1.06–1.12 -model 1) which was attenuated to 4.8% (OR 1.048 95%CI 1.02–1.08) in model 3 with body weight being the most important explanatory variable.

Conclusion: The prevalence of GDM significantly increased in the last decade in Hungary reaching epidemic proportions based on WHO-2013 diagnostic criteria. Almost half of this increase was explained by adverse time trends in GDM risk factors (such as body weight, age, family history) however increasing levels of obesity seemed to be most important underlying factor.

Early-onset gestational diabetes compared to late gestational diabetes: maternal characteristics and obstetrical outcomes in a French cohort of 2948 patients

A. Vambergue[1], A. Raynaud[2], A. Caron[1], S. Thinat[2], M. Cazaubiel[2], W. Karrouz[2], G. Ficheur[1], P. Deruelle[1];
[1]University of Lille, Lille, [2]Department of Diabetology, Lille, France.

Background and aims: Based on the IADPSG recommendations, the French guidelines suggested screening with fasting plasma glucose (FPG) test at the first prenatal visit and a 75-g OGTT between 24 and 28 weeks' gestation for gestational diabetes (GDM) diagnosis. The aim of this study was to compare the clinical characteristics and pregnancy outcomes of women with GDM who were diagnosed and treated early in pregnancy (<20 weeks of gestation) with women who were diagnosed and treated late in the pregnancy (24–28 weeks of gestation).
Materials and methods: This study was carried out in Lille between February 2011 and December 2016. Women with risk factors were screened for GDM with a FPG at the first prenatal visit and between 24–28 weeks with a 75-g OGTT using the IADPSG criteria. During this period, we diagnosed 3460 women with GDM. We analyzed the data in a cohort of 2948 women: 1445 women were diagnosed and treated early in pregnancy (<20 weeks of gestation) and 1503 women late in the pregnancy (24–28 weeks of gestation). All women were treated according to the French guidelines. We analyzed the association between time of diagnosis (early versus late) and large for gestational age (LGA) after adjustment on confounding factors as age, parity, pregestational BMI. LGA was defined above the 90th percentile of gestational age adjusted for parity, fetal sex and maternal biometrics.
Results: 41.7% of women were classified as early-onset gestational diabetes. There was no significant difference for age and parity in the two groups. Women with early-onset GDM had a higher BMI ($p < 0.001$) and were more often treated by insulin (41.2% versus 22.4% $p < 0.001$) compared to late GDM. The mean of HbA1c was significantly lower in the early-onset GDM compared to late GDM group ($p < 0.001$). The rate of LGA was not significantly different between the groups. The rate of obstetric were not significantly different between the 2 groups except a lower rate of shoulder dystocia in the early-onset GDM ($p < 0.05$). In multivariate analysis, there was not significant relationship between time of diagnosis and LGA (RR: 1.07 CI 95% 0.88–1.30).
Conclusion: In this large cohort, a high proportion of women with GDM have been diagnosed early in pregnancy. However, the time of diagnosis has no influence on the rate of LGA. There is an urgent need for randomized controlled trials that investigate any benefits and possible harms of treatment of early-onset GDM
Disclosure: **A. Vambergue:** None.

Pregnancy and neonatal diabetes outcomes in remote Australia: the PANDORA study

L. Maple-Brown[1], A. Brown[2], I.-L. Lee[1], F. Barzi[1], C. Connors[1], J.A. Boyle[3], E. Moore[4], C. Whitbread[1], M. Kirkwood[1], D. Longmore[1], K. O'Dea[1], J. Oats[5], H.D. McIntyre[6], P. Zimmet[3], J.E. Shaw[7];
[1]Menzies School of Health Research, Darwin, [2]South Australian Health and Medical Research Institute, Adelaide, [3]Monash University, Melbourne, [4]Aboriginal Medical Services Alliance, NT, Darwin, [5]Melbourne University, Melbourne, [6]Mater Medical Research Institute, Brisbane, [7]Baker Heart and Diabetes Institute, Melbourne, Australia.

Background and aims: In Australia's Northern Territory, 33% of babies are born to Indigenous mothers, and type 2 diabetes in pregnancy prevalence is 10 times higher than in non-Indigenous mothers. The PANDORA study is a longitudinal birth cohort recruited from a hyperglycaemia in pregnancy register. Here we assess relationships between metabolic markers in cord blood and perinatal outcomes.
Materials and methods: Data include antenatal and birth clinical information, cord blood, neonatal anthropometry. Of 1135 women (48% Indigenous, 32% Europid, 7% Indian subcontinent), 900 had diabetes: 175 type 2 diabetes (T2D), 86 newly diagnosed diabetes in pregnancy (DIP), 639 GDM. Women without hyperglycaemia in pregnancy were also recruited (NGT, $n = 235$). Glucose, lipids, c-peptide, c-reactive protein (CRP) were measured in cord blood for 723 babies (NGT = 168, GDM/DIP = 442, T2D = 113). Data were analysed using t-tests, chi-squared tests, multivariate logistic regression and mediation analysis for outcomes of birth weight z-score, large for gestational age (LGA), neonatal fat (calculated from anthropometry) and small for gestational age (SGA). C-peptide, triglycerides were log-transformed.
Results: Among those with cord blood samples, diabetes type differed for Indigenous ($n = 374$) and non-Indigenous ($n = 349$) women (T2DM, 27% vs 3%; GDM/DIP, 50% vs 73%, $p < 0.001$), with similar proportions with NGT (23% vs 23%). Indigenous women were younger and had a higher BMI. Trends were evident across diabetes types (NGT to GDM/DIP to T2D) for: increasing c-peptide [mean (95% CI), 0.35 nmol/L (0.31, 0.39), 0.39 nmol/L (0.37, 0.42), 0.66 nmol/L (0.57, 0.75), $p < 0.001$], decreasing glucose [4.4 mmol/L (4.2, 4.6), 4.1 mmol/L (3.9, 4.2), 4.1 mmol/L (3.9, 4.4), $p < 0.029$], decreasing HDL-cholesterol [0.7 mmol/L (0.66, 0.74), 0.66 (0.63, 0.68), 0.56 (0.52, 0.61), $p < 0.001$], decreasing triglycerides [0.43 mmol/L (0.40, 0.47), 0.37 (0.35, 0.69), 0.43 (0.39, 48), $p = 0.001$], increasing rates of CRP >0.3 mg/L (26%, 49%, 47%, $p < 0.001$). After adjustment for diabetes type, maternal age, ethnicity, BMI and parity; c-peptide and glucose (inverse) were independently associated with birthweight z-score, LGA and neonatal fat. Triglycerides were associated, independent of c-peptide and glucose, directly with SGA and inversely with birthweight z-score. Adjustment for medication did not change results. On pathway analysis c-peptide mediated 20% (95% CI 15%–38%) of the contribution of maternal BMI to LGA and 14% (10%–22%) for birth weight z-score.
Conclusion: In this observational birth cohort, high c-peptide was the metabolic marker that was independently associated with neonatal adiposity outcomes. The inverse relationship of cord blood triglycerides with birthweight (and direct with SGA) is consistent with previous European GDM studies, hypothesised to be related to enhanced lipoprotein lipase activity with increased adipose tissue. Longitudinal study of the cohort will inform the significance of these findings on the child's subsequent risk profile.

Randomised controlled trial of very tight versus less tight glycaemic targets in women with gestational diabetes: preliminary results

P. Popova[1,2], A. Tkachuck[1], Y. Bolotko[1], A. Gerasimov[1], E. Pustozerov[1,3], E. Vasilyeva[1], O. Li[1], I. Zazerskaya[1], E. Grineva[1,2];
[1]Almazov National Medical Research Centre, Saint Petersburg, [2]Saint Petersburg Pavlov State Medical University, Saint Petersburg, [3]Saint Petersburg State Electrotechnical University, Saint Petersburg, Russian Federation.

Background and aims: There is wide variation in international guidelines concerning glycaemic treatment targets for women with gestational diabetes (GDM). We conducted a randomized clinical trial to assess the effect of different intensities of glycaemic control in pregnant women with GDM on maternal and infant health outcomes.
Materials and methods: We randomly assigned women who were in the 8th to 31st week of gestation and who met the World Health Organization (WHO 2013) criteria for GDM to 2 groups per target glycaemic levels: GDM1 (very tight glycaemic targets, fasting blood glucose (FBG) <5.1 mmol/L and <7.0 mmol/L postprandial) and GDM2 (less tight glycaemic targets, <5.3 mmol/L and <7.8 mmol/L, respectively). All participants were instructed on diet and lifestyle changes. In case of

exceeding the target blood glucose levels (in 2 or more measurements per week in group 1 and in more than 1/3 of measurements per week in group 2) insulin therapy was started. The primary study outcome was the incidence of large for gestational age (LGA) infants. Secondary outcomes were: for the baby - composite of neonatal death or severe morbidity (nerve palsy, bone fracture and shoulder dystocia), gestational age at birth, birthweight, macrosomia (birth weight >4000 g), small-for-gestational age (SGA) and hypoglycaemia; for the woman - pre-eclampsia, mode of birth, mean daily fasting and postprandial capillary glucose (PPG) concentration during treatment, proportion of glucose values within target, proportion of women requiring insulin therapy.
Results: The women from GDM1 ($N = 201$) and GDM2 ($N = 194$) groups did not differ in terms of age (31.9 ± 4.6 vs 31.8 ± 4.5 years, $p = 0.681$) and pre-pregnancy BMI (25.4 ± 5.4 vs 25.8 ± 6.6 kg/m^2, $p = 0.481$). We observed no significant difference between the groups in the frequency of LGA infants (15.9% and 16.5%, for GDM1 and GDM2, respectively, $p = 0.892$) using intention-to-treat analysis. There were no perinatal deaths. Between the two groups, there were no significant differences with regard to the frequency of the composite outcome (2.0% and 1.6%, $P = 1.0$), gestational age at birth (38.9 ± 1.3 vs 38.8 ± 1.5 weeks, $p = 0.223$), birthweight (3435 ± 489 vs 3396 ± 519 g, $p = 0.438$), macrosomia (13.4% and 11.9%, respectively, $p = 0.653$), SGA (9.0% and 9.3%, respectively, $p = 1.0$), hypoglycaemia (7.6% and 8.1%, $p = 1.0$), pre-eclampsia (16.8% and 16.3%, $p = 1.0$), cesarian section rate (24.5% and 30.6%, $p = 0.214$), and mean daily FBG (4.8 ± 0.4 mmol/L vs 4.9 ± 0.4 mmol/L, $p = 0.066$). GDM1 group achieved lower mean daily PPG values (6.2 ± 0.5 mmol/L vs 6.4 ± 0.6 mmol/L, $p < 0.001$). The proportion of women with glucose values within GDM1 targets was 29% and 16% in GDM1 and GDM2 groups, respectively ($p = 0.007$). The proportion of women with glucose values within GDM2 targets was 85.2% and 70.5% in GDM1 and GDM2 groups, respectively ($p = 0.002$). The proportion of women requiring insulin therapy was higher in GDM1 compared to GDM2 group (49% and 27%, $p < 0.001$).
Conclusion: Striving for very tight target glycaemic levels in women with GDM did not improve pregnancy outcomes but almost doubled the proportion of women requiring insulin therapy.

Glyburide versus insulin for the prevention of perinatal complications of gestational diabetes: a pragmatic, non inferiority, randomised trial

F. Lorenzini[1], H. Affres[2], C. Rolland[3], A. Vambergue[4], M. Cazaubiel[4], H. Legardeur[5], P. Rosenberg[6], N. Bourcigaux[7], F. Maillot[8], A. Rod[9], I. Heron[10], V. Castera[11], S. Laboureau[12], F. Bretelle[13], M.-V. Senat[14,15];
[1]CHU, Toulouse, [2]APHP, Le Kremlin Bicêtre, [3]APHP, Clamart, [4]CHRU, Lille, [5]APHP, Colombes, [6]CH, Poissy, [7]APHP, Paris, [8]CHU, TOURS, [9]CHU Côte de Nacre, Caen, [10]CHU, Rouen Bois Guillaume, [11]Hopital Saint Joseph, Marseille, [12]CHU, Angers, [13]APHM, Marseille, [14]APHP, Le Kremlin-Bicêtre, [15]INSERM, Le Kremlin Bicêtre, France.

Background and aims: Use of oral hypoglycemic drugs in gestational diabètes (GDM) is unusual in european countries, because of results of metanalysis of 7 randomized clinical trials (RCT) comparing Glyburide and Insulin, showing an increase in macrosomia and neonatal hypoglycemia. However, primary outcome in those trials was maternal blood glucose control and not prevention of neonatal complications. Thus, we decided to compare oral glyburide and subcutaneaous insulin for prevention of perinatal complications in women with GDM requiring pharmacotherapy
Materials and methods: We conducted a non-inferiority RCT between 2012 and 2016 in France. Participants were women with singleton pregnancies and GDM diagnosed between 24 and 34 weeks. They were randomly assigned to receive Glyburide (2.5 to 20 mg/d) or Insulin after failure of 10-day well-conducted lifestyle measures.Primary outcome was a composite neonatal criterion including macrosomia, neonatal hypoglycemia or hyperbilirubinemia. Secondary outcomes were maternal glycemic control, maternal/neonatal complications, including maternal hypoglycemia, and maternal satisfaction. Non-inferiority was demonstrated if the difference in composite criteria between groups was <7%.
Results: 914 women were randomized; 18% switched from Glyburide to Insulin. 367 and 442 women and their neonates were analyzed in the Glyburide and the Insulin groups, respectively, in a per-protocol perspective. Frequency of the composite criterion was 23.4% in Insulin group and 27,6% in Glyburide group. Difference was 4.2% 95%CI [−2%; 10.5%]. RR: 1.2 [0.9; 1.5], mainly due to neonatal hypoglycemia, more frequent in Glyburide group. However, we found no difference in severity of hypoglycemia, neonatal transfer, or delivery complications. Maternal glycemic control during pregnancy was significantly better in Glyburide group, mainly for fasting glycaemia. Maternal hypoglycemia <0.4 g/l were more frequent in the Glyburide group, but decrease along the study. Women satisfaction was significantly better in the Glyburide group.
Conclusion: Non-inferiority of glyburide was not demonstrated since the non-inferiority limit was included in the confidence interval. Nevertheless, easy use of oral glyburide, small difference in frequency of the composite criterion, improved maternal glycemic control with low number of symptomatic hypoglycemia, and better maternal satisfaction , should encourage to consider glyburide as an option in treatment strategy of GDM. Prescription strategy of oral drug, including diet advice remains to be established to avoid maternal hypoglycemia.

Which growth standards should be used to assess infant size in pregnancies affected by type 1 diabetes? An ancillary study from the CONCEPTt clinical trial

C.L. Meek[1], R. Corcoy[2], D.S. Feig[3], H.R. Murphy[4];
[1]Metabolic Research Laboratories, University of Cambridge, Cambridge, UK, [2]Hospital de la Santa Creu i Sant Pau, Barcelona, Spain, [3]Mount Sinai Hospital, Toronto, Canada, [4]University of East Anglia, Norwich, UK.

Background and aims: Pregnant women with type 1 diabetes (T1D) are at risk of multiple complications during pregnancy and frequently give birth to infants who are large for gestational age (LGA: >90th percentile for gestational age). However, there is considerable controversy about the optimal method for assessing and comparing infant size at birth. Although neonatal growth references have been used in the past, growth standards are now in common use, which describe expected fetal growth and birthweight under optimal conditions. Examples include the INTERGROWTH and GROW data which incorporate various neonatal and/or maternal parameters to enhance the precision of the birthweight centile estimate. The CONCEPTt study identified high levels of LGA in T1D offspring. The aim of the current study was to assess the methods available for calculation of birthweight centile, and to compare which approach is most useful for infants of women with T1D.
Materials and methods: The CONCEPTt trial was a multicentre, open-label, randomised controlled trial which recruited women with T1D in pregnancy or planning pregnancy. Women monitored their blood glucose using home capillary glucose monitoring (HGM) and were randomized to receive additional continuous glucose monitoring (CGM). Participants were recruited at 31 hospitals in Europe, Canada and North America. 200 infants were born to mothers enrolled in CONCEPTt. Birthweight and anthropometry were measured by trained staff. Centiles were

calculated for each infant using GROW, INTERGROWTH and WHO standards. Rates of LGA were compared for each centile method.
Results: 200 infants were born during CONCEPTt, with mean gestational age 37.0 weeks (sd 1.7 wks) and a mean birthweight of 3564 g (sd 714 g). Using country specific data for GROW, which incorporates maternal height, weight, ethnicity and parity and infant sex and gestational age, the mean birthweight centile was 81.9, median 94.9, and 122 (61%) of infants were LGA. Using INTERGROWTH, which incorporates infant sex and estimated gestational age, the mean centile was 85.2, median 94.6, and 132 (66%) of infants were LGA. WHO standards identified only 29% of infants as LGA. Calculation of LGA using GROW standards identified 48/70 (69%) infants admitted to NICU for >24 hours and 32/43 (74%) infants with neonatal hypoglycaemia. Calculating LGA by INTERGROWTH standards, identified 51/70 (73%) infants admitted to NICU and 32/43 (74%) infants with neonatal hypoglycaemia. For SGA, GROW standards identified 3/70 infants with NICU admission and 1/43 infants with neonatal hypoglycaemia. For SGA, INTERGROWTH standards identified 2/70 infants with NICU admission and 0/43 infants with neonatal hypoglycaemia.
Conclusion: Rates of LGA varied depending upon the standards used. This is most likely due to their different approaches to preterm infants. INTERGROWTH and GROW centiles performed similarly but each has strengths and limitations when applied to the T1D population. INTERGROWTH and GROW were both able to identify similar proportions of infants at risk of complications. WHO standards do not make allowance for preterm infants which renders them unsuitable for use in T1D offspring.

OP 10 Where, when and hows of rapid acting insulins

55

Total and severe hypoglycaemia is reduced with use of inhaled Technosphere Insulin (TI) relative to insulin aspart in type 1 diabetes

F. Pompilio[1], L. Blonde[2], S. Bruce[3], M. Grant[4], D.M. Kendall[1];
[1]MannKind Corporation, Westlake Village, [2]Ochsner Clinic, New Orleans, [3]MannKind Corporation (Clinical Development Consultant), Westlake Village, [4]MannKind Corporation, Danbury, USA.

Background and aims: Hypoglycemia (HG) and fear of HG limit effective insulin therapy and contribute to suboptimal glycemic control. Ultra-short acting insulins reduce HG risk by providing glucose-lowering effect early and reducing the risk of late post-prandial HG. AFFINITY-1, a treat-to-target study in T1D on multiple daily injection therapy, demonstrated one such ultra-short acting insulin, TI, was non-inferior to SC aspart in A1C reduction. Consistent with its action profile, a lower rate of HG was observed in TI users overall, particularly in the 2–5 h post-meal interval and in those achieving target A1C <7%. This analysis evaluates the rates of HG as a function of A1C achieved in subjects treated with TI compared to insulin aspart at the end of 24 weeks of treatment.
Materials and methods: In this post hoc analysis rates of HG were compared relative to end of treatment A1C levels in subjects treated with either TI or insulin aspart from the AFFINITY 1 study. A total of 18,706 HG events occurred in 129 subjects treated with TI and 150 subjects treated with insulin aspart. A negative binomial regression including treatment, region, type of basal insulin, and A1C at end of treatment was conducted to determine LS-mean HG rates for the two treatment groups.
Results: On average, subjects on TI experienced 30% fewer HG events than those on aspart: 6983 events in 129 subjects (54.1 events per subject) vs. 11723 events in 150 subjects (78.2 events per subject). The incidence of severe HG was similarly reduced (21.7% vs. 31.3%). Additionally, subjects on TI who reported severe HG experienced fewer events than those on aspart (59 events in 28 subjects or 2.1 severe HG events per subject during the trial) vs. 127 events in 47 subjects or 2.7 severe HG events per subject during the trial). Mean rates for all HG and severe HG obtained from combined SMBG and AE reporting were significantly lower with TI than with aspart. The negative binomial regression analysis yielded an LS-mean HG rate for patients on TI 26% lower than comparable patients on aspart across the entire A1C range (mean ratio: 0.74, 95%CI: 0.68–0.81).
Conclusion: TI's rapid onset and ultra-short action provide insulin when needed at meals and between meals. This profile improves overall and prandial glucose control and, as demonstrated in AFFINITY-1, has the potential to reduce the risk of late post-meal HG.

Structured self-management education for insulin pump therapy (INPUT): results from a randomised controlled trial

D. Ehrmann[1], B. Kulzer[1], M. Schipfer[1], B. Lippmann-Grob[2], T. Haak[2], N. Hermanns[1];
[1]Research Institute of the Diabetes Academy Bad Mergentheim (FIDAM), Bad Mergentheim, [2]Diabetes Clinic Mergentheim, Bad Mergentheim, Germany.

Background and aims: Continuous subcutaneous insulin infusion (CSII) offers many technological features which allow users to individualise their therapy to optimise glycaemic control. However, patients need a vast amount of skills and training to effectively use these features. No structured education programme has been developed specifically for CSII-therapy that has been evaluated in a randomised controlled trial. We developed a structured self-management education program for CSII-therapy (INPUT) and evaluated its efficacy in a randomised controlled trial with a six-month follow-up.
Materials and methods: 254 patients with CSII-therapy were randomized to either receive the INPUT education programme or treatment-as-usual. All patients were already performing CSII-therapy for 8.7 ± 6.8 years, with a mean diabetes duration of 23.1 ± 12.6 years. Primary outcome was reduction in HbA1c from baseline to six months after the end of the intervention. Secondary outcomes were incidence of severe hypoglycaemic events requiring third party assistance, diabetes distress, depressive symptoms, and usage of pump features.
Results: At the six-month follow-up, the INPUT-group showed a significant reduction in HbA1c (8.33 ± 0.8 vs. 8.04 ± 0.9; $p < 0.0001$), but HbA1c in the control group remained unchanged (8.33 ± 1.0 vs. 8.27 ± 1.0; $p = 0.11$). The between-group difference in HbA1c reduction was significant, favouring INPUT (Δ −0.22%, 95% CI −0.38 to −0.06; $p = 0.003$). Furthermore, the chance to achieve optimal glycaemic control at follow-up (HbA1c <7.5%) was 1.98-times higher in the INPUT-group than in the control group (95% CI 1.04 to 3.78; $p = 0.03$). Incidence rate ratio of severe hypoglycaemia was 3.55-times higher for participants in the control group than for those in the INPUT-group (95% CI 1.50 to 8.43; $p = 0.004$). Diabetes distress (Δ −5.80; 95% CI −8.87 to −2.73; $p = 0.0003$) and depressive symptoms (Δ −2.08; 95% CI −3.89 to −0.29; $p = 0.011$) were significantly more reduced in the INPUT-group. After the end of the intervention, participants in the INPUT-group also started to use temporary basal rates ($p = 0.014$) as well as bolus options ($p = 0.01$) more often than participants in the control group.
Conclusion: In this study, participants already performed CSII-therapy without achieving optimal glycaemic control. The beneficial effects of participating in INPUT were not only seen in medical outcomes such as improvement in glycaemic control and reduction of severe hypoglycaemic events, but also in psychosocial outcomes and behavioural changes. Therefore, the efficacy of the INPUT education programme could be demonstrated. Considering the higher costs of CSII-therapy, these beneficial effects of a relatively inexpensive group education programme have health-economic implications.

The ultra-rapid insulin BioChaperone Lispro shows favourable pharmacodynamics and pharmacokinetics compared to faster insulin aspart and insulin aspart in insulin pumps

G. Meiffren[1], O. Klein[2], C. Seroussi[1], A. Ranson[1], J. Arrubla[2], J. Correia[1], M. Gaudier[1], O. Soula[1], R. Soula[1], B. Alluis[1], S. Glezer[1], T. Heise[2], B. Bode[3];
[1]Adocia, Lyon, France, [2]Profil, Neuss, Germany, [3]Atlanta Diabetes Associates, Atlanta, USA.

Background and aims: BioChaperone Lispro is an ultra-rapid insulin lispro formulation designed to better mimic the physiological timing of prandial insulin action than conventional insulin analog formulations and to achieve a more stable blood glucose control. This clinical trial is the first to investigate the pharmacodynamic (PD) and pharmacokinetic (PK) properties of the two ultra-rapid insulins BioChaperone Lispro (BCLIS) and faster insulin aspart (FIA) and of the conventional insulin analog aspart (ASP).
Materials and methods: Forty-three otherwise healthy participants with type 1 diabetes were enrolled in this phase 1 single center, double blind, randomised, three period cross-over clinical trial. Each insulin formulation was administered with an insulin pump under automated euglycaemic clamp conditions (blood glucose target 5.5 mmol/L). A priming dose was injected around 5 hours before a bolus dose of 0.15 U/kg given at time = 0 on top of a 0.01 U/kg/h basal infusion maintained from pump priming to the end of the clamp procedure, 10 hours after the bolus administration. PK was assessed using a validated assay for insulin aspart and insulin lispro.
Results: BCLIS was associated with significantly higher early insulin exposure ($AUC_{INS\ 0\text{-}1h}$ BCLIS 68 ± 27; ASP 43 ± 22; FIA 59 ± 21 h.mU/L, $p < 0.001$ for BCLIS vs ASP; $p = 0.028$ for BCLIS vs FIA), lower late exposure ($AUC_{INS\ 2\text{-}6h}$ 81 ± 43 vs. 95 ± 41 vs. 93 ± 45 h mU/L, $p < 0.001$; $p = 0.002$) and earlier time to late half-maximum exposure ($t_{late0.5INSmax}$ 147 ± 48 vs 183 ± 68 vs 165 ± 59 min, $p < 0.001$; $p = 0.003$) than FIA and even higher differences to ASP (figure). Compared to ASP, BCLIS had significantly faster-on and faster-off activity with higher area under the glucose infusion rate curves in the first two hours ($AUC_{GIR\ 0\text{-}2h}$, mean ± SD 592 ± 275 vs. 500 ± 244 mg/kg, $p < 0.0038$), lower $AUC_{GIR\ 2\text{-}6h}$ (784 ± 402 vs 980 ± 453 mg/kg, $p = 0.0015$) and earlier times to early and late half-maximum GIR ($t_{early0.5GIRmax}$ 44 ± 22 vs 58 ± 19 min, $p < 0.0001$; $t_{late0.5GIRmax}$ 210 ± 68 vs 232 ± 52 min, $p = 0.0020$). Compared to FIA, BCLIS showed similar early glucose-lowering effects and a significantly lower late glucose-lowering effect with reaching $t_{late0.5GIRmax}$ earlier (147 ± 48 vs 165 ± 59 min, $p = 0.0017$). All three formulations were safe and well tolerated.
Conclusion: Administered with an insulin pump, BCLIS exhibits ultra-rapid PK and PD properties compared to ASP, and favorable profiles compared to the ultra-rapid FIA formulation.

Figure: Mean baseline adjusted glucose infusion rate (GIR) (left) & PK (right) profiles after a subcutaneous bolus dose of BCLIS, FIA or ASP administered with an insulin pump on top of a basal infusion.

Long-term safety and efficacy of intraperitoneal insulin infusion from implanted pumps in a large series of patients with type 1 diabetes and initial high glucose variability

E. Renard[1,2], B. Guerci[3,4], N. Jeandidier[5,6], EVADIAC;
[1]Department of Endocrinology, Diabetes, Nutrition, CHU Montpellier, Montpellier, [2]Institute of Functional Genomics, University of Montpellier, INSERM, CNRS, Montpellier, [3]Department of Endocrinology, Diabetes and Nutrition, CHU Nancy, Vandoeuvre les Nancy, [4]University of Lorraine, Nancy, [5]Department of Endocrinology, Diabetes and Nutrition, CHU Strasbourg, Strasbourg, [6]University Louis Pasteur, Strasbourg, France.

Background and aims: Intra-peritoneal (IP) delivery allows an alternative route for insulin therapy in patients with type 1 diabetes (T1D) who present high glucose variability under subcutaneous insulin treatment. We assessed from the data of a post authorization safety study the long-term safety and efficacy on glucose control of IP insulin therapy.
Materials and methods: Two hundred and fifty-three patients followed in 12 university hospitals have been enrolled in a multinational, multicenter, observational, prospective cohort study for patients with T1D who are treated with Insuman Implantable 400 IU/mL in Medtronic MiniMed implantable pumps. Visits occurred according to routine clinical practice for the use of an implantable pump, which is at refill visits (every 40–45 days) and at ad hoc visits related to complications of the insulin treatment regimen or pump. The primary objective of the study was to better characterize identified risks of severe hypoglycemia, hyperglycemia (caused by insulin underdelivery due to pump jamming, pump dysfunction or catheter occlusion), pump pocket infection, abnormal healing (at the surgical incision site after device implantation), and skin erosion. Data after a follow-up of 0.9 ± 0.3 year (>1 year in 97.6%) has been analyzed, representing a cumulated experience of 343.5 patient-years (PY).
Results: The cohort includes 241 T1D patients who had been using MIP for 15.1 ± 7.7 years at inclusion and 12 new patients. The patient characteristics at inclusion were: 149F/104M, age: 56.6 ± 10.9, BMI: 25.7 ± 4.3, T1D duration: 35.4 ± 12.1 years, HbA1c: 7.6 ± 1.0%. IP insulin was motivated by brittle diabetes in 68% cases and frequent severe hypoglycemia in 26.9%. Comorbities included: cardiovascular diseases in 26%, retinopathy in 51.4%, nephropathy in 23.3%, neuropathy in 31.5%. Premature discontinuation occurred in 4 cases: 2 by patient decision and 2 deaths of cardiovascular origin. The incidences of severe hypoglycemia, hyperglycemia due to insulin underdelivery, pump pocket infection and skin erosion were 7.3, 18, 1.2 and 0.3 per 100 PY, respectively. No ketoacidosis was reported. Surgical outcomes included 7 temporary and 1 definitive explantations, and 9 catheter replacements (incidence: 2.6/100 PY). Longer duration of IP experience was significantly associated with lower risk of hyperglycemic events.
Conclusion: Our study shows sustained efficacy of IP insulin on glucose control with a low incidence of severe hypoglycemia in these patients with multiple comorbidities and initial high glucose variability. Hyperglycemic episodes related to underdelivery events were limited and solved in most cases with no surgical intervention. This data supports the utility of IP insulin delivery from implanted pumps in T1D patients with major glucose control issues.

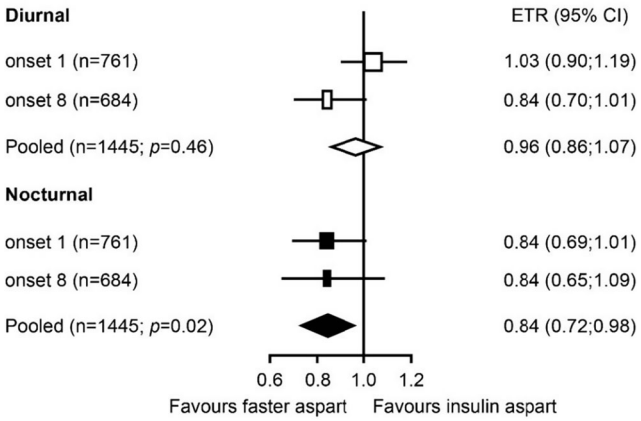
Hypoglycaemia with mealtime fast-acting insulin aspart versus insulin aspart across two large type 1 diabetes trials

C. De Block[1], A. Carlson[2], L. Rose[3], T. Gondolf[4], A. Gorst-Rasmussen[4], T.W. Boesgaard[4], W. Lane[5];
[1]Department of Endocrinology-Diabetology-Metabolism, Antwerp University Hospital, Antwerp, Belgium, [2]International Diabetes Center, Minneapolis, USA, [3]Institute of Diabetes Research, Münster, Germany, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Mountain Diabetes and Endocrine Center, Asheville, USA.

Background and aims: Hypoglycaemia is a ubiquitous challenge with insulin treatment in type 1 diabetes (T1D), with nocturnal episodes of particular concern. The aim of this analysis was to investigate the safety of mealtime fast-acting insulin aspart (faster aspart) across two large double-blind, treat-to-target, randomised T1D trials comparing faster aspart and insulin aspart (IAsp).
Materials and methods: Analysis of severe (as defined by the American Diabetes Association) or blood glucose-confirmed (3.1 mmol/L [<56 mg/dL]) hypoglycaemia was performed across two trials evaluating the efficacy and safety of faster aspart vs IAsp by multiple daily injections in adults with T1D: a 52-week trial in combination with insulin detemir (onset 1; $n = 761$), and a 26-week trial in combination with insulin degludec (onset 8; $n = 684$).
Results: Faster aspart was confirmed to be non-inferior to IAsp regarding change from baseline in HbA_{1c} in both trials, with a statistically significantly greater HbA_{1c} reduction with faster aspart in onset 1. Importantly, nocturnal hypoglycaemia rates were consistently lower with faster aspart vs IAsp in both trials (pooled estimated treatment rate ratio [ETR] 0.84 [95% CI: 0.72;0.98]; $p = 0.02$) (Figure), while no significant difference was observed for overall (pooled ETR 0.94 [95% CI: 0.85;1.05]) and diurnal hypoglycaemia rates (pooled ETR 0.96 [95% CI: 0.86;1.07]) with some heterogeneity across trials.
Conclusion: Analysis across two large trials supports the safety of mealtime faster aspart, with lower rates of nocturnal hypoglycaemia with faster aspart vs IAsp.

Figure: Diurnal and nocturnal severe or blood glucose-confirmed hypoglycaemic events[a]



[a]An episode that is severe (requiring assistance of another person to actively administer carbohydrate or glucagon, or take other corrective actions) or blood glucose-confirmed by a plasma glucose value 3.1 mmol/L (<56 mg/dL) with or without symptoms consistent with hypoglycaemia.
Pooled ETR and CI is obtained from a fixed-effects meta-analysis. Study duration of onset 1 was 52 weeks and onset 8 was 26 weeks. For onset 1, weighted contribution is 63.5% for diurnal hypoglycaemia and 65.2% for nocturnal hypoglycaemia. For onset 8, weighted contribution is 36.5% for diurnal hypoglycaemia and 34.9% for nocturnal hypoglycaemia.
CI, confidence interval; ETR, estimated treatment rate ratio; faster aspart, fast-acting insulin aspart; N, total number of subjects in faster aspart/insulin aspart arm.

Ultra rapid lispro (URLi) reduces postprandial glucose excursions vs lispro in patients with type 1 diabetes at multiple meal-to-dose timing intervals

L. Plum-Morschel[1], J.K. Leohr[2], R. Liu[2], S.R. Reddy[2], M.A. Dellva[2], S.T. Lim[3], M.T. Loh[3], M.P. Knadler[2], T.A. Hardy[2], C. Kazda[4];
[1]Profil Mainz GmbH & Co. KG, Mainz, Germany, [2]Eli Lilly and Company, Indianapolis, USA, [3]Lilly-NUS Centre Clin Pharm Pte Ltd, Singapore, Singapore, [4]Lilly France, Neuilly-sur-Seine, France.

Background and aims: Ultra Rapid Lispro (URLi; LY900014), a novel mealtime insulin in Phase 3 development, is shown to reduce postprandial glucose after subcutaneous injection.
Materials and methods: This 2-part, randomised, double-blind, Phase 1b study evaluated the differences in PK and PD between URLi and lispro (Humalog®) in 30 patients with T1D. Part A used a 6-period crossover design to evaluate safety and compare PK and postprandial glucose response to solid mixed meal tolerance tests (MMTT) with the same, individualised doses of URLi or lispro at different injection-to-mealtime intervals (−15, 0, and +15 min). Part B evaluated the safety, PK, and PD during 2 wks of multiple daily dosing (immediately before a meal) in a parallel design. Patients were stabilised overnight to a fasting blood glucose level of 7 mmol/L before the MMTT procedure.
Results: In Part A, URLi reduced glucose excursions (assessed as change in area under the concentration curve vs. time [ΔAUC]) vs. lispro during the first 2 hrs (ΔAUC0-2h) and entire 5 hrs (ΔAUC0-5h) of the MMTT regardless of dose timing (Figure). URLi reduced ΔAUC0-2h by 103% ($p = 0.008$), 39% ($p = 0.031$), and 16% ($p = 0.096$), and ΔAUC0-5h by 40% (p = NS), 44% ($p = 0.097$), and 42% ($p = 0.026$) vs. lispro at −15, 0, and +15 min (significance level = 0.1). The PK and PD profiles for URLi and lispro were sustained after 2 wks of outpatient dosing (Part B). Similar numbers of hypoglycaemic events occurred between treatments during MMTTs. During 2 wks of outpatient dosing, the number of events was numerically lower for URLi vs. lispro. Local tolerability was similar between treatments.
Conclusion: These results provide preliminary evidence that URLi may improve postprandial glucose control in T1D.

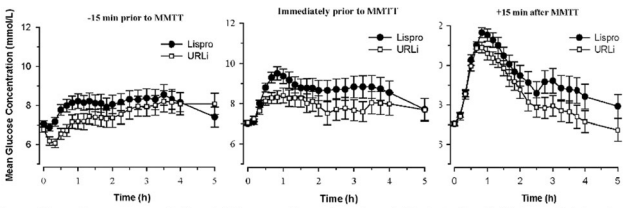

Figure: Mean glucose concentration (±SE) versus time when dosed 15 min before (left), immediately prior (middle), and 15 min post-test meal (right) by treatment following a single dose (Part A).

OP 11 Pain is in the brain

61

Painful diabetic neuropathy is characterised by impaired sensory cortex and thalamic haemodynamic response to exogenous pain

M. Greig[1], I.D. Wilkinson[2], R. Gandhi[1], D. Selvarajah[2], S. Tesfaye[1];
[1]Royal Hallamshire Hospital, Sheffield, [2]University of Sheffield, Sheffield, UK.

Background and aims: Diabetic peripheral neuropathic pain (DPNP) negatively impacts quality of life of affected individuals and exacts an enormous socio-economic cost. Currently treatments provide inadequate management of pain in many patients. Our understanding of the risk factors that underlie the development of chronic neuropathic pain is limited. Recent studies have suggested an important contribution of dysfunction in descending pain modulatory circuits to pain 'chronification'. The aim of this study was to measure cerebral perfusion of the pain processing areas of the brain using MR-Dynamic Susceptibility Contrast (MR-DSC) imaging at rest and under experimental pain condition.
Materials and methods: 74 subjects [55 with T1DM (20 DPNP, 23 painless-DPN, 13 no-DPN) and 19 healthy non diabetic volunteers] underwent detailed clinical and neurophysiological assessment (NISLL+7 tests of nerve function; DN4 pain questionnaire). MR images were obtained at 3T using a MR-DSC, T2*-weighted technique (TR/TE = 12]0/35 ms; 72 dynamics) to assess the passage of a bolus of intravenous gadolinium-chelate through cerebral vascular bed. Subjects were scanned at baseline and during 90s of heat-pain applied to the right lateral thigh (non-neuropathic area). The time-to-peak (TTP) concentrations of gadolinium in the right and left thalami (Rt-T and Lt-T), and right and left sensory cortices (Rt-SC and Lt-SC), were measured.
Results: At baseline, the mean TTP concentrations (s) in the regions of interest (ROIs) were shorter in the DPNP group [*e.g.* Rt-T: Mean (SD): 9.22(1.13) *vs* HV 9.83 (0.99), no-DPN 9.59 (0.90), painless-DPN 9.94 (0.97)] although these were not statistically significant (e.g. Rt-T, $p = 0.058$). However, the change in TTP in response to thermal pain was significantly prolonged in the DPNP group in the ROIs: Lt-T ($p = 0.021$), RT ($p = 0.003$), Lt-SC ($p = 0.009$), Rt-SC ($p = 0.008$). Whilst healthy volunteers respond to thermal pain by shortening the TTP in ROIs, the DPNP group do the reverse ($p < 0.05$).
Conclusion: Subjects with painful-DPN have a paradoxical delay in TTP in response to exogenous thermal pain. This suggests that chronic neuropathic pain state may result in a failure to mount a hemodynamic response to external pain indicating abnormal pain processing and impaired descending inhibition. This novel finding may serve as an objective marker of chronic DPNP, and a potential target for the development of novel treatments.

62

Pain network functional connectivity in painful diabetic neuropathy: Resting State Functional MRI study

D. Selvarajah, I.D. Wilkinson, M. Awadh, K. Teh, S. Pallai, S. Tesfaye; University of Sheffield, Sheffield, UK.

Background and aims: Painful neuropathy (Painful-DPN) affects up to a fifth of patients with diabetes and can lead to progressive disability and poor quality of life. There are no objective biomarkers and current treatments are less than optimal. We examined the resting functional connectivity of the cortical pain network in painful DPN as a possible objective biomarker for neuropathic pain.
Materials and methods: 54 patients with diabetes (No DPN, $n = 16$; Painful DPN, $n = 23$ Painless DPN, $n = 15$) and 16 healthy volunteers underwent detailed clinical and neurophysiological assessments (NIS[LL]+7tests). Resting state fMRI data were acquired at 3T

(Achieva, Philips Healthcare) and data analysis was performed using the Conn Functional Connectivity Toolbox in SPM. Seed region of interest analysis was performed in the somatosensory cortex and insula cortex to represent the sensory discriminatory and affective components of pain processing respectively.
Results: There was increased functional connectivity in the somatosensory cortex (−42, −22, 56; TFCE, corrected $p < 0.05$) and reduced functional connectivity in the insular cortex (34, 62, 60; TFCE, corrected $p < 0.05$) in patients with painful DPN compared to other study cohorts. Somatosensory functional connectivity significantly correlated overall neuropathy severity score ($r = 0.57$; $p = 0.03$). There were no significant correlations between quantitative pain assessments with somatosensory functional connectivity (HADS-A $r = -0.35$, $p = 0.20$), Short Form 36, $r = -0.43$; $p = 0.11$ and Chronic Pain Acceptance Questionnaire $r = -0.16$, $p = 0.57$). Conversely, insula cortex functional connectivity was significantly correlated with affective measures of the chronic pain condition (HADS-A $r = -0.48$, $p = 0.02$; SF-36 $r = -0.51$, $p = 0.01$; CPAQ $r = -0.65$, $p = 0.001$) but not with neuropathy composite score ($r = -0.09$, $p = 0.70$).
Conclusion: This is the first study to examine resting state pain network functional connectivity in DPN. We have demonstrated that abnormal pain network functional connectivity reflects closely the roles of each brain region. Alterations in functional connectivity of the insula cortex, which is involved with interoceptive awareness and the emotional experience, correlated with subjective measures of pain and behaviour unique to the chronic pain condition. Whereas, the somatosensory cortex which is involved with nociceptive/sensory discrimination was more closely related to objective measures of neuropathy severity based on neurophysiological assessments. This novel, quick (five minute) MRI scan captures the multi-dimensional aspects of chronic pain and has a great potential to be an objective assessment tool in both clinical trials and practice.

Pericyte mediated reduction in spinal cord blood flow in diabetic neuropathic pain

R.P. Hulse[1], M.E. Da Vitoria Lobo[2], D.O. Bates[2];
[1]Nottingham Trent University, Nottingham, [2]University of Nottingham, Nottingham, UK.

Background and aims: The role that the neurovascular network within the spinal cord plays in regulating nociception has not been investigated; especially in neuropathic pain. We have recently identified that blood vessels in the spinal cord of diabetic animals are narrower than in non-diabetic animals, and that this was accompanied by development of pain. We hypothesise that this reduction in vessel diameter could be a result of vasoconstriction, related to changes in the cells surrounding these vessels (pericytes) due to alterations in the hormone angiotensin II, and activation of its receptors.
Materials and methods: All Experiments were designed in accordance with UK Home Office legislation, Animals (Scientific Procedures) Act 1986 and ARRIVE guidelines. A rodent model of type 1 diabetes was induced in Female Sprague dawley rats (~200 g) ($n = 6$/group). Streptozotocin (intraperitoneal 50 mg/kg) was administered and animals were insulin supplemented. All studies were carried out with age matched controls. Animals body weight was monitored and levels of blood glucose determined (hyperglycaemia >15 mmol/l). 8 weeks following streptozotocin administration, animals were administered with hypoxyprobe (60 mg/kg) intraperitoneal 30 minutes prior to being terminally anaesthetised (intraperitoneal 60 mg/kg Sodium Pentobarbital) and cardiac perfused with 4% paraformaldehyde. Lumbar spinal cords were extracted and processed (40 μM thick sections) for confocal microscopy to identify the endothelium (CD31), pericytes (NG2, PDGFRβ) and AT1R.
Results: In diabetic animals that displayed neuropathic pain there was a significant reduction in vessel diameter in the spinal cord versus age matched controls ($p < 0.0001$). This was associated with increased levels of hypoxia indicated through increased hypoxyprobe staining in the dorsal horn of the spinal cord of diabetic animals ($p < 0.05$, $p < 0.0001$). Furthermore, this vasconstriction in diabetic animals was significantly prevalent when in close proximity to pericytes (AT1R positive, $p < 0.05$).
Conclusion: This demonstrates that pericyte function has a role in modulating the neurovascular network and pain. This highlights a novel mechanism by which diabetic neuropathic pain may manifest.

Regional brain volume reduction in diabetic peripheral neuropathy: a magnetic resonance imaging volumetry study

S. Tesfaye, S. Pallai, F. Heiberg-Gibbons, K. Teh, I.D. Wilkinson, D. Selvarajah;
University of Sheffield, Sheffield, UK.

Background and aims: Diabetic peripheral neuropathy (DPN) is a common and serious complication, which was hitherto considered a disease of the peripheral nervous system. The is increasing evidence of significant central nervous system involvement in DPN. We have conducted a series of magnetic resonance imaging (MRI) experiments to examine structural brain alterations in DPN.
Materials and methods: 102 patients with type 1 and 2 diabetes (34 No DN, 34 Painless DN & 34 Painful DN) and 34 healthy volunteers underwent detailed clinical and neurophysiological assessments. All subjects underwent 3-dimensional T1-weighted brain MRI (3.0T, Philips). Brain volume analysis was performed using SIENAX (www.fmrib.ox.ac.uk/fsl) and Freesurfer (http://surfer.nmr.mgh.harvard.edu/). Segmented brain volumes (total brain, peripheral and total grey, white matter and CSF) and regional cortical thickness (postcentral gyrus, precentral gyrus and insula cortex) were measured.
Results: Groups were matched for age and gender ($p > 0.05$). Total brain volume was significantly lower in both neuropathy groups (painful DN [1401.7 (10.7)ml], painless DN [1393.5 (69.6)ml]) compared to the HV [1457.2(79.2)ml] and No DN [1437.2(60.9)ml]; ANOVA $p \leq 0.01$). Total grey matter volume was significantly lower in painful DN [713.9(67.1)ml] and painless DN [717.2(42.4)ml] compared to controls (HV [758.4(46.5)] ; $p \leq 0.01$; No DN [747.3(41.1)]; $p = 0.015$). There were no significant differences in white matter (ANOVA $p = 0.18$) and CSF (ANOVA $p = 0.23$) volumes. Painful DN subjects had significantly lower cortical thickness in the right postcentral gyrus [1.83(0.14)mm vs HV 1.91(0.13)mm]; ($p = 0.02$); left precentral gyrus [2.31(0.16)mm vs HV [2.39(0.12)mm]; ($p = 0.02$) and no DN [2.38(0.14)mm]; ($p = 0.04$); and left insula [2.81(0.15)mm] vs HV [2.97(0.14)mm];($p \leq 0.01$).
Conclusion: This is the largest cohort study of brain volume changes in subjects with DN examined to date. We have demonstrated significant reduction in grey matter volume in painful and painless DN subjects. In painful DN this is localised within the somatomotor cortex and insula. These findings highlight significant CNS involvement in DN that provides clues to the pathogenesis of this condition.

Efficacy of platelet rich plasma injection in diabetic neuropathy: double blinded randomised controlled trial

W.A.M. Khalifa[1], M.M. Hassanien[2], A.-R. Al-awamy[3], H.M. Abdelhafez[4], Y.S. Hussien[2];
[1]Internal Medicine, Assiut University, Assiut, [2]Rheumatology and Rehabilitation department, Faculty of Medicine, Assiut University,

Assiut, [3]Anesthesia department, Assuit University, Assiut, [4]Clinical Pathology department, Assiut University, Assiut, Egypt.

Background and aims: Till now there is no available effective therapy for the treatment of diabetic peripheral neuropathy (DPN). Autologous platelet rich plasma (PRP) is an easy and cost effective method as it provides necessary growth factors for axon regeneration. Aim: To evaluate the clinical efficacy of PRP perineural injection in the treatment of DPN compared to traditional medical treament
Materials and methods: Double blinded randomized controlled trial was conducted. All included patients had type2DM, DPN of at least 5 years. Neuropathy was assessed by the modified Toronto Clinical Neuropathy score (mTCNs). Baseline pain and nerve conduction studies were done.Regardless of age and gender participants were divided into two groups, both the control and experimental groups received primary treatment and strictly control blood glucose. Group I underwent PRP perineural injection under ultrasound guidance. Group II received medical treatment only. Patients were followed for 6 months. Independent student's test was used for comparisons between groups.
Results: The study included 60 patients, 33(55%) were female with a mean age of 35.27 ± 12.86 years with duration of DPN 7.42 ± 1.51 years. 40 patients underwent PRP peri-neural injection. Significant symptomatic improvement in group I versus group II (P value ≤0.001). both mean motor nerve conduction velocity and Sural conduction velocity were accelerated in group I after 6 months of PRP application (P value <0.05, ≤0.001 respectivly), also mTCNS had improved in group I post PRP injection (P value ≤0.001).
Conclusion: Application of PRP perineural injection is an effective adjunct therapy in diabetic peripheral neuropathy, also it significantly improves neuropathic symptoms
Clinical Trial Registration Number: NCT03250403

Improvement in painful diabetic neuropathy after 3 months from administration of a supplement containing SOD, ALA, B_{12} and Carnitine

T. Didangelos, E. Karlafti, K. Tziomalos, Z. Kontoninas, C. Margaritidis, N. Krikis, A. Hatzitolios;
Diabetes Center, 1st Prop. Department of Internal Medicine, "AHEPA" Hospital, Aristotele University, Thessaloniki, Greece.

Background and aims: To investigate the effect of a new combination of four elements [Superoxide Dismutase (SOD), Alpha Lipoic Acid (ALA), Acetyl L-Carnitine (AC), Vit. B12] contained in one pill in Painful Diabetic Neuropathy (PDN). It is a combination of two antioxidants plus Vit B12 and Carnitine.
Materials and methods: In current prospective, double-blind, placebo controlled, age matched study, 65 patients with Diabetes Mellitus Type 2 (DMT2), 31 women, with mean age 63 ± 11 years, mean duration of DM 15 years randomized in two groups: group A: $n = 32$ received placebo and group B: $n = 33$ received the pill with the combination of the four elements (SOD, ALA, B12, ACL). All patients were on treatment either with a combination of antidiabetic drugs or with a combination with insulin and drugs. Treatment of diabetes did not change during the three months of follow up. The following methods for detecting Diabetic Peripheral and Autonomic Neuropathy (DPN, DAN) used: Michigan Neuropathy Screening Instrument Questionnaire and Examination (MNSIQ and MNSIE), measurement of vibration perception threshold with biothesiometer (BIO) and Cardiovascular Reflex Tests (CRT): R-R variation during deep breathing [assessed by mean circular resultant (MCR)], Valsalva maneuver (Vals), 30:15 ratio and blood pressure response to standing (OH). We used a pain (PS) and a quality of life (QL) questionnaire, also.
Results: All indices of measurements between the two groups including HbA1c (group A 6.8 ± 1.2 vs group B 7.2 ± 1.2 $p = 0.660$) did not differ at baseline. The following indices increased significantly in group B (baseline vs final): BIO 35 ± 13 vs 28 ± 15 ($p < 0.001$), MNSIQ 4.3 ± 3.0 vs 4.2 ± 2.99 ($p = 0.009$), QL 39.0 ± 11.4 vs 37.2 ± 10.9 ($p < 0.001$) and PAIN 20.5 ± 7.1 vs 18.6 ± 6.7 ($p < 0.001$). Indices of CARTS and MNSIE did not differ significantly in group B (baseline vs final). We did not observe a significant change in all indices: in group A (placebo group).
Conclusion: In current study after three months from the administration of the combination with four elements in one pill, we observed an improvement in vibration perception threshold as measured by biothesiometer, in Pain, in Quality of Life and in MNSI Questionnaire. The pill contains two anti-oxidants (SOD, ALA), Vit B12 and Acetyl L-Carnitine and those could be helpful in the management of painful symptoms in patients with PDN or could be a good starting point for a valid adjuvant for the treatment of pain symptoms.

OP 12 Beta cell identity, degeneration and type 2 diabetes

67

$tRNA^{Gln}$ fragmentation in patient iPSC-derived beta-like cells mediates apoptosis in TRMT10A diabetes

C. Cosentino[1], S. Toivonen[1], E. Diaz Villamil[1], S. Demine[1], A. Schiavo[1], N. Pachera[1], D. Balboa[2], T. Otonkoski[2], P. Marchetti[3], D.L. Eizirik[1], M. Cnop[1,4], M. Igoillo-Esteve[1];
[1]ULB Center for Diabetes Research, Univertsité Libre de Bruxelles, Bruxelles, Belgium, [2]Research Programs Unit, Molecular Neurology and Biomedicum Stem Cell Centre, University of Helsinki, Helsinki, Finland, [3]Department of Endocrinology and Metabolism, University of Pisa, Pisa, Italy, [4]Division of Endocrinology, Erasmus Hospital, Université Libre de Bruxelles, Bruxelles, Belgium.

Background and aims: Loss-of-function mutations in *TRMT10A*, a transfer RNA (tRNA) methyltransferase, cause early onset diabetes and microcephaly. tRNAs play a crucial role in cellular homeostasis and post-transcriptional modifications, such as methylation, modulate tRNA function and fragmentation. tRNA-derived halves (tiRNAs, 29–50 nt) and fragments (tRFs, 14–30 nt) are a new class of functional small noncoding RNAs, involved in cellular stress responses. Here we investigated the molecular mechanisms underlying β-cell demise in TRMT10A deficiency.
Materials and methods: Induced pluripotent stem cell (iPSC) lines were derived from a TRMT10A-deficient patient and healthy controls. TRMT10A expression was silenced in EndoC-βH1 cells by siRNA. Reactive oxygen species (ROS) were measured using HPF fluorescent probe. qRT-PCR was used to detect guanine-9 methylation (m_1G^9) in tRNAs. tRNA fragmentation was assessed by Northern blot and qRT-PCR. Synthetic tRNA fragments and tRF inhibitors were transfected by lipofection. Apoptosis was examined by nuclear dyes, Western blot and immunocytochemistry.
Results: iPSCs from controls and TRMT10A diabetic patients were successfully differentiated into β-like cells using a 7-stage protocol. Stage-7 cells expressed insulin and glucagon-like peptide-1 receptor mRNA at levels comparable to EndoC-βH1 cells and human islets ($n = 9–12$). In iPSC-β-like cells and TRMT10A-depleted EndoC-βH1 cells (≥70% knockdown, $p < 0.001$) m_1G^9 methylation was reduced in a subset of cytosolic tRNAs, including $tRNA^{Gln}$ ($p < 0.05$, $n = 6–12$). Hypomethylation of $tRNA^{Gln}$ resulted in fragmentation and increased 5′-$tiRNA^{Gln}$ and 5′-tRF^{Gln} in patient-derived cells (1.5 ± 0.5 fold increase vs controls, $p < 0.05$ $n = 3–6$). Transfection of TRMT10A-competent EndoC-βH1 cells with synthetic 5′-$tiRNA^{Gln}$ and 5′-tRF^{Gln} induced apoptosis. Conversely, transfection of antisense oligonucleotides targeting 5′-$tiRNA^{Gln}$ and 5′-tRF^{Gln} protected TRMT10A-deficient β-cells from apoptosis ($23 \pm 2\%$ apoptosis in TRMT10A-silenced cells vs $17 \pm 2\%$ following antisense transfection, $p < 0.05$). TRMT10A deficiency induced oxidative stress ($p < 0.05$, $n = 5$) and triggered the intrinsic pathway of apoptosis. The ROS scavengers Tiron (25 μM) and NAC (1 mM) protected TRMT10A-deficient β-cells from apoptosis ($20 \pm 2\%$ apoptosis without NAC vs $14 \pm 2\%$ with NAC, $p < 0.05$, $n = 4$).
Conclusion: Using patient iPSC-derived β-like cells and RNA interference we show that TRMT10A deficiency induces oxidative stress and activation of the intrinsic pathway of apoptosis. TRMT10A deficiency leads to hypomethylation and fragmentation of tRNAs. We demonstrate that 5′-$tRNA^{Gln}$ fragments are key mediators of β-cell death. Our study provides unequivocal evidence for the importance of tRNA modifications in human pancreatic β-cells and identifies tRNA hypomethylation and fragmentation as a novel mechanism of β-cell demise in diabetes.

Role for a lncRNA at the Pax6 locus in controlling beta cell identity and function

R.M. Callingham[1], S. Itzkovitz[2], L. Farack[2], T.J. Pullen[1], G.A. Rutter[1];
[1]Cell Biology and Functional Genomics, Imperial College Lonodn, London, UK, [2]Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel.

Background and aims: Long non-coding RNAs (lncRNA) regulate expression of several β-cell transcription factors (TFs) (*Pdx1, Nkx2.2*). *Pax6* is an essential TF for endocrine development of both β- and α-cells, and is preferentially expressed in the latter. Here, we examine the role of a lncRNA (*Pax6os1*) expressed from the *Pax6* locus in β-cell function.
Materials and methods: *Pax6os1* expression was silenced in MIN6 β-cells using small interfering RNAs (siRNA). RNA sequencing was performed on an Illumina platform (HiSeq 2000) and differentially expressed genes identified with DESeq2. Cell proliferation was assessed using a Cyquant kit (Thermo Fisher). Subcellular location was determined with fractionation and differential centrifugation as well as single molecule fluorescent *in situ* hybridization (smFISH). The MIT CRISPR design tool was used to development a two gRNA system to delete a ~733 bp region spanning *Pax6os1*exon 1 and its upstream promoter in MIN6 cells and C57BI6/J mice.
Results: Silencing of *Pax6os1* led to a $25 \pm 0.07\%$ ($n = 9$ independent experiments, $p = 0.0015$) increase in *Pax6* expression. RNA-seq revealed differential expression of genes involved in β-cell identity, including 'disallowed' β-cell genes. Upregulation of essential β-cell genes (*Ins1, Gck, Slc2a2, Pdx1*) with a coordinated downregulation of genes involved in alternative β-cell fates (*Slc16a1, Ldha, Pdk1*) were observed. Cellular proliferation was significantly reduced ($p < 0.05$) 72 h post siRNA transfection. Assessment of subcellular localisation in MIN6 cells revealed that *Pax6os1* was enriched 2.5-fold ($p = 0.0001$, $n = 3$) within the cytoplasm, while localisation of *Pax6* mRNA also tended to be preferentially (1.6-fold) enriched in the nuclear fraction. mRNA encoding other islet TFs (*Pdx1, Nkx6.1*) showed no preferential retention in the nucleus. Cytoplasmic localisation of *Pax6os1*and *Pax6* were enhanced by incubation for 6 h at elevated (25 vs 5 mmol/l) glucose concentrations. Prolonged glucose incubation (15 h) further exacerbated *Pax6os1* and *Pax6* cytoplasmic localisation (ns). Single molecule FISH on fixed pancreatic tissue of C57BI6/J mice confirmed the enriched nuclear location of *Pax6* mRNA ($p = 0.0015$) while *Pax6os1* was too weakly expressed for reliable quantification. Removal of exon 1 plus ~600 bp upstream of *Pax6os1* was achieved in MIN6 cells using to two gRNAs. The same system was used to generate a *Pax6os1* null mouse line which will be subject to phenotypic characterisation with the addition of diabetic challenge.
Conclusion: Our findings indicate that *Pax6os1* is a negative regulator of *Pax6* expression. Interestingly, *Pax6* mRNA sequestration in the nucleus, and *Pax6os1* action, thus appear to attenuate *Pax6* expression and function in the β-cell. Enhanced *Pax6* function during hyperglycaemia may facilitate a drift in β-cell identity towards an α-cell fate.

Islet microRNA miR-183-5p is a regulator of beta cell apoptosis and dedifferentiation in NOD mouse pancreatic islet

F. Mancarella[1], G. Ventriglia[1], L. Nigi[1], G.E. Grieco[1], N. Brusco[1], C. Gysemans[2], D. Cook[2], C. Mathieu[2], G. Sebastiani[1], F. Dotta[1];
[1]Diabetes Unit Department of Medical Science, Surgery and Neuroscience, University of Siena, Italy; Umberto Di Mario Foundation ONLUS, Toscana Life Sciences, Siena, Italy, [2]Laboratory of Experimental Medicine, University of Leuven, Leuven, Belgium.

Background and aims: MicroRNAs (miRNAs) are a class of small non coding RNAs that negatively regulate gene expression. Several studies

demonstrated that miRNAs could be involved in cell dedifferentiation and apoptosis, as well as in pancreas development and β cell function, and that their alteration may contribute to the development of type 1 diabetes. Aim of this study was to analyze the expression profile of miRNAs in pancreatic islets of diabetic NOD mice, in order to gain insight into their possible role in β cell damage.

Materials and methods: Expression profile of 384 miRNAs was analyzed using Taqman Array Microfluidic cards in islet endocrine tissue collected using Laser Capture Microdissection (LCM) from NOD SCID, NOD Normoglycemic and recent diabetic NOD mice (3 mice per group). RT-PCR single assay validation on differentially expressed microRNAs was also performed from the same mice as well as from another cohort of $n = 5$ NOD SCID, $n = 8$ NOD Normoglycemic and $n = 8$ recent diabetic NOD mice. Additionally, NOD mouse pancreatic islets were separately captured based on the degree of islet infiltration (insulitis score) and analyzed for expression of miRNA and genes of interest (respectively miR-183-5p, ALdh3a1 and Foxo1). Finally, differentially expressed miRNAs were modulated in MIN6 murine cell line for 48h and treated or not with a cytokine mix (IFNγ, IL-1β, TNFα) for 24h in order to evaluate apoptosis (picnotic nuclei count) and miRNA target genes expression.

Results: MiRNA expression profiling revealed a significant downregulation ($p < 0.05$) of miR-183-5p in LCM-captured islets from NOD recent onset diabetic vs normoglycemic and NOD SCID mice; this was confirmed by single assay analysis. Of note, miR-183-5p resulted downregulated ($p < 0.05$) in heavily infiltrated islets vs low infiltrated islets, highlighting that miR-183-5p reduced expression correlates to the degree of islet inflammation. Interestingly, in highly inflamed islets the reduction of miR-183-5p was paralleled by a higher expression of dedifferentiation marker Aldh3a1 as well as by a reduction of the differentiation marker FOXO1, thus potentially linking miR-183-5p downregulation to an ongoing dedifferentiation process. In murine β-cell line MIN6, miR-183-5p inhibition significantly reduced cytokines-induced apoptosis ($p < 0.001$), indicating that miR-183-5p could be able to modulate apoptotic mechanisms under cytokine stress. Indeed, bioinformatic analysis of miR-183-5p target genes revealed the anti-apoptotic transcription factor Bach2, whose expression was significantly higher ($p < 0.05$) in MIN6 transfected with miR-183-5p inhibitor. Of note, among miR-183-5p target genes, we identified the epithelial-mesenchymal transition modulator Quaking, thus supporting the hypothesis that β-cells undergo dedifferentiation during inflammation as a potential protective mechanism.

Conclusion: In conclusion, miR-183-5p reduction in NOD mouse pancreatic islets may contribute to beta-cell dedifferentiation and to protection from apoptosis, through the modulation of anti-apoptotic factor Bach2 and, potentially, Quaking.

Metabolic insufficiency caused by cellular stresses is implicated to beta cell dedifferentiation in a mouse model of Wolfram syndrome

K. Shinoki-Amo[1], K. Tanabe[1], M. Hatanaka[1], H. Masutani[2], Y. Tanizawa[1];
[1]Department of Endocrinology, Metabolism, Hematological Sciences and Therapeutics, Yamaguchi University Graduate School of Medicine, Ube, [2]Tenri Health Care University, Tenri, Japan.

Background and aims: β cell failure is central in the pathogenesis of both type 1 and type 2 diabetes. It results from reduced β cell mass and function. Wolfram syndrome, caused by the *WFS1* gene mutations, is characterized by insulin dependent diabetes mellitus and optic atrophy. Genetically determined pancreatic β cell loss results from augmented ER and oxidative stresses. We investigated the contribution of these two processes to β cell failure using mice lacking *Wfs1*.

Materials and methods: In vivo metabolic profile was assessed by standard methods. We used genetic lineage tracing to examine beta cell fate. Pancreatic tissues obtained from various age of mice were stained by the antibodies to Insulin, Glucagon, Somatostatin, MafA, Pdx1, Neurogenin3 and so on. For islet studies, we assessed energy metabolisms and mitochondria function by metabolomics analysis and a use of extracellular metabolic flux analyzer.

Results: In the $Wfs1^{-/-}$ mice, β cells become dedifferentiated and revert to endocrine progenitor-like cells expressing Neurogenin3. Lineage-tracing experiments demonstrated that loss of β cells was mainly due to β cell de-differentiation and that a subset of β cells takes α cell fate. Such β cell plasticity appears after nursing, independently of hyperglycemia, and becomes more apparent along with diabetes progression accompanied with no significant increase in apoptosis. We have found that genetic inhibition of Txnip, which is a stress response molecule involving in various cellular processes, preserved β cell mass and maintained glucose homeostasis in the $Wfs1^{-/-}$ mice. This suggests its roles in the regulation of β cell plasticity in the setting of *Wfs1* deficiency. One clue to the mechanisms underlying β cell dedifferentiation was the reduction of acetyl-CoA, citrate and ATP content in the $Wfs1^{-/-}$ islets. Although glycolysis assessed by measuring extracellular acidification rate after glucose loading was apparently decreased, metabolomics analysis revealed that pyruvate and intermediate glycolytic products were apparently accumulated. These abnormalities in glucose catabolic process were correlated with an increase in phosphorylated pyruvate dehydrogenase (p-PDH). Importantly, Txnip directly interacts with the both PDH kinase as well as PDH, indicating its involvement in the regulation of PDH activity. Indeed, islets of $Wfs1^{-/-}$ mice lacking *Txnip*demonstrated a robust reduction of phosphorylated PDH and a restoration of capabilities of ATP production in response to glucose. Consistently, severely decreased glycolysis and oxygen consumption rate after glucose loading in $Wfs1^{-/-}$ islets were significantly reversed by *Txnip* deficiency.

Conclusion: These finding illustrate energy insufficiency associated with impaired glucose catabolism in β cells under the chronic stress conditions and suggest that β cells may possibly become dedifferentiated to adapt to metabolic insufficiency caused by unresolvable stresses. This provides new insights into molecular mechanisms underlying β cell loss in diabetes related to cellular stresses, such as Wolfram syndrome.

An islet gene expression module containing AldoB is correlated with progression of hyperglycaemia and type 2 diabetes in humans

M. Ibberson[1], F. Burdet[1], K.-P. Knoch[2], M. Barovic[2], A. Dahl[2], P. Marchetti[3], A. Schulte[4], M. Solimena[2];
[1]Vital-IT, SIB Swiss Institute of Bioinformatics, Lausanne, Switzerland, [2]TU Dresden, Dresden, Germany, [3]University of Pisa, Pisa, Italy, [4]Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany.

Background and aims: Surgical specimens of metabolically phenotyped pancreatectomized patients (PPP) represent a novel source for studies on pancreatic islets in health and type 2 diabetes (T2D). In this study we sought to identify islet gene co-expression modules correlated with progression of hyperglycemia and T2D.

Materials and methods: Based on their medical history and preoperative values for fasting glucose, HbA1c and OGTT 138 PPP were classified as non-diabetic (ND, $n = 18$), impaired glucose tolerant (IGT, $n = 44$), having <1 year-long diabetes secondary to the pancreatic disease (T3cD, $n = 37$) or long standing (mean duration: 11 yrs) type 2 diabetes (T2D, $n = 39$), according to the ADA guidelines. Islets were retrieved from snap-frozen surgical specimens by laser capture microdissection (LCM) and

profiled by RNAseq. Weighted gene co-expression network analysis (WGCNA) was performed on normalised count data to identify islet gene co-expression modules, which were then correlated to available clinical traits.

Results: A total of 40 gene co-expression modules were identified with a mean size of 500 genes. Correlation of these modules to 25 clinical traits led to the identification of a module of 78 genes that was the most strongly correlated to HbA1c, fasting glucose, 1H glucose during OGTT and diabetes status. *ALDOB*, encoding Fructose-1,6-bisphosphate aldolase, was the highest-ranking gene in this module in terms of intramodular connectivity and HbA1c correlation and was the top "Hub" gene for this trait. Other top-ranking "Hub" genes for HbA1c were involved with extracellular matrix remodelling, lipid transport and metabolism.

Conclusion: We present an unsupervised analysis of islet gene expression data from the largest biobank of LCM surgical pancreas specimens to date. Exploration of the islet gene co-expression module uncovers mechanisms of islet response to chronic elevated glucose in patients and/or islet dysfunction in type 2 diabetes.

Beta Cell and Diabetes Platform (BCDP): a sustainable solution for IMI project data

I. Xenarios[1], R. Liechti[1], M. Gossel[2], M. Solimena[3], P. Marchetti[4], A.M. Schulte[2], C. Magnan[5], C. Cruciani-Guglielmacci[5], R. Scharfmann[6], O. Bernard-Poenaru[7], D. Madsen[8], B. Thorens[9], P. Hecht[7], W. Kramer[10], M. Ibberson[1];

[1]Vital-IT, SIB Swiss Institute of Bioinformatics, Lausanne, Switzerland, [2]Sanofi Deutschland, Frankfurt, Germany, [3]TU Dresden, Dresden, Germany, [4]University of Pisa, Pisa, Italy, [5]Paris Diderot University, Paris, France, [6]INSERM U1016, Paris, France, [7]Servier, Suresnes, France, [8]Novo Nordisk, Copenhagen, Denmark, [9]University of Lausanne, Lausanne, Switzerland, [10]Biomedical and Scientific Consulting, Mainz, Germany.

Background and aims: A wealth of data and results are collected by projects funded by the Innovative Medicines Initiative and other EU projects. Often though, once the project reaches completion the only way to share knowledge is through publication, which only represent a fraction of the total data and results generated. We aim to provide a framework for sustainable access to IMI project data in the diabetes area.

Materials and methods: Data and results from the IMI1 project IMIDIA are hosted at the Swiss Institute of Bioinformatics (SIB). Integrative analysis was performed during IMIDIA and made available through various web tools for data exploration. Data from the project were converted into a standardized format, Resource Description Framework (RDF) to enable future interoperability with other resources. Clinical data were aligned using CDISC standards. Web tools provide continued access to data and results to BCDP consortium partners.

Results: BCDP so far contains islet gene expression, lipidomics and clinical/phenotypic data derived from human organ donors and pancreatectomized patients ($N = 498$) and six metabolically challenged mouse strains (C57BL/6, DBA2/J, 129S2, BALB/cJ, AKR and A/J) followed over time. Patient parameters available include standard measures such as age, gender, BMI and multiple functional parameters such as HbA1c, GSIS and OGTT measurements. Available mouse phenotypes are GSIS, OGTT, ITT and beta/alpha cell mass estimations. Web-based tools are available to (i) query the human biobank for detailed patient/sample information, (ii) analyse gene expression profiles across datasets and (iii) analyse gene co-expression networks and their correlations to the different clinical and functional parameters. For mouse, web-based tools are available to (i) analyse how physiological measurements differ across strains and diets over time, (ii) analyse how plasma and islet lipids changes across strains and diets over time, (iii) analyse gene expression changes induced by HF diet across strains and time-points, and (iv) analyse gene co-expression networks and their correlations to physiological measurements. Functionality also exists for cross-querying between human and mouse: for example, genes selected through analysis of human data can be used to directly query the mouse data or *vice versa* using orthology relationships (NCBI Homologene).

Conclusion: The BCDP is the first fully funded sustainable platform for an IMI diabetes resource. IMIDIA represents the cornerstone for the BCDP. SIB is currently acting as data coordinator for several IMI projects in the diabetes area and the plan is to include further interoperable datasets in the future. The BCDP platform is already in use for the IMI2 project RHAPSODY. This therefore represents an opportunity to provide sustainable access to multiple IMI projects whilst ensuring different access restrictions on these data due to ethical/legal constraints.

Cardiovascular safety and efficacy of exenatide once-weekly in patients with moderate renal dysfunction in the EXenatide Study of Cardiovascular Event Lowering (EXSCEL)

A.F. Hernandez[1], M.A. Bethel[2], G.L. Bakris[3], P. Merrill[1], S.M. Gustavson[4], B.G. Katona[4], P. Ohman[4], Y. Lokhnygina[1], R.J. Mentz[1], R.R. Holman[2], for the EXSCEL Study Group;
[1]Duke Clinical Research Institute, Durham, USA, [2]Diabetes Trials Unit, Oxford, UK, [3]University of Chicago Medicine, Chicago, USA, [4]AstraZeneca, Gaithersburg, USA.

Background and aims: EXSCEL, a multinational, randomized, placebo-controlled cardiovascular (CV) outcome trial of 2 mg once-weekly exenatide added to usual care, demonstrated CV safety in patients with type 2 diabetes (T2D) with or without previous CV disease. We report the impact of exenatide on confirmed CV outcomes, all-cause mortality, and key CV safety parameters according to baseline renal function (moderate dysfunction [<60 mL/min/1.73 m^2] and within Stage 3 [3a: eGFR 45–59 or 3b: 30–44 mL/min/1.73 m^2] chronic kidney disease).
Materials and methods: For the subgroups by baseline renal function, Cox proportional hazards models were fit to the time to first event of the three-component major adverse CV event (MACE-3) composite outcome (death from CV causes, nonfatal myocardial infarction, or nonfatal stroke). Secondary outcomes were time to all-cause mortality, death from CV cause, nonfatal or fatal myocardial infarction, nonfatal or fatal stroke, hospitalization for heart failure, and hospitalization for acute coronary syndrome.
Results: Of 14,752 patients in the ITT population, 3191 (22%) had eGFR <60, 2288 (16%) had eGFR 45–59 and 889 (6%) had eGFR 30–44 mL/min/1.73 m^2. Participants with moderate renal dysfunction had a higher mean age (67 vs 61 years) and longer duration of T2D (median [IQR] 14 [9, 21] vs 11 [6, 17] years). In univariate subgroup analyses, there was no significant interaction between randomized treatment and renal function, either based on eGFR thresholds (±60 mL/min/1.73 m^2; p for interaction = 0.12) or on CKD stages (p for interaction = 0.51). In those with eGFR <60 mL/min/1.73 m^2, first MACE-3 events occurred in 283 (18.1%) participants in the exenatide group and 284 (17.5%) in the placebo group (hazard ratio [HR] 1.01, 95% CI 0.86–1.19). HR and 95% CI for other important CV outcomes are shown in the Table.
Conclusion: In patients with moderate renal dysfunction, 2 mg once-weekly exenatide had a neutral impact on CV outcomes. In univariate analyses unadjusted for multiplicity, modest risk reductions were seen with exenatide in those with baseline eGFR ≥60 mL/min/1.73 m^2 for MACE-3, all-cause mortality, CV death and fatal or non-fatal stroke.

Table. Hazard ratio (HR) and 95% confidence interval (CI) for CV outcomes for allocation to 2mg once-weekly exenatide compared with placebo, according to baseline renal function

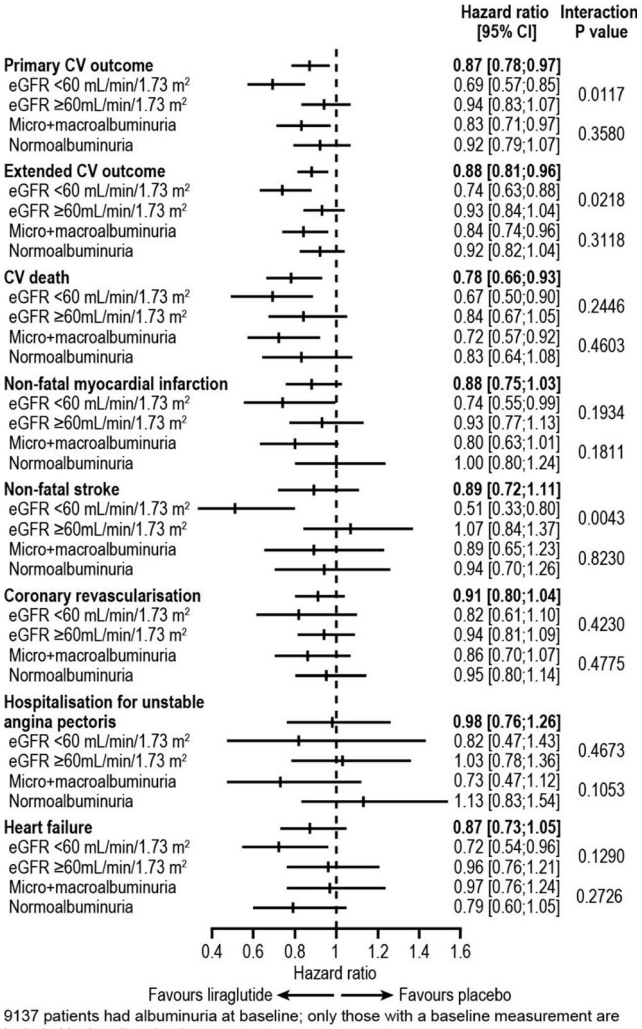
Liraglutide reduces major cardiovascular events in patients with chronic kidney disease: results from the LEADER trial

N. Poulter[1], J. Mann[2], V. Fonseca[3], O. Mosenzon[4], I. Raz[4], H. Frimer-Larsen[5], B. von Scholten[5], T. Idorn[5], on behalf of the LEADER Trial Steering Committee and Investigators;
[1]Imperial College London, London, UK, [2]KfH Kidney Center, Munich, Germany, [3]Tulane University Health Sciences Center, School of Medicine, New Orleans, USA, [4]Hadassah Hebrew University Hospital, Jerusalem, Israel, [5]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: People with type 2 diabetes (T2D) and chronic kidney disease (CKD) are at high risk of cardiovascular (CV) events. We analysed the effect of liraglutide vs placebo (PBO) on CV outcomes in patients with T2D and CKD in the LEADER trial.
Materials and methods: LEADER was a randomised, double-blind, multicentre, CV outcome trial with liraglutide 1.8 mg/day vs PBO, both in addition to standard of care for 3.5–5 years, in 9340 patients with T2D and high CV risk. The primary composite outcome was defined as first occurrence of death from CV causes, non-fatal myocardial infarction, or non-fatal stroke. The expanded composite CV outcome additionally included coronary revascularisation, and hospitalisation for unstable angina pectoris or hospitalisation for heart failure (HF). In this analysis, CV outcomes were assessed in patients with CKD based on estimated GFR (eGFR) (<60 and ≥60 mL/min/1.73 m^2) and on albuminuria (≥30 mg/g: micro/macroalbuminuria and <30 mg/g: normoalbuminuria).
Results: The mean eGFR in patients with baseline eGFR <60 (n = 2158) and ≥60 mL/min/1.73 m^2 (n = 7182) was 45.7 ± 10.9 and 90.8 ± 21.6 mL/min/1.73 m^2, respectively. Versus PBO, liraglutide was associated with reductions in the risk of the primary composite outcome: HR 0.69 (CI 0.57; 0.85) for the eGFR <60 subgroup and HR 0.94 (CI 0.83; 1.07) in the eGFR ≥60 subgroup. Equivalent reductions in the expanded composite CV outcome were observed (Figure). In the eGFR <60 mL/min/1.73 m^2 subgroup, liraglutide significantly reduced the risk of CV death, non-fatal stroke and hospitalisation for HF vs PBO (Figure). Liraglutide also reduced the risk of the primary composite outcome, the expanded composite CV outcome and CV death in the micro/macroalbuminuria subgroup vs PBO (Figure).
Conclusion: In LEADER, there was a significant reduction of major CV events in patients with CKD.



9137 patients had albuminuria at baseline; only those with a baseline measurement are included in the albuminuria group.

Canagliflozin and cardiovascular outcomes in patients with chronic kidney disease

V. Perkovic[1], B.L. Neuen[1], T. Ohkuma[1], B. Neal[1], D.R. Matthews[2], D. de Zeeuw[3], K.W. Mahaffey[4], G. Fulcher[5], M. Desai[6], Q. Li[1], H. Deng[6], N. Rosenthal[6], M. Jardine[1], G. Bakris[7];
[1]The George Institute for Global Health, Sydney, Australia, [2]Oxford Centre for Diabetes, Endocrinology and Metabolism and Harris Manchester College, University of Oxford, Oxford, UK, [3]University of Groningen, University Medical Center Groningen, Groningen, Netherlands, [4]Stanford Center for Clinical Research, Department of Medicine, Stanford University School of Medicine, Stanford, USA, [5]Royal North Shore Hospital, Sydney, Australia, [6]Janssen Research & Development, LLC, Raritan, USA, [7]University of Chicago Medicine, Chicago, USA.

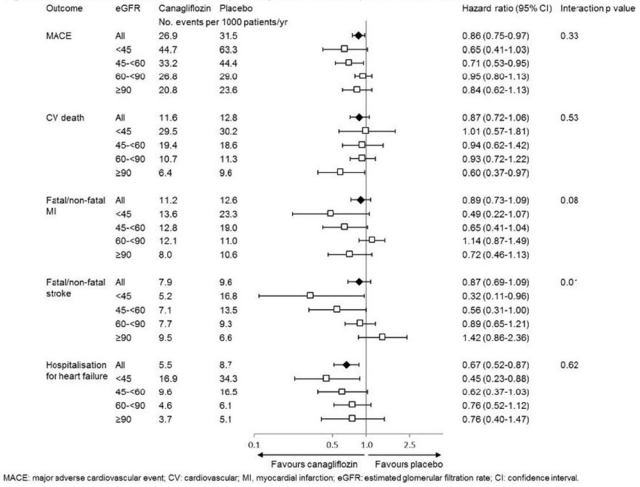
Background and aims: SGLT2 inhibitors are approved for glucose lowering in type 2 diabetes (T2DM) and have proven cardiovascular (CV) benefits, but are not approved for people with significantly reduced kidney function as glycaemic efficacy is dependent on glomerular filtration. This analysis of the CANagliflozin cardioVascular Assessment Study (CANVAS) Program assessed effects of canagliflozin on CV outcomes in patients with T2DM and established CV disease or ≥2 CV risk factors according to baseline kidney function.

Materials and methods: The primary outcome of the CANVAS Program was the composite of CV death, nonfatal myocardial infarction, and nonfatal stroke (major adverse cardiovascular events [MACE]). The primary outcome and other CV outcomes were assessed in participants by baseline estimated glomerular filtration rate (eGFR; <45, 45–<60, 60–<90, and ≥90 ml/min/1.73 m^2). Incidence rates, hazard ratios (HRs), and 95% confidence intervals (CIs) were calculated for each outcome.

Results: The CANVAS Program included 2039 patients (20.1%) with baseline eGFR <60 ml/min/1.73 m^2 (mean age 68 y, BP 138/76 mmHg, HbA1c 8.3%, eGFR 49 ml/min/1.73 m^2, median urinary albumin:creatinine ratio 22 mg/g). Effects of canagliflozin on HbA1c and body weight were smaller in patients with eGFR <60 vs ≥60 ml/min/1.73 m^2 (−0.43 vs −0.64%, *P*-heterogeneity <0.0001, and −1.16 vs −1.43 kg, *P*-heterogeneity = 0.0002), but BP effects were similar (−3.89 vs −4.11 mmHg, *P*-heterogeneity = 0.21). Relative effects on the primary and most other CV outcomes were similar across four eGFR subgroups, with possible heterogeneity suggested only for the exploratory outcome of stroke (Figure). Results for almost all safety outcomes were also consistent across eGFR subgroups.

Conclusion: Despite smaller glycaemic effects in people with reduced eGFR, the cardioprotective benefits of canagliflozin are similar across different levels of kidney function.

Figure. Cardiovascular outcomes in participants by baseline eGFR (eGFR <45, 45-<60, 60-<90, and ≥90 ml/min/1.73 m²).



MACE: major adverse cardiovascular event; CV: cardiovascular; MI, myocardial infarction; eGFR: estimated glomerular filtration rate; CI: confidence interval.

Lesser eGFR decline with dulaglutide regardless of weight changes in people with type 2 diabetes and moderate to severe chronic kidney disease (AWARD-7)

K.R. Tuttle[1], M.C. Lakshmanan[2], B. Rayner[3], R.S. Busch[4], A.G. Zimmermann[2], D.B. Woodward[2], F.T. Botros[2];

[1]Providence Health Care, Spokane, USA, [2]Eli Lilly and Company, Indianapolis, USA, [3]Division of Nephrology and Hypertension, Groote Schuur Hospital and University of Cape Town, Cape Town, South Africa, [4]Division of Community Endocrinology, Albany Medical Center, Albany, USA.

Background and aims: Body weight (BW) changes may affect muscle mass and thus creatinine (Cr) levels. Estimating glomerular filtration rate (eGFR) by Cr-based equations may not accurately reflect changes in kidney function when BW changes. While muscle mass changes affect serum Cr levels, cystatin C is not affected by muscle mass changes. Dulaglutide (DU) treatment was associated with BW loss and lesser eGFR (Cr-CKD-EPI) decline in people with type 2 diabetes (T2D) and moderate to severe chronic kidney disease (CKD) compared to insulin glargine (IG) (Table). The aim was to evaluate if the lesser eGFR decline observed with DU is related to BW loss.
Materials and methods: Changes in eGFR were evaluated at the end of the treatment period (52 weeks) with Cr-based equations (MDRD, CKD-EPI) and cystatin C-CKD-EPI equation. Creatinine clearance (CrCL) was evaluated with the Cockcroft-Gault equation. Pearson correlation analysis was used to determine the relationship between change in body weight and changes in serum Cr, cystatin C, or eGFR.
Results: Baseline characteristics were similar between treatments ([mean ± SD] eGFR (Cr-CKD-EPI): 38.3 ± 12.8 mL/min/1.73 m^2, HbA_{1c}: 8.6 ± 1.0%, age: 64.6 ± 8.6 y, T2D duration: 18.1 ± 8.7 y). All equations consistently show that eGFR remained stable with DU, but significantly decreased with IG regardless of BW loss in DU or gain in IG (Table). Since BW is a factor in CrCL calculations, compared to eGFR equations, BW loss in DU led to bias toward greater reductions in CrCL. This bias disappeared when using lean BW (Table). Overall, there were no correlation between changes in body weight and changes in serum creatinine ($r = -0.006$, $n = 473$, $p = 0.904$), serum cystatin C ($r = -0.056$, $n = 470$, $p = 0.224$), or eGFR (Cr-CKD-EPI [$r = -0.074$, $n = 473$, $p = 0.106$], cystatin C-CKD-EPI [$r = -0.041$, $n = 471$, $p = 0.379$]).
Conclusion: In conclusion, compared to IG, DU was associated with lesser eGFR decline in people with T2D and moderate to severe CKD regardless of BW changes.

Table. Effects of dulaglutide and glargine on body weight, eGFR, and creatinine clearance in the study participants at 52 weeks

Treatment Group	Body weight (kg)	eGFR (mL/min/1.73 m^2)			Creatinine clearance (CrCL) (mL/min)	
		CKD-EPI cystatin-C	CKD-EPI creatinine	MDRD creatinine	Total body weight (kg)	Lean body weight (kg)

Lixisenatide and renal outcomes in patients with type 2 diabetes: a post-hoc analysis of the ELIXA trial

M.H.A. Muskiet[1], H.J.L. Heerspink[2], L. Tonneijck[1], Y. Huang[3], M. Liu[4], A. Saremi[3], D.H. van Raalte[1];
[1]Diabetes Center, Department of Internal Medicine, VU University Medical Center, Amsterdam, Netherlands, [2]Department of Clinical Pharmacy and Pharmacology, University of Groningen, Groningen, Netherlands, [3]Sanofi, Bridgewater, NJ, USA, [4]BDM Consulting, Somerset, USA.

Background and aims: Limited data exist on the long-term effects of glucagon-like peptide-1 (GLP-1) receptor agonists on kidney function and albuminuria in type 2 diabetes (T2D).
Materials and methods: This was a post hoc analysis of ELIXA, which was a study of cardiovascular safety of lixisenatide (Lixi) vs placebo over a median follow-up of 25 months in 6068 patients with T2D and an acute coronary event ≤180 days before screening. A mixed-effect model with repeated measures for comparisons between treatment groups of changes in urine albumin-to-creatinine ratio (UACR) was performed. The estimated glomerular filtration rate (eGFR, per the 4-variable modification of diet in renal disease formula) and UACR by baseline albuminuria status were assessed. A Cox proportional hazards model adjusted for baseline and on-trial HbA_{1c} was used to estimate the incidence of macroalbuminuria in patients without macroalbuminuria at baseline.
Results: Slower progression of UACR was seen with Lixi vs placebo. In the mixed-effect model, the interaction between treatment and baseline UACR categories was significant ($p < 0.01$). UACR percent change from baseline was lower for Lixi vs placebo in patients with micro- or macroalbuminuria (Table). In the Cox proportional hazards model, Lixi was associated with a 23% lower risk for first macroalbuminuria event in patients without baseline macroalbuminuria (HR 0.77; 95% CI: 0.62, 0.96; $p = 0.0174$). eGFR was not significantly different for Lixi vs placebo overall or by baseline albuminuria status.
Conclusion: In patients with T2D and a recent acute coronary event, the renal benefit of Lixi was beyond glycaemic control. Lixi reduced UACR progression in patients with baseline micro- or macroalbuminuria and was associated with lower incidence of macroalbuminuria.

Table. Change in UACR from baseline to Week 108 in the ELIXA trial according to baseline albuminuria status (ITT population)

		Placebo		Lixi	
		BL	Week 108	BL	Week 108
Normoalbuminuria (BL UACR <30 mg/g)	UACR ± SD, mg/g	8.1 ± 4.7 (n=2191)	11.3 ± 11.8 (n=1101)	8.2 ± 4.8 (n=2250)	11.5 ± 11.6 (n=1110)
	Percent change from BL ± SE, %*	46.0 ± 4.0		44.3 ± 3.9	
	Difference ± SE (95% CI), %†	–1.7 ± 5.2 (–11.9, 8.5); p=0.7424			
Microalbuminuria (BL UACR ≥30 mg/g to <300 mg/g)	UACR ± SD, mg/g	76.5 ± 46.6 (n=596)	85.6 ± 117.4 (n=280)	73.6 ± 47.2 (n=552)	62.6 ± 94.2 (n=239)
	Percent change from BL ± SE, %*	14.8 ± 8.6		–6.4 ± 7.6	
	Difference ± SE (95% CI), %†	–21.1 ± 10.8 (–42.3, 0.0); p=0.0505			
Macroalbuminuria (BL UACR ≥300 mg/g)	UACR ± SD, mg/g	930.3 ± 809.5 (n=207)	960.8 ± 1312.5 (n=87)	959.2 ± 858.3 (n=182)	577.8 ± 955.2 (n=76)
	Percent change from BL ± SE, %*	11.0 ± 14.5		–31.6 ± 9.7	
	Difference ± SE (95% CI), %†	–42.6 ± 16.6 (–75.0, –10.2); p=0.0084			

All data are geometric means unless stated otherwise
*Percent change from BL and between treatment group differences were calculated with log-transformed UACR values using the MMRM with treatment (Lixi, placebo), visit (Weeks 24, 76, and 108), region, intake of ACE inhibitors at BL (yes or no) and intake of ARB at BL (yes or no) as fixed effects, and both treatment and BL UACR by visit interaction. Results in the log scale were back-transformed to provide the estimates of the geometric means
†Lixi vs placebo; calculated based on estimates from the MMRM
ARB=angiotensin-receptor blocker; BL=baseline; ITT=intent-to-treat; MMRM=mixed-effect model with repeated measures; SE=standard error

Semaglutide treatment and renal function in the SUSTAIN 6 trial

R. Silver[1], J. Gumprecht[2], T. Vilsbøll[3,4], T. Hansen[5], J. Pettersson[5], H. Vrazic[5], J. Wilding[6];
[1]Southern New Hampshire Medical Center, Nashua, USA, [2]Medical University of Silesia, Katowice, Poland, [3]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [4]University of Copenhagen, Hellerup,

Denmark, [5]Novo Nordisk A/S, Søborg, Denmark, [6]University of Liverpool, Liverpool, UK.

Background and aims: Semaglutide is a glucagon-like peptide-1 analogue for the once-weekly treatment of type 2 diabetes (T2D). Semaglutide demonstrated superior glycaemic control and body weight loss vs placebo and active comparators across the SUSTAIN phase 3a clinical trial programme. SUSTAIN 6 was a 2-year cardiovascular (CV) outcomes trial conducted in 3,297 subjects with T2D at high risk for CV events that compared subcutaneous semaglutide 0.5 mg or 1.0 mg once weekly vs placebo. The results showed that semaglutide-treated subjects had a significant 26% lower risk of major adverse CV events (MACE: a primary composite outcome of non-fatal myocardial infarction, non-fatal stroke or CV death) vs those receiving placebo over 2 years (hazard ratio [HR], 0.74; 95% confidence interval [CI], 0.58;0.95). This *post hoc* analysis assessed the effect of semaglutide on renal function and renal adverse events (AEs) by baseline estimated glomerular filtration rate (eGFR [Modification of Diet in Renal Disease model; MDRD]) in SUSTAIN 6.

Materials and methods: Changes in renal function, urine albumin-to-creatinine ratio (UACR) and acute renal AEs were assessed in subjects categorised by baseline eGFR (mL/min/1.73 m^2: normal [≥90], mild impairment [<90], moderate impairment [<60] and severe impairment [<30]).

Results: Overall, mean eGFR decreased from baseline to week 104 across all treatment groups and subgroups. The largest decreases were in subjects with normal renal function: −9.6 vs −7.4 mL/min/1.73 m^2 with semaglutide 0.5 mg vs placebo and −8.6 vs −6.5 mL/min/1.73 m^2 with semaglutide 1.0 mg vs placebo, respectively. The corresponding changes in eGFR from baseline were −4.8 vs −4.2 mL/min/1.73 m^2 and −3.2 vs −5.6 mL/min/1.73 m^2 for subjects with mild renal impairment; −2.1 vs −4.8 mL/min/1.73 m^2 and −2.4 vs −4.2 mL/min/1.73 m^2 for subjects with moderate renal impairment; and −4.1 vs −1.8 mL/min/1.73 m^2 and −0.5 vs −2.6 mL/min/1.73 m^2 for subjects with severe renal impairment. UACR decreased with increasing renal impairment with semaglutide 1.0 mg, but not with other treatment groups (**Table**). The number of AEs related to acute renal failure was generally higher in subjects with greater renal impairment at baseline, except with semaglutide 0.5 mg. The proportion of subjects experiencing new or worsening nephropathy was lower with both semaglutide doses vs placebo: 36/826 (4.4%) vs 54/824 (6.6%) with semaglutide 0.5 mg, and 23/822 (2.8%) vs 45/825 (5.5%) with semaglutide 1.0 mg. The majority of this was due to reductions in persistent macroalbuminuria: 22 (2.7%) vs 42 (5.1%) and 19 (2.3%) vs 38 (4.6%), respectively.

Conclusion: No renal-related safety issues were observed with semaglutide regardless of baseline renal function in SUSTAIN 6.

Table. UACR (change from baseline to week 104) and renal-related safety endpoints (week 104) stratified by baseline renal function in the SUSTAIN 6 trial

	Semaglutide 0.5 mg		Placebo 0.5 mg		Semaglutide 1.0 mg		Placebo 1.0 mg

Superior efficacy of insulin degludec/liraglutide vs insulin glargine as add-on to sodium-glucose co-transporter-2 inhibitor in patients with type 2 diabetes: DUAL IX trial

A. Philis-Tsimikas[1], L.K. Billings[2,3], R. Busch[4], C. Morales Portillo[5], R. Sahay[6], N. Halladin[7], R. Gronskyte[7], S. Harris[8];
[1]Scripps Whittier Diabetes Institute, San Diego, USA, [2]NorthShore University HealthSystem, Evanston, USA, [3]University of Chicago Pritzker School of Medicine, Chicago, USA, [4]Albany Medical Centre, Albany Medical Centre, USA, [5]Hospital Virgen Macarena, Seville, Spain, [6]Osmania Medical College, Hyderabad, India, [7]Novo Nordisk, Søborg, Denmark, [8]Western University, London, Canada.

Background and aims: The DUAL IX study investigated the safety and efficacy of insulin degludec/liraglutide (IDegLira) versus insulin glargine 100 units/mL (IGlar U100) as an add-on to sodium-glucose co-transporter-2 inhibitor (SGLT2i) ± other oral antidiabetic drug therapy (OAD) in patients with type 2 diabetes (T2D).

Materials and methods: In this 26-week, phase 3b, open-label trial, 420 patients with T2D uncontrolled on SGLT2i ± other OADs were randomised 1:1 to receive add-on therapy of IDegLira or IGlar U100 (100 units [U]/mL). Starting doses were 10 U in both treatment arms. Doses were titrated twice-weekly to a fasting glucose target of 4.0–5.0 mmol/L; only IDegLira had a maximum dose (50 dose steps). Analysis values for HbA_{1c}, body weight and insulin dose based on analysis of covariance model with treatment, pre-trial OAD and region as factors and corresponding baseline value as covariate; missing data are imputed using unconditional reference-based multiple imputation including data obtained after premature treatment discontinuation. Number of hypoglycaemic episodes were analysed by negative binomial regression model with a log link and the logarithm of the exposure time +7 days as offset; the model includes treatment and pre-trial OAD as fixed factors and missing data are imputed using multiple imputation. Hypoglycaemia defined as severe (requiring the assistance of another person) or blood glucose-confirmed (<3.1 mmol/L) symptomatic hypoglycaemic episodes.

Results: Mean HbA_{1c} decreased from 8.2% at baseline to 6.3% at week 26 for IDegLira and from 8.4 to 6.7% for IGlar U100; IDegLira superiority confirmed ($p < 0.0001$). IDegLira treatment resulted in unchanged mean body weight versus 2.0 kg weight gain with IGlar U100 ($p < 0.0001$). The rate of treatment-emergent hypoglycaemic episodes was 58% lower ($p = 0.0035$) with IDegLira (0.37 events/patient-year of exposure [PYE]) versus IGlar U100 (0.90 events/PYE). Total daily insulin dose after 26 weeks was 36 U for IDegLira versus 54 U for IGlar U100 ($p < 0.0001$). Adverse event rates were low in both treatment arms with no unexpected safety issues.

Conclusion: Superiority of IDegLira versus IGlar U100 as an add-on to SGLT2i was confirmed for glycaemic control, body weight, hypoglycaemia rate and total daily insulin dose.

Similar glycaemic control and less or comparable hypoglycaemia with insulin glargine 300 U/ml vs degludec 100 U/ml in insulin naive type 2 diabetes: the BRIGHT randomised study

A. Cheng[1], J. Rosenstock[2], R. Ritzel[3], Z. Bosnyak[4], C. Devisme[5], P. Stella[6], A.M.G. Cali[7], X. Wang[8], J. Frias[9], R. Roussel[10], G.B. Bolli[11];
[1]Division of Endocrinology and Metabolism, University of Toronto, Toronto, Canada, [2]Dallas Diabetes Research Center at Medical City, Dallas, USA, [3]Klinikum Schwabing and Klinikum Bogenhausen, Städtisches Klinikum München GmbH, Munich, Germany, [4]Sanofi, Paris, France, [5]AIXIAL, Boulogne-Billancourt, France, [6]Sanofi, Budapest, Hungary, [7]Sanofi, Tokyo, Japan, [8]Sanofi, Beijing, China, [9]National Research Institute, Los Angeles, USA, [10]Assistance Publique Hôpitaux de Paris, Bichat Hospital, Paris, France, [11]Perugia University Medical School, Perugia, Italy.

Background and aims: BRIGHT is the first head-to-head clinical trial investigating the efficacy and safety of insulin glargine 300 U/ml (Gla-300) vs insulin degludec 100 U/ml (IDeg-100).
Materials and methods: In this 24-week, multinational, open-label, parallel-group, treat-to-target trial, 929 insulin-naïve adults with type 2 diabetes (T2DM) inadequately controlled with oral antihyperglycemic drugs ± glucagon-like peptide-1 receptor agonists, were randomised 1:1 to once-daily Gla-300 or IDeg-100. Primary endpoint: HbA_{1c} change from baseline to week 24. Secondary endpoints included hypoglycaemia, blood glucose levels, and adverse events.
Results: The included individuals had mean HbA_{1c} of 8.6%, diabetes duration of 10.6 years and BMI of 31.5 kg/m^2. Non-inferiority of Gla-300 vs IDeg-100 was demonstrated for the primary endpoint (**Table**). Gla-300 had similar fasting self-measured plasma glucose reduction to IDeg-100 (**Table**), with final daily insulin doses of 0.54 and 0.43 U/kg from starting evening doses, per label, of 0.2 U/kg and 10 U/day (0.12 U/kg), respectively. Over the 24-week period, incidence of confirmed (≤3.9 mmol/l) or severe hypoglycaemia was comparable, but event rates were lower with Gla-300 vs IDeg-100, by 14% at any time of day (24 h) and 19% at night (00:00–05:59 h) (**Table**).
Conclusion: BRIGHT showed that Gla-300 provides similar glycaemic control to IDeg-100, with less or comparable hypoglycaemia, in previously inadequately controlled, insulin-naïve adults with T2DM.

Reducing insulin degludec around regular exercise improves time spent in euglycaemia in people with type 1 diabetes: a randomised cross-over trial

O. Moser[1], M.L. Eckstein[1], A. Mueller[2], P. Birnbaumer[2], F. Aberer[3], G. Koehler[3], C. Sourij[3], H. Kojzar[3], P. Holler[4], H. Simi[4], P. Pferschy[3], P. Dietz[2], R.M. Bracken[1], P. Hofmann[2], H. Sourij[3];
[1]Swansea University, Swansea, UK, [2]University of Graz, Graz, Austria, [3]Medical University of Graz, Graz, Austria, [4]FH JOANNEUM, Bad Gleichenberg, Austria.

Background and aims: Insulin degludec (IDeg) is associated with a similar risk of exercise-induced hypoglycaemia compared to insulin glargine. Though adjustment of bolus insulin is commonly recommended around exercise with an unaltered background of IDeg, no research has explored the impact of intermittent IDeg dose reduction in patients regularly exercising on a few consecutive days. Therefore, the aim of this study was to compare the time spent in euglycaemia in people with type 1 diabetes (T1D) during 5 consecutive days of continuous moderate-intensity exercise, on either 100% or 75% of their usual IDeg dose.
Materials and methods: 9 participants with T1D (4 females, age 32.1 ± 9.0 years, BMI 25.5 ± 3.8 kg/m^2, HbA_{1c} 7.2 ± 2.8% (55 ± 7 mmol/mol)) performed a cardio-pulmonary exercise test on a cycle ergometer to determine maximum oxygen uptake (VO_{2max}) as well as the first (LTP_1) and the second lactate turn points (LTP_2). Afterwards, a flash glucose monitoring sensor was inserted, and participants were switched to IDeg if not running on that insulin before. 3 days before the first exercise phase participants were randomised to either 100% or 75% of their usual IDeg dose. Then participants exercised on a cycle ergometer for 55 min at a moderate intensity (midpoint between LTP_1 and LTP_2 (~65% VO_{2max})) for 5 consecutive days in the evening at the clinical research facility. After a washout period of 4 weeks, participants performed the second exercise phase

for 5 consecutive days with the remaining allocation. Time spent in eu- (3.9–10 mmol/l), hypo- (<3.9 mmol/l) and hyperglycaemia (>10 mmol/l), AUC for these glycaemic ranges, numbers of hypoglycaemic events, glycaemic CV and insulin as well as carbohydrate intake were compared for the entire 5 days. Data were compared between groups by paired t-test and Wilcoxon matched-pairs signed rank test, $p < 0.05$.

Results: A 25% reduction in IDeg dose around regular exercise achieved a longer time spent in euglycaemia ($p = 0.04$) with no effect on numbers of hypoglycaemic events ($p = 0.91$) or time spent in hypo- ($p = 0.07$) or hyperglycaemia ($p = 0.38$) (table 1). The amount of carbohydrates and dose of bolus insulin injections were similar between the two dosing regimens ($p > 0.05$).

Conclusion: This is the first study demonstrating that people with T1D should be encouraged to reduce IDeg dose by 25% when performing regular exercise on consecutive days.

Background and aims: People with type 2 diabetes (T2DM) require effective insulin titration to achieve HbA_{1c} targets. However, most fail to achieve HbA_{1c} goals in clinical practice, owing to patient- and physician-related barriers. This study evaluated whether the second-generation basal insulin, insulin glargine 300 U/ml (Gla-300) empowered patients to self-titrate effectively.

Materials and methods: This 24-week, multicentre, randomised, open-label, parallel-group study compared the efficacy and safety of a simple Gla-300 titration algorithm (fasting self-monitored blood glucose [SMBG] >7.2 mmol/l, +3 U; <4.4 mmol/l, −3 U), when managed by patients vs physicians, in people with uncontrolled T2DM. Participants ($N = 631$) from 10 European countries were randomised 1:1 to each group.

Results: Baseline characteristics were similar in both groups. The least squares (LS) mean difference for patient- vs physician-led groups in HbA_{1c} change from baseline was −0.13% [95% CI: −0.2619 to −0.0004], demonstrating superiority for self-titration ($p = 0.0247$). The proportion of participants achieving a fasting SMBG of 4.4–7.2 mmol/l without confirmed (<3.0 mmol/l) or severe hypoglycaemia was 67% and 58% in the patient- and physician-led groups ($p = 0.0187$), and 31.2% and 23.7% of participants, respectively, achieved HbA_{1c} <7% ($p = 0.0269$). Severe hypoglycaemia was reported in 0.6% and 0.3% of the patient- and physician-led groups, respectively. Similar decreases in LS mean Diabetes Distress Scale total score were observed in both groups from baseline to week 24: −0.24 (95% CI: −0.32 to −0.15) in the patient- and −0.16 (−0.25 to −0.08) in the physician-led group (difference: −0.07 [−0.19 to 0.04]). More patients with high distress (mean total score ≥3) were observed in the physician-led titration group at week 24 (12.2% vs. 8.5% in the patient-led group). LS mean Diabetes Empowerment Scale scores similarly improved from baseline to week 24 in the patient- (0.19 [0.14 to 0.24] and physician-led (0.12 [0.07 to 0.17]) groups (difference: 0.07 [0.00 to 0.14]).

Conclusion: Self-titration of Gla-300 in T2DM provides more effective glycaemic control without increased hypoglycaemia, with as-confident and a trend towards less-distressed patients, versus physician-led titration.

The clinical benefits of IDegLira in DUAL VII were achieved while using a simple regimen with fewer injections and dose adjustments compared with basal-bolus therapy

E.M. Miller[1], E. Jodar[2], K. Khunti[3], D. Sugimoto[4], P. Orsy[5], M.F. Ranthe[5], A. Viljoen[6];
[1]Diabetes Nation, Bend, USA, [2]University Hospital Quiron Salud, Madrid, Spain, [3]Leicester General Hospital, Leicester, UK, [4]Cedar Crosse Research Center, Chicago, USA, [5]Novo Nordisk A/S, Søborg, Denmark, [6]Lister Hospital, Stevenage, UK.

Background and aims: Complex treatment regimens, such as basal-bolus insulin therapy (BB), are associated with lower compliance, greater treatment burden and poor patient satisfaction. Complex regimens are also a major concern for physicians since they require more resources and clinical decisions, both of which become more problematic as type 2 diabetes (T2D) progresses. In DUAL VII, insulin degludec/liraglutide (IDegLira) resulted in non-inferior HbA_{1c} reductions (as per the trial design), weight loss (−0.9 vs. 2.6 kg), and an 89% reduction in rates of hypoglycaemia compared with BB in patients with T2D. This *post hoc* analysis evaluated the treatment complexity of IDegLira vs. BB in terms of number of injections and dose adjustments.

Materials and methods: In a 26-week, open-label trial, patients with T2D uncontrolled on metformin and 20–50 U insulin glargine 100 U/mL (IGlar U100) were randomised 1:1 to IDegLira ($N = 252$) or BB (IGlar U100 + insulin aspart ≤4 times/day; $N = 254$). IDegLira was initiated at 16 dose steps/units (U) (16 U insulin degludec +0.58 mg liraglutide); initial IGlar U100 dose was the pre-trial dose (mean: 33 U). Both were titrated twice-weekly, based on the mean of three pre-breakfast self-monitored plasma glucose (SMPG) readings, to a target of 4–5 mmol/L. Insulin aspart was initiated at 4 U/main meal and titrated twice-weekly to a pre-prandial and bedtime SMPG target of 4–6 mmol/L. This analysis reports the observed mean number of insulin injections and dose adjustments during 26 weeks.

Results: Despite the lower starting basal insulin component dose with IDegLira vs. BB, the number of basal insulin dose adjustments were similar during treatment (Table). The mean number of bolus insulin adjustments increased steadily during the trial to 200 per patient (median [min; max]: 218 [1; 569]). 66.5% of patients in the BB group were receiving ≥3 bolus injections/day at Week 26 in addition to their basal insulin and SMPG measurements in connection with each injection.

Conclusion: Burdensome regimens impact on patients' quality of life, treatment adherence and ability to achieve good glycaemic control. Compared with BB, the clinical benefits of IDegLira (comparable HbA_{1c} reduction, lower hypoglycaemia rates and weight loss) are achieved using a more convenient regimen in the DUAL VII study. In addition to the clinical benefits, this simple regimen has the advantages of fewer daily injections, SMPG readings and dose adjustments, requiring fewer clinical decisions.

Regimen complexity at 26 weeks

	IDegLira	Basal–bolus
Mean number (SD) of basal insulin dose adjustments	16.6 (6.8)	17.1 (10.2)
Mean number (SD) of bolus insulin dose adjustments	–	200.1 (118.6)
Number (%) of patients receiving the following bolus injections/day		
0	–	3 (1.3)
1	–	18 (7.8)
2	–	56 (24.3)
≥3	–	153 (66.5)

CONFIRM: a comparative effectiveness study of insulin degludec and insulin glargine 300 units/ml (glargine U300) in insulin-naive patients with type 2 diabetes

J. Tibaldi[1], S. Haldrup[2], V. Sandberg[2], M.L. Wolden[2], H.W. Rodbard[3]; [1]Fresh Meadows Diabetes and Endocrinology, New York, USA, [2]Novo Nordisk A/S, Søborg, Denmark, [3]Clinical Research, Rockville, USA.

Background and aims: The Clinical Outcome Assessment of the Effectiveness of Insulin Degludec in Real-life Medical Practice (CONFIRM) study compared the real-world effectiveness of insulin degludec (degludec) and insulin glargine 300 units/mL (glargine U300) in insulin-naïve patients with type 2 diabetes.

Materials and methods: This retrospective, non-interventional, comparative effectiveness study used electronic health records of US-based patients from Explorys, with propensity-score matching to balance baseline characteristics between cohorts. The primary endpoint, Δ HbA_{1c} from baseline to 6 months' follow-up, was estimated using a repeated-measure analysis with subject as random effect. Rate of hypoglycaemic episodes (defined using International Classification of Diseases codes 9/10) and proportion of patients with hypoglycaemia were estimated using negative binomial and logistic regression, respectively. Time-to-discontinuation of basal insulin was analysed using a Cox Proportional Hazard model. This study included adults with type 2 diabetes treated with oral antidiabetic drugs, intensified with either degludec or glargine U300.

Results: Data from 4056 patients were analysed. After matching, baseline characteristics of the groups were comparable ($n = 2028$ in each group). At follow-up, Δ HbA_{1c} was significantly lower with degludec (−1.5%) versus glargine U300 (−1.2% [treatment difference, −0.3%, $p = 0.029$]). Rates of hypoglycaemia were significantly lower with degludec versus glargine U300 (rate ratio: 0.70, $p = 0.045$). Similarly, the proportion of patients experiencing hypoglycaemia was significantly lower with degludec (odds ratio: 0.64; $p < 0.01$). Patients treated with glargine U300 had a 37% higher risk of treatment discontinuation versus degludec (hazard ratio: 1.37, $p < 0.01$).

Conclusion: Data from the largest real-world comparative effectiveness study of degludec and glargine U300 to date demonstrated improved glycaemic control, lower rates of hypoglycaemia and lower risk of discontinuation with degludec versus glargine U300.

THE I-HART CGM study: hypoglycaemic episodes reduced with continuous glucose monitoring compared to Flash in adults with type 1 diabetes

P. Avari[1], V. Moscardo[2], N. Jugnee[1], M. Reddy[1], N. Oliver[1];
[1]Imperial College London, London, UK, [2]Universitat Politècnica de Valencia, Valencia, Spain.

Background and aims: The I-HART CGM Study is the first head-to-head glucose monitoring study designed to assess impact of flash and continuous glucose monitoring (CGM) in highest risk adults with type 1 diabetes mellitus (T1DM). We have previously shown CGM was associated with reduced hypoglycaemia exposure compared to flash. In this analysis, we assess the number of hypoglycaemic episodes in each group.
Materials and methods: Forty participants with highest risk diabetes (Gold Score ≥4 or recent severe hypoglycaemia using insulin injections) were recruited to this randomized, parallel group trial. Following two weeks of blinded CGM, participants were randomized to CGM (DexcomG5; $n = 20$) or flash (Freestyle Libre; $n = 20$) for 8-weeks. An open extension phase enabled participants on CGM to continue for a further 8 weeks, and those on flash to switch to CGM over this period. A non-parametric analysis was performed. Significance was calculated between flash and CGM throughout the study period, and between flash switching to CGM with the corresponding weekly interval. The number of hypoglycaemic episodes were analyzed for each week. Each episode of hypoglycaemia was defined with a duration of 20 minutes and a separation time of 15 minutes.
Results: Over the first 8 weeks, a reduced number of serious hypoglycaemic episodes (<3.0 mmol/L) was observed with CGM compared to flash during each consecutive week. Statistical significance between groups was observed at weeks 4–6 ($p < 0.05$). Less serious hypoglycaemic episodes (<3.9 mmol/L) showed similar reduction in events at weeks 5 and 6 ($p < 0.05$), however, the difference between the two groups was less marked. Between 8–16 weeks, no significant change was observed in the group continuing on CGM. A significant reduction in hypoglycaemic events was observed when switching flash to CGM ($p < 0.05$) for serious hypoglycaemia <3.0 mmol/L at weeks 10 and 12–16 ($p < 0.05$). For hypoglycaemia <3.9 mmol/L, reduced events were noted at weeks 13, 14 and 16.
Conclusion: Real-time CGM shows greater beneficial impact on reducing hypoglycaemic episodes compared with flash in adults with T1DM at highest risk of hypoglycaemia. In particular, the benefits of CGM was observed with more serious, clinically important hypoglycaemia (<3.0 mmol/l). However, the significant effect on reducing hypoglycaemic episodes with CGM was not sustained throughout the 16 weeks, and may reflect the small cohort numbers or user fatigue with alarms. Switching flash to CGM significantly reduced hypoglycaemic episodes. These findings are important when selecting monitoring techniques to minimize the clinical and cost, impact of hypoglycaemia.

First assessment of the performance of an implantable continuous glucose monitoring (CGM) system through 180 days in a primarily adolescent population with type 1 diabetes

A. Abitbol[1], R. Aronson[2], R. Rastogi[3], C. Mdingi[3], X. Chen[3], K.S. Tweden[3];
[1]LMC Diabetes & Endocrinology, Oakville, Canada, [2]LMC Diabetes & Endocrinology, Toronto, Canada, [3]Senseonics, Incorporated, Germantown, USA.

Background and aims: An implantable continuous glucose monitoring (CGM) system (Eversense® XL, Senseonics, Maryland USA) recently received CE Mark for 180-day duration in adults. The current study is the first investigation of the performance of the Eversense XL through 180 days in a primarily adolescent population with type I diabetes (T1D).
Materials and methods: This study was a prospective, single-center, single-arm, 180-day study that evaluated the effectiveness and safety of the implantable CGM system among Canadian adolescent and adult participants with T1D. Effectiveness measures included mean absolute relative difference (MARD), system agreement with Yellow Springs Instrument (YSI) glucose values, and Clarke Error Grid analysis using paired CGM and reference YSI glucose analyzer values. Adult participants were inserted with two sensors and adolescent participants were inserted with one sensor in the upper arm. CGM system accuracy studies were performed every 30 days. The safety assessment included the incidence of insertion/removal-procedure and device-related serious adverse events (SAEs) through 180 days post-insertion.
Results: Thirty-Six participants (30 adolescent/6 adult, 13 female/23 male, mean age 17 ± 9.2 years, mean BMI 22 ± 4 kg/m^2) received the CGM system. One subject withdrew at Day 1 due to intravenous access issues. CGM system agreement with YSI glucose within 15 mg/dL or 15% of YSI glucose values ($N = 7163$) through 60, 120 and 180 days was 82.9%, 83.6% and 83.4% (95% CI: 79.7%–85.5%), respectively. Overall MARD was 9.4% (95% CI: 8.6%–10.5%). Clarke Error Grid analysis showed 99% of paired values in clinically acceptable error zones A and B. No insertion/removal or device-related SAEs were reported.
Conclusion: The Eversense XL CGM system is safe and accurate through 180 days of Sensor wear in a primarily adolescent population.

Development of a computerised, guideline based continuous glucose monitoring (CGM) directed therapy algorithm to assist physicians in the management of patients with type 2 diabetes

R.A. Vigersky, S. Guan, C. McMahon, B. Huhta, P. Agrawal, R. Buechler, P. Chung, O. Cohen, G. Hamer, J. Smith, S. Lee, R. Morawiec, L. Resurreccion, K. Saad, F. Kaufman;
Medtronic Diabetes, Northridge, USA.

Background and aims: To address the clinical inertia that often occurs in T2D treatment, facilitate interpretation of CGM-derived data, and promote adherence to professional organizations' guidelines, a computerized decision support system (CDSS) for physicians has been developed.
Materials and methods: The CDSS is based on retrospective CGM data and linked to the medication guidance of the American Diabetes Association and the American Association of Clinical Endocrinology. While CDSS's are used in diabetes management, none have included CGM-derived data with pattern analysis to help address the wide range

of pharmacotherapeutic possibilities in patients with T2D. Inputs to the system include: 1) A1C target; 2) current medication dose and frequency; and 3) retrospective CGM data. The CDSS algorithm includes all classes of diabetes medications except dopamine agonists and bile acid sequestrants and considers a wide range of baseline medication states from therapy-naïve to triple therapy combinations. Major patterns are identified by a pattern-recognition algorithm. The CDSS provides 0–6 therapy considerations (by class) matching the clinically most important pattern with the predominant action of a drug. These considerations are based on mean sensor glucose, current medication(s) and dose(s), and presence/absence of hyperglycemic symptoms. Therapy considerations include making no change in the baseline therapy, increasing or reducing the dose of a current medication(s), or adding/substituting/stopping a medication including the initiation of insulin therapy, where appropriate. Since large scale head-to-head trials of comparative effectiveness are not available for most drugs, the therapy considerations are arranged alphabetically. Importantly, physicians must apply their professional judgement in assessing these options and consider important clinical factors such as past medication use/tolerance, allergies, renal and hepatic function before making a therapy decision.

Results: The CDSS output from over 300 cases was presented to over 75 physicians in the U.S., Europe, and Asia. Examples: In a patient taking metformin and glimepiride with a primary pattern of low sensor glucose overnight, therapy considerations would be: "reduce or stop sulfonylurea" and "consider replacing sulfonylurea with a non-hypoglycemia inducing medication"; in a patient on glipizide-XR, metformin and basal insulin the morning with a primary pattern of high sensor glucose from 1600–2400 hours, a therapy consideration would be: "increase basal insulin". There was a high degree of concordance with the pattern identification and therapy considerations. The CDSS may be customized to reflect the guidance from other professional organizations or governmental bodies.

Conclusion: We anticipate that CDSS's such as this one will become important tools in assisting physicians to make appropriate medication changes in a complex therapy environment.

Continuous glucose monitoring in healthy non-diabetic participants: a multicentre prospective study

A. Peters[1], Z. Li[2], S. DuBose[2], R. Beck[2], V. Shah[3], R.S. Weinstock[4], M. Tansey[5], D. Sparling[6], S. Woerner[7], F. Vendrame[8], R. Bergenstal[9], J. Sherr[10], J. Shine Dyer[11], S.E. Watson[12], B. Tamborlane[10];
[1]USC, Los Angeles, [2]JCHR, Tampa, [3]BDC, Aurora, [4]SUNY Upstate, Syracuse, [5]Univ Iowa, Iowa City, [6]Univ Oklahoma, Oklahoma City, [7]Indiana Univ, Indianapolis, [8]Univ Miami, Miami, [9]IDC Park Nicollet, St Louis Park, [10]Yale, New Haven, [11]COPEDS, Columbus, [12]Wendy Novak, Louisville, USA.

Background and aims: Much effort has been placed on standardization of CGM-based outcomes that are increasingly being used in clinical research related to newer therapeutics and devices. This study was undertaken to determine the distribution of sensor glucose levels in healthy, non-diabetic participants using the recently approved DexCom G6 system.

Materials and methods: In this multicenter study, healthy, non-diabetic children and adults (age 7 to 80 years, BMI <25 kg/m^2 or between 5th and 85th percentile, and HbA1c <5.7%) were included. Each subject wore a blinded DexCom G6 for ~10 days and kept a daily log of exercise, meals, and sleep. Only participants with no positive islet antibodies and at least 72 hours of CGM data were analyzed. Participants were divided into 5 age cohorts for analysis.

Results: A total of 201 healthy non-diabetic participants were screened and 151 enrolled and analyzed. The cohort was 67% female, 84% non-Hispanic White, and had mean HbA1c of 5.1%. Participants ≥18 years old had mean BMI of 24 kg/m^2 and those <18 years had mean BMI percentile of 51%. Overall mean 24-hour sensor glucose level was 100 ± 7 mg/dL, a finding that was consistent except for those participants 60+ years who had slightly higher glucose levels (104 ± 9 mg/dL). Peak postprandial glucose was 129 mg/dL with no major differences across age groups. Overall, meal related increases in sensor glucose resulted in daytime glucose levels 2 mg/dL higher than nighttime values. Sensor glucose levels above 120 and below 70 mg/dL were not uncommon across all age groups but sensor values above 180 mg/dL were rarely observed except in participants 60+ years old (Table). In all age groups, sensor levels <54 mg/dL were rarely seen. Overnight mean and nadir sensor glucose levels following exercise days were slightly lower compared with sedentary days, but the differences were not statistically significant (data not shown).

Conclusion: As greater emphasis is placed on glycemic metrics beyond HbA1c levels, the current study provides a normative set of sensor glucose levels that can be used for comparison for clinical trials. It is noteworthy that sensor glucose levels >180 and <54 mg/dL were very uncommon in our healthy non-diabetic participants, which support these levels as the thresholds for clinically important hyper- and hypoglycemia in diabetes. With improvements in both pharmacologic agents and mechanical solutions the ultimate goal may be to attain tighter glycemic control in those living with diabetes by altering the hyperglycemic threshold to 160 mg/dL.

Table: Sensor glucose levels overall and by age in healthy non-diabetic subjects (n=151)

		Age (Years)				
	All (n=151)	7 to 11 (n=26)	12 to 17 (n=30)	18 to 24 (n=28)	25 to 59 (n=41)	60+ (n=26)

Decreased time <70 mg/dl for patients previously using pumps, multiple daily injections, CGM or no CGM before using a predictive low glucose suspend system: the PROLOG study

B.A. Buckingham[1], Z. Li[2], J.E. Pinsker[3], G.P. Forlenza[4], E. Cengiz[5], L. Ekhlaspour[1], M. Church[3], P. Wadwa[4], S.A. Weinzimer[5], W. Woodall[2], B.B. Dokken[6], V. Swanson[6], J. Lum[2], C. Kollman[2], R. Beck[2];
[1]Department of Pediatric Endocrinology, Stanford University, Palo Alto, [2]Jaeb Center for Health Research, Tampa, [3]Sansum Diabetes Research Institute, Santa Barbara, [4]Barbara Davis Center, Aurora, [5]Department of Pediatric Endocrinology and Diabetes, Yale University, New Haven, [6]Department of Clinical Affairs, Tandem Diabetes Care, San Diego, USA.

Background and aims: Hypoglycemia is a major concern for patients with type 1 diabetes. The predictive low glucose suspend (PLGS) feature on the t:slim X2 insulin pump with Basal-IQ Technology allows for automatic basal rate suspension when the sensor glucose is predicted to reach 80 mg/dL within 30 min, and resumes immediately when glucose begins to rise. Previous studies have found increased hyperglycemia associated with some PLGS systems.

Materials and methods: A randomized crossover trial was conducted at 4 sites in the US. Participants had type 1 diabetes (age ≥6 years, n = 103) and were previously treated with MDI (n = 17) or pump therapy (n = 86), either with (n = 87) or without CGM (n = 16). Subjects used the t:slim X2

with Basal-IQ (PLGS) during one 3-week period and sensor augmented pump (SAP) during another 3-week period. The order of treatment was randomized. The primary outcome was the percentage of CGM sensor glucose values <70 mg/dL compared between treatment arms using a repeated measures regression model. Pump suspension or resumption of insulin did not generate alarms.

Results: Sensor time <70 mg/dL decreased by 31% relative to SAP in the PLGS arm (4.5% ± 3.9% SAP vs. 3.1% ± 2.8% PLGS, mean values; $P < 0.001$) with no change in mean glucose between groups (159 ± 27 mg/dL SAP vs. 159 ± 25 mg/dL PLGS). Time in range (70 mg/dL–180 mg/dL) modestly but significantly increased by 3% in the PLGS arm relative to the SAP arm (63% ± 15% SAP vs. 65% ± 15% PLGS, mean values, $P < 0.001$). The mean duration of pump suspensions was 18 minutes, and only 3% lasted for >1 hr. The mean number of suspensions each day was 5.7 ± 4.3 which was associated with a significant reduction in basal insulin delivery from a mean of 21.5 units/d to 20.3 units/d ($P < 0.001$), while bolus delivery was unchanged. There was a 30% decrease in mean percent time <70 mg/dL for subjects previously using pumps and a 34% decrease for subjects previously using MDI. For subjects previously using CGM there was a 33% decrease in time <70 mg/dL, and for non-CGM users there was a 20% decrease. Participants found the system easy to use, documented with a high System Usability Score of 88.8 out of 100.

Conclusion: The t:slim X2 with Basal-IQ was safe and associated with a significant reduction of hypoglycemia and increased time in range compared to SAP. Subjects experienced with or naïve to pump and sensor technologies had similar reductions in hypoglycemia and user satisfaction ratings.

Closed-loop insulin delivery in suboptimally controlled type 1 diabetes: a multicentre, 12-week, randomised trial

M. Tauschmann[1], H. Thabit[1,2], J.M. Allen[1], J. Sibayan[3], C. Kollman[3], P. Cheng[3], M.L. Evans[1,4], D.B. Dunger[1], D. Elleri[5], R.M. Bergenstal[6], F. Campbell[7], V.N. Shah[8], A. Criego[6], L. Leelarathna[2], R. Hovorka[1];
[1]University of Cambridge, Cambridge, UK, [2]Central Manchester University Hospitals NHS Foundation Trust, Manchester, UK, [3]Jaeb Center for Health Research, Tampa, USA, [4]Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK, [5]Royal Hospital for Sick Children, Edinburgh, UK, [6]International Diabetes Center, Minneapolis, USA, [7]Leeds Children's Hospital, Leeds, UK, [8]University of Colorado, Denver, USA.

Background and aims: We assessed the safety and effectiveness of day-and-night hybrid closed-loop insulin delivery compared with sensor augmented pump therapy in youths and adults with suboptimally controlled type 1 diabetes.

Materials and methods: In an open-label, multi-centre, multi-national (UK and USA), single-period, parallel study, we randomly assigned subjects with type 1 diabetes aged 6 years and older treated with insulin pump therapy and suboptimal glycaemic control (HbA1c between 7.5% and 10%) to receive either closed-loop insulin delivery with Cambridge control algorithm ($n = 46$) or sensor-augmented pump therapy ($n = 40$; control) over 12 weeks of unrestricted living. Training on study pump and continuous glucose monitor took place over a 4-week run-in period.

Results: In an intention to treat analysis and relative to run-in period, closed-loop increased time that glucose was in target range by 13 ± 8 percentage points compared with a 2 ± 6 percentage point increase in control group (primary endpoint; $p < 0.001$; closed-loop vs control). In closed-loop group, HbA1c was reduced from screening value of 8.3 ± 0.6% to 8.0 ± 0.6% post run-in and 7.4 ± 0.6% post intervention. In control group these values were 8.2 ± 0.5%, 7.8 ± 0.6% and 7.7 ± 0.5%; reductions in A1c levels were significantly greater in closed-loop group compared to control group (mean difference in change 0.4%; 95% CI, 0.2% to 0.6%; $p < 0.001$). Mean sensor glucose was lower in closed-loop group ($p < 0.001$) as was the time spent with sensor glucose levels below 3.9 mmol/L ($p = 0.008$) and above 10.0 mmol/L ($p < 0.001$) (table). Time spent with glucose levels in significant hypoglycaemia (<2.8 mmol/L) was not different between interventions ($p = 0.11$). Similarly, total daily insulin dose was not different ($p = 0.09$). No severe hypoglycaemia occurred. One diabetic ketoacidosis presented in closed-loop group due to infusion set failure and none in control group.

Conclusion: Hybrid closed-loop is safe and improves glucose control and HbA1c while reducing the risk of hypoglycaemia across a wide age range in suboptimally controlled type 1 diabetes supporting adoption of closed-loop in clinical practice.

Table. Study endpoints by treatment group

	Closed-loop (N=46)	Control (N=40)	p-value*
Time spent at glucose level (%)			
3.9-10.0 mmol/L**	**65 ± 8**	**54 ± 9**	**<0.001**
<3.9 mmol/L	2.6 (1.9-3.6)	3.9 (1.7-5.3)	0.008
<2.8 mmol/L	0.3 (0.2-0.6)	0.5 (0.2-0.9)	0.11
>10.0 mmol/L	32 ± 8	42 ± 10	<0.001
>16.7 mmol/L	3.5 (1.9-4.6)	4.4 (2.9-6.5)	<0.001
Mean glucose (mmol/L)	8.9 ± 0.7	9.7 ± 1.0	<0.001
Glucose SD (mmol/L)	3.5 ± 0.5	3.8 ± 0.5	<0.001
Glucose CV (%)	40 ± 4	40 ± 4	0.50
Total daily dose (U/kg/day)	0.81 ± 0.25	0.71 ± 0.19	0.09

Impaired mitochondrial function of human ventricular myocardium in insulin resistance and type 2 diabetes

E. Zweck[1,2], D. Scheiber[1,2], T. Jelenik[1], P. Horn[2], S. Albermann[1,2], U. Boeken[3], D. Saeed[3], M. Kelm[2,4], M. Roden[1,5], R. Westenfeld[2], J. Szendroedi[1,5];
[1]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research, Heinrich Heine University and German Center for Diabetes Research, Düsseldorf, [2]Division of Cardiology, Pulmonology and Vascular Medicine, Medical Faculty, Heinrich Heine University, Düsseldorf, [3]Clinic for Cardiovascular Surgery, Medical Faculty, Heinrich Heine University, Düsseldorf, [4]Cardiovascular Research Institute Düsseldorf, Medical Faculty, Heinrich Heine University, Düsseldorf, [5]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Düsseldorf, Germany.

Background and aims: Type 2 Diabetes Mellitus (T2DM) is associated with increased risk of heart failure independent of other risk factors like coronary artery disease and arterial hypertension. While underlying mechanisms are only partially understood, recent studies detected mitochondrial alterations in atrial tissue of patients with T2DM suffering from ischemic or valvular heart disease and requiring open-heart surgery. These studies yielded controversial results concerning a direct link between insulin resistance and mitochondrial dysfunction. We hypothesized that mitochondrial capacity and coupling efficiency are reduced in ventricular tissue of insulin resistant and humans with T2DM and normal heart function.
Materials and methods: High resolution respirometry was performed ex-vivo in transcatheter ventricle biopsies of 29 healthy heart transplant recipients with normal left ventricular function (left ventricular ejection fraction: 64 ± 8%) and without allograft rejection. We assessed three-hour oral glucose insulin sensitivity (OGIS), fasting insulin resistance via homeostasis model assessment (HOMA-IR) and redox potential (ORP) reflecting systemic oxidative stress.
Results: Glucose tolerant humans (CON; $n = 16$) and T2DM ($n = 13$) had comparable age (54 ± 14 vs. 58 ± 12 years), sex (81% vs. 85% male) and time since transplantation (26 ± 24 vs. 25 ± 26 months), while body mass index was higher in T2DM (25.0 ± 2.9 vs. 28.1 ± 4.9 kg/m^2; $p < 0.05$). Myocardial state 3 respiration was 20% lower in T2DM compared to CON at saturating levels of octanoyl carnitine (101 ± 25 vs. 81 ± 20 pmol/(s*mg); $p < 0.05$), 23% lower at additional glutamate (123 ± 35 vs. 95 ± 27 pmol/(s*mg); $p < 0.05$), but not different at additional succinate (178 ± 60 vs. 143 ± 51 pmol/(s*mg)). Lipid-linked respiration related negatively to Hb_{A1c} ($r = -0.45$; $p < 0.05$) and fasting blood glucose levels ($r = -0.48$; $p < 0.05$), but positively to OGIS ($n = 18$; $r = 0.57$; $p < 0.05$). Respiration with additional substrates of complex I and II of the respiratory chain specifically correlated with OGIS ($r = 0.51$; $p < 0.05$). Respiratory control ratios (RCR) on lipids were 21% lower in T2DM (1.6 ± 0.4 vs. 1.2 ± 0.3; $p < 0.05$) and correlated negatively with Hb_{A1c} ($r = -0.44$; $p < 0.05$) and HOMA-IR ($r = -0.488$; $p < 0.05$). Additional substrates of complex I and II resulted in 22% lower RCR in T2DM (2.7 ± 0.8 vs. 2.1 ± 0.5; $p < 0.05$). ORP was 24% higher in T2DM (127 ± 23 vs. 157 ± 25 mV; $p < 0.01$) and related to Hb_{A1c} ($r = 0.45$; $p = 0.02$).
Conclusion: This study demonstrates reduced mitochondrial respiration and coupling efficiency in ventricular myocardium of humans with T2DM, which associates whole-body insulin resistance, impaired glycemic control and oxidative stress. These findings point to cardiomyocyte energy metabolism as a novel target for T2DM-related heart failure.

Total mortality: the key-feature of type 2 diabetes

J. vor dem Esche;
Codiplan GmbH, Herrsching am Ammersee, Germany.

Background and aims: Until today, most clinical trials performed in patients with type 2 diabetes have focussed on cardiovascular outcomes only, taking not into consideration non-cardiovascular causes of death and other major health-threats such as serious infections. Therefore, lethal and non-lethal, but potentially life-threatening events are meta-analysed.
Materials and methods: The data gathered from randomized controlled clinical trials conducted in patients with type 2 diabetes are evaluated by rates per person-years to define a disease appropriate ranking of serious outcomes.
Results: In the seventy-two selected publications, total mortality with an annual rate of 2.4% is by far the dominant outcome (R: 0.0244; 95% CI: 0.0229–0.0258, $p < 0.0001$), independent from the baseline risks. These figures are based on the analysis of all trials and all endpoints of interest (1,342,482 patient-years with 30,221 lethal events). Approximately 44% of the mortality events are non-cardiovascular death events. The results serious infections (R: 0.015; 95% CI: 0.012–0.019), cancer (R: 0.012; 95% CI: 0.008–0.016), heart failure (R: 0.012; 95% CI: 0.008–0.015), non-fatal myocardial infarction (R: 0.011; 95% CI: 0.008–0.015), and non-fatal stroke (R: 0.007; 95% CI: 0.004–0.011) are ranked from two to six.
Conclusion: Total mortality is the key-feature of type 2 diabetes. Apart from non-fatal myocardial infarction and non-fatal stroke, serious infections, cancer, and heart-failure should be included in a primary safety endpoint. By focussing on cardiovascular morbidity and mortality only, the current practice to evaluate efficacy and safety of antiglycaemic treatment strategies appears not to be fully appropriate for the real threats associated with type 2 diabetes.

Screening for diabetes and early treatment reduces mortality in peripheral arterial disease over seven years

C. Hoebaus[1], C.T. Herz[2], G. Pesau[1], B. Zierfuss[1], R. Koppensteiner[1], G.-H. Schernthaner[1];
[1]Medicine II - Angiology, Medical University of Vienna, Vienna, [2]Medicine III - Endocrinology and Metabolism, Medical University of Vienna, Vienna, Austria.

Background and aims: Diabetes mellitus type 2 (T2D) is a well-known risk factor for atherosclerosis development. The combination of T2D and peripheral arterial disease (PAD) is known to reduce survival. We investigated if intensified screening and early treatment for T2D is able to enhance survival over seven years in elderly PAD patients.
Materials and methods: Repetitive screening for T2D was performed in a PAD patient cohort ($N = 367$, 123 women, Fontaine stage I-II) three times every six month. Procedures included a 75 g oGTT and HbA1c measurement. T2D was defined using the current ADA guidelines or by active use of an anti-diabetic agent. Newly detected T2D was primarily

treated with metformin. Patients were stratified according to HbA1c (cut-off 53 mmol/mol) in adequate glucose control (AGC) or inadequate glucose control (IGC) at baseline and mean HbA1c was calculated over the first year. Estimated glomerular filtration rate (eGFR) was calculated by the Chronic Kidney Disease Epidemiology Collaboration equation. Data is presented as median (25th–75th percentile). Mann-Whitney-*U* and log-rank test were used as appropriate. Survival curves were calculated by the Kaplan-Meier method.

Results: This PAD cohort included 229 patients with presumed absence of glucose disturbance and 138 patients with known T2D. Initial intensified screening revealed 26 new T2D patients; 13 additional patients were diagnosed by screening over one year. T2D patients with AGC ($N = 100$) vs. IGC ($N = 64$) at baseline exhibited similar patient age (78 (69–83) vs. 76 (68–82) years, $p = 0.521$), LDL-cholesterol (2.36 (1.94–2.94) vs. 2.56 (2.08–3.01) mmol/L, $p = 0.746$), and eGFR (63.7 (52.2–81.4) vs. 64.8 (52.5–77.2) ml/min/1.73 m², $p = 0.683$), but presented a higher BMI (27.7 (25.1–30.8) vs. 28.2 (26.3–31.8) kg/m², $p = 0.05$). 94 PAD patients deceased during the study period. Survival of PAD patients decreased between patients without T2D ($N = 202$, 78.8%) to patients with AGC ($N = 100$, 73%), and patients with IGC ($N = 64$, 62.5%) over seven years ($p = 0.019$). Similar survival rates after the one-year screening were seen in patients categorized according to mean HbA1c for patients without T2D (81.7%), AGC (75%), and IGC (58.9%) ($p = 0.02$). The mortality difference between patients without T2D (18.3%) and AGC (25%) was not statistically significant ($p = 0.164$). During the first year of observation patients with newly diagnosed T2D exhibited similar survival rates to those with AGC (71.8 vs. 75%, $p = 0.786$; figure 1).

Conclusion: This study highlights that adequate glucose control in elderly PAD patients is able to reduce long-term mortality rates. Furthermore, this trial underlines the importance to actively screen for diabetes in PAD patients to treat T2D early and ameliorate diabetes complications and patient survival.

Effects of treatment-achieved HbA_{1c} on incidence of micro-/macrovascular complications in patients with diabetes

M. Harada[1], K. Fujihara[1], T. Osawa[1], M. Yamamoto[1], M. Kaneko[1], M. Ishizawa[1], Y. Matsubayasi[1], T. Yamada[1], N. Yamanaka[2], S. Hiroyasu[2], S. Kodama[1], H. Sone[1];

[1]Diabetes and Endocrinology, Niigata University, Niigata, [2]Japan Medical Data Center Co, Tokyo, Japan.

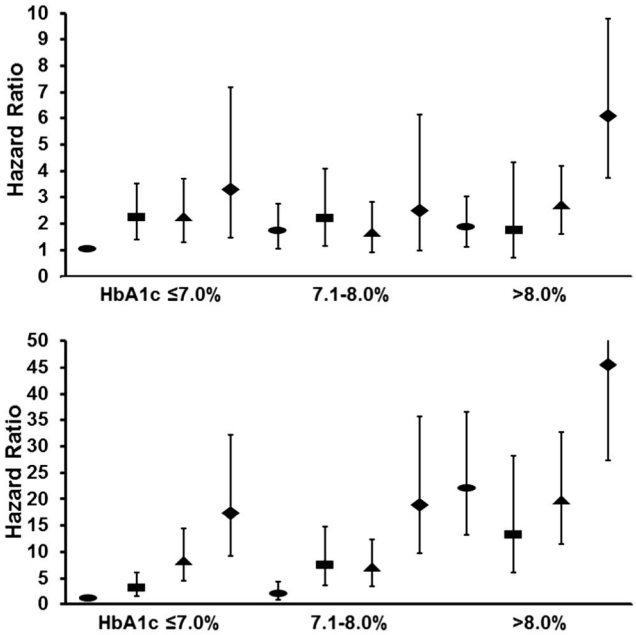
Background and aims: Although a so-called "J"- or "U"-shaped relationship between treatment-achieved HbA1c and risk of coronary artery disease (CAD) has been repeatedly reported, it is not yet clarified whether the association is maintained across various treatment modalities including diet only for both macro- and microvascular complications of diabetes. Thus, we investigated the effects of treatment-achieved HbA1c on the incidence of CAD and treatment-required diabetic eye disease (TRDED) in four treatment groups, i.e. diet only, insulin (INS), sulfonylurea (SU) and antihyperglycemic agents other than glinides, SU, or INS.

Materials and methods: We analyzed data using a nationwide claim-based database that included 296,504 people who belong to a health insurance provider for company employees and their dependents in Japan. Participants aged 18–72 years between 1 April 2008 and 31 March 2013 were included, with the final follow up ending 31 August 2016. Of the 295,570 individuals with available data, data were analyzed on 14,633 without CAD at baseline and with health examination data that included blood tests. Treatment modalities were classified into four groups: diet only, INS, SU, and antihyperglycemic agents other than glinides, SU or INS. Treatment-achieved HbA1c was categorized as follows: ≤7.0, 7.1–8.0, and >8.0. Cox regression model identified variables related to the incidence of CAD and TRDED according to treatment modalities and HbA1c category.

Results: A significant linear trend in the association between HbA1c and CAD events was only seen in the diet only group. Significantly higher risks for CAD were observed in the INS and SU groups whose HbA1c was ≤7.0% or >8.0% compared to diet only group patients with HbA1c ≤7.0%. Conversely, risk for TRDED was strongly dependent on achieved HbA1c regardless of treatment modalities. However, risks of TRDED did not differ significantly between categories of ≤7.0% and 7.1–8.0% among SU and INS groups.

Conclusion: These results implied the necessity of setting different target HbA1c goals according to treatment modalities for prevention of micro-/macrovascular complications.

Figure



Adjusted hazard ratios (95%CI) for (upper) coronary artery disease and (bottom) treatment required diabetic eye disease by 4 treatment modalities (diet only, circles; antihyperglycemic agents other than glinides, sulfonylurea or insulin, squares; sufonylurea, triangles; insulin, rhombus) in three HbA1c categories. Covariates include sex, age, smoking status, BMI, systolic blood pressure, HDL cholesterol, LDL cholesterol

Disclosure: **M. Harada:** None.

95

Effect of preoperative metformin use on lactate levels in patients with type 2 diabetes undergoing coronary artery bypass graft surgery

S.K. Mishra[1], T. Bano[1], M.S. Kuchay[1], Y. Mehta[2], A. Mithal[1];
[1]Division of Endocrinology & Diabetes, Medanta The Medicity Hospital, Gurugram- Delhi NCR, [2]Institute of Critical Care and Anesthesiology, Medanta The Medicity Hospital, Gurugram- Delhi NCR, India.

Background and aims: Lactic acidosis is one of the rare but serious complications associated with metformin use. Relative hypoxemia and hypovolemia during major surgery are risk factors for lactic acidosis in patients with diabetes. Guidelines regarding perioperative use of metformin are debatable. According to some guidelines, metformin should be withdrawn 48 hours before major surgery. Therefore, current study was undertaken to examine whether perioperative use of metformin is associated with increased risk of lactate levels.
Materials and methods: In this prospective observational study, 1,800 consecutive subjects who underwent CABG surgery were enrolled from November 2015 to October 2017. A total of 860 subjects with elective CABG surgeries were included for final analysis; out of which 426 (49.5%) patients with type 2 diabetes received metformin (group 1), 263 (30.5%) subjects with type 2 diabetes were non metformin users (group 2) and 171 (19.8%) patients were having no diabetes (group 3). Subjects with eGFR <30 ml/min/1.73^2 (MDRD formula), severe left ventricular ejection fraction (<30%), overt thyroid dysfunction and hemodynamic instability were excluded. Metformin was continued till night before surgery in eligible subjects. Lactate levels were monitored using arterial blood gas (ABG) machine RADIOMETER ABL 800 BASIC. ABG was done in preoperative period, immediate postoperative period, and then every 6 hourly for 24 hrs. Other parameters recorded included pH, PCO2 and bicarbonate. Student t test was used for comparison of individual quantitative parameters. One-way- analysis of variance ANOVA was used to test the difference between the means of different groups.
Results: Baseline characteristics were similar between groups for age, gender and body mass index. There was increased prevalence of hypertension, triple vessel coronary artery disease, chronic kidney disease and low ejection fraction amongst patients with type 2 diabetes as compared to patients with no diabetes. Intra-operatively there was no difference between groups with respect to type of CABG surgery (on pump or off pump) and use of venous or radial grafts. In all groups there was increase in lactate levels and decrease in pH and bicarbonate levels postoperatively. Mean preoperative pH in groups 1, 2 and 3 were 7.43, 7.44 and 7.40 respectively. Mean postoperative pH in groups 1, 2 and 3 were 7.40, 7.40 and 7.40 respectively. There was no significant difference between groups in postoperative pH. Mean preoperative lactate levels (mmol/l) in groups 1, 2 and 3 were 1.66, 1.64 and 1.48 respectively. Mean postoperative lactate levels in groups 1, 2 and 3 were 1.94, 2.06 and 2.04 respectively. There was no statistical significance for lactate levels among metformin users (group 1) and non-diabetes patients (group 1 vs. 3, $p = 3 = 0.138$). Similarly, there was no difference for lactate levels between group 2 (diabetes without metformin) vs. group 3 (no diabetes) ($p = 0.740$). Although there was significant change in lactate levels between group 1 vs. group 2 ($p = 0.032$), but the change in lactate levels was well below the cut-off for lactic acidosis.
Conclusion: Current study suggests that continuation of metformin in preoperative period is not associated with raised lactate levels in subjects undergoing CABG surgery.
Disclosure: **S.K. Mishra:** None.

Intermittent fasting delays the progression of cardiomyopathy in a pre-diabetic obese rat model

D. Abdurrachim, X.-Q. Teo, C.-C. Woo, J. Lalic, P.T.H. Lee;
Singapore Bioimaging Consortium (SBIC), Agency for Science, Technology and Research (A*STAR), Singapore, Singapore.

Background and aims: Diabetes increases the risk for heart failure by two to three times. Alterations in cardiac substrate metabolism in diabetes have been thought to contribute to the development of diabetic cardiomyopathy. Caloric restriction has been proposed to be beneficial for cardiometabolic health. In this study, we investigated the effects of caloric restriction via intermittent fasting (IF) on cardiac function and metabolism in pre-diabetic obese spontaneously hypertensive heart failure-prone (SHHF) rats.
Materials and methods: Pre-diabetic obese SHHF rats (10 weeks of age) were randomly divided into non-fasting group ($N = 8$) and IF group ($N = 7$). IF group was fasted for 24 hours on alternate days for a period of six months. At 5 weeks and 6 months of IF, magnetic resonance imaging (MRI) was performed to measure left ventricular mass (LVM) and ejection fraction (EF). In addition, at 6 months of IF, cardiac ^{13}C magnetic resonance spectroscopy (MRS) was performed to measure cardiac pyruvate utilization in vivo, by quantifying the production of downstream metabolites (i.e. [1-^{13}C] lactate, [1-^{13}C] alanine, and [1-^{13}C] bicarbonate) within 2 minutes after hyperpolarized [1-^{13}C] pyruvate injection. Blood glucose, FFA, TG, and insulin were determined at 6 months of IF. Statistical significance was determined using Student's t-test for data with a single time point, and using a repeated measures ANOVA with Bonferroni post hoc test for data with more than one time points.
Results: After 6 months of IF, body weight gain was 46% less in IF rats than in non-fasting rats ($P < 0.001$). In IF rats, fed blood glucose levels tended to be 30% lower than in non-fasting rats ($P = 0.06$), while fed serum FFA, TG, and insulin levels were 61%, 40%, and 85% lower compared with non-fasting rats ($P = 0.014$, $P < 0.001$, $P = 0.021$, respectively), which suggests an improvement of insulin sensitivity in the IF rats. Non-fasting rats exhibited progressive LV hypertrophy as indicated by an increase in LVM/tibia length (LVM/TL) by 44% and 115% at 5 weeks ($P < 0.001$) and 6 months of study period ($P < 0.001$) compared with baseline, respectively. The increase in LVM/TL in non-fasting rats was accompanied by a 6% decrease in EF at 6 months of study period ($P = 0.032$ vs. baseline). In contrast, the increase in LVM/TL was lower in IF rats (i.e. 25% and 76% at 5 weeks ($P = 0.011$) and 6 months of IF ($P < 0.001$) compared with baseline, respectively), while EF was maintained ($P > 0.99$ at 6 months of IF vs. baseline). At 6 months of IF, the production of [1-^{13}C] bicarbonate upon injection of [1-^{13}C] pyruvate was 33% higher in IF rats than in non-fasting rats ($P = 0.042$), which indicates higher cardiac pyruvate dehydrogenase (PDH) flux in the IF rats. The production of [1-^{13}C] alanine was 48% higher in IF rats compared with non-fasting rats ($P < 0.001$), while the production of [1-^{13}C] lactate was not altered in the IF rats ($P = 0.109$ vs. non-fasting rats).
Conclusion: Six months of IF delays the progression of LV hypertrophy and prevents cardiac dysfunction in pre-diabetic obese SHHF rats, which may be associated an improvement in insulin sensitivity and an increase in cardiac pyruvate utilization. Our results suggest that IF may improve cardiac-metabolic health by modulating cardiac substrate metabolism.

OP 17 Exercise: running back and forth from the gym to the culture dish

97

Effects of different types of physical activity on metabolic control in type 1 diabetic patients

I. Stotl[1], T. Kambic[2], A. Zdolsek[2];
[1]University Medical Centre Ljubljana, Ljubljana, [2]Faculty of Sport, University of Ljubljana, Ljubljana, Slovenia.

Background and aims: Physical activity (PA) has an important role in treatment of patients with type 1 diabetes. Research shows that PA doesn't usually affect HbA1c, but it can increase the frequency of hypoglycaemia in type 1 diabetic patients. Non-exercise activity thermogenesis (NEAT) represents the additional energy expenditure besides active sports-like exercise and resistance training in daily life. To date the effect of NEAT in patients with type 1 diabetes was not investigated; therefore the aim of this study was to determine the effects of PA and NEAT on metabolic control in this group of patients.
Materials and methods: A total of 109 subjects with type 1 diabetes (55 women and 54 men) - average age of 38 ± 10 years, average weight of 77.33 ± 15.70 kg, HbA1c 7.03 ± 0.89 were included in the study. Participants were asked to complete multiple PA questionnaires, including NEAT questionnaire, WHO physical activity questionnaire and hypoglycaemia questionnaire. Clinical data such as frequency of hypoglycaemia, insulin therapy, HbA1c, blood pressure and serum lipid profiles were also obtained to investigate the relationship with PA and NEAT score.
Results: Regression model predicting levels of HbA1c from total amount of PA (WHO, combined moderate and vigorous PA) revealed positive multiple correlation between total PA and HbA1c levels ($r = 0.20$), while the regression model was not significant. After total amount of PA was separated into moderate and vigorous PA only the latter was significantly correlated with HbA1c ($r = 0.20$; $P < 0.05$). There was a significant regression model predicting HbA1c from NEAT score ($p < 0.05$) with positive correlation between NEAT score and HbA1c ($r = 0.23$; $P < 0.05$). Moreover, a regression model predicting frequency of hypoglycaemia from NEAT score was borderline significant ($P = 0.051$), whereas correlation between NEAT score and frequency of hypoglycaemia was negatively significant ($r = -0.198$; $P < 0.05$). A significant regression model ($P < 0.01$) was obtained when predicting systolic blood pressure from moderate, vigorous PA and NEAT score. Beta coefficient showed significant effect of vigorous PA ($\beta = 0.36$; $P < 0.01$) and NEAT score ($\beta = -0.31$; $P < 0.01$) on systolic blood pressure levels. Similar effects and correlations were not obtained when the predictions of diastolic blood pressure were made. There was a significant negative correlation between vigorous PA ($r = -0.31$; $P < 0.05$) and total serum cholesterol ($r = -0.301$; $P < 0.05$), while NEAT score and moderate PA were not significantly correlated with total cholesterol levels. Furthermore, a significant regression model ($P < 0.05$) was obtained when serum value of low-density lipoprotein (LDL-C) was predicted from moderate, vigorous PA and NEAT score. Vigorous PA ($r = -0.324$; $P < 0.05$) and NEAT score ($r = -0.229$; $P < 0.05$) were significantly correlated with (LDL-C) levels. Additionally, when predicting serum levels of high-density lipoprotein (HDL-C) and triglycerides from combined PA and NEAT score, no significant effects or correlation were observed.
Conclusion: Our data suggest that higher amount of NEAT is associated with lower frequency of hypoglycaemia, lower systolic blood pressure, lower LDL-C and higher HbA1c in type 1 diabetic patients. We have also demonstrated a positive metabolic effect of vigorous PA levels on total serum cholesterol and LDL-C concentration.
Disclosure: **I. Stotl:** None.

Combined effects of timing of exercise and high intensity exercise on plasma NEFA, glucose and insulin concentrations in type 2 diabetic and prediabetic men

P. Calders[1], B. Lapauw[2], S. Shadid[3], B. Celie[1];
[1]Rehabilitation Sciences and Physiotherapy, University of Ghent, Ghent, [2]Endocrinology, University Hospital of Ghent, Ghent, [3]Endocrinology, University Hospital of Ghent, Ghent, Belgium.

Background and aims: Exercise is beneficial in type 2 diabetes (T2DM), but both the preferred exercise type (continuous or interval) and timing of exercise (fasted versus fed) is still on debate. Postprandial continuous exercise has been shown to acutely blunt glycaemia in both healthy persons and patients with T2DM, while exercising in the fasted state did not affect glycaemia. There are no available data about the effects of fasted state continuous exercise in T2DM. In a healthy population this exercise type acutely increases free fatty acid concentration in both fasted and postprandial state. Considering this lack of knowledge and because there are no data available on the effects of an acute high intensity exercise bout (HIT) in T2DM patients, the aim of this study was to evaluate the effect of HIT on glucose, insulin and NEFA concentration in fasted versus postprandial state in patients with pre(diabetes and T2DM.
Materials and methods: We have studied 11 adult overweight or obese males with prediabetes or T2DM, defined as an HbA1c ≥6.0%, using metformine monotherapy ($n = 9$) or diet/exercise ($n = 2$). Patients were tested three times. First, they performed an incremental exercise test until exhaustion on a cycle ergometer to evaluate maximal oxygen consumption (VO2max). The second and third test (cycling), consisted of 3 minutes warming up at 50W, followed by 20 minutes HIT (ten times: 60 seconds at 80% of VO2max and 60 seconds at 50 Watt), finishing with 40 minutes recovery (including 3 minutes cooling down). Exercise tests were carried out in fasted or postprandial state (90 minutes after a standard meal (carbohydrates: 56%; fat: 22%; proteins: 22%)). Nutritional status was randomized. Glucose, insulin and non-esterified fatty acids (NEFA) were measured before and after warming up, after 10, 20 minutes of HIT and 40 minutes recovery in a venous blood sample. Data are expressed as mean (SD). A Repeated measures ANOVA was executed with post hoc Sidak to evaluate interaction effects (time * condition) and time effects. Significance level was set at $P < 0.05$.
Results: Patients had a mean age of 42 (5.6) years; a mean BMI of 31.9 (5.11) kg/m^2, an HbA1c of 6.6 (0.49) % and a relative maximal oxygen uptake of 21.4 (5.33) ml/kg min. *Glucose, insulin and NEFA concentration in fasting and postprandial condition (fig 1):* Glucose and insulin concentration decreased significantly in postprandial state during HIT ($P < 0.05$ versus pre-HIT), but remained stable in the fasting state. Resting NEFA concentrations were increased in the fasting versus the postprandial condition ($P < 0.05$) and remained stable during HIT ($P < 0.05$).
Conclusion: Postprandial interval exercise possesses the ability to blunt postprandial glycaemia in patients with prediabetes and T2DM while NEFA concentrations are higher in the fasted state but remain stable during HIT.

Interleukin-6 blockade ameliorates the effect of exercise on cardiac fat in abdominally obese individuals

R. Christensen[1], L. Lang Lehrskov[1], A.-S. Wedell-Neergaard[1], R. Krogh-Madsen[1], K. Karstoft[1], H. Ellingsgaard[1], J. Rosenmeier[2], B.K. Pedersen[1];
[1]The Capital Hospital of Denmark, Copenhagen, [2]Bispebjerg Hospital, Copenhagen, Denmark.

Background and aims: Excessive cardiac adipose tissue has been associated with the incidence and severity of type 2 diabetes and cardiovascular disease. Exercise training reduces cardiac adipose tissue and may therefore be a strategy to prevent type 2 diabetes and coronary heart disease. The underlying mechanisms for exercise-mediated adaptations of cardiac fat are unclear, but may involve actions of interleukin-6 (IL-6). IL-6 is a myokine which is released in response to exercise and it has been shown to increase lipolysis in adipose tissue. Whether this mechanism is operative in cardiac adipose is unknown. Therefore, the aim of this study was to investigate whether blocking of IL-6 can ameliorate the effects of exercise on cardiac fat volume.
Materials and methods: This was a 12-week, double-blinded, randomised, placebo-controlled exercise and drug intervention trial. 52 abdominally obese participants were enrolled to endurance exercise (3 x sessions per week of interval-based high-intensity training of 70–85% of VO_2 max) or no exercise groups combined with IL-6 blockade (Tocilizumab, 8 mg/kg, toci) or placebo (saline). Cardiac fat volume was assessed by MRI at baseline and post intervention. Data is expressed as mean ± SD. A 2-way ANCOVA was used to assess whether IL-6 blockade influenced the effect of exercise on cardiac fat.
Results: 13 (25%) were men, with an age average of 44 ± 13 years. Baseline mean cardiac fat was 203 ± 111 ml. There were no differences in baseline cardiac fat levels between participants ($p = 0.07$). Cardiac fat was reduced by 16% (95% CI −31; −1, $p = 0.041$) after 12 weeks of endurance exercise compared to no exercise (Figure 1). The reduction in cardiac fat was ameliorated in the group that exercised and received IL-6 blockade ($p = 0.021$). IL-6 blockade alone did not lead to any significant changes on cardiac fat in groups that did not exercise ($p = 0.083$) (Figure 1).
Conclusion: In a randomised placebo-controlled exercise and drug intervention we found that IL-6 blockade can ameliorate the effects of exercise on cardiac fat in abdominally obese individuals. These data suggest IL-6 is required to mediate the adipose reducing effects of exercise specifically on cardiac adipose tissue.

Contraction-induced changes in mitochondrial function and insulin sensitivity of myocytes rely on the functional Ndufb6 subunit of the electron transport system complex I

T. Jelenik[1], S.W. Görgens[1], N. Krako Jakovljevic[1], I. Rokitta[1], N.M. Lalic[2], J. Eckel[1], M. Roden[1];
[1]German Diabetes Center, Duesseldorf, Germany, [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia.

Background and aims: Impaired mitochondrial function associates with insulin resistance in skeletal muscle, yet causal relationships and underlying mechanisms are unclear. In humans, we have previously shown that the G/G-single nucleotide polymorphism (SNP) in the Ndufb6 subunit of the mitochondrial complex I relates to impaired mitochondrial plasticity after exercise and insulin resistance. Here we hypothesize that reduced Ndufb6 activity impairs oxidative capacity and inhibit insulin signaling in contracted myotubes.
Materials and methods: C2C12 myotubes were treated with Ndufb6 siRNA to induce its knockdown (siNdufb6) or negative control siRNA (NT). The myotubes underwent studies under basal, palmitate-treated, and/or electrical pulse-stimulated (EPS) conditions, the latter simulating muscle cell contraction ($n = 4$–6). Mitochondrial oxidative capacity was assessed in digitonin-permeabilized cells using high-resolution respirometry. Reactive oxygen species (ROS) were detected by DCF fluorimetry. Insulin signaling at the level of Akt phosphorylation was assessed at baseline and in insulin-treated cells by Western blots.
Results: After 24 h of siRNA treatment, Ndufb6 mRNA and protein levels were silenced by 70% (siNdufb6: 0.24 ± 0.06 vs. NT: 0.82 ± 0.15 AU; $p < 0.05$) and by 40% (0.61 ± 0.07 vs. 0.99 ± 0.11; $p < 0.05$), respectively. Complex I-linked state u respiration was 36% lower in siNdufb6 than in NT (211 ± 15 vs. 327 ± 19 pmol/s/10^6cells; $p < 0.05$). While there were no differences in respiration with octanoyl-carnitine, EPS-stimulated complex I-linked respiration was markedly decreased in siNdufb6 myotubes (271 ± 10 vs. 435 ± 34 pmol/s/10^6cells; $p < 0.001$). However, ROS production was 19% higher in siNdufb6 ($p < 0.01$) and not further stimulated by palmitate. In contrast to NT, EPS did not rescue the palmitate-induced reduction in pAkt(Ser473), which was decreased by 35% in siNdufb6 (0.72 ± 0.15 vs. 1.10 ± 0.05 AU; $p < 0.01$).
Conclusion: Reduced Ndufb6 activity redirects electrons from oxidative phosphorylation towards electron leakage. Lower oxidative capacity and higher ROS production could contribute to the impaired insulin sensitivity and lower exercise responsiveness, as observed in humans with the G/G-SNP in the Ndufb6 gene.

Impaired exercise performance and glucose disposal in Tbc1d4-deficient mice is rescued by regular exercise training

A. Chadt[1,2], C.A. Springer[1,2], L. Toska[1], A. Grieß[1], S. Karpinski[1], C. de Wendt[1], M. Dille[1], H. Backes[3], A. Cremer[3], J.C. Brüning[3], H. Al-Hasani[1,2];
[1]German Diabetes Center, Duesseldorf, [2]German Center for Diabetes Research (DZD), Düsseldorf, [3]Max Planck Institute for Metabolism Research, Cologne, Germany.

Background and aims: The Rab-GTPase-activating protein TBC1D4 (=AS160) represents a key regulator of insulin-mediated glucose transport into skeletal muscle and adipocytes. Moreover, as a direct target of

AMPK, TBC1D4 plays a crucial role in contraction-dependent skeletal muscle metabolism. In mice, *Tbc1d4*-deficiency leads to substantially reduced levels of the insulin-responsive glucose transporter GLUT4 in skeletal muscle and adipocytes. Recently, a muscle-specific loss-of-function variant in the *TBC1D4* gene was identified in the Greenlandic population which defines a specific subtype of non-autoimmune diabetes characterized by elevated post-prandial glucose levels. Our aim was to elucidate whether regular exercise training can overcome the initial defect in glucose disposal using *Tbc1d4*-deficient mice.

Materials and methods: Wildtype (WT) and *Tbc1d4*-deficient (D4KO) mice were fed a high-fat diet (HFD) with 60% fat from calories from week 8 on, and subjected to forced exercise training on treadmills for 4 weeks starting from week 12. Glucose sensitivity and physical condition were determined and compared with sedentary controls. *Ex vivo* analyses of skeletal muscle and adipose tissue and *in vivo* PET (Positron-emission tomography) imaging were conducted to determine insulin responsiveness of peripheral tissues. Statistical analysis was performed using two-way ANOVA.

Results: Sedentary D4KO mice showed impaired physical activity during an acute exercise exhaustion test that was rescued after 4 weeks of treadmill training (trained vs sedentary D4KO; 8.2 ± 0.3 vs 9.5 ± 0.4 min, $n = 8$, $p < 0.05$). In addition, glucose and insulin tolerance were significantly improved in D4KO mice following the exercise intervention (AUC trained vs sedentary D4KO; glucose tolerance: 464.2 ± 29.4 vs 333.7 ± 8.1 a.u., $n = 8$–9, $p < 0.05$; insulin tolerance: 580.1 ± 15.6 vs 472.0 ± 25.5 a.u., $n = 8$, $p < 0.001$). Interestingly, no compensation for the initial reduction in GLUT4 protein abundance nor for the impaired insulin-stimulated glucose uptake in skeletal muscle was achieved due to the exercise training. In contrast, total GLUT4 protein content and insulin-stimulated glucose transport were substantially increased in white adipose tissue from D4KO animals (trained vs sedentary D4KO; GLUT4 protein: 56.9 ± 6.6 vs 91.1 ± 9.6 a.u., $n = 12$–15, $p < 0.05$; insulin-stimulated glucose uptake: 52.2 ± 8.1 vs 148.7 ± 36.8 CPM/mg lipid, $n = 12$; $p < 0.01$), completely ameliorating the initial impairment caused by the *Tbc1d4*-deficiency. Moreover, gene expression of a set of browning factors such as *Ucp-1* and *Cidea* were significantly elevated in white adipose tissue from trained D4KO mice, indicating enhanced mitochondrial activity.

Conclusion: In summary, our results demonstrate that deletion of the RabGAP TBC1D4 leads to impaired physical activity, presumably due to reduced glucose uptake into skeletal muscle and adipose tissue. After treadmill training, D4KO mice were able to normalise their exercise performance, glucose and insulin tolerance, respectively, to a degree comparable to WT controls. We show that the adipose tissue is responsible for these beneficial effects, potentially by a combination of pathways leading to increased GLUT4 content and enhanced mitochondrial activity.

Roles of neutrophils and IL-1 in intramuscular immunometabolic niche for priming GLUT4 translocation during exercise

M. Kanzaki[1], S. Sekiai[1], H. Hatakeyama[1], C. Chaweewannakorn[2], K. Sasaki[2], Y. Hagiwara[3], E. Itoi[3], M. Tsuchiya[4];
[1]Biomedical Engineering, Tohoku University, Sendai, [2]Graduate School of Dentistry, Tohoku University, Sendai, [3]Orthopaedic Surgery, Tohoku University, Sendai, [4]Tohoku Fukushi University, Sendai, Japan.

Background and aims: Immunomodulation of metabolism involving pro-inflammatory interleukin-1 (IL-1) has been intensively investigated under unfavorable conditions of excess nutrition such as obesity, and obesity-induced low-grade chronic inflammation involving IL-1 has been widely implicated as a detrimental factor in insulin resistance. Recently, however, employing a masticatory behavior (Restrained/Gnawing) model, we demonstrated that mice deficient in both IL-1α and IL-1β (IL-1-KO mice) exhibited apparent dysregulation of muscle glucose uptake with accompanying ease of fatigability during masseter muscle activity (PLoS ONE, Chiba et al 2015). Our previous study also revealed that neutrophils producing IL-1β were markedly recruited within working masseter muscles. To further explore our findings, the present studies were designed to clarify the favorable IL-1 actions and its underlying mechanism on the working skeletal muscles by using the running-wheel-based exercise model and electric pulse stimulation (EPS)-evoked in situ muscle contraction.

Materials and methods: We examined IL-1-KO mice and neutrophil-depleted mice, focusing on muscle GLUT4 translocation, by utilizing the running-wheel-based exercise model and EPS-evoked in situ muscle contraction model.

Results: Upon 2h of walking exercise, IL-1-KO mice displayed rapid exhausted behavior attributable to the dysregulation of exercise-stimulated GLUT4 translocation and glucose uptake along with the depletion of intramuscular glycogen. We also found in WT mice that neutrophils producing IL-1β were markedly recruited within the working skeletal muscle tissues such as quadriceps femoris muscles (QFMs). To directly investigate significance of the neutrophils, we utilized the neutrophil-depleted mice and found that neutrophil depletion resulted in essentially the same phenotypes with IL-1 KO mice in terms of the undermined walking performance in accordance with the impaired exercise-dependent glucose uptake. Intravital-imaging analysis using the skeletal muscle-specific GLUT4-EGFP-expressing transgenic mice demonstrated that EPS-evoked in situ contraction promptly induced GLUT4 translocation to sarcolemma and T-tubules, which was remarkably blunted in the neutrophil-depleted mice. Biochemical analysis of exercise-related intracellular signals demonstrated that both IL-1-KO mice and neutrophil-depleted mice displayed obvious derangements in the Rac1 signaling cascades, while no obvious defects in the AMPK signaling cascade, including Tbc1d1 (Ser237) phosphorylation, were observed.

Conclusion: Taken together, these findings shed new light on the roles of IL-1 and neutrophils, which emerges to be positively involved in exerting exercise-dependent responses especially on muscle glucose homeostasis via GLUT4 translocation. Importantly, these metabolic benefits involving both IL-1 and neutrophils directly engaged in fatigue alleviation of the working skeletal muscles.

A new dual reporter embryonic stem cell line for the purification of SOX9-positive pancreatic progenitors

O. Naujok, C. Davenport, J. Kresse, U. Diekmann;
Institute of Clinical Biochemistry, Hannover Medical School, Hannover, Germany.

Background and aims: The high mobility group box transcription factor SOX9 is involved in the maintenance of embryonic and adult ducts cells, which are believed to serve as a pool for NGN3-positive endocrine progenitors committed to islet progeny. In order to analyze the role of SOX9 during pancreatic differentiation of human embryonic stem cells (ES cells) we sought to establish a conservative dual reporter cell line by means of CRISPR/Cas9-mediated homology directed repair. This reporter line shall give insights into developmental processes during human pancreatic organogenesis and pave the way for the purification of pure pancreatic cells by magnetic or fluorescence-activated cell sorting.
Materials and methods: Three sgRNAs targeting ±15 bp next to the stop codon of the *SOX9* locus were cloned and validated by the T7EI-assay. Then HES3 ES cells were nucleofected with the functional CRISPR/Cas9 and a targeting vector comprising a P2A-H-2KK-F2A-GFP2 gene cassette flanked by 500 bp 5′ and 3′ homology arms. A floxed hygromycin gene was used for clonal selection of targeted cells. Cell clones were then screened by PCR and DNA sequencing and then the functionality of the knock-in was tested by differentiation into pancreatic endoderm using an adopted differentiation protocol.
Results: Out of three designed CRISPR/Cas9 the sgRNA T5 effectively introduced DSBs into the *SOX9* locus of the HEK293 model cell line. The nucleofection of HES-3 embryonic stem cells with T5 and the HDR vector yielded after selection in 48 cell clones from which 32 showed a homozygous integration, 7 a heterozygous integration, and 9 clones that were only resistant to hygromycin without homology directed repair. All tested clones activated GFP2 upon differentiation into pancreatic endoderm. The HES3 SC30 clone was then used for further characterization. GFP2-positive cells appeared after PDX1-positive duodenal cells at d8 with a peak of 50–60% positive cells at day 12–13 of differentiation as measured by flow cytometry. FACS-sorted GFP2-positive cells expressed SOX9, PDX1, HNF6, and NKX6.1 but not NGN3 whereas GFP2-negative cells remained largely negative for these markers. GFP2-positive cells also expressed the surface antigen H-2KK which allowed simple MACS-assisted cell purification. Further differentiation of SOX9/H-2KK/GFP2-positive cells showed that these cells are highly capable of endocrine differentiation into insulin/C-peptide-positive and glucagon-positive cells.
Conclusion: In summary, this study reports the derivation of a new ES dual reporter cell line which comprises the knock-in of the fluorescence reporter GFP2 and the surface antigen H-2KK into the *SOX9* locus. Due to the design of the targeting vector, the *SOX9* locus remains unharmed so that GFP2 and H-2KK are expressed along with SOX9 under the control of the endogenous gene promoter. The analysis of GFP2-expressing cells showed that they co-express SOX9, PDX1, HNF6, and NKX6.1, all markers of the pancreatic endoderm. The duality of the reporter gene knock-in allows the purification by magnetic or fluorescence-activated cell sorting. Thus, we conclude that this cell line is a powerful tool to study the mechanisms of duct-to-islet conversion during pancreatic development. Furthermore, this cell line can be used to purify pancreatic endodermal cells for cell replacement therapy of diabetes.

PKC activation promotes resolution of polyhormonality toward alpha cell fate in human pluripotent stem cell (HPSC) derived alpha cells

B. Tyrberg[1], Q.P. Peterson[2,3], A. Veres[2], J. Kenty-Ryu[2], M.Q. Slama[3], L. Chen[1], Q. Zhou[2], M.R. Brown[3], A. Matveyenko[3], M. Sörhede-Winzell[1], D.A. Melton[2];
[1]Cardiovascular, Renal and Metabolism, IMED Biotech Unit, AstraZeneca, Mölndal, Sweden, [2]Stem Cell and Regenerative Biology, Harvard University, Cambridge, USA, [3]Physiology and Biomedical Engineering, Mayo Clinic, Rochester, USA.

Background and aims: HPSCs holds great promise as a source of specialized cells for drug discovery and mechanistic interrogation of cell signaling. In diabetes research pancreatic endocrine cells are critical when studying hormone secretion and cell proliferation/survival, but primary cell supply is scarce. Currently, only insulin-producing beta-cell lines and beta-cell HPSC protocols are available. Therefore, we aimed to develop a differentiation protocol specifically generating alpha-cells.
Materials and methods: We have developed a protocol to differentiate glucagon-producing alpha-cells from HPSCs based on our previously published beta-cell differentiation protocol. We substantially modified stage 4–5 of the protocol driving alpha-cell differentiation only by BMP and ALK5 inhibition (LDN193189, SJN2511). Briefly, for the phenotypic screen of HPSCs in differentiation stage 6, we plated cells in 384-well plates and treated with compounds for 4 days. We examined the differentiated alpha-cells *in vitro* for glucagon secretion and *in vivo* following transplantation into immunodeficient mice.
Results: Like primary cells, these alpha-cells secrete glucagon in response to low glucose (low glucose: 0.51 ± 0.2 pM per 1000 cells vs. high glucose: 0.28 ± 0.1 pM per 1000 cells, $P < 0.05$), and their ultrastructure resembles primary human alpha-cells. Following transplantation, mice demonstrate elevated fasting blood glucose (7.5 ± 0.5 mM vs. 5.6 ± 0.4 mM, $P < 0.05$) and transplanted cells prevent hypoglycemia in response to insulin. Surprisingly, the cells are bihormonal *in vitro* and also express insulin, although not secreting insulin (alpha cells: 0.08 ± 0.04 μIU/ml per 1000 cells vs. human islets: 10.6 ± 0.3 μIU/ml per 1000 cells, $P < 0.05$). We hypothesized that the cells are not fully mature and that interfering with the appropriate signaling pathway would convert the cells to monohormonal alpha-cells. In a phenotypic screen with the bihormonal alpha-cells we found that the PKC activator PdbU increase glucagon expression and diminish insulin expression. By modifying stage 6 of the differentiation protocol with PdbU we now achieve 46 ± 4% monohormonal alpha-cells instead of 23 ± 3% without PdbU treatment.
Conclusion: We have developed the first HPSC differentiation protocol that generates monohormonal alpha-cells in large quantities. This complements HPSC derived beta-cells and makes possible recreation of human islet mini-organs with multiple endocrine cell types and intact paracrine signaling. The cells are consequently suitable for drug discovery and interrogation of human alpha-cell biology that has hitherto not been possible.

Endocrine cell specification and beta cell maturation require the transcriptional co-activator MED15

A.Z. Kadhim[1], E.E. Xu[2], T. Speckmann[2], C. Nian[2], R. Cullen[1], R. Shi[2], D.S. Luciani[2], S. Taubert[1], F.C. Lynn[2];
[1]Medical Genetics, The University of British Columbia, Vancouver, [2]Surgery, The University of British Columbia, Vancouver, Canada.

Background and aims: The Mediator complex, a co-regulator required for RNA polymerase II activity, interacts with specific transcription

factors through distinct subunits such as MED15. These interactions promote the expression of defined gene sets both during development and for tissue homeostasis. As MED15 is highly expressed starting in nascent immature beta cells, we generated several developmental stage specific knockout mice to determine a role for MED15 during pancreatic islet differentiation. The results obtained from these lines will allow us to dissect when and where MED15 is required for beta cell differentiation, maturation and function.

Materials and methods: We crossed *Pdx1-Cre*, *Neurog3-Cre*, and *Ins1-Cre* transgenic mice with *Med15*$^{flox/flox}$ mice to delete *Med15* in pancreatic progenitors, endocrine progenitors, and beta cells, respectively. RNA-Sequencing, Taqman, and immunofluorescence analyses were performed to determine changes in expression in these knockout models. Glucose uptake assays were performed using fluorescent glucose 2-NBDG, and insulin secretion along with mitochondrial activity were assessed via perifusion and Seahorse XF extracellular flux analyzer, respectively. Co-immunoprecipitation (CoIP) in mouse insulinoma (MIN6) cells was used to identify MED15 interacting partners. Chromatin immunoprecipitation followed by sequencing (ChIP-Seq) in MIN6 cells and primary islets was used to determine MED15 genomic occupancy.

Results: In the *Pdx1-Cre* model, we observed a reduction of Neurog3$^+$ cells, demonstrating that MED15 is required for endocrine progenitor specification. As expected, 8-week old mice showed reduced viability, were glucose intolerant, and had fasting hyperglycemia. The *Neurog3-Cre*; *Med15*KO mice showed a 50% reduction in beta cell mass (student's t test, $p < 0.05$). Transcriptome profiling demonstrated that MED15 is required for expression of the beta cell maturation markers UCN3, IAPP, MAFA, and GLUT2 in the *Ins1-Cre* model. In agreement with reduced GLUT2 expression, *Ins1-Cre*; *Med15* KO cells had impaired glucose uptake, reduced glucose-stimulated oxygen consumption, and reduced first-phase insulin secretion. Using native CoIP experiments in MIN6 cells, we found that MED15 interacts with NKX6-1. Furthermore, MED15 was found to bind NKX6-1 bound enhancer loci, both in MIN6 and mouse islets. As such, we conclude that MED15 drives beta cell maturation by interacting with the transcription factor NKX6-1 at genomic enhancer regions.

Conclusion: Taken together, these results demonstrate a critical role for MED15 in endocrine lineage specification, differentiation, and beta cell maturation. As the Mediator complex has not previously been studied in the pancreas, we provide the first evidence of its importance in this tissue. A greater understanding of how Mediator and MED15 regulate beta cell maturation could help refine the generation of cell-based therapies for diabetes.

GPR56 is highly expressed by pancreatic progenitor cells and it regulates beta cell development and function

O.E. Olaniru, K. Toczyska, A.-M. Cujba, P. Atanes, R. Sancho, P.M. Jones, S.J. Persaud;
Department of Diabetes, King's College London, London, UK.

Background and aims: GPR56, the most abundant islet-expressed G protein coupled receptor, is known to regulate proliferation, apoptosis and organ development. We have previously reported that GPR56 activation by its endogenous ligand, collagen III, led to potentiation of glucose-stimulated insulin secretion from islets. Here, we investigated the expression and function of GPR56 in developing mouse and human pancreases and determined the effect of a small peptide agonist of GPR56, TYFAVLM, on β-cell function.

Materials and methods: Using IHC and RNAscope in-situ hybridisation (ISH), the expression of GPR56 and its co-localisation with PDX1$^+$, NGN3$^+$ and SOX9$^+$ progenitor cells was investigated in human fetal pancreas (CS13, 10, 12, 14 and 17 post conception weeks) and mouse pancreas at embryonic days E11, E13, E15, E18 and at P9. GPR56 mRNA expression in pancreatic progenitors derived from human induced pluripotent stem cells (hiPSCs) was determined by qPCR. Pancreas sections from WT and GPR56 KO mice were immunoprobed for Ki67, BrdU, insulin, glucagon, and images were quantified by Image J. Effects of 100 μM TYFAVLM on insulin secretion from human islets were investigated by radioimmunoassay, while its effects on β-cell apoptosis and intracellular calcium [(Ca^{2+})i] were investigated by measuring caspase 3/7 activities and calcium microfluorimetry respectively, in native β-cells and in β-cells in which GPR56 had been knocked down by CRISPR-Cas9.

Results: ISH and IHC revealed that GPR56 was strongly expressed by endocrine progenitor cells in developing mouse and human pancreas, with high expression early in pancreas development and lower expression as the cells differentiated (pancreas, % area GPR56$^+$ cells; E11: 0.87 ± 0.04, E13: 0.85 ± 0.06, E15: 0.36 ± 0.08, E16: 0.15 ± 0.05); (hiPSCs, GPR56 mRNA relative to GAPDH; undifferentiated hiPSCs: 0.11 ± 0.01, End stage (ES)1: 0.26 ± 0.01, ES2: 0.36 ± 0.01, ES3: 0.21 ± 0.03, ES4: 0.001 ± 0.003). GPR56 was then upregulated in pancreas at the stage of β-cell replication (% area GPR56$^+$ cells; E18: 0.15 ± 0.05, P9: 0.47 ± 0.07, $n = 10$). The number of cells proliferating and remaining in the cell cycle was significantly lower in GPR56KO islets at P9 (BrdU$^+$Ki67$^+$ cells/μm^2; WT: 115.9 ± 18.2, KO: 50.9 ± 6.3, $n = 3$, $p < 0.05$), leading to less β-cells (% β-cells/islet; WT: 68.5 ± 0.8, KO: 54.8 ± 3.0, $n = 3$, $p < 0.05$), but higher numbers of α-cells in GPR56KO islets (% α-cells/islet; WT: 17.7 ± 0.9, KO: 33.7 ± 2.8, $n = 3$, $p < 0.01$). TYFAVLM increased [(Ca^{2+})i] in WT β-cells but not in GPR56KO β-cells (basal to peak ratio; WT, 2mM glucose: 0.02 ± 0.01, +TYFAVLM: 0.13 ± 0.01, $n = 3$, $p < 0.01$; KO, 2 mM glucose: 0.01 ± 0.003, +TYFAVLM: 0.02 ± 0.001, $p > 0.2$) and it potentiated glucose-induced insulin secretion from human islets (Insulin pg/islet/min; 2 mM glucose: 3.21 ± 0.3, 20 mM glucose: 5.25 ± 0.72, 20 mM glucose+TYFAVLM: 12.2 ± 1.85, $n = 3$, $p < 0.05$). TYFAVLM protected WT β-cells from cytokine-induced apoptosis, but had no effect in GPR56KO β-cells (luminescence values; WT, control: 306,910 ± 11,301, +TYFAVLM: 268,499 ± 11,315, +10% FBS: 158,668 ± 8,151, $n = 8$, $p < 0.0001$; KO, control: 177,575 ± 9208, +TYFAVLM: 187,823 ± 10,620, +10% FBS: 104,482 ± 10,932, $n = 8$, $p > 0.1$).

Conclusion: Our data suggest that GPR56 plays an important role in islet development, and it is required for an appropriate α-/β-cell ratio in islets. Moreover, GPR56 is activated by TYFAVLM to stimulate insulin secretion and protect β-cells from apoptosis.

Modelling congenital hyperinsulinism in patient stem cell derived beta like cells

V. Lithovius, J. Saarimäki-Vire, D. Balboa, J. Ustinov, S. Eurola, H. Grym, T. Otonkoski;
Biomedicum Stem Cell Center, University of Helsinki, Helsinki, Finland.

Background and aims: Mutations in the genes encoding the K_{ATP}-channel of the pancreatic beta cell are the most common cause of congenital hyperinsulinism (CHI). In Finland, the most common single cause is the *ABCC8* mutation V187D, which leads to a trafficking defect of the SUR1 protein, causing a drug resistant, severe form of the disease, characterized by continuous insulin secretion regardless of blood glucose concentration. Our objective was to recapitulate this CHI phenotype with patient induced pluripotent stem cell (iPSC) -derived beta-like cells *in vitro* and in a humanized mouse model. This model can be used to investigate the effect of the K_{ATP}-channel defect on the development, function, proliferation and apoptosis rates of human beta cells *in vitro* and *in vivo*. The

model also enables future studies in testing novel pharmaceuticals and PET-tracers for improved management and diagnostics of CHI.

Materials and methods: iPSCs were derived from a patient with severe, diazoxide unresponsive diffuse CHI caused by homozygous *ABCC8*-V187D -mutation. iPSCs from a healthy donor and the patient iPSCs corrected with CRISPR/Cas9 technology were used as controls. The cells were differentiated towards beta-cell fate, using a 7-stage, 35-day protocol which yielded islet-like clusters containing 20–40% insulin-positive monohormonal cells (beta-like cells; BLCs). These were studied *in vitro* with static sequential exposures to glucose and pharmaceuticals acting on K_{ATP}-channels and other targets. The BLCs were transplanted to immunocompromised NOD scid gamma mice and subjected to an insulin tolerance test 4 months after transplantation. The explanted grafts were stained and quantitative analyses on the endocrine cell populations and proliferation and apoptosis rates were conducted.

Results: Mutant BLCs failed to shut down secretion when exposed to diazoxide as compared to healthy control cells (fold change to basal 1.00 ± 0.19 vs. 0.44 ± 0.11 $p < 0.001$) and did not increase secretion in response to tolbutamide (fold change 0.91 ± 0.25 $n = 5$ vs. 1.56 ± 0.31, $p < 0.001$, $n = 5$). The mutant BLCs could inhibit their secretion in response to clonidine and calcium chelation similarly to control cells. The CHI-mice had lower fasting blood glucose (4.3 ± 1.6 vs. 7.6 ± 2.3 mmol/l, $p < 0.05$) and higher human C-peptide (816 ± 298 vs. 152 ± 58 pmol/l, $p < 0.01$). Most importantly, human C-peptide secretion was not inhibited by insulin-induced hypoglycemia in the CHI-mice (reduction at 40 min after insulin administration 13.5 ± 26.7% $n = 5$ vs. 73.8 ± 11.6% $n = 8$, $p < 0.01$). The CHI-explants had more insulin+ cells (47.7 ± 9.7% vs. 19.2 ± 13.3%, $p < 0.01$) and fewer somatostatin+ cells (2.7 ± 1.0% vs. 7.7 ± 2.8%, $p < 0.05$), there was no difference in the proliferation rate of the explanted insulin+ cells. (All Mean ± 95%CI)

Conclusion: We have successfully recapitulated the CHI phenotype in beta-like cells derived from patient iPSC and created a humanized mouse model for CHI.

New insights into beta cell development: a specific CNOT1 mutation impairs early pancreatic and neurological development in both humans and mice

A.T. Hattersley[1], R. Watson[2], S.E. Flanagan[1], S. Ellard[1], H. Heimberg[3], A. Caliebe[4], A. Deeb[5], A. Green[2], W.J. Weninger[6], E. De Franco[1], I. Barroso[2];

[1]University of Exeter Medical School, Exeter, UK, [2]Wellcome Sanger Institute, Hinxton, UK, [3]Vrije Universiteit, Brussels, Belgium, [4]Institut fuer Humangenetik, Keil, Germany, [5]Mafraq Hospital, Abu Dhabi, United Arab Emirates, [6]Medical University of Vienna, Vienna, Austria.

Background and aims: Discovering the genes causing pancreatic agenesis in humans is crucial to identify factors needed for human pancreatic and hence beta-cell development. To date we and others have identified 6 causes of pancreatic agenesis, many of which were not initially suspected from mouse studies. We aimed to identify the genetic cause in patients where the genetic aetiology of pancreatic agenesis is not known as this has the potential to give key insights into development of the human pancreas.

Materials and methods: We investigated 9 patients without an identified aetiological mutation from an international cohort of 106 patients with pancreatic agenesis. We performed exome sequencing on the DNA from the cases and all available parents to allow detection of *de novo* heterozygous mutations that represent the commonest causes of both pancreatic agenesis and neonatal diabetes in patients born to unrelated parents. To allow more detailed study of the mechanisms whereby the aetiological gene caused pancreatic agenesis, we created a mouse line harbouring the *Cnot1* mutation with CRISPR. The mouse model was phenotyped in detail including volumetric measurement of the fetal pancreas.

Results: The same novel missense variant in *CNOT1*, p.(Arg535Cys), was identified in 3 patients. This mutation was predicted to affect the protein's function in silico and was proven to have arisen *de novo* in the 2 families where both unaffected parents were available. The three patients not only had pancreatic agenesis requiring both insulin treatment and exocrine replacement therapy but also had holoprosencephaly (a failure of forebrain fusion) in 2 cases and probable holoprosencephaly in the 3rd (brain imaging was declined by the parents). We hypothesised a mutation-specific mechanism and generated a mouse line harbouring the same C*not1* mutation by CRISPR engineering. Gross morphological assessment suggested no phenotype in heterozygous mice while homozygosity for the mutation was embryonically lethal. We therefore investigated mouse embryos at E14.5. Homozygous embryos had markedly abnormal brain development (exencephaly $p = 3.2 \times 10^{-9}$), eye defects (coloboma $p = 5.5 \times 10^{-8}$) and significantly reduced dorsal pancreas size.

Conclusion: Our results identify a specific mutation in *CNOT1* as the genetic cause of a rare syndrome of pancreatic agenesis and holoprosencephaly. The phenotype in homozygous mice carrying the mutation recapitulates the human disease, confirming causality of the specific mutation. CNOT1 has been proposed to have a role in maintaining stem cells in a pluripotent state. We therefore propose a new mechanism resulting in pancreatic agenesis resulting from stem cells being maintained in their pluripotent state and prevented from differentiating towards the pancreatic line. This study establishes *CNOT1* as a key gene in very early pancreatic and neurological development in man and mouse, consistent with the proposed role in stem cells.

Bioenergetics of myeloid angiogenic cells: its role in the damage induced by stearic acid and in the protective action of empagliflozin

F. Fantuzzi[1], V. Spigoni[1], G. Cinquegrani[1], R. Aldigeri[1], E. Derlindati[1], A. Dei Cas[2], R.C. Bonadonna[2];
[1]University of Parma, Parma, [2]University of Parma and AOU of Parma, Parma, Italy.

Background and aims: In muscle biopsies of patients with type 2 diabetes, dapagliflozin reduced glucose oxidation and ATP synthesis - as a consequence of decreased tricarboxylic acid (TCA) cycle flux. In our lab, empagliflozin and dapagliflozin curbed inflammation and oxidant stress induced by stearic acid (SA) in human myeloid angiogenic cells (MAC; elsewhere named endothelial progenitor cells). We asked the question whether cell bioenergetics may be involved in the effects exerted by SA and/or SGLT2-inhibitors in MAC, which are thought to play major roles in atherosclerosis and cardiovascular risk. Aim of the study was to assess in human MAC whether: 1. SA-induced increases in inflammation and oxidant stress are accompanied by bioenergetic alterations; 2. empagliflozin anti-lipotoxic action is concomitant with coherent changes in bioenergetic metabolism.
Materials and methods: MAC were isolated from peripheral blood of healthy volunteers and incubated in the presence/absence of SA (100 μM) for 3 hours with/without empagliflozin (EMPA 100 μM). Respiration (O_2 consumption rate: VO_2) and glycolysis (GLYC; measured as extracellular acidification rate) were recorded in real-time by Seahorse technology (XFp Extracellular Flux Analyzer, Agilent). Basal and maximal VO_2, ATP-linked and non-mitochondrial respiration and spare respiratory capacity were quantified by serially adding oligomycin (ATP synthase inhibitor), FCCP (protonophore) and rotenone/antimycin A (inhibitors of complex I and III of electron transport chain) into the culture medium, according to a well established protocol. All parameters were adjusted for the number of viable cells.
Results: SA, at the concentration (100 μM) causing inflammation and increased oxidant stress, extensively altered cell bioenergetics of human MAC, with overall reductions both in basal/maximal VO_2, ATP production and spare respiratory capacity (all $p < 0.05$ or less *vs* control), all pointing to mitochondrial dysfunction, and in GLYC ($p < 0.05$), indicating no induction of Warburg effect. EMPA, at the concentration counteracting SA-induced lipotoxicity, both alone and in the presence of SA, caused alterations in cell bioenergetics quite similar to those induced by SA alone ($p < 0.05$ or less *vs* control).
Conclusion: In human MAC: 1. SA induces extensive alterations in cell bioenergetics, concomitantly with increase in inflammation and oxidant stress; 2. EMPA may inhibit TCA cycle/mitochondrial respiration, extending a previous observation made with dapagliflozin in muscle biopsies and suggesting a potential class effect; 3. the protective effect of EMPA against SA-induced lipotoxicity is unlikely to be mediated through bioenergetic metabolism.

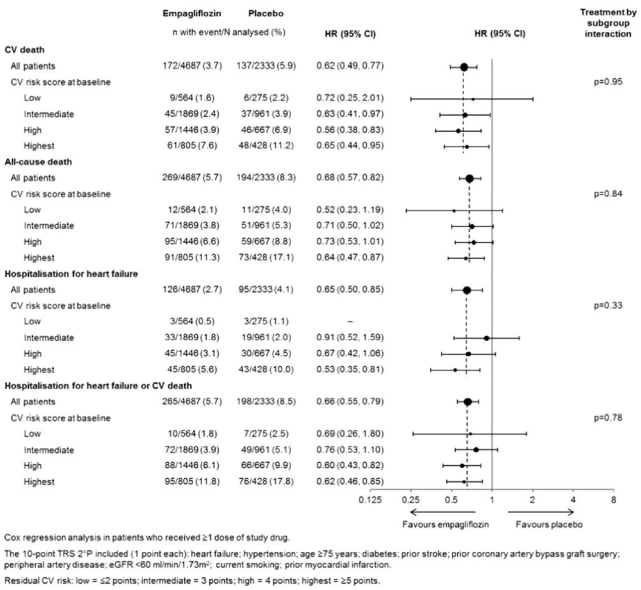
Empagliflozin reduces mortality and hospitalisation for heart failure irrespective of cardiovascular risk score at baseline

D. Fitchett[1], S.E. Inzucchi[2], C.P. Cannon[3], D.K. McGuire[4], O.E. Johansen[5], S. Sambevski[6], U. Hehnke[6], J.T. George[6], B. Zinman[7];
[1]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [2]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [3]Cardiovascular Division, Brigham and Women's Hospital, Boston, USA, [4]University of Texas Southwestern Medical Center, Dallas, USA, [5]Boehringer Ingelheim Norway KS, Asker, Norway, [6]Boehringer Ingelheim International GmbH, Ingelheim, Germany, [7]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Canada.

Background and aims: In the EMPA-REG OUTCOME trial in patients with type 2 diabetes and established cardiovascular (CV) disease, empagliflozin added to standard of care reduced CV death vs placebo by 38% (HR 0.62 [95% CI 0.49, 0.77]), all-cause death by 32% (HR 0.68 [95% CI 0.57, 0.82]) and hospitalisation for heart failure (HHF) by 35% (HR 0.65 [95% CI 0.50, 0.85]). We investigated whether residual CV risk at baseline influenced the effect of empagliflozin on these outcomes.
Materials and methods: We investigated CV death, all-cause death, HHF and the composite of HHF or CV death with empagliflozin vs placebo in subgroups by degree of CV risk at baseline based on the 10-point TIMI Risk Score for Secondary Prevention (TRS 2°P). *P* values for treatment-by-subgroup interaction were obtained from tests of homogeneity of treatment group differences among subgroups with no adjustment for multiple testing.
Results: Based on the TRS 2°P risk score, of 7020 patients who received study drug in the EMPA-REG OUTCOME trial, 12%, 40%, 30% and 18% were at low, intermediate, high and highest residual CV risk, respectively, at baseline. In the placebo group, from low to highest predicted risk, the proportion of patients with CV death increased from 2.2% to 11.2% and the proportion of patients with HHF increased from 1.1% to 10.0%. Effects of empagliflozin on CV death, all-cause death, HHF and HHF or CV death were consistent across subgroups by baseline CV risk score (Figure).
Conclusion: The benefits of empagliflozin on key clinical outcomes in the EMPA-REG OUTCOME trial occurred irrespective of residual CV risk at baseline.



Cox regression analysis in patients who received ≥1 dose of study drug.
The 10-point TRS 2°P included (1 point each): heart failure; hypertension; age ≥75 years; diabetes; prior stroke; prior coronary artery bypass graft surgery; peripheral artery disease; eGFR <60 ml/min/1.73m²; current smoking; prior myocardial infarction.
Residual CV risk: low = ≤2 points; intermediate = 3 points; high = 4 points; highest = ≥5 points.

Canagliflozin versus other antihyperglycaemic agents on the risk of below-knee amputation for patients with type 2 diabetes: a real world analysis of >700,000 US patients

P. Ryan[1], J.B. Buse[2], M. Schuemie[1], F. DeFalco[3], Z. Yuan[1], P. Stang[1], J.A. Berlin[4], N. Rosenthal[3];
[1]Janssen Research & Development, LLC, Titusville, [2]University of North Carolina School of Medicine, Chapel Hill, [3]Janssen Research & Development, LLC, Raritan, [4]Johnson & Johnson, Titusville, USA.

Background and aims: Sodium glucose co-transporter 2 inhibitors (SGLT2i) are indicated for treatment of type 2 diabetes mellitus (T2DM); some SGLT2i have reported a cardiovascular (CV) benefit and some have reported a risk of below-knee amputation (BKA).
Materials and methods: US claims databases were analysed using a prespecified protocol to examine canagliflozin (CANA)-associated effects on BKA and hospitalisation for heart failure (HHF) versus other SGLT2i and non-SGLT2i antihyperglycaemic agents (AHAs). Analyses used a propensity score adjusted new user design with numerous sensitivity analyses. The 4 databases included 142,000 new users of CANA, 110,000 of other SGLT2i, and 460,000 of non-SGLT2i AHAs. Meta-analysis results are reported when heterogeneity across databases was not substantial ($I^2 < 0.4$).
Results: There was no evidence of increased risk of BKA with CANA versus non-SGLT2i AHAs or other SGLT2i in on-treatment or intention-to-treat (ITT) analyses (Table). HHF benefits were demonstrated in these analyses, consistent with clinical trials. Similar BKA and HHF results were seen in a subgroup with established CV disease.
Conclusion: In this large comprehensive analysis, neither CANA nor other SGLT2i showed an increased risk of amputation versus non-SGLT2i AHAs. Because on-treatment median exposure was <6 months, future observational studies with longer duration are needed. This study helps to further characterise the potential benefits and harms of SGLT2i as observed in routine clinical practice to complement the evidence from clinical trials and prior observational studies.

Table. Risk of BKA and HHF in the overall population.*

The inTandem 2 study: 52-week efficacy and safety of sotagliflozin, a dual SGLT1 and SGLT2 inhibitor, as adjunct therapy to insulin in adults with type 1 diabetes

B. Cariou[1], T. Danne[2], P. Banks[3], M. Brandle[4], H. Brath[5], E. Franek[6], J.A. Kushner[7], P. Lapuerta[3], D.K. McGuire[8], A. Peters[9], S. Sangeeta[10], P. Strumph[3];
[1]l'institut du thorax, Department of Endocrinology, CHU de Nantes, Nantes, France, [2]Department of Diabetes, Endocrinology and Clinical Research, Hannover Medical School, Hannover, Germany, [3]Lexicon Pharmaceuticals, Inc., The Woodlands, USA, [4]Department of Internal Medicine, Kantonsspital St Gallen, St Gallen, Switzerland, [5]Diabetes Outpatient Clinic, Health Center South, Vienna, Austria, [6]Polish Academy of Sciences, Warsaw, Poland, [7]Department of Pediatrics, Baylor College of Medicine and Texas Children's Hospital, Houston, USA, [8]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, USA, [9]Keck School of Medicine of the University of Southern California, Los Angeles, USA, [10]Lexicon Pharmaceuticals, Inc, The Woodlands, USA.

Background and aims: Sotagliflozin (SOTA), a dual SGLT1 and SGLT2 inhibitor, is currently in development as an oral adjunct to insulin in type 1 diabetes (T1D).
Materials and methods: In this double-blind, 52-week European study, 782 adults with Type 1 diabetes (T1D) treated with multiple daily insulin injections or pump therapy were randomized 1:1:1 to placebo ($n = 258$), sotagliflozin (SOTA) 200 mg ($n = 261$) or SOTA 400 mg ($n = 263$) once daily after 6 weeks of insulin optimization. Primary endpoint was change from baseline in A1C at Week 24. Other endpoints were A1C, documented hypoglycemia (DH), weight and fasting plasma glucose (FPG) change at Week 52, patient (pt) reported outcomes (PROs) and net clinical benefit (NCB) - the proportion of pts with A1C <7.0% without severe hypoglycemia (SH) or diabetic ketoacidosis (DKA).
Results: Baseline characteristics were similar between groups. Compared with placebo, treatment with SOTA 200 or 400 mg improved A1C and pt satisfaction at Week 24 and reduced A1C, DH rate, weight, FPG and pt distress at Week 52 (Table). More pts achieved NCB in the SOTA arms vs placebo (Table). Pts receiving SOTA 400 mg had the least SH events, but more genital mycotic infections, DKA, and diarrhea than placebo.
Conclusion: SOTA 200 and 400 mg provided statistically significant A1C reductions that were sustained ($P < 0.05$) at Week 52, as well as improvement in DH and PROs. There was more DKA, but less SH, with SOTA 400 mg relative to placebo at Week 52.

SGLT2i vs bolus insulin as add-on to stable basal insulin treatment in type 2 diabetes and risk of cardiovascular disease and mortality: a nationwide observational study

J.W. Eriksson[1], J. Bodegard[2], A. Norhammar[3], M. Thuresson[4], D. Nathanson[5], T. Nyström[5];

[1]Uppsala University, Uppsala, Sweden, [2]AstraZeneca Nordic-Baltic, Oslo, Norway, [3]Karolinska Institutet, Stockholm, Sweden, [4]Statisticon AB, Uppsala, Sweden, [5]Södersjukhuset, Stockholm, Sweden.

Background and aims: Cardiovascular outcome trials (CVOTs) have recently shown improved prevention of cardiovascular (CV) disease with sodium-glucose cotransporter-2 inhibitors (SGLT2i). Large observational studies have indicated similar effects in broader T2D populations. A significant proportion of the CVOT-patients were on concomitant insulin treatment. The aim of this observational study was to examine the risk of cardiovascular disease and mortality in new users of SGLT2i versus bolus insulin, when added to stable basal insulin treatment in T2D. These patients have advanced T2D with a need for treatment intensification.
Materials and methods: All T2D patients on basal insulin treatment (intermediate-, long-acting- or premixed insulin for >1 year) were identified in mandatory, nationwide health care registries during 2013–2016. New users of SGLT2i and bolus (short-acting) insulin as add-on to basal insulin treatment were matched 1:1 by propensity scores for the likelihood of receiving SGLT2i (calculated by using >90 relevant patient characteristic variables). The primary combined endpoint was hospitalization for heart failure (HHF; in-/outpatient) or CV mortality. In addition, major cardiovascular adverse events (MACE; myocardial infarction, stroke or CV mortality) and severe hypoglycaemia (hospital admission) were assessed. Patients were followed until death, end of study period or treatment discontinuation. Unadjusted Cox survival models estimated hazard ratios.
Results: A total of 2 988 patients were identified after matching, mean age 64 years, 32% had established CV disease with no imbalances at baseline. Follow-up time was 2 736 patient years (mean 0.92 years), in the SGLT-2i group dapagliflozin contributed with 87% and empagliflozin with 13%. Add-on of SGLT-2i versus bolus insulin to stable insulin treatment was significantly associated with lower risk of the combined outcome (HR 95% CI; 0.51:0.32–0.82), and also HHF and CV mortality separately; MACE (0.54:0.34–0.87) and severe hypoglycemia (0.61:0.40–0.93), which was the most common event. No significant differences for myocardial and stroke were found.
Conclusion: In patients with ongoing basal insulin treatment, add-on of SGLT2i versus bolus insulin carried significantly less risk of CV mortality, HHF and MACE. Notably, the event rate of severe hypoglycaemia in this population was lower with SGLT2i treatment.

	SGLT-2i No. Events (Event rate per 100 patient-years)	Bolus insulin No. Events (Event rate per 100 patient-years)	Hazard ratio	CI 95%	p-value
HHF or CV mortality	28 (1.93)	50 (3.90)	0.51	(0.32-0.82)	0.005
HHF	21 (1.45)	35 (2.73)	0.54	(0.32-0.93)	0.027
CV mortality	8 (0.55)	19 (1.46)	0.40	(0.17-0.91)	0.030
MACE (includes CV mortality)	27 (1.86)	46 (3.57)	0.54	(0.34-0.87)	0.011
Myocardial infarction	13 (0.89)	16 (1.24)	0.73	(0.35-1.52)	0.400
Stroke	9 (0.62)	14 (1.08)	0.59	(0.25-1.36)	0.214
Severe hypoglycemia	35 (2.44)	53 (4.20)	0.61	(0.40-0.93)	0.022
All-cause mortality	18 (1.23)	56 (4.31)	0.30	(0.18-0.51)	<0.001

Efficacy and safety of empagliflozin-based quadruple therapy compared to insulin glargine-based therapy in poorly controlled type 2 diabetes

E. Ku, H. Jeon, T. Oh;
Internal medicine, Chungbuk National University Hospital, Cheongju-si, Republic of Korea.

Background and aims: Empagliflozin is a potent and selective sodium-glucose cotransporter 2 (SGLT2) inhibitor. Empagliflozin showed the glucose lowering effects in the mono- or dual combination therapy with metformin, sulfonylurea (SU), dipeptidyl peptidase 4 inhibitors (DPP4i) and insulin. However, there was no study with quadruple combination with empagliflozin. The aim of this study was to examine the efficacy and safety of the empagliflozin as add-on therapy compared to basal insulin-based oral antidiabetic agents in patients with type 2 diabetes mellitus (T2DM) inadequately controlled on triple oral antidiabetic agents (OADs) in a real clinical practice.
Materials and methods: A single center, 24-week, open-label, prospective study in 257 patients comparing empagliflozin (25 mg/day, EMPA, n = 138) and insulin glargine (INS, n = 119) added to metformin (2000 mg/day) plus SU (glimepiride 8 mg/day) plus DPP4i (maximal dose). The inclusion criteria were defined as follow; HbA_{1c}: 7.5–12%, with stable OADs dose before 12 weeks. Efficacy outcomes included the change in HbA1c, fasting plasma glucose (FPG), bodyweight, systolic blood pressure (SBP) from baseline to week 24. Safety outcomes included adverse events (AEs), hypoglycemia, genitourinary tract infections (GUTIs) and laboratory tests.
Results: At week 24, reductions from baseline in mean HbA_{1c} were significantly greater in the EMPA group (−1.47 ± 1.19%) compared with the INS group (−1.17 ± 1.44%) (P = 0.003). Significant changes were also observed in FPG (−69.3 ± 57.2 vs −40.1 ± 65.9 mg/dL, EMPA and INS, respectively, P < 0.001). Reductions from baseline in bodyweight were significantly greater with the EMPA group (−1.5 ± 8.1 vs +1.2 ± 3.0 kg, P < 0.001). In terms of the differences in the SBP; changes from baseline at week 24 were −3.0 ± 14.6 mmHg with the EMPA group and +5.6 ± 21.6 mmHg with the INS group (P = 0.008). Confirmed hypoglycemic AEs were in 10.9% and 26.1%, of EMPA and INS group, respectively (P = 0.002). Events consistent with GUTIs were reported in 5.1% of subjects on EMPA group and 0.8% of subjects on INS group, respectively (P = 0.072).
Conclusion: The quadruple OADs combination of empagliflozin resulted in a significant reduction in HbA_{1c} and FPG compared with the insulin glargine-based OADs combination therapy at week 24 in patients with inadequately controlled T2DM.

OP 20 Overriding mechanisms of NAFLD

115

Role of the receptor RANK and its ligand RANKL in the development of NAFLD

F. Phan[1,2], M. Hu[1], I. Hainault[1], V. Ratziu[1,3], O. Bourron[1,2], F. Foufelle[1];
[1]INSERM UMRS1138 Cordeliers Research Centre, Paris, [2]Assistance Publique-Hôpitaux de Paris, Department of Diabetology, Paris, [3]Assistance Publique-Hôpitaux de Paris, Department of Hepatology, Paris, France.

Background and aims: Non Alcoholic Fatty Liver Disease (NAFLD) is highly associated with type 2 diabetes. Hepatic steatosis represents the first stage of NAFLD and is characterized by lipid accumulation and insulin resistance. Lipotoxicity promotes ballooning and inflammation leading to steatohepatitis (NASH). Thus, insulin resistance and inflammation play a major role in the progression of the disease. Nuclear factor-kB (NF-kB) plays a central role in inflammation. Its hepatic activation leads to insulin resistance, steatosis and inflammation. Here, we are interested in the role of the TNF receptor related member RANK and its ligand RANKL, known to induce NF-κB activity, in the onset and progression of NAFLD.
Materials and methods: Mice overexpressing RANK in the myeloid lineage (TgRANK) are fed under normal chow (NC) or high fat diet (HFD). The expression of RANK and those of lipogenic and gluconeogenic enzymes are measured by RT-qPCR from the livers of NAFLD-related animal models, from biopsies of NAFLD patients and from the liver of TgRANK. Hepatic insulin signalling is analysed by Western blot.
Results: RANK expression is markedly induced in the liver of NASH-related mice models. Its expression is the highest in hepatic macrophages and proportional to the inflammatory state. In human biopsies, RANK expression is increased in NASH patients compared to NAFL and control patients. Interestingly, in our human cohort, RANK expression is negatively correlated with fasting glycaemia. Mice overexpressing RANK in the myeloid cells are generated and analysed. These mice display a lower basal glycemia and an improved insulin sensitivity during glucose tolerance test and insulin sensitivity test. In the liver of TgRANK, the phosphorylation of key proteins of the insulin signaling pathway is enhanced compared to control littermates. As a consequence, the expression of lipogenic enzyme is increased and those of gluconeogenic enzyme decreased. We next try to understand how RANK overexpression in macrophages, can induce this metabolic phenotype. We observe that TgRANK macrophages secrete more IL10 than macrophages of control mice. In the presence of insulin, treatment of primary hepatocytes with IL10 enhances insulin signaling. Conditional medium isolated from TgRANK macrophages trigger insulin signalling when added to cultured hepatocytes. We finally challenge RANK-overexpressing mice with 8 weeks of HFD and show that these animals are protected from hepatic steatosis and insulin resistance.
Conclusion: In conclusion, our results reveal that RANK expression is increased in macrophages under NAFLD conditions. We believe this could be a compensatory mechanism against insulin resistance and inflammation seen in NAFLD.

Osteoprotegerin promotes hepatic steatosis through ERK-PPARγ-CD36 pathway

Y. Lin[1], L. Li[1], G. Yang[2];
[1]Key Laboratory of Diagnostic Medicine (Ministry of Education) and Department of Clinical Biochemistry, Chongqing Medical University, Chongqing, [2]Department of Endocrinology, the Second Affiliated Hospital, Chongqing Medical University, Chongqing, China.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is characterized dysregulated lipid homeostasis and an aberrant accumulation of triglycerides in the liver, but underlying mechanisms are unknown. It has been reported that circulating Osteoprotegerin (OPG) is associated with metabolic diseases in humans, including NAFLD. However, the studies of mechanism are lacking. The purpose of the present study is to investigate the roles of OPG in the progression of obesity-associated fatty liver and possible mechanisms.
Materials and methods: Expression of hepatic OPG was investigated in mouse and human livers with hepatic steatosis. In vitro, adenovirus expressing OPG (Adv-OPG) and small hairpin RNA (Adv-shOPG) were used in L02 cells and Hepal1-6 cells and OPG-Fc was used in mouse primary hepatocytes (MPHs) to investigate the role of OPG on hepatic steatosis. In vivo, hepatic triglyceride metabolism and related genes were analyzed in male WT and OPG knockout ($OPG^{-/-}$) mice fed with standard diet (SD) or high fat diet (HFD). Then, MPHs from CD36 knockout ($CD36^{-/-}$) mice were treated with OPG-Fc to further verify if OPG regulation of lipid accumulation in the liver relies on CD36. GW9662, a PPARγ inhibitor, and SCH772984, an ERK inhibitor, were respectively used to verify the association of OPG with CD36, PPARγ and ERK in cultured cells.
Results: OPG expression was down-regulated in obese mice than in SD-fed C57BL/6 mice, and down-regulated in NAFLD patients than in healthy individuals. In vitro, up-regulation of OPG in cell lines and MPHs increased TG contents and lipid droplets. In contrast, Ad-shOPG treatment decreased lipid accumulation. In vivo, under SD and HFD feeding, hepatic steatosis in $OPG^{-/-}$ mice were significantly decreased compared with WT mice. In parallel, decreased steatosis were found in MPHs from $OPG^{-/-}$ mice compare with MPHs from WT mice. Importantly, the deficiency of OPG reduced expressions of CD36 and PPARγ in the liver of $OPG^{-/-}$ mice and cultured cells. In contrast to, overexpression of OPG increased CD36 and PPARγ expressions in cultured cells. The effect of OPG on lipid accumulation was blocked by the deficiency of CD36 in MPHs from $CD36^{-/-}$ mice. With a series of truncated promoters and site-directed mutated promoter of CD36 gene, luciferase assay showed that PPREs binding site of CD36 promoter was indispensable for OPG activation of CD36 promoter activity. Treatment with GW9662, a PPARγ inhibitor, could completely eliminate OPG-induced CD36 protein expression. Furthermore, the overexpression or deficiency of OPG led to decreasing or increasing ERK phosphorylation in the liver of $OPG^{-/-}$ mice and cultured cells. And SCH772984, an ERK inhibitor, eliminated the decrease of CD36 and PPARγ expression induced by knockdown of OPG.
Conclusion: These data indicate that OPG play an important role in NAFLD through targeting ERK-PPARγ-CD36 pathway.

NREP bridges TGF-beta signalling and lipid metabolism in the epigenetic programming of NAFLD

D.F. De Jesus[1,2], K. Orime[1], E. Dirice[1], D. Kaminska[3], C.-H. Wang[1], J. Hu[1], V. Mannisto[3,4], A.M. Silva[5], Y.-H. Tseng[1], J. Pihlajamaki[3,4], R.N. Kulkarni[1];
[1]Joslin Diabetes Center and Harvard Medical School, Boston, USA, [2]University of Porto, Porto, Portugal, [3]University of Eastern Finland, Kuopio, Finland, [4]Kuopio University Hospital, Kuopio, Finland, [5]University of Tras-os-Montes and Alto Douro, Vila Real, Portugal, [6]University of Eastern Finland, Kuopio, Finland.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) prevalence is increasing worldwide and few studies have associated maternal diabetes and altered birth weights with increased risk for NAFLD. We aimed to determine the genetic and epigenetic effects of paternal versus maternal genetic insulin resistance on the developmental programming in the offspring of the liver-specific insulin receptor knockout (LIRKO) mice.
Materials and methods: We used a unique non-dietary model manifesting hyperglycemia and hyperinsulinemia - two hallmarks of gestational and type 2 diabetes. Male control F1 offspring from father LIRKO (FL), mother LIRKO (ML) or control mothers and fathers (C) were weaned on a chow or high-fat-diet (HFD) and followed for 3 months. We further validated a set of candidate genes by using an *in-vitro* model of hepatic steatosis in HepG2 cells and human primary hepatocytes. Finally we validated the clinical translation of these findings by evaluating our candidate genes expression in samples from patients with steatosis.
Results: FL and ML showed impaired growth and body weight composition. FL and ML developed hepatic steatosis compared to C when challenged with HFD and exhibited increased hepatic expression of lipogenesis-associated genes. Hepatic transcriptomic and genome-wide DNA methylation analyses of FL and ML on chow diet presented enriched-pathways associated with TGF-β signaling and lipid synthesis. FL and ML hepatic NREP mRNA levels were decreased 50% ($p < 0.05$) on HFD compared to C. *In-vivo* and *in-vitro* modeling of hepatic steatosis in HepG2 and human primary hepatocytes decreased *NREP* mRNA and protein levels. Knock-down experiments performed in HepG2 cells revealed that *NREP* acts by regulating triglyceride and cholesterol synthesis transcriptional network via regulation of ATP-citrate lyase (ACL) in a phospho-AKT dependent manner. To investigate the translational relevance of these findings, we investigated NREP levels in patients with steatosis. Consistently, *NREP* mRNA levels were decreased by 40% ($p < 0.05$) in patients with steatosis as compared to controls and looking into public available datasets we were able to identify a strong negative correlation between *NREP* and *ACL* expression. Next, to examine whether plasma NREP levels mimic the changes seen in patients with NAFLD, we analyzed NREP plasma levels in controls ($n = 106$), simple steatosis ($n = 36$) and NASH ($n = 28$) patients in a comprehensive obese liver biopsy-proven cohort (the Kuopio cohort). Indeed, several clinical parameters negatively correlated with NREP levels, including steatosis grade ($p < 0.0002$) and NAFL activity score ($p < 0.0001$).
Conclusion: These findings and recent preclinical trials implicating ACL in NAFLD highlight the translation relevance of our findings. Together these data suggest that prenatal insulin resistance epigenetically regulates a novel protein, NREP that has detrimental effects on metabolic adaptation and transcriptional regulation of hepatic metabolism in the development of NAFLD.

Role of PKD1 in the control of liver endoplasmic reticulum stress responses during non-alcoholic fatty liver disease progression

P. Rada[1,2], A. Mosquera[1,2], C. García-Monzón[3], T. Iglesias[1,4], Á.M. Valverde[1,2];
[1]Instituto de Investigaciones Biomédicas Alberto Sols (UAM-CSIC), Madrid, [2]Centro de Investigación Biomédica en Red sobre Diabetes y enfermedades metabólicas asociadas (Ciberdem), Madrid, [3]Liver Research Unit, Instituto de Investigación Sanitaria Princesa, University Hospital Santa Cristina, CIBERehd, Madrid, [4]Centro de Investigación Biomédica en Red sobre enfermedades neurodegenerativas (CIBERNED), Madrid, Spain.

Background and aims: Protein kinase D1 (PKD1) is a ubiquitous serine/threonine kinase belonging to the CAMK family. It is increasingly implicated in the regulation of fundamental biological processes such as apoptosis, cell proliferation, trafficking and oxidative stress. It has been previously reported that PKD1 plays a role in different tissues including skin, immune cells, cardiac myocytes and pancreas. However, its role in liver metabolism remains unclear.
Materials and methods: A mouse model that lacks PKD1 in hepatocytes was generated by using the Cre-loxP system ($PKD1^{\Delta Hep}$ and $PKD1^{fl/fl}$ as control mice). Primary hepatocytes from $PKD1^{fl/fl}$ and $PKD1^{\Delta Hep}$ mice were isolated by two-step collagenase perfusion. As an *in vivo* model of non-alcoholic fatty liver disease (NAFLD) linked to obesity, 8 week-old male $PKD1^{\Delta Hep}$ and $PKD1^{fl/fl}$ mice were fed Chow (CHD) or High Fat Diet (HFD) for 20 weeks. Parameters that assess glucose homeostasis, whole body and hepatic insulin sensitivity as well as NAFLD progression were analyzed.
Results: Primary hepatocytes from $PKD1^{\Delta Hep}$ mice presented higher levels of endoplasmic reticulum (ER) stress markers under basal conditions (pPERK $p < 0.01$ vs $PKD1^{fl/fl}$; pIRE1α $p < 0.05$ vs $PKD1^{fl/fl}$; CHOP $p < 0.05$ vs $PKD1^{fl/fl}$) and after palmitic acid (PA) stimulation. In addition, under conditions of chow diet, liver sections of $PKD1^{\Delta Hep}$ mice showed a more pronounced dilation of the ER lumen compared to $PKD1^{fl/fl}$ mice, suggesting that PKD1 might contribute to the maintenance of ER homeostasis in the liver. Since obesity induce ER stress response and insulin resistance, male mice from both strains were fed HFD for 20 weeks. After this period, $PKD1^{\Delta Hep}$ mice exhibited a higher increase in body weight when compared to $PKD1^{fl/fl}$ mice ($p < 0.05$ vs HFD-fed $PKD1^{fl/fl}$: $PKD1^{fl/fl}$ 47.4 ± 2.4 g, $PKD1^{\Delta Hep}$ 53.9 ± 1.2 g). Moreover, glucose (GTT), insulin (ITT) and pyruvate (PTT) tolerance tests revealed that HFD-fed $PKD1^{\Delta Hep}$ mice presented a moderate alteration in glucose homeostasis and a significant decrease in hepatic insulin sensitivity than control mice (PTT $p < 0.05$ vs HFD-fed $PKD1^{fl/fl}$ mice). These results were also confirmed by analysis of phosphorylation levels of insulin receptor and AKT ($p < 0.001$ vs HFD-fed $PKD1^{fl/fl}$ mice). Interestingly, histological analysis revealed that steatosis, inflammation and ballooning (NAS score) were slightly but not significantly higher in $PKD1^{\Delta Hep}$ mice than in $PKD1^{fl/fl}$ mice under CHD, but more importantly, when both mice were fed HFD, these differences were statistically significant between both genotypes (steatosis $p < 0.001$ vs HFD-fed $PKD1^{fl/fl}$; inflammation $p < 0.05$ vs HFD-fed $PKD1^{fl/fl}$; ballooning $p < 0.001$ vs HFD-fed $PKD1^{fl/fl}$).
Conclusion: Taken together, our results strongly suggest a possible protective role of PKD1 to maintain the liver ER homeostasis that could delay the progression of liver pathologies associated to ER stress such as NAFLD.

Therapeutic effect of a novel long-acting GLP-1/GIP/Glucagon triple agonist (HM15211) in NASH and fibrosis animal models

J. Kim, I. Choi, J. Lee, E. Park, Y. Kim, S. Jung, S. Kim;
Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea.

Background and aims: Nonalcoholic steatohepatitis (NASH), a progressive form of nonalcoholic fatty liver disease (NAFLD), may lead to end stage liver disease including cirrhosis and hepatocellular carcinoma. Despite its severity and prevalence, NASH currently lacks effective therapies. In this respect, we developed a novel long-acting, GLP-1/GIP/Glucagon triple agonist, HM15211. HM15211, with a unique activity profile, provides synergistic benefits on body weight loss and lipid profile improvement while avoiding hyperglycemic risk. Previously, we showed that HM15211 exerts potent reductions in body weight and hepatic triglycerides (TG) in DIO mice. In addition, HM15211 shows liver preferential distribution, suggesting a potential treatment for NASH. Here, we evaluated the effect of HM15211 in NASH and fibrosis in Methionine choline-deficient (MCD) diet mice model with various disease induction periods utilizing up-to-date imaging techniques and histopathological analysis. In addition, efficacy of HM15211 was further evaluated in obese and NASH monkeys.
Materials and methods: MCD-diet mice model was induced for 6 and 10 weeks for moderate and severe fibrosis induction, respectively. Comparators including liraglutide 50 nmol/kg, twice-daily (BID) (for 6 week induction) or selonsertib and OCA 30 mg/kg once-daily (QD) (for 10 week induction) were used along with HM15211 0.72 nmol/kg, once every 2 days (Q2D). During the treatment, MRI/MRS was utilized for real-time liver fat analysis. At the end of treatment, the animals were sacrificed for liver TG, TBARS (oxidative stress assay), hydroxyproline assay (surrogate for hepatic collagen fiber), marker gene expression analysis, and NAFLD activity score (NAS). Lastly, obese and NASH cynomolgus monkeys were treated with HM15211 (starting with 3 weeks titration period followed by 9 weeks single dose treatment) to further evaluate its therapeutic efficacy in non-human primates.
Results: HM15211 treated MCD-diet mice (6 weeks induction) showed significant reduction in hepatic TG (−82.6% *vs.* vehicle) and TBARS (−60.7% *vs.* vehicle), which coincided with significant reduction in blood liver functional markers such as ALT and bilirubin. Time course MRI/MRS imaging further confirmed the progressive steatosis resolution by HM15211 while liraglutide showed minimal effect. Furthermore, histopathological analysis indicated that HM15211 significantly reduced hepatic inflammatory gene expression and NAS (1.3 for HM15211, 3.4 for liraglutide, and 2.7 for vehicle). In MCD-diet mice with overt liver fibrosis (10 weeks induction), NASH improvement in HM15211 treated groups was confirmed with improved blood liver functional markers and related gene expression along with reduced hydroxyproline contents. Moreover, HM15211 treated groups showed complete reversal in NAS while selonsertib and OCA had marginal effect (0.0 for HM15211, 1.2 for selonsertib, 0.9 for OCA, and 2.1 for vehicle). Finally, HM15211 effectively treated obese and NASH cynomolgus monkeys as indicated by potent BWL, improved liver functional markers and histopathological analysis.
Conclusion: According to its efficacy in various NASH animal models, HM15211 may offer therapeutic potential in NASH and fibrosis as well as obesity.

Background and aims: Dietary fructose has been suggested to play an important role in the pathogenesis of nonalcoholic fatty liver disease (NALFD). However, the exact underlying mechanism remains unclear. Fructose could contribute to NAFLD as either a substrate for *de novo* lipogenesis (direct pathway) or as a signal molecule that induces transcription factors such as carbohydrate-responsive element-binding protein (ChREBP) that stimulate *de novo* lipogenesis (indirect pathway). The study of inborn errors of fructose metabolism may aid to make a distinction between these two pathways. Since aldolase B is involved in the final step of fructolysis, patients with a deficiency in this enzyme serve as an excellent human model to study the contribution of the indirect pathway to the pathogenesis of fructose-induced NAFLD (independent of the direct pathway).
Materials and methods: In this case-control study, intrahepatic triglyceride (IHTG) content was measured using proton magnetic resonance spectroscopy (^{1}H-MRS) in 15 confirmed aldolase B deficient (aldoB$^{-/-}$) patients and 15 age-, sex-, and BMI-matched control subjects. All individuals filled out a three-day food diary to determine their daily fructose intake and underwent an oral glucose tolerance test (OGTT). Plasma transferrin glycosylation patterns, used as a surrogate for hepatic fructose-1-phosphate concentrations, were measured with high-resolution mass spectrometry.
Results: IHTG content was higher in aldoB$^{-/-}$ patients when compared to healthy controls (median IHTG content: 2.5% and 0.6% respectively, $p = 0.001$). Plasma glucose excursions during the OGTT were higher in aldoB$^{-/-}$ patients, resulting in a significantly different area under the curve ($p = 0.043$). The most fructose-intolerant patients -indicated by the lowest dietary fructose intake- had the highest IHTG content (Spearman's rho = −0.77, $p = 0.001$). Hypoglycosylated transferrin was more abundant in aldoB$^{-/-}$ patients when compared to controls ($p < 0.001$) and tended to be higher in aldoB$^{-/-}$ patients with relevant IHTG content (i.e. >3%, $n = 5$) compared to those without ($n = 10$) ($p = 0.09$).
Conclusion: This study demonstrates that the direct pathway is not necessary for the pathogenesis of fructose-induced NAFLD in humans. The increased IHTG content in aldoB$^{-/-}$ suggests that intermediates of fructolysis, i.e. fructose-1-phosphate, play a prominent role through indirect pathways.

Reduce the risk for repeat percutaneous coronary intervention: the importance of HbA_{1c} control in prediabetes

H. Yu[1], Y. Zhang[2], X. Liu[3], J. Li[1];
[1]Tongji University School of Medicine, Shanghai, [2]Shanghai Tenth People's Hospital affiliated to Tongji University School of Medicine, Shanghai, [3]Shanghai Tongji Hospital affiliated to Tongji University School of Medicine, Shanghai, China.

Background and aims: According to the current guidelines, patients with percutaneous coronary intervention (PCI) were recommended to have strict lipid profile and plasma glucose control. However, many patients with well-controlled risk factors also experienced repeat PCI. The risk factors for repeat PCI were still unclear.
Materials and methods: Consecutive 5545 inpatients with CHD were enrolled from the Shanghai Eastern Hospital Affiliated to Tongji University from November 2011 to March 2015. Anthropologic measurements and medical records of these patients were collected.
Results: 5545 participants, including 3559 acute coronary syndrome (ACS) patients, received PCI procedure, of whom the incidence of repeat PCI was 10.80% in total population and 10.65% in ACS patients, respectively. In multivariate logistic regression, prediabetes (HbA1c 39–46 mmol/mol, 5.7–6.4%) and diabetes (HbA1c ≥48 mmol/mol, 6.5%) were significant and independent risk factors for repeat PCI with OR of 1.61 (1.21–2.13) and 2.97 (2.13–4.12), respectively. Similar results were observed in ACS patients, with OR of 1.87 (1.30–2.68) and 3.32 (2.16–5.10), respectively. Moreover, even in patients with LDL-C <1.80 mmol/L, poorly glycemic-control (HbA1c ≥39 mmol/mol, 5.7%) was also significant and independent risk factor for repeat PCI with OR of 2.16 (1.18–3.95).
Conclusion: Prediabetes and diabetes are crucial risk factors for the repeat PCI in post-PCI patients, even in those with well-controlled lipid profile.

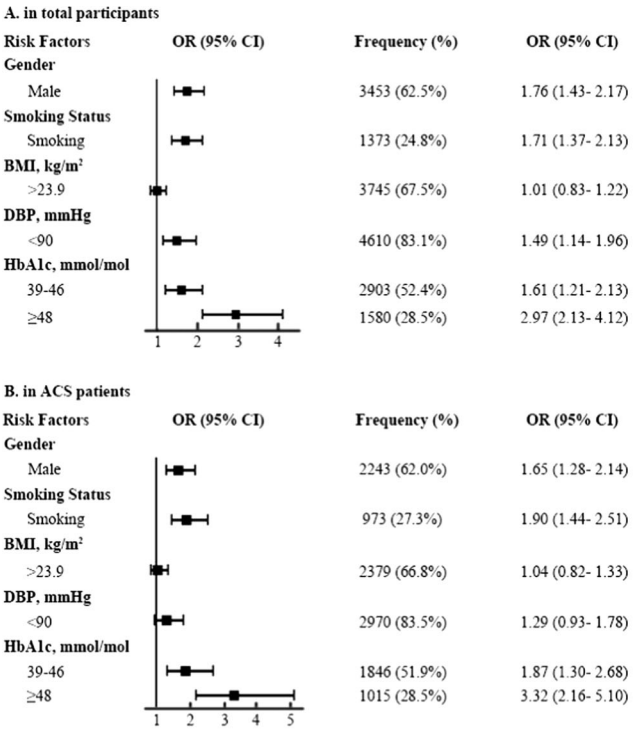

Figure 1. Association of risk factors with repeat PCI after adjustment for lesion number, left main disease and medication treatments [a]

Variables were graded according to current guidelines and their clinical significance respectively, see details in Methods.
ACS, acute coronary syndrome; DBP, diastolic blood pressure; PCI, percutaneous coronary intervention.

The updated mean HbA_{1c} level is more strongly related to mortality compared to a single HbA_{1c} measurement: The Hoorn Diabetes Care System Cohort study

G. Nijpels[1], P. Elders[1], J. Beulens[2], F. Rutters[2], A. van der Heijden[1];
[1]General Practice and Elderly Care, VU University Medical Center, Amsterdam, [2]Epidemiology and Biostatistics, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: When the association between glycemic control and mortality risk for people with type 2 diabetes (T2D) is studied, most often the last glycemic measurement available is used. However, T2D is a progressive disease and treatment can lower HbA1c. Furthermore, previously intensive glycemic control was associated with increased mortality rates. To date, the relative importance of average HbA1c levels over time, as proxy for longer term glycemic control in T2D in the association with mortality remains uncertain. Therefore, we compared last measured HbA1c and the updated mean of HbA1c and their association with relative mortality risk in people with T2D
Materials and methods: A prospective observational study of 14.420 people with T2D included in the Hoorn Diabetes Care System (DCS) cohort was performed. The DCS includes all people with T2D in the region West-Friesland in the Netherlands. From 1997 till 2017, data were collected every year on among others, blood pressure, HbA1c, lipids, smoking status. All-cause mortality was extracted from national registries. 4,960 people with T2D included in the DCS within two years after the diagnosis of T2D with at least five HbA1c follow-up measurements were included. The last measured HbA1c and the updated mean of the

HbA1c level ($T = 1$ to $T = 5$) were associated to all-cause mortality with two Cox regression models, adjusted for sex, age, smoking status, diabetes duration, total cholesterol and systolic blood pressure. Because a diabetes diagnosis at a younger age may result in a higher complication risk, effect modification by age of diabetes onset (<55 years, 55–65 years, and ≥65 years) was tested by adding cross product terms with HbA1c to the model. Hazard ratios (HR's and 95% confidence intervals (CIs) are reported.

Results: During a mean follow-up period of 6.7 years (range: 0–16 years), 770 people (15.5%) died. Statistically significant effect modification was found between age of onset of diabetes and both measures of HbA1c ($p < 0.1$). Consequently, all results were stratified for age of diabetes onset. The fully adjusted models are shown in the table, with updated mean of HbA1c showed stronger associations with mortality in all categories of age of onset of diabetes, compared to assessing only the last HbA1c measurement. For both measures of HbA1c, the association with mortality (per 1% increase) was stronger in in people with an age of onset <55 years (HR: 1.50 (95% CI: 1.24 to 1.81), compared to onset of diabetes ≥65 years (HR: 1.14 (95%CI: 1.00 to 1.29)) (Table).

Conclusion: In this prospective cohort of people with T2D, the updated mean of HbA1c is more strongly associated with all-cause mortality, compared to last measured HbA1c, even more pronounced in people with a diagnosis at early age. The predictive role of the course of HbA1c levels for mortality should be further investigated.

Table. Hazards ratio for mortality risk by HbA1c (%) according to category of age of onset of diabetes.

Single measurement of HbA1c	< 55 years	55-65 years	≥ 65 years
Model 1	1.37 (1.17 to 1.61)	1.11 (0.97 to 1.28)	1.08 (0.96 to 1.21)
Model 2	1.38 (1.17 to 1.63)	1.11 (0.97 to 1.27)	1.08 (0.97 to 1.21)
Updated mean of HbA1c			
Model 1	1.50 (1.25 to 1.81)	1.21 (1.03 to 1.42)	1.13 (0.99 to 1.28)
Model 2	1.50 (1.24 to 1.81)	1.20 (1.03 to 1.40)	1.14 (1.00 to 1.29)

Model 1: adjusted for age and sex
Model 2: further adjusted for smoking status, diabetes duration, total cholesterol, and systolic blood pressure.

Trends in prevalence, incidence and mortality of type 1 and type 2 diabetes in Denmark 1996–2016

B. Carstensen, P.F. Rønn, M.E. Jørgensen;
Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Registers provide a unique opportunity to assess diabetes demography; however, many diabetes registers cannot distinguish between type 1 and type 2 diabetes. Thus, the current national prevalence and incidence rates of diabetes are either done for the total diabetes population or limited by imprecise classification of type 1 and type 2 diabetes. We aimed to provide more precise estimates of the prevalence, incidence and mortality separately for type 1 and type 2 diabetes during a 20-year period in Denmark.

Materials and methods: We constructed a Danish national diabetes register based on existing health care registers in Denmark. We included persons as diabetes patients based on first diabetes diagnosis in the National Patient Register or Danish Adult Diabetes Database (DADD); purchase of any anti-diabetic medication (Prescription Register); use of podiatry or eye examination for diabetic complications (Health Services Registers). Classification of type was based on the clinical reports in the DADD. Analyses were conducted separately for diabetes type and sex. For dates 1 January 1996 to 2016 we modeled prevalence by age using a binomial model with log-link. Incidence and mortality rates were analysed using Poisson regression. Incidence rates were modeled by current age, calendar time and birth cohort using natural splines. Mortality rates were additionally modeled by diabetes duration and age at diagnosis, also using natural splines.

Results: At the start of 1996, a total of 23,652 persons were alive with type 1 diabetes and 69,975 with type 2 diabetes. In 2016 the numbers were 30,244 and 245,879 respectively. The overall prevalence of type 1 diabetes increased from 0.42% to 0.52% (0.6% per year) and from 1.3% to 4.3% (5.1% per year) for type 2 diabetes. The fraction of type 1 diabetes of all diabetes patients was 50% at 40 years of age and about 10% for ages 60+. The age-specific prevalences from 1996–2016 are shown in figure 1 for men and women. We observed an average annual decrease in incidence of type 1 diabetes of 0.7% per year, and increase in incidence rates of type 2 diabetes of 3.5% per year before 2012 and a decrease of 10% per year from 2012 to 2016. Mortality rates showed a slight decrease of 1.5% per year for type 1 patients and 3.5% per year for type 2 patients. The overall mortality rate ratio between type 1 and type 2 patients was 1.29 (controlling for age and calendar time).

Conclusion: In the period 2012–2016 we saw a decrease in incidence of type 2 diabetes which was not seen for type 1, which makes the decrease unlikely to be a registration artifact. A reduction in mortality was observed for both type 1 and 2 but most for type 2, probably due to improved treatment and/or earlier diagnosis. The mortality RR between type1 and type 2 may to some extent be explained by differing duration of disease, however it is not meaningful to control for disease duration in the comparison because the overlap of age and duration between type 1 and type 2 diabetes is limited.

Cardiovascular disease risk in OGTT-diagnosed diabetes patients with and without confirmation by HbA_{1c} values: the Whitehall II study

A.G. Tabák[1,2], E.J. Brunner[2], M.J. Shipley[2], M. Kivimaki[2,3];
[1]Semmelweis University, Budapest, Hungary, [2]University College London, London, UK, [3]University of Helsinki, Helsinki, Finland.

Background and aims: Several diabetes associations currently recommend non-fasting test (HbA1c- A1C) for diagnosing diabetes leading to declining use of fasting glucose and oral glucose tolerance test (OGTT) in clinical practice. It is well known that the overlap between people

diagnosed by an OGTT or an A1C is limited. We investigated (1) the natural history of OGTT-based diabetes in terms of confirmation by A1C and (2) the risk of cardiovascular disease (CVD) in people with A1C-confirmed and unconfirmed OGTT-diagnosed diabetes compared to the diabetes-free background population.

Materials and methods: During clinical phases 7 (2002–2004) and 9 (2007–2009) of the Whitehall II cohort study, both A1C and OGTT tests were performed ($N = 9149$). We determined how many of the 384 incident diabetes cases diagnosed only by OGTT were confirmed by AIC-based diagnosis during the next 14 years and examined which factors predicted confirmation. We followed participants for CVD up to 2015 to investigate differences in CVD risk between participants with health-care diagnosed diabetes at phase 7 ($n = 632$), incident diabetes cases at phases 7 and 9, and those without diabetes throughout the study ($n = 8133$).

Results: During a mean follow-up of 12 years, 223 (58.1%) of the 384 OGTT cases were confirmed by HbA1c. The OGTT-diagnosis was more frequently confirmed in people with higher BMI ($HR_{per\ 1kg/m2} = 1.07$, 95%CI 1.05–1.10), higher fasting glucose ($HR_{per\ 1mmol/l} = 1.20$, 95%CI 1.12–1.29), and if both the fasting and 2-hour glucose were diagnostic (HR = 1.99, 95%CI 1.27–3.10). After adjustment for age, sex, ethnicity and social status, participants with health-care diagnosed diabetes and A1C-confirmed OGTT-based diabetes had an increased CVD risk (HR = 1.87, 95%CI 1.50–2.30 and HR = 1.63, 95%CI 1.11–2.41, respectively), while OGTT-cases not confirmed by AIC had risk (HR = 1.13, 95%CI 0.75–1.69) similar to the diabetes-free population. Further adjustment for classical CVD-risk factors similarly attenuated the excess risk associated with health-care diagnosed diabetes and A1C-confirmed diabetes although the latter no longer reached statistical significance at conventional levels.

Conclusion: OGTT and A1C methods identify different populations with diabetes and only a subsample of OGTT cases will be confirmed by A1C during an extended follow-up. The OGTT-cases not confirmed by A1C have a CVD risk similar to diabetes-free population, while A1C-confirmed OGTT cases have an increased CVD risk. These findings suggest that losing OGTT cases that cannot be confirmed by A1C is not harmful in term of CVD prevention.

Multiplex proteomics for prediction of major cardiovascular events in type 2 diabetes

C. Nowak[1], A.C. Carlsson[1], C.J. Östgren[2], F.H. Nyström[2], M. Alam[3], T.R. Feldreich[3], J. Sundström[4], J.J. Carrero Roig[5], J. Leppert[4], P.O. Hedberg[4], A.C. Cordeiro[6], L. Lind[4], E. Ingelsson[7], T. Fall[4], J. Ärnlöv[1,3]; [1]Department of Neurobiology, Care Sciences and Society (NVS), Karolinska Institutet, Huddinge, Sweden, [2]Linköping University, Linköping, Sweden, [3]Dalarna University, Falun, Sweden, [4]Uppsala University, Uppsala, Sweden, [5]Karolinska Institutet, Solna, Sweden, [6]Dante Pazzanese Institute of Cardiology, Sao Paolo, Brazil, [7]Stanford University School of Medicine, Stanford, USA.

Background and aims: Multiplex proteomics could improve understanding and risk prediction of major adverse cardiovascular events (MACE) in type 2 diabetes. This study assessed 80 cardiovascular and inflammatory proteins for biomarker discovery and prediction of MACE in type 2 diabetes.

Materials and methods: We combined six prospective studies of 30-to-77 year-olds with type 2 diabetes in whom 80 circulating proteins were measured by proximity extension assay. Multivariable-adjusted Cox regression was used in a discovery/replication design to identify biomarkers for incident MACE. We used gradient boosted machine learning in a random 75% training subsample to assess whether adding proteins to an established risk model based on the Swedish National Diabetes Register improved prediction of MACE in the separate 25% validation subsample.

Results: In 1,211 adults with type 2 diabetes (32% women), 211 experienced a MACE over 6.4 ± 2.3 years. We replicated associations (<5% false discover rate) between eight proteins and risk of MACE: matrix metalloproteinase-12, interleukin-27 subunit alpha, T-cell immunoglobulin/mucin domain-1, fibroblast growth factor-23, protein S100-A12, tumor necrosis factor receptor (TNFR)-1, TNFR-2 and TNF-related apoptosis-inducing ligand receptor-2. Addition of the 80-protein assay to the established risk model improved discrimination in the separate validation sample from 68.6% (95%-CI, 68.2%–68.9%) to 74.8% (95%-CI, 74.6%–75.1%).

Conclusion: We identified eight protein biomarkers, four of which are novel, for risk of MACE in community residents with type 2 diabetes, and found improved risk prediction by combining multiplex proteomics with an established risk model. Multi-protein arrays may improve the selection of persons with diabetes for more aggressive cardiovascular prevention.

Reduced eGFR and/or increased urinary albumin excretion rate are powerful determinants of survival among insulin treated patients with type 2 diabetes in routine practice

U. Anyanwagu, R. Donnelly, I. Idris;
Royal Derby Hospital Centre, University of Nottingham, Derby, UK.

Background and aims: Low estimated glomerular filtration rate (eGFR) and increased urinary albumin-to-creatinine ratio (ACR) are well recognised diagnostic and prognostic markers of chronic kidney disease (CKD) and cardiovascular (CV) risk, but their precise relationship with CV disease and total mortality among insulin-treated Type 2 Diabetes (T2D) patients in routine clinical care is unclear.

Materials and methods: We analysed data for insulin users with T2D from UK general practices between 2007 and 2014 and examined the association between mortality rates and CKD [categorised by low eGFR (<60 mL/min/1.73 m^2); high eGFR (≥60 mL/min/1.73 m^2); low ACR (<300 mg/g); and high ACR (≥300 mg/g) at insulin initiation] after a 5-year follow-up period using Cox proportional hazard models.

Results: A total of 18,227 patients with T2DM on insulin therapy were identified (mean age: 61.5 ± 13.8 yrs, mean HbA1c: 8.6 ± 1.8%; 53% male). After adjusting for confounders, mortality curves for each CKD category are shown below (log-rank p value <0.001). When compared to adults on insulin therapy with an eGFR <60 and an ACR ≥300 (low eGFR + high ACR) after a follow up period of 5 years, patients with an eGFR <60 and an ACR <300 (low eGFR + low ACR) had a 6% lower mortality rate (aHR: 0.94; 95%CI: 0.79 to 1.12); those with an eGFR >60 and an ACR ≥300 (high eGFR + high ACR) had a 20% lower mortality rate (aHR: 0.80; 95%CI: 0.68 to 0.96); and those with an eGFR >60 and an ACR <300 (high eGFR + low ACR) had the lowest death rate (28% less; aHR: 0.72; 95%CI: 0.59 to 0.87) after adjusting for confounders.

Conclusion: This study shows that among a big cohort of insulin-treated T2DM patients in routine practice, the combination of reduced eGFR with increased ACR was associated with the greatest risk of premature death, followed closely by those with reduced eGFR and normal ACR levels. Adoption of aggressive CV risk management strategies to reduce mortality in patients with a low eGFR and albuminuria is essential in these high risk patients with T2D.

High glucose exposure reduces DNA demethylation of cAMP response element (CRE) region in eNOS promoter during pro-angiogenic CD34$^+$ stem cell differentiation

M. Vinci, V. Vigorelli, J. Resta, S. Genovese, G. Pompilio;
Centro Cardiologico Monzino - IRCCS, Milan, Italy.

Background and aims: Diabetic patients have reduced number and activity of circulating CD34$^+$ stem cells. This clinical observation has been associated with serious endothelial dysfunction and elevated risk of adverse cardiovascular events, strengthening the concept that the functional impairment of CD34$^+$ stem cells allows further progression of vascular disease. The expression of endothelial nitric oxide synthase (eNOS) in CD34$^+$-derived endothelial progenitor cells (EPCs) is a marker of proangiogenic differentiation and its product, the nitric oxide (NO), plays a key role in the mechanisms of bone marrow mobilization, migration, and homing. NO bioavailability along with proangiogenic properties of CD34$^+$-derived EPCs are impaired in diabetic patients. We aimed at investigating whether reduced proangiogenic capacities of CD34$^+$-derived EPCs and altered NO bioavailability induced by hyperglycemia were associated with a defective epigenetic eNOS promoter activation and gene expression.

Materials and methods: CD34$^+$ cells were purified from cord blood of healthy donors and expanded in normal-glucose (NG; with 30 mM mannitol for osmotic control) or high-glucose (HG; 30 mM) serum-free medium plus cytokines (FLT3, SCF, IL3 and IL6) for up to 20 days. NG and HG-CD34$^+$ cells were then cultured in proangiogenic EGM2 medium. After 15 days NG and HG-CD34$^+$-derived EPC phenotype was evaluated by DiLDL-UEA-1 double-positive cell count. Their proangiogenic properties were assessed by the ability to form colony forming units-endothelial cell (CFU-EC) and by incorporation into endothelial tube-like structure. NO production and eNOS mRNA expression were detected by flow cytometry with DAF-2DA and qPCR, respectively. The DNA methylation of eNOS promoter was assessed by two-step qPCR method followed by bisulfite cloning Sanger sequencing. Data were then analyzed by QUMA software (http://quma.cdb.riken.jp/).

Results: After 15 days of culture in proangiogenic medium NG and HG-CD34$^+$-derived EPCs were evaluated for their proangiogenic phenotype. HG-CD34$^+$-derived EPCs displayed a significantly lower number of double-positive stained cells (DiLDL-UEA-1) than their NG counterpart ($n = 3$; 0.59 ± 0.03 vs 0.44 ± 0.03; $p \leq 0.05$). The reduction of EPC differentiation marker associated with an impaired ability of HG-CD34$^+$-derived EPCs to form CFU-EC ($n = 4$; 6.74 ± 1.0 vs 3.38 ± 1.2; $p \leq 0.01$) and to incorporate into endothelial tube-like structure ($n = 9$; 92.7 ± 11.8 vs 27.7 ± 7.8; $p \leq 0.01$). In line with the impairment of proangiogenic functionality, HG cells also showed reduced eNOS mRNA expression ($n = 3$; FC 1 ± 0.2 vs 0.5 ± 0.1; $p \leq 0.05$) and NO production ($n = 3$; $69\% \pm 10$ vs $28\% \pm 5$ $p \leq 0.05$). We further evaluated DNA demethylation events occurring on eNOS promoter of CD34$^+$stem cells during proangiogenic differentiation. Interestingly, we found that eNOS mRNA transcription in CD34$^+$-derived EPCs occurred after CRE region DNA demethylation of eNOS promoter. Consistent with gene expression data, eNOS promoter of HG cells displayed higher DNA CRE region methylation as assessed by two-step qPCR method ($n = 5$; FC 1 ± 0.3 *vs* 4.9 ± 1.6; $p \leq 0.05$) and bisulfite sequencing.

Conclusion: CRE region DNA demethylation of eNOS promoter is involved in eNOS mRNA expression and fosters proangiogenic differentiation of CD34$^+$ stem cells. This activating epigenetic modification is impaired by high glucose concentration.

Apabetalone (RVX-208) an epigenetic modifier lowers risk of MACE in diabetes patients with CVD by affecting monocyte adhesion to endothelial cells

N.C.W. Wong[1], L. Tsujikawa[1], E. Kulikowski[1], C. Calosing[1], S. Wasiak[1], D. Gilham[1], C. Halliday[1], J.O. Johansson[2], M. Sweeney[2];
[1]Resverlogix Corp., Calgary, AB, Canada, [2]Resverlogix Inc., San Francisco, USA.

Background and aims: Apabetalone (RVX-208, 200 mg/d) when given orally to patients with type 2 diabetes mellitus (T2DM) and CVD for 6 months leads to a 57% relative risk reduction in major adverse cardiovascular events (MACE). RVX-208 is a selective inhibitor (BETi) of bromodomain extra-terminal (BET) proteins that are epigenetic readers of acetylated lysines in the tail of histones. The benefits on CVD in T2DM patients is explored here by examining effects of RVX-208 to disrupt a key pathologic step of monocyte adhesion to endothelial cells and the genes underlying this process in CVD. Cellular adhesion and genes believed to be part of this process are examined in response to T2DM defects, high glucose (HG, 25.6 mM) and increased dietary metabolite trimethyl-amine oxide (TMAO).
Materials and methods: Cultured THP-1 monocytes, HUVEC endothelial cells and primary human hepatocytes (PHH) exposed to HG or varying levels TMAO (10–100 uM).
Results: In HG or TMAO, adhesion of THP-1 to HUVEC cells was enhanced almost 2.4-fold but 20 uM RVX-208 blocked this process by 30–70%. In addition, HG induced Very Late Antigen-4 (VLA-4) mRNA, a gene mediating THP-1 adhesion by 1.3-fold and RVX-208 suppressed it >50%. Similarly, BETi blocked TMAO induction of VLA-4 mRNA by >50% in THP-1. In HUVECs RVX-208 abrogated HG induction of E-selectin and MYD88 mRNA by 2- and 1.3-fold, respectively and lowered TMAO induction of these mRNAs by >50%. Microbiome processing of dietary phospholipids followed by hepatic flavin mono-oxygenase-3 (FMO3) metabolism yields TMAO. In PHH exposed for 24 hrs to RVX-208, FMO3 mRNA was lowered by 40% but it also suppressed an important regulator of FMO3 gene transcription, farnesoid X receptor (FXR). BETi suppressed both FXR mRNA and protein within 6 hrs by >80% suggesting a direct effect of BETi on the FXR gene. Additionally, ChiP data showed that BRD4, a BET protein, dissociated rapidly from FXR DNA upon exposure to RVX-208. Since BRD4 guides a complex containing RNA pol II along actively transcribed genes containing highly acetylated histones, dissociation of BRD4 from FXR DNA halts transcription of the gene.
Conclusion: Apabetalone inhibits HG and TMAO enhanced adhesion of THP-1 to HUVECs, a process that is believed to trigger the vascular inflammation component of CVD. RVX-208 suppresses genes that underlie cellular adhesion; VLA-4 in THP-1 and both E-selectin plus MYD88 in HUVECs. BETi blocks not only activity of TMAO but also its production by inhibiting FXR expression, a regulator of FMO3 gene transcription. The rapid actions of BETi in dissociating BRD4 along with pol II from FXR DNA suggests a direct effect of RVX-208 on FXR gene transcription. Studies here examine potential roles of monocytes, endothelial cells, hepatocytes and microbiome in CVD that contribute to enhanced CVD risks in T2DM. Apabetalone a BETi affects activity of these cells by altering function in such a way as to limit their contribution to CVD. This action of BETi across cell types suggests that RVX-208 affects many pathways underlying CVD and provides potential explanation for why apabetalone in targeting BRD4, leads to many benefits for lowering CVD risks in T2DM patients.

129

Liraglutide improves vascular dysfunction via regulating cAMP-independent PKA-SIRT1/AMPK-PGC1α pathway in perivascular adipose tissue in obese mice

X. Sun, F. Han, N. Hou;
Department of Endocrinology, Affiliated Hospital of Weifang Medical University, Weifang, China.

Background and aims: Perivascular adipose tissue (PVAT), with characteristics of both white and brown adipose tissues (BAT), loses its anti-contractile effect in endothelial-dependent pathway and exacerbates endothelial dysfunction in obese subjects. Glucagon-like peptide-1 receptor (GLP-1R) agonist possessed cardiovascular protective effects including restoring endothelial dysfunction in obesity. However, these studies were performed with the conditions of PVAT removed. Therefore, the aim of this study was to determine whether liraglutide, GLP-1R agonist, could improve vascular dysfunction (both anti-contractile effect of PVAT and endothelial function) via regulating PVAT-related signaling pathways in obesity.
Materials and methods: C57BL/6 mice were fed with a normal-chow diet or a high-fat diet (HFD) with or without liraglutide treatment. Vascular contraction and endothelial-dependent vasodilation (EDV) of the thoracic aorta with or without PVAT (PVAT+ or PVAT−) were determined by the response to norepinephrine or acetylcholine, respectively. Protein levels of PKA-SIRT1/AMPK-PGC1α signaling pathways in PVAT were determined by western blot. BAT-related gene, pro-inflammatory and antioxidant genes expression in PVAT were analyzed by PCR.
Results: Treatment of HFD mice with liraglutide improved metabolic profiles, glucose tolerance and insulin sensitivity (body weight, 29.2 ± 0.6 g vs. 38.5 ± 0.4 g; glucose, 102.22 ± 3.66 mg/dl vs. 114.54 ± 3.64 mg/dl; NEFA 0.86 ± 0.16 mmol/L vs. 1.21 ± 0.25 mmol/L; AUC glucose 21899 ± 483 vs. 29121 ± 828; AUC insulin 9404 ± 130 vs. 11587 ± 413; $P < 0.05$). PVAT from control mice had a significant anti-contractile effect on the aortic rings, which were attenuated in HFD mice (maximal attenuation rate: 3.56% vs. 15.01%; $P < 0.05$). However, it was improved when treatment of HFD mice with liraglutide or pre-incubation of PVAT with liraglutide *ex vivo*, with the maximal attenuation rates increasing from 3.56% to 12.40% and from 4.23% to 14.48%, respectively ($P < 0.05$). For EDV, there was a significant impairment in EDV in aortic rings (both PVAT+ and PVAT−) from HFD mice and this impairment was significantly exacerbated by PVAT (34.8% vs. 47.4%, $P < 0.05$). However, liraglutide treatment alleviated the impairment with no significant difference in maximal vasodilation between PVAT+ ring and PVAT− ring (68.9% vs. 70.9%, $P < 0.05$). Pre-incubation of aortic ring (PVAT+) from HFD mice with liraglutide *ex vivo* also restored this impairment of EDV. However, Blockade or knockdown PKA, SIRT1 or AMPK but not cAMP, attenuated or abolished these beneficial effects of liraglutide on the anti-contractile capability and endothelial function. Liraglutide treatment induced browning-related genes expression (Cidea and UCP-1), activated AMPK-eNOS signaling pathway. Additionally, we observed liraglutide effectively enhanced heme oxygenase-1 gene expression and reduced TNF-α expression, indicative of antioxidant and anti-inflammatory abilities. These beneficial effects were due to activation of PKA-SIRT1/AMPK-PGC1α signaling pathway by cAMP-independent way, as demonstrated by western blot and PCR.
Conclusion: Our study indicates that liraglutide improves vascular dysfunction via regulating cAMP-independent PKA-SIRT1/AMPK-PGC1α pathway in PVAT from obese mice. These findings provide a novel mechanism for cardiovascular protection of liraglutide via regulating PVAT function in obesity.

Methylglyoxal driven endothelial dysfunction in hyperglycaemia targets protein folding, protein synthesis, glycolysis and gluconeogenesis pathways

N. Rabbani[1], A. Ashour[2], Z. Irshad[1], J. Larkin[3], M. Xue[1], P.J. Thornalley[1];
[1]University of Warwick, Coventry, UK, [2]Taif University, Taif, Saudi Arabia, [3]University of Oxford, Oxford, UK.

Background and aims: Endothelial cell (EC) dysfunction in diabetes is linked to development of diabetic vascular complications. It is characterized by increased inflammatory signalling, expression of adhesion molecules and secretion of inflammatory cytokines**,** apoptosis and processes supporting atherosclerosis. ECs accumulate methylglyoxal (MG) and MG-derived advanced glycation endproduct (AGE)-modified proteins in hyperglycemia - suppression of which prevents EC dysfunction. Our aim is to identify proteins modified by MG that may be mediators of EC dysfunction in hyperglycemia.
Materials and methods: Human aortal endothelial cells (HAECs) were incubated in primary culture with 5 mM (model normoglycemia) or 20 mM glucose (model hyperglycemia) for 6 days and cytosolic extracts prepared. A cytosolic extract of human endothelial HMEC-1 cells was incubated with exogenous MG to increase the modification by MG-derived AGE, MG-H1, by 10-fold - typical of the upper limit of increased MG in diabetes. Cytosolic protein extracts were reduced, alkylated and digested with trypsin and lys-C and tryptic peptides analysed by nanoflow liquid chromatography-Orbitrap Fusion™ (Thermo) high resolution mass spectrometry. Proteins were identified by detection of at least 2 unique peptides using Progenesis QI 2.0 software (Nonlinear Dynamics, Newcastle, UK). REACTOME, INTERPRO and receptor binding domain (RBD) analysis was used for pathway, protein domain enrichment and functional domain analysis, respectively.
Results: In high glucose concentration cultures of HAECs, only two proteins were detected with MG modification: rho GDP-dissociation inhibitor 2 (RhoGDI2) and far upstream element-binding protein 2 (FUBP2); others were < limit of detection. In MG-modified HMEC1 cytosolic extract, 1262 proteins were detected of which 220 (17%) had MG modification. MG-H1 modification was on 411 sites with highest modification found on pyruvate kinase-M, β-actin, α-enolase and heat shock protein 90-beta. Pathways analysis showed that MG-modified proteins were enriched in: protein folding, protein synthesis, glycolysis and gluconeogenesis. Enriched protein domain targets of MG modification were: TCP-1 and GroEL chaperonins, phosphoserine and phosphothreonine binding sites of 14-3-3 proteins, proteasome alpha/beta subunits and conserved sites of aminoacyl-tRNA synthases. All have conserved functional arginine residues. To assess if MG modification was likely associated with functional impairment, we deduced the proportion of the MG modifications found in sites of protein functional interaction by RBD analysis. There was a relatively high proportion of MG modification in functional sites, 36%, with at least one modification on 47% of proteins.
Conclusion: MG modification of FUBP2 - checkpoint for inflammatory cytokines - may increase inflammatory signaling, and modification of RhoGDI2 may activate Rac2 and endothelial NADPH oxidase, driving oxidative stress in ECs in hyperglycemia. MG glycation is damaging because its produces loss of arginine residue charge and arginine targets are enriched in protein functional domains. MG modification may mediate impaired chaperone activity, serine/threonine kinase signalling, proteasomal proteolysis and protein synthesis associated with vascular complications of diabetes.

Increased hexokinase-2-catalysed entry of glucose into glycolysis: key driver of metabolic dysfunction in endothelial cells in hyperglycaemia

P. Thornalley[1], Z. Irshad[1], M. Xue[1], A. Ashour[2], N. Rabbani[1];
[1]University of Warwick, Coventry, UK, [2]Taif University, Taif, Saudi Arabia.

Background and aims: Metabolic dysfunction of endothelial cells in hyperglycemia contributes to the development of vascular complications of diabetes. Multiple pathways of metabolic dysfunction are involved, including mitochondrial dysfunction, hexosamine, protein kinase C and advanced glycation endproduct pathways. This requires increased entry of glucose into glycolysis catalysed by hexokinase-1 and -2 (HK-1 and HK-2). These enzymes are saturated with glucose substrate even under normoglycemic conditions. We investigated the mechanism of increased entry of glucose into glycolysis in endothelial cells in model hyperglycemia *in vitro*.
Materials and methods: Human aortal endothelial cells (HAECs) were incubated in primary culture with 5 mM glucose (model normoglycemia) or 20 mM glucose (model hyperglycemia) for 6 days. Glucose consumption and net flux of formation of L-lactate were measured by enzymatic assays. Fructosyl-lysine (FL) content of cell protein was determined by stable isotopic dilution analysis liquid chromatography-tandem mass spectrometry. HK-1 and HK-2 mRNA was quantified by RT-PCR and HK-1 and HK-2 protein by label-free quantitative proteomics in cytosolic protein extracts by nanoflow liquid chromatography-Orbitrap Fusion™ mass spectrometry (Thermo), corroborated by Western blotting.
Results: In high glucose cultures, FL content of cellular protein was increased, compared to low glucose control (5.71 ± 1.05 versus 2.92 ± 1.60 mmol/mol lys, $n = 3$; +96%, $P < 0.01$), indicating persistent cytosolic hyperglycemia linked to GLUT1-dependent glucose uptake. The flux of glucose consumption in high glucose concentration was increased, compared to low glucose concentration control (2079 ± 246 versus 1175 ± 87 nmol/10^6 cells/day, $n = 8$; +77%, $P < 0.01$). The net flux of formation of L-lactate was also increased. Proteomics analysis showed the abundance of HK-1 was unchanged in high glucose concentration cultures whereas HK-2 was increased 40% ($P < 0.05$). This was confirmed by Western blotting. There was no increase of HK-1 and HK-2 mRNA, suggesting that HK-2 protein is selectively stabilised from proteolysis in high glucose concentration. HK-2 is degraded by chaperone-mediated autophagy where heat shock cognate 71 kDa protein binds to motif $_{712}$QRFEK$_{716}$. This motif is directly involved in the binding of glucose at the active site in the C-terminal domain of HK-2 but not in HK-1. In the presence of cytosolic hyperglycemia, increased binding of glucose masks the degradation motif and HK-2 protein is stabilised to proteolysis. The turnover number of HK-2 is ca. 5-times that of HK-1 and hence glucose metabolism is highly sensitive to increased HK-2 protein. Increased cellular glucose-6-phosphate in high glucose concentration cultures displaces HK-2 from mitochondria, driving mitochondrial dysfunction in hyperglycemia. Decrease of HK-2 to normal levels by treatment with *trans*-resveratrol-hesperetin combination corrected increased HK-2, glucose consumption and metabolic dysfunction.
Conclusion: Increased HK-2-catalysed entry of glucose into glycolysis is a key driver of metabolic dysfunction in endothelial cells in hyperglycemia. Combination of GLUT1-dependent glucose uptake and HK-2 expression are likely key criteria for damaging effects which may explain the sensitivity of the vasculature, kidney, retina and peripheral nerve to damage in hyperglycemia.

Comparative study in various model organisms regarding the effect of the loss of glyoxalase 1

B. Fuchs[1], J. Morgenstern[1], J. Tyedmers[1], E. Lodd[2], J. Kroll[2], D. Schuhmacher[3], M. Freichel[3], P. Nawroth[1,4], T. Fleming[1,4];
[1]Department of Internal Medicine I and Clinical Chemistry, University Hospital Heidelberg, Heidelberg, [2]Medical Faculty Mannheim, Center for Biomedicine and Medical Technology Mannheim, Mannheim,

[3]Institute of Pharmacology, University Heidelberg, Heidelberg, [4]German Center for Diabetes Research (DZD), Neuherberg, Germany.

Background and aims: The generation of methylglyoxal-derived advanced glycation end products has an important role in the development of diabetes and late diabetic complications. Detoxification by glyoxalase 1 (GLO1) might therefore play an important role in the context of dicarbonyl-induced damage in patients suffering from diabetes. This assumption was based on findings in less developed organisms. Recent findings in murine cell lines indicate that GLO1 is less significant in higher organisms. It was shown that loss of GLO1 is compensated by increased Aldo-Keto-Reductase and Aldehyde Dehydrogenase activity and improves the resistance against various toxins and radiation. Therefore, the major aim of this study was to address potential differences in complex organisms regarding their dependency on GLO1.
Materials and methods: The total knock-out of GLO1 ($GLO1^{-/-}$) was achieved in several murine cell lines and in a mouse model using the CRISPR-Cas9 technique. $GLO1^{-/-}$ of yeast, C. elegans and zebrafish were provided by collaboration partners. To determine the effect of $GLO1^{-/-}$, the survival rate after toxin exposure was determined by counting the survival/living organisms. MG-H1 expression was quantified via Western blotting. Intracellular levels of MG and MG-H1 were measured by LC-MS/MS.
Results: $GLO1^{-/-}$ models of less evolved organisms such as yeast and C. elegans were more sensitive to hydrogen peroxide and formaldehyde. In those organisms MG-H1 was accumulated. The $GLO1^{-/-}$ zebrafish embryos seem to be slightly resistant against toxins compared to wild-type animals. Furthermore, a mouse model showed an increased natural survival rate when GLO1 is missing.
Conclusion: Complex organisms are less dependent on GLO1 and less prone to damage despite the loss of GLO1 than expected. In $GLO1^{-/-}$ mice and isolated murine cells, $GLO1^{-/-}$ phenotype even showed a protective character. Therefore, we claim that the loss of GLO1 has less severe effects on higher organisms than expected and might even lead to an advantage on survival. The clinical relevance of GLO1 and possible compensatory pathways on the development of late diabetic complications in different organs has to be addressed in future studies.

OP 23 How our brain impacts on diabetes

133

The influence of brain metabolism in insulin secretion and action assessed with FDG-PET in humans

E. Rebelos[1], M. Bucci[1], M.-J. Honka[1], A. Latva-Rasku[1], M. Laakso[2], K.A. Virtanen[1], J.C. Hannukainen[1], L. Nummenmaa[1], A. Mari[3], P. Iozzo[4], P. Nuutila[1];
[1]Turku PET Centre, Turku, Finland, [2]Institute of Clinical Medicine, University of Eastern Finland, Kuopio, Finland, [3]Institute of Neuroscience, National Research Council, Padua, Italy, [4]Institute of Clinical and Experimental Physiology, Pisa, Italy.

Background and aims: Recent intervention studies have shown that brain glucose uptake (BGU) measured during euglycemic hyperinsulinemia and [^{18}F]FDG-PET imaging is increased in subjects with impaired glucose tolerance and morbidly obese subjects compared to normal glucose tolerant and lean subjects. The aim of this study was to evaluate insulin stimulated BGU and endogenous glucose production (EGP) and beta cell function in a larger cohort of subjects studied in our center.
Materials and methods: Data from 151 subjects were pooled together. Brain FDG-PET images were similarly pre-processed and BGU parametric images were calculated. Statistical analysis was performed with Statistical parametric mapping (SPM). Endogenous glucose production ($n = 132$) was calculated with FDG data. Beta cell function ($n = 67$) was estimated by C-peptide modelling during OGTT.
Results: In the whole dataset ($n = 151$) insulin-stimulated BGU was negatively associated with age ($p = 0.0006$, $r = -0.28$), M-value ($p < 0.0001$, $r = -0.38$) (**Figure** 1A) and positively associated with BMI ($p < 0.0001$). In a multivariate analysis including age, BMI, M-value, gender only the association between insulin-stimulated BGU and age, and insulin-stimulated BGU and M-value remained significant. Across all subjects ($n = 132$) there was no association between insulin-stimulated BGU and insulin-suppressed EGP. When dividing the subjects in tertiles of BMI, a positive association between BGU and EGP was found in the higher 2 tertiles ($p = 0.03$, $r = 0.24$) (**Figure** 1C), but not in the lean's group. We found a positive association between insulin-stimulated BGU and basal insulin secretion ($p = 0.0002$, $r = 0.45$, $n = 67$) (**Figure** 1B) and total insulin secretion ($p = 0.002$, $r = 0.37$, $n = 67$). After correcting for the M-value the association between BGU and basal insulin secretion remained significant ($p < 0.001$), but not for total insulin secretion.
Conclusion: In this large dataset including subjects across a wide spectrum of age, BMI, and insulin sensitivity, BGU was associated positively with EGP in the overweight and obese subjects. BGU also associated positively with basal insulin secretion and negatively with insulin sensitivity. These data suggest that central metabolism in humans, assessed with insulin-stimulated BGU, is involved in the regulation of both insulin secretion and peripheral insulin action.

Hypothalamic orexin system prevents the development of non-alcoholic fatty liver disease in diet-induced obese mice

H. Tsuneki, K. Kon, S. Takata, T. Maeda, K. Otsuka, T. Wada, T. Sasaoka;
Department of Clinical Pharmacology, University of Toyama, Toyama, Japan.

Background and aims: Whole-body energy balance is maintained by inter-organ networks. In this mechanism, hypothalamic orexin system plays a central role by synchronizing the daily rhythms of sleep-wake, feeding-fasting, and glucose/energy metabolism. However, it remains unclear whether orexin prevents metabolic disorders under the conditions of obesity. Therefore, we investigated the functional significance of orexin in preventing non-alcoholic fatty liver disease (NAFLD) in obese mice.
Materials and methods: Male orexin knockout (OXKO) mice, female OXKO mice with or without ovariectomy (OVX), and their controls were fed a high fat diet (HFD) for 16–24 weeks. Also, OVX-OXKO mice and their controls were fed a high fat and high fructose diet (HFFD) for 20 weeks. Orexin A was intracerebroventricularly (ICV) injected to type 2 diabetic db/db mice. The expression profiles of mRNAs and miRNAs in peripheral tissues were examined by RT-qPCR and GeneChip microarray analyses, respectively. Hepatic fibrosis was determined by Sirius-red staining.
Results: HFD-fed male OXKO mice showed severer obesity and impairment of glucose tolerance than wild-type (WT) controls. In the liver and white adipose tissue (WAT), the tissue weight, the levels of chronic inflammation markers (e.g., Mcp-1 mRNAs), and hepatic triglyceride content were more rapidly increased in OXKO than WT mice on HFD. Also, in females, these metabolic parameters were markedly increased in the liver and WAT of OXKO mice when compared to WT mice on HFD, and the levels were further increased by ovariectomy (i.e., in OVX-OXKO mice). Pathway analysis of hepatic miRNA profiles demonstrated that orexin deficiency promoted development of NAFLD. Importantly, hepatic fibrosis developed in OXKO but not WT mice on HFD. Moreover, when fed HFFD, obvious fibrosis was observed in the liver sections of OXKO but not WT mice, despite similar hepatic triglyceride accumulation. The fibrosis was exacerbated in the following order: HFD/HFFD-fed controls << HFD-fed OXKO ≤ HFD-fed OVX-OXKO < HFFD-fed OVX-OXKO. Repetitive ICV injection of orexin A reduced the levels of proinflammatory markers in the WAT of db/db mice.
Conclusion: The present results provide the first evidence that endogenous orexin contributes to prevent obesity-related disorders, including NAFLD, in both sexes of mice. Since the orexin expression is down-regulated by diabetic hyperglycemia, enhancement of the orexin action is considered to be a novel therapeutic approach to prevent obesity/type 2 diabetes-induced NAFLD.

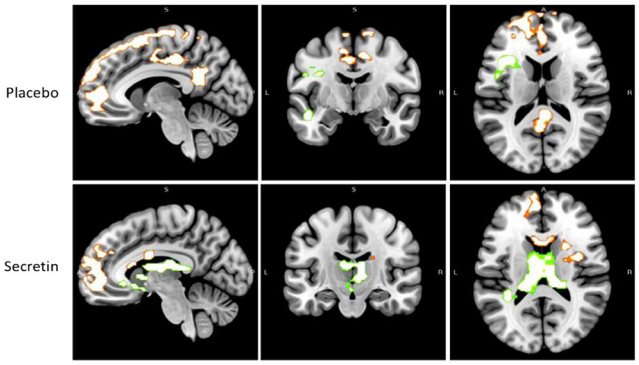
Secretin activates brown fat and induces satiation in humans

S. Laurila[1,2], M. Lahesmaa[1,2], L. Sun[2], K. Braun[3,4], K. Virtanen[2], K. Laitinen[5], M. Klingenspor[3,4], L. Nummenmaa[2], P. Nuutila[1,2];
[1]Department of Endocrinology, Turku University Hospital, Turku, Finland, [2]Turku PET Centre, University of Turku, Turku, Finland, [3]ZIEL - Institute for Food and Health, Technical University Munich, Freising, Germany, [4]Chair for Molecular Nutritional Medicine, EKFZ - Else Kröner-Fresenius Center, Technical University Munich, Freising, Germany, [5]Department of Biomedicine, University of Turku, Turku, Finland.

Background and aims: Cold-induced brown adipose tissue (BAT) activation in humans is by now a well known phenomenon. Recent preclinical studies suggest that secretin induces satiation in mice through activation of an endocrine gut - BAT - brain axis. Our aim was to investigate whether secretin administration effects BAT activation and satiation in humans as well.
Materials and methods: Fifteen healthy, normal weight males (age 41.6 ± 12.1 years, BMI 24.0 ± 1.9) were recruited. The study consisted of two phases: the assessment of BAT metabolic activity using PET/CT (n = 15) and brain functional magnetic resonance imaging (fMRI) to investigate satiation (n = 10). In both parts, study subjects were randomized and blinded to receive placebo (saline) and secretin (2 IU/kg secretin pentahydrochloride) prior to scans on separate days. For PET studies, tissue glucose uptake was measured with [^{18}F]-FDG and whole body energy expenditure monitored by indirect calorimetry. For fMRI studies, neural activity intensity response was assessed while subjects viewed appetizing and bland food images. Subjects filled in a subjective visual analogue scale questionnaire to measure composite satiety score.
Results: Secretin induced an increase in glucose uptake in BAT (1.1 ± 0.7 vs 0.7 ± 0.3 μmol/100 g/min, p = 0.02) and skeletal muscle (1.2 ± 0.5 vs 0.8 ± 0.2 μmol/100 g/min, p = 0.002). Secretin administration also induced an increase in whole body energy expenditure (1680 ± 150 vs 1640 ± 130 kilocalories/day, p = 0.01). The composite satiety score at fasting was increased after secretin administration compared to placebo (46.4 ± 10.3 vs 41.1 ± 12.03 millimeters p = 0.01). Secretin also

downregulated the brain reward circuitry during the fMRI food-reward experiment (statistical significance was thresholded at $p < 0.05$).
Conclusion: In the post-absorptive state, secretin not only increases whole body energy expenditure by activating brown adipose tissue and muscle, but also induces satiation and attenuates reward. These results suggest that secretin has a role in regulating appetite and food intake in humans, possibly via the activation of BAT.



Contrasts are made between appetizing and bland foods.
Orange signifies increased and green signifies reduced activity

Impaired brain plasticity in obesity: effects of bariatric surgery and gut hormones

G. Daniele[1], A. Dardano[1], C. Lunghi[2], L. Giusti[1], A. Ciccarone[1], F. Santini[1], G. Ceccarini[1], R. Bellini[3], C. Moretto[3], R. Miccoli[1], G. Penno[1], M. Morrone[2], S. Del Prato[1];
[1]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, [2]Department of Translation Research on New Technologies in Medicine and Surgery, University of Pisa, Pisa, [3]Bariatric and Metabolic Surgery Unit, University of Pisa, Pisa, Italy.

Background and aims: Obesity and diabetes are associated with reduced plasticity in the hippocampus and impairment of memory and learning. It is still unclear whether obesity can alter plasticity in the sensory cortex. Gut hormones play a crucial role in neuroplasticity (NP) but to which extent it can mediate obesity's effects on NP and cognition is still poorly evaluated. The aims of the study were to evaluate: i) the effect of obesity and bariatric surgery (RYGB) on NP ii) the relationship between NP and gut hormones (GLP-1, GIP and VIP) changes 6 months (6m)after RYGB iii) the relationship between NP, BDNF, Leptin and cognitive performance
Materials and methods: NP was assessed testing binocular rivalry between orthogonal gratings (size: 2°, contrast: 50%, SF: 2cpd) before and after 2 h of monocular deprivation (index of brain plasticity in the visual cortex). NP evaluation has been performed on 20 healthy volunteers (NS) (age 26 ± 10 years, BMI 21.7 ± 2.6 kg/m^2) and 31 obese subjects (OB) (age: 40 ± 11 years; BMI: 41.6 ± 6.7 kg/m^2) in fasting condition. A subgroup of OB ($n = 13$; BMI 45.8 ± 4.9 kg/m^2; age 43.7 ± 9.5 years; HbA1c 41.5 ± 5.4 mmol/mol) underwent a 75 g OGTT before and 6m after RYGB. NP was performed at baseline, 1, 3 and 6 m after RYGB. Gut hormones, BDNF, leptin and cognitive performance were assessed at baseline and 6 m after RYGB
Results: In the whole population NP was lower in OB as compared to NS (0.12 ± 0.05 vs. 0.04 ± 0.08, $p < 0.0001$) and NP was inversely correlated with BMI ($r = -0.55$; $p < 0.001$). In the OB subgroup 6 m after RYGB a significant BMI reduction (45.8 ± 4.9 to 34.3 ± 1.6 kg/m^2; $p < 0.001$) was associated withimproved glucose metabolism (HOMA-IR: 4.7 ± 0.9 to 1.6 ± 0.4; $P = 0.006$; Disposition Index: 0.07 ± 0.02 to 0.81 ± 0.30 mUI × ml^{-1}/mg × dl^{-1} × 1/mUI × ml^{-1}; $P < 0.05$). NP was progressively restored (ANOVA: F(3.24) = 5.7, $p = 0.002$) with a 10 fold increase of NP 6 m after RYGB (0.01 ± 0.03 to 0.11 ± 0.04; $p = 0.008$). Post-OGTT GLP-1 increased (5336 ± 2263 to 11132 ± 3412 pmol/l × 120 min; $p < 0.05$) as well as GIP (4140 ± 3659 to 5791 ± 4537 pg/ml × 120 min; $p = 0.01$). The NP increase was correlated to active GLP-1 and negatively with GIP increase($p < 0.05$). VIP levels did not change 6 m after RYGB with no correlation with NP. Fasting plasma leptin decreased (73.8 ± 45.5 to 14.3 ± 5.9 pmol/l; $p < 0.008$) and it was inversely correlated with NP increase ($p < 0.05$). Baseline BDNF was inversely correlated with fasting insulin ($r = -0.76$; $p = 0.007$) and it did not change after 6m RYGB. Post-RYGB BDNF inversely correlated with NP ($p < 0.05$) but positively with both total and active GLP1 ($p < 0.05$). NP correlated with cognitive performance ($p < 0.05$). In a multiple linear regression analysis, addition of post-RYGB gut hormones, BDNF and Leptin to BMI and fasting glucose improved the r^2 associated to post-RYGB NP (r^2 change: 0.881; F change: 10732.19; $p = 0.007$)
Conclusion: Obesity is associated with abnormal NP in visual cortex that can be reversed by weight-loss following bariatric surgery, supporting a strong effect of peripheral metabolism on early sensory plasticity and function. The relationship between NP increase, circulating gut hormones, BDNF and Leptin suggest a potential role of these hormones in the NP restoration and cognitive function in humans

Genetic disruption of Adipose Triglycerides Lipase (ATGL) in mediobasal hypothalamic neurons induces overweight and metabolic disturbances

R. Manceau[1], K. Bouyakdan[1], A. Fisette[1], D. Rodaros[1], G. Mitchell[2], S. Fulton[1], T. Alquier[1];
[1]Cardiometabolic, CRCHUM, Montreal, [2]CRCHU Ste Justine, Montreal, Canada.

Background and aims: Adipose Triglyceride Lipase (ATGL) acts as the first lipase in the hydrolysis of triglycerides (TG). Recent studies show that ATGL in peripheral tissues plays major roles on energy homeostasis. We found that ATGL is expressed in the mediobasal hypothalamus (MBH) and in hypothalamic neuronal cell lines, in line with our recent study suggesting that neurons accumulate TG. ATGL expression is increased in the MBH of high fat-fed mice that maintain a healthy body weight compared to mice that become obese. In addition, ATGL expression in the MBH is increased in response to fasting. This suggests that increased ATGL may play a role in maintaining a healthy metabolic profile. We propose that hypothalamic ATGL regulates lipid metabolism in the brain that in turn contributes to energy balance.
Materials and methods: To test this hypothesis, synapsin-Cre or -GFP expressing AAV are stereotaxically injected in the arcuate nucleus (ARC) of male ATGL *flox* mice to KO ATGL specifically in neurons (ARC-ΔATGL).
Results: First, we validated that ATGL expression is reduced by 50% in ARC-ΔATGL mice compared to ARC-WT. We found that ARC-ΔATGL have increased weight gain on a chow diet compared to control animals that is associated with reduced energy expenditure and increased food intake and fat mass. In addition, chow-fed ARC-ΔATGL mice have an increased fasting glycaemia and mild glucose intolerance. Finally, pharmacological inhibition of ATGL in hypothalamic neurons in vitro increases intracellular TG content.
Conclusion: Together, our findings suggest that the ATGL pathway in MBH neurons beneficially regulates glucose and energy homeostasis by

mechanisms that may involve regulation of TG and lipid droplets metabolism.

Brain insulin action stimulates pancreatic insulin secretion: results from hyperglycaemic clamps

M. Heni[1,2], R. Wagner[1,2], C. Willmann[1,2], B.A. Jaghutriz[1,2], A. Vosseler[1,2], C. Kübler[1], A. Peter[1,2], H.-U. Häring[1,2], H. Preissl[1,2], S. Kullmann[2,3], A. Fritsche[1,2];
[1]Division of Endocrinology, Diabetology, Nephrology, Vascular Disease and Clinical Chemistry, University Hospital Tübingen, Tübingen, [2]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Centre Munich at the University of Tübingen, Tübingen, [3]German Center for Diabetes Research (DZD), Neuherberg, Germany.

Background and aims: Animal studies and initial correlative analyzes in humans indicate that insulin action in the brain may affect pancreatic insulin secretion. An important brain region for this process appears to be the hypothalamus. Like other human brain areas, the hypothalamus can also develop insulin resistance. We now investigated whether induction of brain insulin action by intranasal insulin influences pancreatic insulin secretion.
Materials and methods: 15 young, healthy men (27 ± 2.3 years) with a large BMI spectrum (21–28 kg/m²) underwent two hyperglycemic clamps (target blood glucose: 10 mmol/l). In this double-blind study, subjects were randomized to receive 160 units of insulin as a nasal spray on one day and placebo on the other. On another day, the insulin sensitivity of the hypothalamus was determined by functional magnetic resonance imaging.
Results: Glucose levels were comparable on both study days. In the whole group, C-peptide levels were not significantly different between conditions. Though, there was a significant interaction between insulin sensitivity of the hypothalamus x nasal spray x time on C-peptide levels ($p = 4 \times 10^{-05}$). The group was therefore divided according to median hypothalamic insulin sensitivity. In the group with high insulin sensitivity of the brain, C-peptide levels were higher after insulin nasal spray than after placebo spray ($p_{(\text{nasal spray x time})} = 0.004$). This effect was especially noticeable after minute 10 of the hyperglycemic clamp. In the group with low brain insulin sensitivity, the nasal spray did not affect C-peptide levels ($p_{(\text{nasal spray x time})} = 0.4$).
Conclusion: In participants with high hypothalamic insulin sensitivity, insulin action in the brain enhanced insulin secretion from pancreatic beta cells. This reaction could, for example, contribute to a sufficient suppression of hepatic glucose production by portal venous insulin in the postprandial state.

Extended synaptotagmin-1 controls insulin secretion through diacylglycerol transport at ER-PM contact sites

B. Xie, O. Idevall-Hagren;
Medical Cell Biology, Uppsala Univerisity, Uppsala, Sweden.

Background and aims: The endoplasmic reticulum (ER) is essential for protein and lipid synthesis and Ca^{2+} homeostasis. Dysfunctional ER is associated with β-cell failure and death in diabetes. The ER form contacts with other cellular compartments, including the plasma membrane (PM), and these sites are important reactions centres where ion and lipid exchange occurs. The Extended Synaptotagmins (E-Syts) are ER-localized proteins that bind the PM and transport lipids in a Ca^{2+}-dependent manner. Recent studies have shown that the E-Syts participate in diacylglycerol (DAG) clearance from the PM, but the biological relevance of this transport mechanism is still unclear. The aim of our study was to investigate if E-Syt-mediated signalling at ER-PM contacts plays a role in insulin secretion.
Materials and methods: TIRF microscopy was used to study the subcellular distribution kinetics of fluorescently tagged E-Syts and changes in Ca^{2+} (R-GECO) and DAG (mCh/GFP-C1aC1b) levels. An optogenetic tool to generate artificial ER-PM contacts was developed. MIN6 cells were used for all experiments. Cell lines stably expressing non-targeting or E-Syt1-targeting shRNA were also generated. Secretion from single cells was measured using a pH-sensitive fluorescent reporter (VAMP2-pHl) and from batches of cells using the AlphaLISA technique (Perkin-Elmer).
Results: Immunoblotting revealed high expression of E-Syt1 in both MIN6 cells and mouse islets. Fluorescence-tagged E-Syt1 was recruited to the PM by both K^+- and glucose induced Ca^{2+}-increases, and this resulted in expansion of ER-PM contacts that co-localized with L-type voltage-dependent Ca^{2+} channels (55 ± 7% enrichment, $P < 0.001$). Insulin secretion stimulates transient and repetitive DAG formation (spiking) in the PM by autocrine activation of PLC. DAG formation correlated spatio-temporally with E-Syt1 PM-binding, and the overexpression of E-Syt1 suppressed DAG spiking frequency (52%, $P < 0.001$) and amplitude (49%, $P < 0.001$) whereas E-Syt1 knockdown increased spike amplitude (50%, $P < 0.001$) and duration (20%, $p < 0.05$). Together, these observations indicate a role of E-Syt1 in DAG clearance. E-Syt1 knockdown was associated with 76% reduction ($n = 3$, $p < 0.05$) in glucose-stimulated insulin secretion. Optogenetic ER-PM contacts were constructed by replacing the C-terminus of E-Syt1 with CRY2 and anchoring CIBN in the PM by a transmembrane domain. Blue light illumination stimulated CRY2-CIBN binding, resulting in the generation of ER-PM contacts. These contacts did not affect K^+- or glucose-induced Ca^{2+} influx, but suppressed the frequency of secretagogue-induced DAG spikes by 61% ($P < 0.05$). The light-induced expansion of ER-PM contacts resulted in amplification of K^+-induced insulin granule exocytosis (50%, $P < 0.001$).
Conclusion: Plasma membrane DAG levels are regulated by E-Syt1 at ER-PM contact sites in a Ca^{2+} dependent manner. The E-Syt1-mediated removal of DAG positively regulates insulin secretion by an unknown mechanism, and the findings more broadly identify ER-PM contacts as important reaction centres for the regulation of insulin secretion.
Disclosure: **B. Xie:** None.

Regulation of pancreatic beta cell insulin secretion by RGS2

T. Speckmann, P.V. Sabatini, C. Nian, D.S. Luciani, F.C. Lynn;
Dept. of Surgery, University of British Columbia, Vancouver, Canada.

Background and aims: Insulin-secreting β-cells in the pancreatic islets of Langerhans are important regulators of glucose homeostasis. During

type 2 diabetes (T2D), which is associated with hyperglycemia and obesity, excess nutrients such as high glucose or the fatty acid palmitate can cause β-cell stress and exhaustion. We previously found that the calcium-dependent transcription factor, *Neuronal PAS domain protein 4* (NPAS4), can alleviate β-cell stress by reducing both insulin production and secretion, though it remains unknown which target genes mediate this effect. Because regulator of G protein signalling (RGS) protein family members are known to regulate β-cell function and survival, we *hypothesized* that the direct NPAS4 target gene *Regulator of G protein signalling 2* (RGS2) mediates these β-cell cytoprotective effects.

Materials and methods: To test our hypothesis, *Rgs2* was adenovirally overexpressed (Ad-*Rgs2*) and compared to control overexpression (Ad-βGal) in primary mouse islets and MIN6 cells. Furthermore, *Rgs2* loss of function was studied by using CRISPR-Cas9 to derive clonal *Rgs2* knockout MIN6 cell lines.

Results: Compared to control, *Rgs2* overexpression blunted glucose-stimulated insulin secretion by 30% or 55–70% in mouse islets or MIN6 cells, respectively, whereas KCl-induced insulin release and total insulin content remained unchanged ($p < 0.05$, Student's t test). When examining what caused the decrease in insulin secretion, we discovered that glucose-induced intracellular calcium (Ca^{2+}_i) amplitudes were diminished by 17% in Ad-*Rgs2* overexpressing MIN6 cells compared to control ($p < 0.05$, Student's t test). Moreover, Ad-*Rgs2* islets exhibited 30% reduced oxygen consumption rate (OCR) at high glucose ($p < 0.05$, Student's t test). In order to further elucidate the mechanism by which RGS2 represses glucose-stimulated insulin secretion, clonal *Rgs2* knockout cell lines were derived and loss of RGS2 expression confirmed by western blot. Initial results indicate that insulin secretion is elevated in *Rgs2* knockout cells.

Conclusion: To date, our results suggest that activity-dependent *Rgs2* expression tempers glucose metabolism leading to reduced depolarization, reduced Ca^{2+}_i, and reduced insulin secretion. Of note, *RGS2* expression levels were found significantly reduced in islets from T2D donors, indicating that a population of T2D patients may benefit from restoration of *RGS2*. Additionally, these studies provide a new model for future study of how *Rgs2* expression impacts β-cell function.

Evaluation of the acute metabolic effects and specificity of GPR55 agonists (Abn-CBD and AM251) on islet and enteroendocrine cell function

A.G. McCloskey, M.G. Miskelly, P.R. Flatt, A.M. McKillop;
Diabetes Research Group, Ulster University, Coleraine, UK.

Background and aims: Type-2-diabetic therapies which enhance beta cell regeneration and function are needed and interest has focused on G-protein coupled receptors (GPCRs). G-protein coupled receptor 55 (GPR55), a novel endocannabinoid receptor has been identified as a potential anti-diabetic target, through the regulation of islet and enteroendocrine cell function. GPR55 function was evaluated by identifying and utilising selective GPR55 agonists and assessing their potential as novel therapeutic agents.

Materials and methods: CRISPR/Cas9 gene editing was employed to develop a clonal pancreatic GPR55 knockout BRIN-BD11 cell line. Specificity and insulinotropic activity of GPR55 agonists were assessed in wild type and GPR55 knockout BRIN-BD11 cells, with potency confirmed in human 1.1B4 cells. GPR55 expression and distribution were assessed by qPCR and western blotting in BRIN-BD11 cells and by immunohistochemistry in high fat fed (HFF) induced diabetic mouse pancreas and small intestine. Acute metabolic effects of agonist monotherapy (0.1 μM/kg BW) and combinational therapy (DPP-IV inhibitor [50 mg/kg BW]) *in-vivo* were investigated in HFF-induced diabetic NIH-Swiss mice. Animals were subjected to an oral glucose tolerance test and received either glucose alone (18mmol/kg BW) or glucose in combination with GPR55 agonist monotherapy and/or combinational therapy.

Results: Targeted CRISPR/Cas9 gene editing diminished GPR55 mRNA ($p < 0.001$) and protein expression ($p < 0.001$) in pancreatic BRIN-BD11 cells, with sanger sequencing confirming bi-allelic deletion of the GPR55 start codon. Synthetic agonists Abn-CBD (10^{-9}–10^{-4}M) and AM251 (10^{-8}–10^{-4} M) augmented insulin secretion from BRIN-BD11 and 1.1B4 cells at 5.6 mM ($p < 0.05$–$p < 0.001$) and 16.7 mM ($p < 0.05$–$p < 0.001$) glucose, with no cytotoxic effects. The insulinotropic response of Abn-CBD and AM251 was attenuated ($p < 0.05$) when assessed using the GPR55 knockout BRIN-BD11 cell line. Upon agonist treatment, insulin ($p < 0.01$) mRNA expression was upregulated in BRIN-BD11 cells, with no significant change in GPR55 mRNA expression observed. Confirmatory GPR55 protein expression was demonstrated by western blotting and levels of insulin content by radioimmunoassay. Immunohistochemistry demonstrated regions of co-localisation between GPR55 and insulin in the pancreatic islet and incretin hormones in the small intestine. Orally administered Abn-CBD and AM251 (0.1 μmol/kg BW) improved glucose excursion ($p < 0.001$), increased plasma insulin ($p < 0.001$), gastric inhibitory polypeptide ($p < 0.05$), glucagon-like peptide 1 ($p < 0.05$) and improved satiety ($p < 0.001$) in HFF-induced diabetic mice. Abn-CBD and AM251 agonist combinational therapy (Sitagliptin) diminished DPP-IV activity ($p < 0.001$), whilst improving glucose excursion ($p < 0.05$) through enhanced insulin ($p < 0.05$) and incretin ($p < 0.05$) hormone secretion from islet and enteroendocrine cells respectively.

Conclusion: Abn-CBD and AM251 activate GPR55 and potentiate insulin secretion from BRIN-BD11 cells and HFF-induced diabetic mice. *In-vivo* findings present GPR55 agonist monotherapy and combinational therapy as a novel approach for the treatment of type-2-diabetes.

Activation of PKD1 by autocrine ATP signalling in pancreatic beta cells

S. Khan;
Pharmacology, University of Alberta, Edmonton, Canada.

Background and aims: β-cells co-secrete the neurotransmitter ATP along with insulin. ATP acts as a positive autocrine signal in β cells by activating P2Y1 receptors and resulting in activation of Phospholipase C and production of DAG. However, the downstream signaling that couples P2Y1 activation to insulin secretion remains to be fully elucidated. Since DAG has been shown to activate Protein Kinase D1 (PKD1) to potentiate glucose stimulated insulin secretion, we hypothesize that autocrine ATP signaling activates downstream PKD1 to regulate insulin secretion.

Materials and methods: Western blotting was performed to study agonist-induced, depolarization-induced and antagonist-inhibited activation of PKD1 in response to KCl in INS 832/13 insulinoma cells and in mouse islets. Insulin secretion was measured from intact PKD1 knockout islets. Capacitance measurements of exocytosis were employed in single mouse β cells. Expression of PKD1 mRNA was analysed by RT-PCR in human islets. Correlation between the insulinotropic capacity of PKD1 activation and donor characteristics was examined in human islets.

Results: The P2Y1 receptor agonists, MRS2365 and ATP, induce PKD1 phosphorylation at S916 in mouse islets. Similarly, direct depolarization with KCl causes activation of PKD1. A reduction in PKD1 activation was observed upon application of P2Y1 antagonist, MRS 2500. Insulin secretion was measured from PKD1 KO mouse islets, where potentiation of insulin secretion elicited by P2Y1 activation was lost. Activation of P2Y1 increased the exocytotic response of mouse β cells in a PKD1-dependent manner. Finally, RT-PCR analysis confirmed expression of PKD1 in human islets and the study of donor characteristics revealed a correlation

between the activation of PKD1 and stimulation index - ability of the islets to produce insulin when stimulated by high glucose.
Conclusion: A P2Y1 receptor-dependent activation of PKD1 by ATP increases insulin secretion in mouse islets. In human islets, PKD1 may be involved with potentiation of glucose induced insulin secretion.

cAMP-dependent and -independent actions of GLP-1 to potentiate 1st and 2nd phase GSIS as revealed by Rp-8-Br-cAMPS-pAB - a dual antagonist of PKA and Epac activation

O. Cabrera[1], J. Ficorilli[1], K.R. Jones[2], O.G. Chepurny[3], C.A. Leech[3], F. Schwede[4], G.G. Holz[3];
[1]Islet Biology and Diabetes Drug Hunting Team, Eli Lilly and Company, Indianapolis, USA, [2]Advanced Testing Lab, Blue Ash, USA, [3]Medicine, SUNY Upstate Medical University, Syracuse, USA, [4]BIOLOG Life Sci. Inst., Bremen, Germany.

Background and aims: The novel cAMP antagonist prodrug Rp-8-Br-cAMPS-pAB (Rp-pAB) blocks PKA and Epac activation, and it was reported to act in human and rat islets to abolish 1st -phase glucose-stimulated insulin secretion (GSIS) while instead having a minimal inhibitory action on 2nd -phase GSIS. The aim of the present study was to determine if and how Rp-pAB also alters the ability of incretin hormone GLP-1 to potentiate 1st and 2nd phase GSIS. Such an analysis was expected to reveal cAMP -dependent and -independent actions of GLP-1 that might be selective for 1st or 2nd phase GSIS.
Materials and methods: Perifusion studies of SD rat islets were performed in which GSIS was initiated and terminated by step-wise changes of the glucose concentration (G) from 2.8 to 16.7 mM to 2.8 mM. Rp-pAB and GLP-1 were administered during the initial perifusion in 2.8G, and then also during perifusion with 16.7G. Perifusate fractions were assayed for insulin content, and insulin release was quantified relative to whole-islet DNA content. Static incubation assays using mouse islets were also performed to investigate if very low concentrations of GLP-1 (1 or 10 pM) potentiate GSIS at steady-state 5.6G or 11.1G.
Results: Rat islets exhibited biphasic insulin secretion when challenged with 16.7G (see Figure). GLP-1 (5 nM) potentiated 1st and 2nd -phase GSIS by 4.2-fold and 6.3-fold during assay intervals 60–65 and 65–95 min, respectively. For islets treated with Rp-pAB in the absence of GLP-1, 1st-phase GSIS was nearly abolished, whereas 2nd-phase GSIS was not altered. GLP-1 failed to potentiate 1st-phase GSIS from islets treated with Rp-pAB, whereas it retained a smaller but significant 3.75-fold ability to potentiate 2nd-phase GSIS. These actions of GLP-1 were significant ($n = 3$; $p < 0.05$ for 5 nM GLP-1) and dose-dependent at 100 pM–30 nM. FRET assays using AKAR3 and H188 confirmed that Rp-pAB blocked PKA and Epac activation by GLP-1. Very low concentrations of GLP-1 (1 or 10 pM) failed to potentiate GSIS from mouse islets at either 5.6G or 11.1G, whereas 10 nM GLP-1 was effective.
Conclusion: GLP-1 exerts a cAMP-dependent action to potentiate 1st-phase GSIS from rat islets, an effect that is abrogated by Rp-pAB. Since Rp-pAB reduces but fails to fully block the action of GLP-1 to potentiate 2nd-phase GSIS, there exist cAMP- dependent and -independent actions of GLP-1 to potentiate 2nd-phase GSIS. We propose that GLP-1 enables cAMP-dependent insulin exocytosis to occur during 2nd-phase GSIS, while also enhancing cAMP-independent exocytosis that normally predominates during 2nd-phase GSIS in the absence of GLP-1. Potentially, a cAMP-dependent mechanism of insulin exocytosis explains 1st-phase GSIS, and it is recruited by GLP-1 so that it becomes operational during 2nd-phase GSIS.

GLP-1 analogues protect beta cells in models of Wolfram syndrome

P. Salpea[1], S. Toivonen[1], C. Cosentino[1], A. Musuaya[1], N. Pachera[1], P. Marchetti[2], C. Brown[3], F. Urano[3], D.L. Eizirik[1], M. Cnop[1,4], M. Igoillo-Esteve[1];
[1]ULB Center for Diabetes Research, Université Libre de Bruxelles, Brussels, Belgium, [2]Department of Endocrinology and Metabolism, University of Pisa, Pisa, Italy, [3]Department of Medicine, Washington University School of Medicine, Washington, USA, [4]Division of Endocrinology, Erasmus Hospital, Université Libre de Bruxelles, Brussels, Belgium.

Background and aims: Wolfram syndrome is a rare autosomal recessive orphan disease. The clinical manifestations are young onset diabetes, optic nerve atrophy and deafness. Most Wolfram patients carry mutations in *WFS1*. WFS1 deficiency results in endoplasmic reticulum (ER) stress, leading to neurodegeneration and pancreatic β-cell dysfunction and death. Glucagon-like peptide-1 (GLP-1) analogs and the cAMP inducer forskolin have been shown to protect β-cells from ER stress. Our aim is to test whether GLP-1 analogs confer protection in *in vitro* and *in vivo* Wolfram syndrome models
Materials and methods: WFS1 was silenced in human EndoC-βH1 β-cells and human islets by RNA interference. Wolfram syndrome patients' induced pluripotent stem cells (iPSCs) were differentiated into β-like cells. Synthetic ER stress was induced using tunicamycin (5 μg/ml). β-cell apoptosis was evaluated by Hoechst 33342/propidium iodide staining. Expression of ER stress markers was examined by qPCR. Whole body wfs1 knockout (KO) mice (homozygous exon 8 deletion on 129S background) were treated for 12 weeks with exendin-4 (10 μg/kg/day) or vehicle using miniosmotic pumps. Glucose tolerance was evaluated before, during and at the end of treatment by intraperitoneal glucose tolerance tests.
Results: WFS1 silencing (>70% knockdown, $n = 6$, $p < 0.001$) sensitized EndoC-βH1 cells to tunicamycin-induced apoptosis (29 ± 3% apoptosis in WFS1-deficient cells vs 12 ± 1% apoptosis in control cells, $n = 5$, $p < 0.01$) and increased mRNA expression of the ER stress marker CHOP ($p < 0.001$). Exendin and forskolin protected WFS1-deficient EndoC-βH1 cells from ER stress (29 ± 3% apoptosis with tunicamycin alone vs 22 ± 1% with tunicamycin + exendin or 10 ± 0.3% with tunicamycin + forskolin, $n = 5$, $p < 0.01$). iPSCs from 4 Wolfram syndrome patients were successfully differentiated *in vitro* into β-like cells using a 7-stage protocol. Forskolin protected Wolfram iPSC-β-like cells from tunicamycin-induced apoptosis ($n = 4$, $p < 0.001$) and increased expression of the ER chaperone BiP. wfs1 KO mice had impaired glucose

tolerance compared to wild type littermates as early as 6 weeks of age ($n = 17$, $p < 0.01$). 12 weeks of exendin administration improved glucose tolerance of wfs1-deficient mice when compared to vehicle-treated KO animals ($n = 8$–9 per group, $p < 0.05$).

Conclusion: cAMP induction by exendin and forskolin protects WFS1-deficient β-cells from ER stress-induced apoptosis. *In vivo*, exendin treatment improves glucose tolerance of wfs1 KO mice. These findings provide further evidence for the protective properties of GLP-1 analogs in the context of β-cell ER stress, and suggest that GLP-1 analogs hold preventive and therapeutic potential for Wolfram syndrome-related diabetes.

OP 25 Hypoglycaemia: consequences and prevention

145

Severe hypoglycaemia and cardiovascular or all-cause mortality in the Korean population

S.-A. Cha[1], J.-S. Yun[1], K. Han[2], S.-H. Ko[1], Y.-B. Ahn[1];
[1]Internal medicine, St. Vincent's Hospital, College of Medicine, The Catholic University of Korea, Suwon, [2]Biostatistics, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea.

Background and aims: Previous studies have associated hypoglycemia with an increase in cardiovascular disease and mortality. We investigated the association between the number of severe hypoglycemia (SH) and the risk of cardiovascular disease (myocardial infarction, stroke, congestive heart failure) and all-cause mortality in patients with type 2 diabetes using the National Health Insurance Service database which covers the entire Korean population.

Materials and methods: Baseline and follow-up data ($n = 1{,}583{,}149$) from the patients with T2DM for the period 2006–2016 were retrieved from the National Health Insurance System database. Type 2 diabetes, SH, and major comorbidities were identified using the International Classification of Diseases 10 codes and medication information. We counted the number of SH episodes according to ICD-10 codes during the three years (2006–2009) prior to the index date within the year of 2009–2010. The primary outcome was a new development of 1) myocardial infarction, 2) stroke, 3) congestive heart failure and 4) all-cause mortality.

Results: 20,064 (1.2%) developed at least one SH event during the first three years prior to the index date. The mean follow-up duration was 7.2 years. After adjustment for multiple confounding factors, including age, sex, socioeconomic status, hypertension, dyslipidemia, use of insulin and sulfonylurea, number of metabolic syndrome factors, the presence of major comorbidities, the hazard ratio (HR) of cardiovascular diseases or all-cause mortality significantly increased sequentially. [the group who experienced zero SH episode vs. one SH episode, HR 1.96 95% CI (1.91–2.02); vs. two SH episodes, HR 2.36 (2.22–2.50); vs. three SH episodes, HR 3.14 (2.90–3.41); *P* for trends <0.001]. Similar findings were noted the relationship for the number of SH episodes with myocardial infarction, stroke, and congestive heart failure. The sensitivity analysis which analyzed the 804,503 subjects who had received national health examination did not change the significance of the main findings.

Conclusion: We demonstrated that, in the entire Korean population, the number of SH episode is associated with an increased risk for all cardiovascular outcomes and all-cause mortality. The patients who experienced recurrent SH episode may have a greater risk of cardiovascular events and mortality.

Preserved glucose response to low-dose glucagon after exercise in insulin pump-treated individuals with type 1 diabetes: a randomised crossover study

I.I.K. Steineck[1,2], A. Ranjan[1,2], S. Schmidt[1,2], T.R. Clausen[3], J.J. Holst[4], K. Nørgaard[5];
[1]Department of Endocrinology, research unit (afs. 159), Hvidovre University Hospital, University of Copenhagen, Hvidovre, [2]Danish Diabetes Academy, Odense University Hospital, Odense, [3]Obesity Research, Novo Nordisk A/S, Måløv, [4]Department of Biomedical Sciences and NNF Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, [5]Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: To compare the increase in plasma glucose after a subcutaneous injection of 200 μg glucagon given after 45 minutes of

cycling versus resting and to investigate the effects of glucagon when injected before compared with after 45 minutes of cycling.
Materials and methods: Fourteen insulin pump-treated individuals with type 1 diabetes completed three visits in a randomized, placebo-controlled, single-blinded crossover study. Baseline (mean and range) HbA1c 54 (43–65) mmol/mol or 7.1 (6.1–8.1) %, age 45 (23–66) years, BMI 26 (21–30) kg/m^2, diabetes duration 26 (8–51) years. On each visit, participants consumed a standardized breakfast two hours prior to 45 minutes of cycling or resting. A subcutaneous injection of 200 μg glucagon was either given after cycling, after resting or before cycling and frequent blood sampling occurred until two hours after exercise.
Results: The glucose response to glucagon was higher after cycling compared with after resting (mean ± SD incremental peak: 2.6 ± 1.7 versus 1.8 ± 2.0 mmol/l, $P = 0.02$). As expected, plasma glucose decreased during cycling (−3.1 ± 2.8 mmol/l) but less so when glucagon was given before cycling (−0.9 ± 2.8 mmol/l, $P = 0.002$). The number of subjects reaching hypoglycemia (glucose values ≤3.9 mmol/l) was the same on the three days.
Conclusion: Moderate cycling for 45 minutes did not impair the glucose response to glucagon compared to the glucose response after resting. The glucose fall during cycling was diminished by a pre-exercise injection of 200 μg glucagon. Thus a small glucagon dose can potentially be used to treat exercise-induced mild hypoglycemia and diminish the glucose fall during exercise.

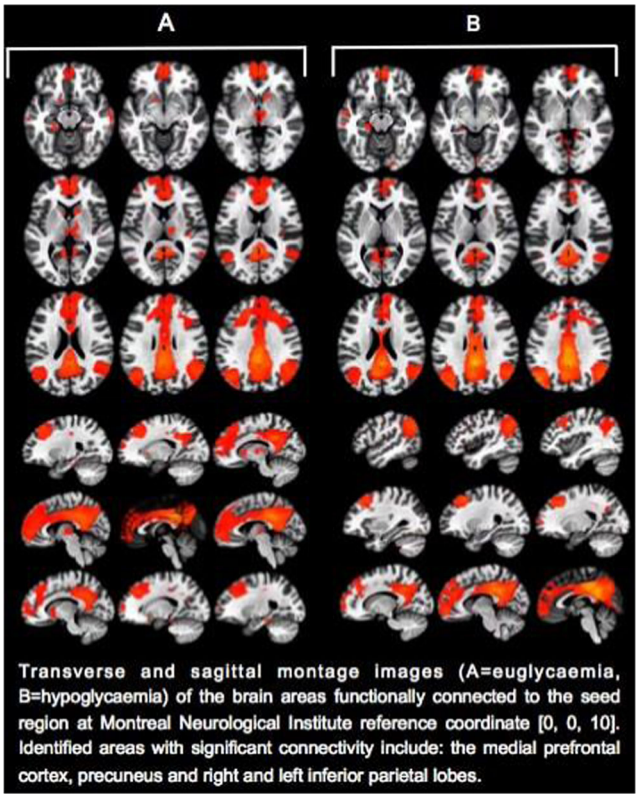
The impact of hypoglycaemic stress on the connectivity of the default mode network in healthy controls

C.E.D. Osborne, O. O'Daly, M. Nwokolo, F.O. Zelaya, P. Choudhary; King's College London, London, UK.

Background and aims: As a physiological stressor, hypoglycaemia is known to stimulate the brain's physiological stress pathway. The brain plays a key role in recognising this stress and generating protective symptomatic and hormonal responses that serve to maintain normoglycaemia. In patients with type 1 diabetes, allostatic mechanisms can cause these responses to become blunted, increasing the risk of dangerous hypoglycaemia. Areas of interest in recognizing this physiological stress are the resting state networks (RSNs), which are networks of brain regions that show similar spontaneous low frequency oscillations while at rest. The default mode network (DMN) is a RSN, which demonstrates reduced connectivity during task-based activity or changes to the system. We investigated whether hypoglycaemic stress disrupts the connectivity of the DMN.
Materials and methods: Fourteen healthy participants underwent a hyperinsulinaemic, two-step glucose clamp procedure during which two blood oxygen-level dependent (BOLD) RSN functional magnetic resonance images (fMRI) were obtained. At euglycaemia [5mmol/L] and hypoglycaemia [2.6 mmol/L] we collected symptom scores using a visual analogue scale and counter-regulatory hormone responses through blood sampling. Seed-to-voxel analysis using statistical parametric mapping was performed using the CONN toolbox in SPM12. The posterior cingulate cortex (PCC) was defined *a priori* as a seed region for the default mode network.
Results: We identified connectivity in the DMN in euglycaemia as well as hypoglycemia. A DMN mask was designed on WFU Pickatlas and applied to the data and formal statistical comparison was performed using a Student's paired t-test. Only results with a family wise error corrected (FWE-corr) cluster size of $p < 0.05$, at a cluster forming threshold of $p < 0.001$ were considered significant. A significant weakening of PCC to right angular gyrus connectivity was identified during hypoglycaemia: $p_{FWE\text{-}corr} = 0.03$; $z = 4.47$; cluster size (k) = 43; Montreal Neurological institute (MNI) coordinate [x, y, z] = [38, −58, 36]. The degree of connectivity alteration was not related to the magnitude of change in serum adrenaline or symptom score. Whole brain exploratory analysis revealed no additional significant regional effects.
Conclusion: During hypoglycemia, we found a reduced functional connectivity primarily in the right angular gyrus, an area involved in converging and processing multisensory information in order to interpret and respond to events. The impact of hypoglycaemia on other RSNs is being explored. Disruption of these RSNs may be key in the process of internal recognition of hypoglycaemia and triggering of the stress response.



Transverse and sagittal montage images (A=euglycaemia, B=hypoglycaemia) of the brain areas functionally connected to the seed region at Montreal Neurological Institute reference coordinate [0, 0, 10]. Identified areas with significant connectivity include: the medial prefrontal cortex, precuneus and right and left inferior parietal lobes.

Individualised nursing support reduces mortality in patients with type 2 diabetes following severe hypoglycaemia requiring ambulance attendance

K. Kulavarasalingam[1], B. Whittam[1], S. Cassidy[1], C. James[2], P. Baxter[3], S. Pearson[1,4], R.A. Ajjan[1,4];
[1]St James's University Hospital, Leeds, [2]Yorkshire Ambulance Service, Wakefield, [3]Division of Biostatistics, Leeds Institute of Cardiovascular and Metabolic Medicine (LICAMM), University of Leeds, Leeds, [4]Division of Cardiovascular and Diabetes Research, LICAMM, University of Leeds, Leeds, UK.

Background and aims: Mortality in patients with diabetes following emergency services call out for severe hypoglycaemia is high and it is unclear whether this can be modified using structured intervention. The aim of this work was to assess the impact of nurse-led intervention on

mortality of patients with diabetes following ambulance call out for hypoglycaemia.

Materials and methods: Patients with diabetes requiring ambulance services intervention for hypoglycaemia, in an area covering 5 million people, were recruited into the study after informed consent. Patients were randomised 1:1 to either receiving intensive nurse-led support (intervention arm) or managed using existing pathways (control arm). A third group of patients did not wish to participate in the study but agreed to have their data collected and were managed as per the control arm. Those assigned to the intensive arm received structured intervention that involved individualised nurse follow up with regular contact in order to alter therapy and provide support for a total period of 3 months. The primary outcome was all cause mortality comparing two study arm during the follow up period.

Results: A total of 323 individuals were recruited into the study between Feb-2013 and Dec-2017. Study withdrawal and lost contact occurred in 24 individuals (7.4%), while the remaining 299 patients were followed up for a median of 915 (IQR: 463–1358) days. Of these patients, 137 (45.8%) had type 1 diabetes mellitus (T1DM) and 150 (50.2%) had type 2 diabetes mellitus (T2DM).In patients with T1DM, there was no difference in mortality in the intervention compared with the control arm [10.4% vs 9.0%, respectively; $p = 0.79$; HR 1.20 (0.39–3.68)]. In contrast, patients with T2DM showed a significant reduction in mortality in the intervention compared with the control arm [27.8% vs 44.8%, respectively; $p = 0.04$, HR 0.55 (0.31–0.99)]. Cox regression analysis suggested that the relatively short period of intervention of 3 months continued to have an effect on mortality for over 3 years (Figure 1).

Conclusion: Our data suggest that in patients with T2DM and severe hypoglycaemic requiring ambulance call-out, close nurse-led individualised intervention reduces mortality compared with standard care. Large scale multicentre studies are warranted to investigate the role of structured nurse intervention on reducing mortality in T2DM patients with a history of severe hypoglycaemia. Figure 1

Reduction in severe hypoglycaemia in paediatric type 1 diabetes during the first year of continuous glucose monitoring: real-world data from the DPV registry

J. Hermann[1], R. Holl[1], B. Rami-Merhar[2], C. Freiberg[3], M. Papsch[4], A. Thon[5], B. Heidtmann[6], K. Placzeck[7], D. Agena[8], T. Kapellen[9], B. Schenk[10], J. Wolf[11], T. Danne[12], DPV initiative;

[1]Institute for Epidemiology, Ulm, Germany, [2]University of Vienna, Vienna, Austria, [3]University of Goettingen, Goettingen, Germany, [4]Childrens Hospital, Gelsenkirchen, Germany, [5]MHH, Hannover, Germany, [6]Catholic Children Hospital, Hamburg, Germany, [7]University Childrens Hospital, Halle, Germany, [8]Pediatric Practice, Hildesheim, Germany, [9]University Children Hospital, Leipzig, Germany, [10]Pediatric Clinic, Schwerin, Germany, [11]Childrens Hospital, Paderborn, Germany, [12]Childrens Hospital, Hannover, Germany.

Background and aims: Controlled studies indicated improved metabolic control in type-1 patients on continuous glucose monitoring. Patients in clinical studies are often biased towards patients with higher education level, higher adherence and better self-management. We therefore used real-world data from the German-Austrian-Luxemburg diabetes patient follow-up (DPV) registry, which includes >80% of pediatric patients in the participating countries, to longitudinally follow metabolic control (HbA1c) and acute complications (severe hypoglycemia, diabetic ketoacidosis (DKA)) in pediatric subjects during the first year after the initiation of continuous glucose monitoring (CGM or FGM).

Materials and methods: Anonymized patient records from the DPV registry were analyzed, using SQL for data integration and SAS 9.4 for statistical analysis. Patients with type-1 diabetes (T1-DM), less than 18 years of age, more than 1 year of diabetes duration and both baseline (6 months prior to CGM start) and at least 1 year of follow-up after initiation of continuous glucose monitoring were selected. Documented sensor use for at least 50% of the observation time was required. Severe hypoglycemia was defined by events requiring external help, or leading to coma or convulsion. DKA was defined by a pH <7.3. Non-parametric paired statistics (McNemar) and Poisson-regression models for repeated measurements were used.

Results: 3171 pediatric patients (median age 11.8 [Q1–Q3: 8.8–14.4] years, median DM-duration 3.9 [2.2–6.5] years, 51.7% males) fulfilled the inclusion criteria. 60.9% of subjects were treated with insulin pumps, 19.1% reported migration background. Metabolic control (median baseline HbA1c: 7.46% [6.86–8.11]/58.0 [51.4–65.1] mmol/mol) did not change within 6 or 12 months after initiation of CGM use. Rate of severe hypoglycemia was 10.7 events per 100 patient-years during the 6 months prior to CGM use, and decreased to 7.6 events during the first 6 months and to 5.9 events 6–12 months after CGM onset ($p < 0.002$). 3.9% of patients experienced a severe hypo event during the baseline period, compared to 2.1% of patients during sensor use ($p < 0.003$). Rate of DKA did not change significantly (baseline: 1.6 events/100 pat.-years, 6–12 months follow-up: 1.2 events per 100 pat.-years).

Conclusion: In this on average well-controlled pediatric group of type-1 patients, initiation and continuous use (>50% of days) of CGM was associated with rapid and persistent reduction of reported severe hypoglycemic events. Reduction of severe hypoglycemia was not accompanied by deterioration of metabolic control. Longer follow-up and additional end-points (e.g. hospitalization) together with subgroup-analysis on baseline metabolic control, diabetes treatment and type of glucose monitoring will allow additional insights into outcome of CGM.

Nasal glucagon: a viable alternative to treat insulin-induced hypoglycaemia in adults with type 1 diabetes

J. Suico[1], U. Hövelmann[2], S. Zhang[1], T. Shen[1], B. Bergman[1], J. Sherr[3], E. Zijlstra[2], B. Frier[4], L. Plum-Moerschel[5];

[1]Eli Lilly & Company, Indianapolis, USA, [2]Profil Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany, [3]Yale University, New Haven, USA, [4]University of Edinburgh, Edinburgh, UK, [5]Profil Profil Institut für Stoffwechselforschung GmbH, Mainz, Germany.

Background and aims: Any insulin-treated individual with diabetes is at risk of severe hypoglycaemia (SH). Glucagon is available as a rescue medication in these instances. Currently available commercial glucagon products require reconstitution and injection, which are cumbersome during an emergency situation. Nasal glucagon (NG) is a nasally administered, drug-device combination product that consists of a dry powder spray formulation with 3-mg synthetic glucagon contained within a single-use device. This study in adults with type 1 diabetes (T1D) aimed to demonstrate non-inferiority between intramuscular glucagon (IMG) and NG as treatment for insulin-induced hypoglycaemia.
Materials and methods: This randomised, two-period, crossover trial was conducted at two clinical sites and used a NG drug product manufactured at commercial scale. The comparator was glucagon [rDNA origin] injection. Hypoglycaemia (plasma glucose [PG] <3.3 mmol/L) was induced by an intravenous insulin infusion. Five minutes after stopping insulin, either 3-mg NG or 1-mg IMG was administered followed by multiple PG measurements up to 90 min. Treatment success was defined as an increase in PG to ≥3.9 mmol/L or an increase of ≥1.1 mmol/L from the PG nadir within 30 min of receiving glucagon. Non-inferiority of NG was declared if the upper limit of the two-sided 95% CI of the difference in percentage of patients achieving treatment success (IMG-NG) was <10%. Besides spontaneously reported adverse events (AEs), a Nasal and Non-Nasal Symptom Questionnaire (NNSQ) assessed local tolerability of NG.
Results: Of the 66 participants included in the primary efficacy analysis who received both NG and IMG, 100% achieved treatment success. The study demonstrated non-inferiority of NG to IMG. All participants achieved treatment success by 25 min with the mean time to treatment success of 11.4 min (NG) and 9.8 min (IMG). As shown in Figure 1, similar glucose responses were observed with NG and IMG within 40 min post glucagon administration. No deaths or other serious AEs occurred. Forty-eight AEs occurred after NG and 51 after IMG. Most AEs were mild and transient, and the frequency was similar between IMG and NG. Treatment-emergent AEs with an incidence ≥5% were nausea (31% NG; 42% IMG), vomiting (14% NG; 17% IMG), and headache (16% NG; 10% IMG). After NG, very common (≥10%) symptoms from the NNSQ included watery eyes, nasal itching, nasal congestion, runny nose, sneezing, redness of eyes, itchy eyes, and itching of throat.
Conclusion: Nasal glucagon was as efficacious and safe as intramuscular glucagon for the treatment of insulin-induced hypoglycaemia in adults, thus supporting the use of nasal glucagon as a rescue treatment for severe hypoglycaemia.

Effects of increased fiber and reduced red meat intake, combined with caloric restriction, on cardiometabolic risk: a randomised and controlled dietary intervention study

C. Willmann[1,2], M. Heni[1,2], K. Linder[1,2], R. Wagner[1,2], N. Stefan[1,2], J. Machann[2,3], H.-U. Häring[1,2], A. Fritsche[1,2];
[1]Department of Internal Medicine IV, University Hospital of Tübingen, Tübingen, [2]Institute for Diabetes Research and Metabolic Diseases (IDM) of the Helmholtz Center Munich at the University of Tübingen, Tübingen, [3]Section on Experimental Radiology, Department of Diagnostic and Interventional Radiology, University Hospital Tübingen, Tübingen, Germany.

Background and aims: Epidemiological studies suggest that increased intake of red meat associates with a higher, while increased intake of fibers associates with a lower risk of type 2 diabetes. We, thus, conducted a randomized intervention study to investigate the effects of these nutritional factors on glucose and lipid metabolism, body fat distribution and liver fat content, in subjects at increased risk of type 2 diabetes.
Materials and methods: This prospective, randomized and controlled dietary intervention study was performed over six months. In the control group ($N = 40$) the participants decreased their daily caloric intake by 400 Kcal. In addition to this caloric restriction, the "no red meat" group ($N = 48$) lowered the intake of red meat and the "fiber" group ($N = 44$) increased intake of fibers to 40 gr/d. Before and after the intervention, anthropometric parameters and a frequently-sampled oral glucose tolerance test were performed. Body fat mass and distribution and liver fat content were assessed by magnetic resonance imaging and ^{1}H-MR spectroscopy.
Results: Glucose tolerance and insulin sensitivity improved during the intervention in all groups (all $p < 0.03$). Body fat mass, as well as visceral fat mass decreased in all groups (all $p < 0.03$). Multivariate analysis revealed that these changes did not differ between the groups. Liver fat content decreased significantly in the "no red meat" and "fiber" groups, but not in the control group.
Conclusion: Our data suggest that reduced intake of red meat or increased intake of fibers may have favourable effects on liver fat content. However, in combination with caloric restriction, there seems to be no additional beneficial impact on the improvement of other cardiometabolic risk parameters.

Eldecalcitol, a vitamin D analogue, for diabetes prevention in impaired glucose tolerance: DPVD study

T. Kawahara[1], G. Suzuki[2], T. Inazu[3], S. Mizuno[4], F. Kasagi[4], Y. Okada[1], Y. Tanaka[1], DPVD clinical study group;
[1]University of Occupational and Environmental Health, Kitakyushu, [2]International University of Health and Welfare Clinic, Ohtawara, Japan, [3]Ritsumeikan University, Kusatsu, [4]Radiation Effects Association, Tokyo, Japan.

Background and aims: In observational studies, it was clear that vitamin D deficiency is associated with insulin resistance and risk of future diabetes. However, the efficacy of vitamin D supplementation in randomized controlled trials for improving glucose tolerance or prevention of type 2 diabetes is still controversial.
Materials and methods: We conducted the *Diabetes Prevention on Vitamin D* (DPVD) study which was a large, randomized, double-blind, placebo-controlled study to examine whether eldecalcitol, an active form of vitamin D analog, can reduce the risk of type 2 diabetes in patients with

impaired glucose tolerance. Participants were randomly assigned to receive eldecalcitol or placebo. The primary endpoint was the incidence of type 2 diabetes and the secondary endpoint was the conversion to normoglycemia. The study duration was 3 years.

Results: The mean follow up was 2.6 years. A total of 1256 participants were enrolled in the study. Fifty-seven of 630 (9.0%) participants in the eldecalcitol group and 64 of 626 (10.2%) in the placebo group developed type 2 diabetes (hazard ratio, 0.87; 95% confidence interval, 0.68 to 1.09; $p = 0.37$). In the subgroup participants with vitamin D deficiency (serum 25-hydroxyvitamin D <20 ng/ml), the difference of the incidence of type 2 diabetes between the two groups was greater; however, there was no statistical significance. Two hundred ninety-five of 630 (46.8%) participants in the eldecalcitol group and 267 of 626 (42.7%) in the placebo group achieved normoglycemia (hazard ratio, 1.10; 95% confidence interval, 0.93 to 1.31; $p = 0.45$). At the end of the study, the mean fasting plasma glucose level was significantly lower in the eldecalcitol group (110.5 mg/dl) than the placebo group (112.8 mg/dl, $p = 0.046$), though plasma glucose levels 2 hours after an oral glucose load were not significantly lower in the eldecalcitol group (165.0 mg/dl vs. 163.1 mg/dl, $p = 0.071$). No serious adverse events related to the intervention were recorded.

Conclusion: Our study showed that treatment with eldecalcitol was not associated with a reduction in the incidence of type 2 diabetes or an increase in the conversion to normal glucose tolerance among patients with impaired glucose tolerance.

Sweetened beverage consumption is associated with autoimmune diabetes in adults only among low risk HLA genotype carriers

J.E. Löfvenborg[1], E. Ahlqvist[2], L. Alfredsson[1], T. Andersson[1,3], M. Dorkhan[2], L. Groop[2,4], A. Rosengren[2], T. Tuomi[5,6], A. Wolk[1], S. Carlsson[1];

[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, [2]Department of Clinical Sciences, Lund University, Malmö, Sweden, [3]Center for Occupational and Environmental Medicine, Stockholm County Council, Stockholm, Sweden, [4]Finnish Institute of Molecular Medicine, Helsinki University, Helsinki, Finland, [5]Div. of Endocrinology, Abdominal Centre, Helsinki University Hospital, Helsinki, Finland, [6]Folkhälsan Research Center, Helsinki, Finland.

Background and aims: Sweetened beverage consumption is associated with increased risk of type 2 diabetes (T2D) as well as autoimmune diabetes. Findings for type 1 diabetes in children suggest that HLA genotype may modify the association. We aimed to investigate whether the association between sweetened beverage intake and latent autoimmune diabetes in adults (LADA) and T2D is modified by HLA DR-DQ genotype.

Materials and methods: Swedish case-control data including incident cases of LADA ($n = 384$) and T2D ($n = 1240$) with matched population-based controls ($n = 879$) was used. Cases were classified based on onset age (≥35 years), GAD autoantibodies (GADA) and C-peptide. Information on diet and potential confounding factors was obtained through an extensive health and lifestyle questionnaire. HLA genotyping was based on SNP data and grouped as high/low risk. Logistic regression models adjusted for age, sex, education, physical activity, smoking, and alcohol intake were used to estimate OR of diabetes (95% CI) per 1 daily 200 mL serving. Dietary factors had little impact on the estimates and are thus not included. BMI was considered as a mediator separately. The association with GADA, insulin resistance (HOMA-IR) and beta cell function (HOMA-B) was explored through linear regression.

Results: Consumption of sweetened beverages was associated with increased risk of LADA and T2D; each daily 200 mL serving conferred 15% increased risk of LADA (OR 1.15, 95% CI 1.01–1.30) and 20% increased risk of T2D (OR 1.20, 95% CI 1.08–1.33). The increased risk may partly be mediated through BMI (Table 1). In HLA-stratified analysis, the association between sweetened beverages and LADA was present also after adjustment for BMI but only for those having low risk HLA genotypes (OR 1.25, 95% CI 1.00–1.56). Similar tendencies were seen for T2D. Sweetened beverage intake was positively associated with HOMA-IR in individuals with low risk HLA genotypes but not in those with high risk HLA variants. These associations were similar in LADA and T2D. Sweetened beverage intake was not associated with HOMA-B or GADA (Table 1).

Conclusion: Our findings suggest that the increased risk of LADA and T2D conferred by consumption of sweetened beverages only pertains to individuals with low risk HLA genotypes, mainly through mechanisms related to overweight and insulin resistance. This concurs with contemporary literature indicating that environmental factors are more important in the development of autoimmune diabetes in low risk HLA genotypes.

Table 1. OR and 95% CI of LADA and type 2 diabetes, and change in GADA, HOMA-IR, and HOMA-B per one daily 200 mL serving of sweetened beverages.

Plant versus animal based diets and insulin resistance, prediabetes and type 2 diabetes: the Rotterdam Study

T. Voortman, M. Zuurmond, O. Franco, Z. Chen;
Erasmus University Medical Center, Rotterdam, Netherlands.

Background and aims: Vegan or vegetarian diets have been suggested to reduce type 2 diabetes (T2D) risk. However, not much is known on whether variation in the degree of having a plant-based versus animal-based diet may be beneficial for prevention of T2D. Therefore, we aimed to investigate whether level of adherence to a diet high in plant-based foods and low in animal-based foods was associated with insulin resistance, prediabetes, and T2D.

Materials and methods: Our analysis included 6798 participants (62.7 ± 7.8 years) from the Rotterdam Study (RS), a prospective population-based cohort in the Netherlands. Dietary intake data were collected with food-frequency questionnaires at baseline of three sub-cohorts of RS (RS-I-1: 1989–93, RS-II-1: 2000–01, RS-III-1: 2006–08). We constructed a continuous plant-based dietary index (range 0–92) assessing adherence to a plant-based versus animal-based diet. Higher score on the plant-based dietary index reflected more plant-based foods intake and less animal-based foods intake. Insulin resistance at baseline and follow-up was assessed using homeostasis model assessment of insulin resistance (HOMA-IR). Prediabetes and T2D were collected from general practitioners' records, pharmacies' databases, and follow-up examinations in our research center until 2012. We used linear mixed models to examine associations of score on the plant-based dietary index with longitudinal HOMA-IR, and used cox proportional-hazards regression models to examine associations of score on the plant-based dietary index with risk of prediabetes and T2D.

Results: During median 5.7 years, and 7.3 years of follow-up, we documented 928 prediabetes cases and 642 T2D cases. After adjusting for

sociodemographic and lifestyle factors, a higher score on the overall plant-based dietary index was associated with lower insulin resistance (per 10 points higher score on the index per day: β = −0.09; 95% CI: −0.10; −0.08), lower prediabetes risk (HR = 0.89; 95% CI: 0.81; 0.98), and lower T2D risk (HR = 0.82; 95% CI: 0.73; 0.92)). After additional adjustment for BMI, associations attenuated and remained statistically significant for longitudinal insulin resistance (−0.05 (−0.06; −0.04)) and T2D risk (0.87 (0.79; 0.98)), but no longer for prediabetes risk.
Conclusion: A more plant-based and less animal-based diet may lower risk of insulin resistance, prediabetes and T2D. These findings strengthen recent dietary recommendations to adopt a more plant-based diet.

Beneficial effects of three months exercise on plasma adipokines levels and inflammation-related gene expression in subcutaneous adipose tissue in men with prediabetes

H.L. Gulseth[1,2], S. Lee[1,2], T.M. Langleite[2], F. Norheim[2], K.I. Birkeland[1,2], C.A. Drevon[2];
[1]Oslo University Hospital, Oslo, [2]University of Oslo, Oslo, Norway.

Background and aims: Obesity and insulin resistance promote several changes in adipose tissue including production and secretion of adipokines. Physical exercise improves insulin sensitivity perhaps through effects on adipokines. Our aim was to examine the effect of long-term exercise on large-scale adipose tissue gene expression and plasma adipokines concentrations, and their relationships with insulin sensitivity in men with or without prediabetes (PD).
Materials and methods: In the MyoGlu clinical study of 26 sedentary men (13 prediabetes (PD) and 13 controls) aged 40–65 years, a 12-weeks intensive combined strength and endurance exercise intervention increased insulin sensitivity by 30%. Before and after 12 w of intervention insulin sensitivity was measured by hyperinsulinemic-euglycemic-clamp, transcriptomics by global RNA-sequencing and RT-PCR of adipose tissue and skeletal muscle biopsies, and plasma adipokines by ELISA. .
Results: Intersected results from three approaches to RNA-sequencing analysis of adipose tissue revealed 90 genes in PD and seven genes in controls responding to 12 w exercise. mRNA-sequencing and RT-PCR results were highly coherent. Evidence for encoding secreted proteins existed for 62/90 and 5/7 genes in PD and controls respectively. The 90 genes that responded for exercise in PD were mostly related to the immune system and inflammatory processes. They displayed elevated expression levels in PD at baseline, but were partly normalized after 12 w exercise, as compared to controls. Baseline expressions of these genes were negatively correlated with insulin sensitivity both at baseline ($r = -0.49$, $p = 0.016$) and with changes in response to 12 w exercise ($r = -0.46$, $p = 0.025$) across all men. Adipose tissue, but not skeletal muscle expression levels of *LEP, ADIPOQ, IL6, SFRP4* and *OPG* (but not *THBS4*) correlated with corresponding plasma protein concentrations. Plasma SFRP4 and OPG concentrations were elevated in PD vs. controls at baseline, and were lowered after 12 w exercise in PD, attenuating the group difference.
Conclusion: We discovered dysregulated inflammation-related genes in PD, which were negatively associated with insulin sensitivity, and partly normalized after 12 w of physical exercise as compared to controls. These gene expression patterns were reflected in plasma adipokines concentrations, and may provide important links to glucose metabolism.

Gut microbiome, insulin resistance, and type 2 diabetes: a large population-based study

Z. Chen[1], D. Radjabzadeh[2], O. Franco[1], M. Ikram[1], A. Uitterlinden[2], R. Kraaij[2], T. Voortman[1];
[1]Department of Epidemiology, Erasmus Medical Center, Rotterdam, [2]Department of Internal Medicine, Erasmus Medical Center, Rotterdam, Netherlands.

Background and aims: Few data on gut microbiome linked to development of type 2 diabetes (T2D) are available. Therefore, we aimed to examine associations of gut microbiome with insulin resistance and T2D in a large Dutch middle-aged and elderly population.
Materials and methods: Our current cross-sectional study was embedded within the Rotterdam study (RS), a population-based cohort study including people aged ≥45 years living in the Ommoord District of Rotterdam. The study has been approved by the Medical Ethics Committee of Erasmus University Medical Center and all participants gave written informed consent. We included 1146 participants (median age: 57 years, 25%–75% range: 51–61 years) from the second examination cycle of the third sub-cohort of the Rotterdam study (RS-III-2: 2012–2014). For the 1146 participants, we collected stool in 2012–13. We detected gut microbiome via stool using sequencing of the 16S rRNA gene. Fasting blood was drawn in 2012–13 to measure glucose and insulin, we calculated the homeostatic model assessment of glucose (HOMA-IR) for insulin resistance. We identified T2D cases using information from general practitioners, pharmacies' databases, and follow-up examinations in our research center until 2012. Alpha diversity and beta diversity of gut microbiome were quantified by Shannon index and Bray-Curtis distance, respectively. We used linear regression models to examine association between Shannon index and insulin resistance, and used logistical regression models to examine association between Shannon index with T2D. Adonis permutation *P* value calculation was used to examine whether Bray-Curtis distance differed by insulin resistance and T2D. We used Multivariate Association with Linear Models (MaAsLin) to examine gut microbial communities in relation to insulin resistance and T2D at multiple taxonomical levels from phylum to genus. We confined the analyses to 11 phyla, 19 classes, 25 orders, 44 families, and 184 genera.
Results: Of 1146 participants, 90 participants had T2D. Of 1056 participants without T2D, 1022 participants had data on insulin resistance (median: 2.1, 25%–75% range: 1.6–2.7). After multivariate adjustment for technical covariates (run batch, time-in -email of stool), age, sex, total energy intake, diet quality score, education, smoking, physical activity, and BMI, higher Shannon index was associated with lower HOMA-IR ($\beta = -0.13$ (95%CI: −0.28, −0.09)), and lower odds of T2D (OR = −0.44 (−0.85, −0.03)). Bray-Curtis distance of beta-diversity was also linked to insulin resistance (genus level, $R^2 = 0.005$, $p = 0.001$), and T2D (genus level, $R^2 = 0.003$, $p = 0.001$). In MaAsLin analyses, higher relative abundance of two genera: *Acetitomaculum* ($\beta = -0.001$, $p = 3*10^{-9}$, $q = 0.004$) and *RuminococcaceaeUCG010* ($\beta = -0.006$, $p = 2*10^{-4}$, $q = 0.02$) were associated lower HOMA-IR, and participants with T2D had lower relative abundance of two genera: *Clostridiumsensustricto1* ($\beta = -0.04$, $p = 4*10^{-7}$, $q = 0.0001$) and *RuminococcaceaeUCG010* ($\beta = -0.03$, $p = 6*10^{-7}$, $q = 0.0001$).
Conclusion: Our findings indicate that increased diversity of gut microbiome may be beneficial for prevention of T2D. Especially, genera: *Acetitomaculum, RuminococcaceaeUCG010, and Clostridiumsensustricto1* may play an important role in the development of T2D.

Insulin regulates the hypothalamic mitochondrial chaperone complex Hsp60/10 and impacts the mitochondrial stress response

K. Wardelmann[1,2], S. Blümel[1,2], M. Rath[1,2], K. Warnke[1,2], E. Alfine[1,2], B.-F. Belgardt[3,2], A. Kleinridders[1,2];
[1]German Institute of Human Nutrition (DifE), Potsdam-Rehbrücke, [2]German Center for Diabetes Research (DZD), Neuherberge, Germany, [3]German Diabetes Center (DDZ), Düsseldorf, Germany.

Background and aims: Type 2 diabetic (T2D) mice exhibit brain insulin resistance, mitochondrial dysfunction and a decrease in the heat shock protein (Hsp)60. Hsp60 with its co-chaperone Hsp10 are crucial for mitochondrial matrix protein folding and represent the key protein-complex of the mitochondrial unfolded protein response (UPRmt) which is induced by the accumulation of misfolded/unfolded proteins. UPRmt is crucial for neuronal health and brain function and knockdown (KD) of UPRmt genes causes metabolic alterations and neurodegeneration. Thus understanding the metabolic regulation of these chaperones and identifying positive regulators for this pathway is vital to ensure proper brain function. Here, we investigate the effect of insulin action on UPRmt regulation and mitochondrial function *in vitro* using hypothalamic neurons and *in vivo* by characterizing the regulation of UPRmt in insulin-resistant brains.
Materials and methods: To this end, we analyzed the expression of key regulators of the UPRmt in insulin deficient and resistant brains using db/db mice, streptozotocin-induced diabetic mice along with C57BL/6N mice on a high fat diet. To address the effect of insulin or insulin resistance on gene and protein expression, we either treated the hypothalamic cell line CLU183 with 100 nM of insulin or mimic insulin-resistance by pretreating cells with 250 μM palmitate. Following we analyzed mitochondrial chaperones expression levels and mitochondrial respiration using the Seahorse XF Analyzer. To further emphasize the direct effect of insulin, we investigated insulin-induced regulation of key proteins of the UPRmt using qPCR and western blot technique.
Results: We observed that T2D mice suffer from brain insulin resistance together with mitochondrial dysfunction which are linked to reduced levels of Hsp60 and 10. Interestingly, mouse models deficient for insulin signaling or exhibiting reduced insulin sensitivity showed a reduction in brain specific Hsp60 and Hsp10 expression by ~50% along with a decrease of their transcription factor CHOP, a key mediator of UPRmt and ER stress. Fitting to these data, we could also demonstrate that the gene expression of Hsp60 and Hsp10 in serum-starved hypothalamic cells over the course of 24 hours is decreased by 15–30%. Palmitate-induced insulin resistance also causes decreased Hsp60 protein expression with a concomitant reduction in basal mitochondrial respiration. Conversely, both chaperones are upregulated by 25–60% after 16h of 100 nM insulin stimulation in hypothalamic neurons on mRNA and protein expression level, as well as a four-fold increased gene expression of CHOP, demonstrating that hypothalamic UPRmt is controlled by insulin action.
Conclusion: In conclusion, we were able to demonstrate for the first time that the hypothalamic UPRmt genes Hsp60 and Hsp10 are insulin regulated genes. Along with it, our results show clearly the importance of functional insulin signaling for the regulation of UPRmt and with this, the ill-fate of mitochondrial function in an insulin-resistant brain.

BMP9 in the hypothalamus regulates hepatic glucose production and hepatic insulin sensitivity through the central PI3K/Akt/mTOR pathway

Q. Li[1], L. Li[1], G. Yang[2];
[1]Key Laboratory of Diagnostic Medicine (Ministry of Education) and Department of Clinical Biochemistry, Chongqing Medical University, Chongqing, [2]Department of Endocrinology, the Second Affiliated Hospital, Chongqing Medical University, Chongqing, China.

Background and aims: Recent studies have shown that bone morphogenetic protein 9 (BMP9) whoes ligands are found to exist in hypothalamus is associated with glucose metabolism and insulin resistance (IR). However, the precise mechanism for how the central BMP9 signaling regulate hepatic glucose production (HGP) and IR remains unclear. The present study was designed to investigate the effects of BMP9 activity in hypothalamus on glucose metabolism and insulin sensitivity and explored the possible mechanism.
Materials and methods: We first performed intracerebroventricular (ICV) injections of adenovirus expressing BMP9 (Ad-BMP9) or adenovirus encoding enhanced green fluorescence protein (Ad-GFP) and evaluated activation of potential signaling candidates. Moreover we examined the expression of hypothalamic BMP9 in db/db, normal chow diet (NCD) feeding or high fat diet(HFD)-fed WT, Adipoq-/- mice and ICV Ad-BMP9 mice. Subsequently, energy expenditure was measured in mice treated with ICV Ad-BMP9 or Ad-GFP. We then examined the effects of overexpression of hypothalamic BMP9 and the hyperinsulinemic-euglycemic clamp (HEC) in NCD- or HFD-fed mice. Furthermore the mRNA and protein levels of PEPCK and G-6-Pase were examined to investigate the effects of ICV Ad-BMP9 on improving hepatic IR. We further examined the effects of ICV Ad-BMP9 on insulin's ability to promote the immunostaining of phosphatidylinositol 3, 4, 5-trisphosphate (PIP3) formation in the hypothalamic neurons.
Results: We found that BMP9 expression in the hypothalamus was downregulated in obese or IR mice. The overexpression of BMP9 in the hypothalamus decreased body weight, food intake and blood glucose, and elevated energy expenditure in HFD feeding mice. Importantly, central BMP9 ameliorated hepatic IR and suppressed HGP in HFD-fed mice. Central BMP9 induced hepatic insulin action and the related metabolic effects were abolished by ICV rapamycin, an inhibitor of the mTOR signaling. Furthermore, central BMP9 increased insulin's ability to promote insulin receptor (InsR) and Akt phosphorylation and to lead phosphatidylinositol 3, 4, 5-trisphosphate formation in hypothalamic neurons. Thereby, the current study provided the first evidence suggesting that activating BMP9 in hypothalamus ameliorates central IR by promoting insulin's ability to activate the mTOR/PI3K/Akt pathways and revealed that the central nervous system (CNS) may be an important target for the metabolic action of BMP9.
Conclusion: These findings reveal a novel role of BMP9 in CNS for the regulation of glucose metabolism and hepatic insulin sensitivity through the central PI3K/Akt/mTOR pathway in vivo.

Hepatocyte p110α controls insulin signalling but is dispensable for free fatty acid and glucose sensing

M. Regnier[1], A. Polizzi[1], C. Lukowicz[1], S. Smati[1], A. Fougerat[1], S. Ellero-Simatos[1], K. Anderson[2], F. Lasserre[1], Y. Lippi[1], J. Bertrand-Michel[3], L. Stephens[2], N. Loiseau[1], C. Postic[4], A. Montagner[3], H. Guillou[1];
[1]Toxalim, UMR 1331, Toulouse, France, [2]Babraham Institute, Cambridge, UK, [3]I2MC, Toulouse, France, [4]Institut Cochin, Paris, France.

Background and aims: Class IA phosphoinositide 3-kinase (PI3K) is involved in insulin signaling through the production of the second messenger phosphatidylinositol 3,4,5 tri-phosphate (PIP3). Mouse with hepatocyte-specific deletion of p110α ("p110α hep-/-"), the catalytic subunit of PI3Kα are glucose intolerant but protected from hepatic steatosis. We used a system biology approach to identify pathways regulated by p110α *in vivo*.
Materials and methods: In this study, p110α hep+/+ and p110α hep-/- were used in different nutritional states: fed, fasted and refed. We combined transcriptomic, lipidomic, proteomic, metabolomic and histological approaches. *In vivo* studies were conducted under the EU guidelines for the use and care of laboratory animals, and they were approved by an independent Ethics Committee.
Results: As previously reported, we confirm that p110α deletion leads to glucose intolerance without steatosis in response to aging and to high fat-induced obesity. We also provide evidence that "p110α hep-/-" mice have normal circadian control of liver transcriptome. Then, we investigated the influence of hepatocyte p110α-dependent signaling on liver transcriptome and proteome in fed and in fasted mice. In line with the role of PI3Kα in insulin signaling, we observed that major transcriptional targets of insulin are disrupted when p110α is lacking in fed mice. This is associated with decreased phosphorylation of insulin-activated proteins. Interestingly, we show that this depends in a 50% reduction in PI(3,4,5)P3 production in response to insulin *in vivo*. However, we found that p110α is dispensable for Chrebp-mediated glucose sensing in hepatocytes. More surprisingly, in fasted mice, p110α deficiency is also very influential on liver transcriptome and lipidome. Gene ontology analysis revealed a major effect on PPARα signaling. Given the well-established role of PPARα in fasting, we further analysed the expression of PPARα target genes in "p110α hep-/-" mice. These genes, including the hepatokine FGF21, which is produced by hepatocytes in a PPARα-dependant response to adipose lipolysis, were highly increased in "p110α hep-/-" fasted mice. Conversely, p110α is dispensable for the inhibition of PPARα target during refeeding. This led us to postulate that, in "p110α hep-/-" mice, the fasting-induced changes in PPARα activity leading to an increase in FGF21 expression and secretion depends on adipose tissue fatty acid remodeling. Consistent with this hypothesis, we found that liver and adipose tissue fatty acid profile is modified in "p110α hep-/-" mice in response to fasting.
Conclusion: Altogether, our data evidence that liver p110α dependent effect on AKT is dispensable for glucose and free fatty acid signaling by CHREBP and PPARα respectively. Moreover, we highlight lipolysis as the dominant signal for hepatocyte PPARα activity.

Longitudinal study of the pathogenesis of hepatic insulin resistance in diet-induced obese mice

C. Geißler[1], C. Krause[1], M. Kähler[2], I. Cascorbi[2], H. Kirchner[1];
[1]Medical Department I, University of Lübeck, Lübeck, [2]Institute of Experimental and Clinical Pharmacology, University Hospital Schleswig-Holstein, Kiel, Germany.

Background and aims: Excess caloric intake leads to obesity and insulin resistance, which is also associated with hepatic fat accumulation. The transition from glucose tolerance to insulin resistance is characterized by altered expression of metabolically relevant genes. As longitudinal studies are scarce, it often remains unclear when this shift happens and whether these changes are cause or consequence of insulin resistance. Therefore we designed a longitudinal experiment in mice to study alterations in gene expression during the development of insulin resistance and to identify the timepoint of the metabolic switch.
Materials and methods: Our longitudinal study based on the frequently used diet-induced obesity model of C57BL/6N mice that were fed high fat diet (HFD) containing 60% fat for up to 12 weeks. Control mice were fed with standard chow. After 1, 2, 4, 8 and 12 weeks 8 mice of each group underwent an i.p. glucose tolerance test and the day after mice were sacrificed for tissue collection. RNA and DNA was extracted from liver. To identify differentially regulated metabolic pathways and genes in early and/or late stages of insulin resistance in liver a transcriptome profiling using microarrays was performed. Differentially expressed genes were validated by qRT-PCR. Hepatic triglyceride (TG) levels were determined by a calorimetric assay. For statistical analysis a 2-Way ANOVA with Holm-Bonferroni correction was used.
Results: The glucose tolerance test revealed that 8 weeks of HFD are sufficient to induce glucose intolerance ($p = 0.0005$). Short term feeding with HFD for 1 and 2 weeks led to slightly elevated TG-levels ($p < 0.01$ and $p < 0.0001$, respectively). HFD-feeding for 8 and 12 weeks led to excessive TG accumulation in the liver ($p < 0.0001$ for both). Pathway analysis of the differentially expressed genes revealed an involvement of the fatty acid metabolism and peroxisome proliferator-activated receptor (PPAR) signaling. 1 week of HFD-feeding resulted mainly in decreased expression of genes activated by PPAR signaling, for example *Fasn* (qRT-PCR data, fold change 0.32, $p < 0.0001$) and *Scd1* (qRT-PCR data, fold change 0.08, $p < 0.0001$), whereas 12 weeks of HFD-feeding induced higher mRNA level of genes activated by PPAR signaling, for instance *Cd36* (qRT-PCR data, fold change 7.52, $p < 0.0001$).
Conclusion: These results indicate that feeding a diet rich in fat causes glucose intolerance after already 8 weeks. However, even before manifestation of the insulin resistance gene expression of metabolically important genes is altered. The transcriptome profiling shows a distinct expression pattern of genes at early and late timepoints in liver. The results indicate a metabolic switch between week 4 and week 8 of HFD-feeding. In the future we will analyze if epigenetic mechanisms are responsible for this switch in hepatic gene expression and diabetes etiology.

Leptin therapy suppresses alanine utilisation in type 1 diabetic mice independent of glutamic pyruvic transaminase

M.M. Kwon[1], S. Chen[2], R.K. Baker[1], P.R. Cullis[2], T.J. Kieffer[1];
[1]Cellular and Physiological Sciences, University of British Columbia, Vancouver, [2]Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada.

Background and aims: Leptin lowers blood glucose levels in diabetic rodents and decreased glucose production in the liver has been suggested to be the mechanism. Since the amino acid alanine is a substrate for glucose production, we sought to determine whether alanine utilization is suppressed by leptin and assess the role of glutamic pyruvic transaminase (*Gpt*), the gene responsible for alanine catabolism, in leptin action.
Materials and methods: We administered leptin by pumps to streptozotocin (STZ)-diabetic mice and performed alanine tolerance tests

and pyruvate tolerance tests as a comparison on day 5 post pump implant. Alanine tolerance tests pointed towards decreased alanine utilization, and the gene responsible for alanine catabolism, *Gpt*, was downregulated in leptin treated STZ-mice. To determine whether this downregulation of *Gpt* is required and sufficient for the anti-diabetic actions of leptin, we performed 2 complementary studies. We overexpressed *Gpt* in the liver of STZ-diabetic mice by hydrodynamic gene delivery then tested the efficacy of leptin therapy 4 days after plasmid injection. In another study, we used siRNA encapsulated in nanoparticles to knockdown *Gpt* in the liver of STZ-diabetic mice then tracked blood glucose levels.

Results: Upon observing normalization of blood glucose levels in leptin treated STZ-mice (22.2 ± 0.4 vs 15.2 ± 5.7 mM day -1 and day 3), STZ-leptin and non-diabetic controls were fasted to the point of mild hypoglycemia and injected with alanine or pyruvate on day 5. In non-diabetic controls, alanine injection increased blood glucose levels (4.7 ± 0.1 vs 6.9 ± 0.4 mM at 0 and 30 minutes), and injection of pyruvate, the breakdown product of alanine, also increased blood glucose levels (4.7 ± 0.2 vs 11.2 ± 0.3 mM at 0 and 30 minutes). In contrast, alanine did not increase blood glucose levels in leptin treated STZ-mice (5.4 ± 0.5 vs 4.5 ± 0.5 mM at 0 and 30 minutes) but injection of pyruvate increased blood glucose levels in leptin treated STZ-mice (5.8 ± 0.6 vs 9.3 ± 0.9 mM at 0 and 30 minutes). These data suggest that alanine breakdown may be blocked by leptin; thus, we measured *Gpt* transcript levels in the liver. *Gpt* transcript levels were downregulated by ~2 fold in leptin treated mice compared to STZ-diabetic controls on day 4 ($p < 0.0001$). Administration of plasmid encoding *Gpt* to leptin treated STZ-mice led to overexpression of *Gpt* in the liver by ~3 fold compared to leptin treated mice receiving empty plasmids as controls ($p = 0.02$). Leptin similarly lowered blood glucose levels in STZ-mice with overexpression of *Gpt* (9.7 ± 0.6 mM) and controls (8.8 ± 0.8 mM) by day 7 post leptin therapy. In a separate study, *Gpt* siRNA led to knockdown of *Gpt* in the liver by ~5 fold and ~10 fold for low and high doses of siRNA, respectively, compared to negative controls receiving *F7* siRNA ($p < 0.01$ for both low and high). STZ-mice with knockdown of *Gpt* remained hyperglycemic on day 10 post siRNA delivery (23.2 ± 0.9 and 23.4 ± 0.9 mM for low and high) comparable to *F7* siRNA controls (24.7 ± 0.7 and 24.6 ± 0.4 mM for low and high doses).

Conclusion: Leptin treated STZ-mice cannot utilize alanine to produce glucose but their ability to utilize pyruvate, a product of alanine breakdown, remains intact. *Gpt*, the gene responsible for alanine breakdown is downregulated by leptin but this is neither required nor sufficient for the anti-diabetic actions of leptin.

Circular dorsal ruffles and IR internalisation

M. Araujo-Correia[1,2], R. Machado de Oliveira[1], D.C. Barral[1], M. Macedo[1];

[1]CEDOC - Centro de Estudos de Doenças Crónicas, Lisboa, [2]ProRegeM - Doctoral Programme in Mechanisms of Disease and Regenerative Medicine, Lisboa, Portugal.

Background and aims: In the postprandial state, insulin is released from the pancreas into the bloodstream, targeting insulin-sensitive organs such as liver, promoting glycolysis and lipogenesis, and skeletal muscle allowing for glucose uptake. Insulin binds to its receptor (IR) at the surface, and the newly-formed complex is rapidly internalized into the cell. Insulin-IR uncoupling leads to signal termination, and to either receptor degradation in lysosomes or recycling to the plasma membrane. The internalization and endocytic process can be mediated by clathrin and caveolin vesicles, or be independent of these proteins. Circular dorsal ruffles (CDRs) are ring-shaped actin-rich structures that form exclusively at the dorsal surface of cells between 5 and 30 min after growth factor stimulation. These are dynamic and transient structures, responsible for tyrosine kinase receptor internalization and fast recycling. IR internalization and trafficking are crucial for peripheral insulin bioavailability, through the balance between insulin secretion and clearance, and to maintain glucose homeostasis in its target organs. Here, we propose that **CDRs are a non-canonical pathway involved in the internalization and fast recycling of the IR both in liver and skeletal muscle, and that this pathway can be disrupted by NO-induced inflammation.**

Materials and methods: Hepa 1-6 mouse hepatocytes, primary mouse hepatocytes and L6 rat muscle cells were used to characterize IR internalization. Cells were insulin stimulated for different timepoints, and processed for immunofluorescence, using phalloidin and cortactin (actin cytoskeleton), as well as antibodies against the IR and nitric oxide sintase (NOS). We also impaired CDR formation by silencing WAVE1, to understand the impact of the absence of these structures in the insulin signaling pathway. Finally, to mimic an inflammatory environment, we overexpressed iNOS and further assessed CDR formation.

Results: Our results show that, upon insulin stimulation, Hepa 1-6 cells and primary mouse hepatocytes form CDRs. We detect CDRs as early as 1 min after stimulation and observe that IR localizes to these structures, suggesting that CDRs mediate IR internalization. Moreover, CDRs are also present in stimulated L6 rat muscle cells, suggesting an important role for these structures in IR internalization in insulin-sensitive tissues. The number of cells with CDRs also increases with increasing insulin concentrations. Preliminary results suggest that disruption of CDR formation by WAVE1 silencing leads to impaired insulin signaling, as inferred by a decrease in Akt phosphorylation. Finally, iNOS overexpression leads to a decrease in CDR formation when compared to sham-transfected cells, suggesting that an inflammatory environment might disrupt this pathway, therefore IR internalization.

Conclusion: Herein, we observed insulin-induced CDR formation in hepatocytes and skeletal muscle cells. Moreover, CDR disruption impairs the insulin signaling pathway and that inflammation impairs CDR formation. This IR internalization route might be a major contributor for the receptor's availability to activate insulin signaling pathways and promote glucose uptake, but also in the insulin internalization itself, allowing for the fast recycling of the receptor and for insulin to fulfill its functions and be metabolized in the liver.

Effects of the novel dual GLP-1R/GCGR agonist SAR425899 on postprandial glucose metabolism in overweight/obese subjects with type 2 diabetes

B. Goebel[1], M. Schiavon[2], R. Visentin[2], M. Riz[1], C. Dalla Man[2], C. Cobelli[2], T. Klabunde[1];
[1]Sanofi, Frankfurt, Germany, [2]University of Padova, Padova, Italy.

Background and aims: SAR425899 is a novel dual glucagon-like peptide-1 receptor/glucagon receptor (GLP-1R/GCGR) agonist. A randomized, double-blind, phase I multiple-ascending-dose study in 27 overweight/obese subjects with type 2 diabetes receiving SAR425899 demonstrated decreased body weight with a safety profile comparable with GLP-1R agonists. Here, we report additional analyses of the effect of SAR425899 on key processes in glucose metabolism.
Materials and methods: Subjects were randomized to receive daily subcutaneous administrations of low-dose SAR425899 (30, 60, 90 μg) or high-dose SAR425899 (60, 120, 180 μg) for 28 days; dose escalation occurred after Days 7 and 14. Mixed meal tests were conducted before treatment (Day −1) and on Days 1 and 28. Oral glucose and C-peptide minimal models were used to quantify metabolic indices of glucose absorption, insulin sensitivity, and β-cell responsiveness.
Results: High-dose SAR425899 had positive effects on glucose control from Day 1. Percent change in area under the curve for rate of meal glucose appearance between 0 and 120 min from Day −1 to Day 28 was −14% and −19% with low- and high-dose SAR425899, respectively. Change in insulin sensitivity was 104% and 262%, respectively. Change in β-cell function was 127% and 145%, respectively (Table).
Conclusion: After 28 days of treatment, SAR425899 improved postprandial glucose control by significantly reducing glucose absorption rate, increasing insulin sensitivity, and enhancing β-cell function.

MEDI0382, a dual GLP-1 glucagon receptor agonist, promotes rapid glucose control and significant weight loss in patients with type 2 diabetes

V. Parker[1], P. Ambery[1], D. Robertson[1], M. Posch[2], L. Plum-Moerschel[3], T. Wang[4], M. Petrone[1], T. Heise[5], J. Meier[6], B. Hirshberg[4];
[1]MedImmune, Cambridge, UK, [2]Charité Research Organisation GmbH, Berlin, Germany, [3]Profil, Mainz, Germany, [4]MedImmune, Gaithersburg, USA, [5]Profil, Neuss, Germany, [6]Ruhr-University, Bochum, Germany.

Background and aims: MEDI0382 is a GLP-1/glucagon receptor dual agonist under development for the treatment of type 2 diabetes mellitus and nonalcoholic steatohepatitis. Balanced GLP-1 and glucagon receptor agonism is predicted to achieve improved glycemic control with clinically significant weight loss via increased energy expenditure and central effects on appetite. The primary objective was to evaluate glucose AUC reduction during a mixed-meal test and body weight change in cohort 1.
Materials and methods: A randomized double-blind placebo-controlled phase 2a study was undertaken to evaluate the efficacy of MEDI0382 and tolerability in different titration schedules. Subjects recruited ($n = 65$) had type 2 diabetes mellitus and were on metformin monotherapy with an HbA1c of 6.5–8.5% and body mass index of 27–40 kg/m^2. Subjects received once-daily subcutaneous MEDI0382 uptitrated from 50 μg to 300 μg in either one or two weekly titration steps (cohorts 1 and 2, respectively) or placebo.
Results: After 49 days of dosing, significant weight loss of 3.4% (3.3 kg) vs placebo, ($P = 0.002$; Figure 1) was observed and 11/26 (42.3%) achieved weight loss of ≥5% ($P = 0.040$). Both postprandial and fasting glucose were significantly decreased; −27.8% for glucose AUC vs placebo ($P < 0.001$) and −1.8 mmol/L for fasting glucose vs placebo ($P < 0.001$). This equated to a reduction in HbA1c of 0.6% vs placebo ($P < 0.001$). Remarkably, this improvement in glycemic parameters was evident after just 7 days of dosing of 50 μg of MEDI0382 (glucose AUC, −27.4% vs placebo, $P < 0.001$ and fasting glucose −1.85 mmol/L vs placebo, $P < 0.001$). Treatment-related adverse events occurred more often with MEDI0382 (31/46 = 67.4%), the most frequent being decreased appetite in 13/46 (28.3%). Nausea and vomiting were recorded in 5/26 (19.2%) and 3/26 (11.5%) after weekly titration and 7/20 (35%) and 4/20 (20%) after two-weekly titration. A significant increase in heart rate of 7.8 bpm was observed after 49 days of dosing, but there were no significant changes in systolic or diastolic blood pressure.
Conclusion: MEDI0382 administered for up to 49 days promoted significant weight loss and led to rapid reduction in both fasting and postprandial glucose levels. The tolerability profile in cohort 1 was comparable to that of marketed GLP-1 analogs; lengthening the titration interval did not improve gastrointestinal tolerability.
Figure 1. Weight loss in kilograms in cohort 1.

Neuroprotective effects of HM15211, a novel long-acting GLP-1/GIP/glucagon triple agonist in the neurodegenerative disease models

J. Kim, S. Lee, S.-H. Lee, S. Jung, Y. Kim, I. Choi, S. Kim;
Hanmi Pharm. Co., Ltd., Seoul, Republic of Korea.

Background and aims: HM15211 is a novel long-acting GLP-1/glucagon/GIP triple agonist that is being developed for the treatment of obesity and non-alcoholic fatty liver disease (NASH). Accumulating evidences have shown that obesity, type 2 diabetes, and NASH increase the risk of

developing progressive neurodegenerative disease such as Parkinson's disease (PD) and Alzheimer's disease (AD). In addition to peripheral contributions, each of incretins consisting HM15211 have neuroprotective effects in several brain diseases like AD, PD, and ischemia. Previously, we demonstrated that HM15211 exerted neuroprotective effects in MPTP induced subacute Parkinson's disease mice model. Here, we evaluated 1) the neuroprotective effects of HM15211 in chronic MPTP/probenecid Parkinson's disease model, and 2) the protection of Alzheimer's disease progression in db/db mice.

Materials and methods: Chronic Parkinson's disease mice model was induced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in combination with probenecid intraperitoneal injection, twice a week for 5 weeks and HM15211 was subcutaneously administered once a week for 6 weeks. A db/db mice are well-established diabetic model and reported that db/db mice develop hyperphosphorylation of tau as they grew older. Thus we chose db/db mice to elucidate the prophylactic effect of HM15211 on Alzheimer's disease. Six weeks old db/db mice were subcutaneously treated with HM15211, once every two days for 12 weeks. For motor function evaluation of chronic PD model, the traction test, pole test and rotarod test were conducted before sacrifice. To assess the histological changes, hemi brain of all mice were sectioned and stained. And for the molecular changes, striata of chronic PD model and cortex were dissected from the other hemi brain and lysed with RIPA buffer and assayed with ELISAs.

Results: Dopaminergic neuronal death in MPTP/probenecid induced chronic PD model was confirmed by immunohistochemistry against tyrosine hydroxylase. The dopaminergic neuronal death was protected by HM15211, which was derived from anti-inflammatory and anti-oxidative stress effect by HM15211. Also HM15211 decreased alpha synuclein in striatum of chronic mice PD model. Together with these efficacies, HM15211 significantly improved the MPTP/probenecid induced motor impairments in behavior tests (rotarod, pole test, and traction test). In db/db mice, after 12 weeks of treatment, HM15211 reversed inflammatory cytokines and oxidative stress marker, which were increased in db/db mice. Also, increased phosphorylated tau in db/db mice was decreased by HM15211.

Conclusion: Based on these observations, HM15211 might be a potential therapeutic option for the neurodegenerative disease.

MEDI4166, a novel antibody-peptide fusion molecule: multiple-ascending-dose study in patients with type 2 diabetes

G. Carlson[1], W. Cook[2], L. Morrow[3], M. Petrone[4], N. White[4], T. Wang[2], P. Ambery[4], B. Hirshberg[2], M. Jain[4];
[1]AstraZeneca, Gaithersburg, USA, [2]MedImmune, Gaithersburg, USA, [3]ProSciento, Chula Vista, USA, [4]MedImmune, Cambridge, UK.

Background and aims: Glucagon-like peptide-1 (GLP-1) agonists are widely utilized for the treatment of type 2 diabetes mellitus (T2DM) with proven effects on glycemic control and, in some cases, beneficial effects on cardiovascular (CV) outcomes. High-intensity statin therapy is recommended in T2DM patients with established CV disease and those at increased CV risk. However, some T2DM patients at high CV risk may require additional lowering of their low-density lipoprotein (LDL)-cholesterol (LDL-c) levels or may be intolerant to high-intensity statin therapy. Blockade of antiproprotein convertase subtilisin/kexin type 9 (PCSK9) is an effective method to lower LDL-c and decrease CV risk by decreasing degradation of the LDL receptor. MEDI4166 is a novel antibody-peptide genetic fusion molecule comprising a PCSK9 antibody and a GLP-1 agonist. Its dual mechanisms of action are designed to lower glucose and LDL-c in patients with T2DM, with the potential to reduce CV risk.

Materials and methods: In this multicenter, double-blind, placebo-controlled, multiple-ascending-dose study, adult subjects with T2DM receiving metformin monotherapy and LDL-c ≥70 mg/dL were randomized to receive subcutaneous MEDI4166 once weekly for 5 weeks at doses of 50 mg [(n = 9), 200 mg (n = 18), or 400 mg (n = 21), or placebo (n = 15) in 3 separate cohorts. The co-primary endpoints were change from baseline to day 36 in LDL-c and area under the plasma glucose concentration-time curve ($AUC_{0\text{-}4h}$) after a mixed-meal tolerance test (MMTT).

Results: Overall, 63 subjects were randomized, of which 55 (87%) completed the study. After multiple doses of MEDI4166, LDL-c levels were significantly decreased vs placebo (Table); no statistically or clinically significant reductions in glucose $AUC_{0\text{-}4h}$ after MMTT were observed. The pharmacokinetic profile supported weekly dosing. Adverse events (AEs) occurred in 79% (38/48) of MEDI4166 treated subjects and 87% (13/15) placebo treated subjects. Gastrointestinal symptoms and injection site reactions were the most common AEs in both groups. No serious AEs were observed. Two subjects discontinued from the study due to AEs; 1 subject in MEDI4166 200-mg dose group due to hyperglycemia considered unrelated to the investigational product, and 1 subject in the placebo group due to dyspepsia. One subject in the 50-mg and 5 subjects in the 400-mg groups discontinued for other reasons. No significant laboratory, vital sign, or ECG abnormalities were identified. Of 48 subjects receiving MEDI4166, 11 (22.9%) showed a treatment-induced antidrug antibody response.

Conclusion: After multiple weekly dosing with MEDI4166 across the dose range of 50–400 mg, significant dose-dependent reductions in LDL-c were observed. There was no improvement in postprandial glucose control versus placebo. Overall, MEDI4166 was well tolerated.

Impact of praliciguat, a soluble guanylate cyclase stimulator, on blood pressure and metabolic parameters in patients with diabetes and hypertension

J.P. Seferovic[1], P. Wilson[1], K.E. Carlson[1], J. Jung[1], J.D. Wakefield[1], P. Miller[1], J.G. Chickering[1], L. Morrow[2], M.G. Currie[1], G.T. Milne[1], A.T. Profy[1], J.P. Hanrahan[1];
[1]Ironwood Pharmaceuticals Inc., Cambridge, [2]ProSciento, Inc., Chula Vista, USA.

Background and aims: Praliciguat (IW-1973), a soluble guanylate cyclase stimulator, increased nitric oxide (NO)-mediated signaling and reduced fasting plasma glucose and proteinuria in an animal model of diabetic nephropathy. In healthy subjects, repeated oral doses of praliciguat (15–40 mg) were well tolerated and lowered blood pressure (BP). We evaluated 2 dosing regimens of praliciguat in a phase 2a trial in patients with type 2 diabetes mellitus (T2DM) and hypertension (HTN).

Materials and methods: In a double-blind, randomized, placebo (PBO)-controlled trial, the effects of oral praliciguat were assessed in 26 patients with T2DM and HTN on stable antihyperglycemic and BP-lowering therapies. Two praliciguat regimens were evaluated: 1) 40 mg once daily (QD) for days 1–14 (N = 10), and 2) 20 mg twice daily for days 1–7 then 40 mg QD for days 8–14 (N = 10). Fasting plasma glucose, serum lipids,

apolipoprotein B, and BP (by 24-h ambulatory BP monitoring; ABPM) results are presented. Least squares mean differences from PBO and associated 95% confidence intervals (LSM [95% CI]) from analysis of covariance models with treatment as a fixed effect and baseline as a covariate are shown. Post-hoc subgroup analyses by concomitant medication use and baseline BP levels were also performed.

Results: Results were similar for both regimens after 14 days of treatment and were therefore combined. Relative to PBO, praliciguat-treated patients overall had decreases in fasting plasma glucose (−13 mg/dL [−32, 7]) and in the subgroup of 16 patients who were using only oral antihyperglycemic agents without insulin (−19 mg/dL [−37, −2]). A similar trend was observed in this subgroup of patients in homeostatic model assessment of insulin resistance-HOMA-IR (−23% [−56, 9]). Total and low-density lipoprotein cholesterol decreased in praliciguat-treated vs. PBO patients overall (−26 mg/dL [−44, −7]) and −20 mg/dL [−37, −3], respectively) and in the subgroup of 18 patients on concomitant statin therapy (−17 mg/dL [−44, 10] and −16 mg/dL [−41, 9], respectively). Lowering of apolipoprotein B levels was also suggested to be more pronounced after praliciguat compared to PBO treatment overall (−119 μg/mL [−295, 57]) and in those on statin therapy (−61 μg/mL [−281, 160]). There were decreases in 24-h ABPM mean arterial pressure (MAP) in praliciguat- vs. PBO-treated patients, overall (−5 mmHg [−10, 1]) and in subgroup of 10 patients with baseline MAP >92 mmHg (overall median at baseline; −14 mmHg [−23, −5]). In contrast, these decreases were not observed in the subgroup with baseline MAP ≤92 mmHg (2 mmHg [−4, 8]). A similar pattern was seen for both systolic and diastolic BP. Tolerability of praliciguat was acceptable in this trial.

Conclusion: In this small study, praliciguat lowered fasting plasma glucose and lipid levels in T2DM patients with HTN on standard therapies, including oral antihyperglycemic agents and statins. These results suggest that praliciguat may lower BP in these T2DM patients, especially those with higher baseline BPs. The metabolic and hemodynamic effects of praliciguat are being further evaluated in ongoing studies of diabetic nephropathy and heart failure with preserved ejection fraction.

Effect of leptin replacement therapy (LRT) on survival and disease progression in generalised and partial lipodystrophy (GL, PL)

K. Cook[1], O. Ali[1], D. Gupta[1], D. Holmqvist[1], D. Lee[1], C. Ng[1], P. Bradt[2], R. Brown[3];
[1]Analysis Group, Menlo Park, [2]Aegerion Pharmaceuticals, A Novelion Therapeutics Company, Cambridge, [3]National Institutes of Health, Bethesda, USA.

Background and aims: Lipodystrophy (LD) is an ultra-rare disease associated with significant morbidity and mortality. Effects of LRT on metabolic disease in GL and PL have been studied; but effects on mortality are unknown. We investigated these effects using data from GL and PL patients treated with LRT at the NIH ($N = 114$) and cared for but not treated with LRT at 3 centers in the US and Turkey ($N = 178$).

Materials and methods: Four abnormalities (liver, kidney, heart, and HbA1c ≥6.5%) were considered. LRT patients had a mean of 2.8 abnormalities prior to treatment, while the mean for untreated patients was 0.7 at a similar age. We used a matching approach to create comparable samples of treated and untreated patients. Each treated patient was matched (using Mahalanobis distance) to an untreated patient to balance across age, gender, type of LD, and number of abnormalities. LRT treatment effect was examined via Cox proportional hazards models of 1) mortality and 2) development of subsequent abnormalities. Additionally, the relationship between abnormalities and mortality was studied in the sample of untreated patients.

Results: A Cox proportional hazards model relating treatment to mortality yielded a hazard ratio for LRT of 0.34 ($p = 0.047$), meaning that LRT was associated with a 66% decrease in mortality risk. Adjusting for covariates including gender, type of LD, and type of organ abnormality results in a larger decrease in mortality risk (HR 0.21, $p < 0.01$). One possible mechanism for the effect of LRT on mortality is its role in mitigating or resolving organ abnormalities. A time-varying Cox proportional hazards model relating number of abnormalities present (0 to 4) to mortality among untreated patients found a positive relationship between additional abnormalities and mortality (HR 3.2, $p < 0.01$). Separately, we found that LRT reduced the likelihood of developing a third (HR 0.47, $p < 0.01$) or fourth abnormality (HR 0.46, $p < 0.05$).

Conclusion: These are the first data suggesting that LRT reduces mortality in LD.

Placental microRNA expression patterns in pregestational diabetes and identification of specific potential biomarkers

A. Ibarra[1], B. Vega[2,3], M. Armas[2,3], D. González[2,3], S. Perera[4], R. Horres[5], R. Valls[4], J.C. Wiebe[3], A.M. Wägner[1,3];
[1]Endocrinology, Complejo Hospitalario Universitario Insular Materno Infantil de Canarias, Las Palmas de Gran Canaria, Spain, [2]Gynecology, Complejo Hospitalario Universitario Insular Materno Infantil de Canarias, Las Palmas de Gran Canaria, Spain, [3]Instituto Universitario de Investigaciones Biomédicas y Sanitarias. Universidad de Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain, [4]Anaxomics SL, Barcelona, Spain, [5]GenXPro GmbH, Frankfurt, Germany.

Background and aims: Offspring of mothers with type 1 diabetes (T1D) are at increased risk of developing T1D, but have a lower risk than offspring of fathers with T1D. This could be explained by intrauterine, epigenetic effects, detectable at birth. Our aim was to assess the effect of maternal T1D on placental expression of miRNAs.

Materials and methods: Samples of the maternal and foetal sides of the placenta were obtained from women with T1D ($N = 38$, 3rd trimester HbA_{1c} 6.4 (0.9)%) and type 2 diabetes (T2D) ($N = 32$, HbA_{1c} 6.1 (0.7)%), women whose partner had T1D ($N = 15$) and controls matched for age and gestational age ($N = 59$). In ten "pools" of 8–10 samples, massive sequencing of mRNA and miRNAs was performed. Selecting miRNAs with a difference in expression between groups ($p < 0.1$) and an inverse difference in the target mRNAs (fold-change <−1/>1), 5 new and 8 known miRNAs were identified. The following were selected for validation via qPCR (EXIQON miRCURY Universal RT Kit; cel-miR-39-3p as internal control) in the individual samples in each pool: miR-372-3p2, miR-127-3p, miR-145-5p, miR-373-3p2, miR-125b-5p, miR-19a-5p, miR-20a-5p and novel Chr11-134. Quantile normalisation was performed and ΔCT values (with miR-16-5p as reference due to its stable expression across groups) were compared (pair-wise, cluster- and principal component analysis (PCA). Data mining techniques were also used to identify potential biomarkers (single miRNAs or combinations of 2–3) specific for T1D and T2D (foetal and maternal sides of the placenta). Feature normalization, selection, extraction and transformation were followed by the application of base classifiers (binomial GLM and naive Bayes). Validation was performed using the "leave one out" method. Classifiers with a cross validated $p < 0.05$ and a cross-validated balanced accuracy >70% were considered.

Results: Analysis of the first 96 samples revealed that the miRNAs that best discriminate the T1D group from the control groups are 19a-5p, 125b-5p, 20a-5p and Chr11-134. The table shows the most relevant classifiers for T1D and T2D. Replication in 188 additional samples is ongoing.

Conclusion: MiRNA expression patterns can distinguish T1D placentas from controls. No common classifiers for T1D and T2D were identified, although two miRNAs were included as classifiers for both T1D and T2D on the maternal side of the placenta and another two on the foetal side of the placenta. Thus, these miRNAs could be related to intrauterine hyperglycemia, and are therefore interesting candidate classifiers for further study.

Inhibition of lncRNA Lincpint expression affects insulin secretion and apoptosis in mouse pancreatic beta cells

Y. Li[1], Y. Zhu[2], Q. Yuan[1];
[1]Department of Endocrinology, the first Affiliated Hospital of Nanjing Medical University, Nanjing, [2]Jiangsu Medical Magazine, Nanjing, China.

Background and aims: Insulin, which is produced and secreted from pancreas islet, is essential for maintaining glucose homeostasis. The decrease of insulin biosynthesis and islet mass may induce to β cell dysfunction, ultimately to various diabetes mellitus. Lots of transcription factors and microRNAs are found to modulate islet function, while a newly identified set of regulatory factors, the long noncoding RNAs (lncRNAs), are rarely known. LncRNAs are recognized as a new class of transcripts longer than 200nt that unable to translate into proteins. They regulate gene expression at transcription, epigenetic and translation levels. Moreover, lncRNAs participate in a variety of biological processes, such as cellular development, differentiation, and cell apoptosis. Recent evidence indicates that lncRNAs are involved in maintaining islet function and diabetes occurrence. Lincpint is a long intergenic noncoding RNA, and is necessary for development and cell function. Here, we investigated its biological functions in mouse pancreatic β cells both in vivo and vitro.

Materials and methods: Lincpint expression levels were detected in BALB/c mice tissues (including heart, liver, spleen, muscle, kidney, pancreas) and pancreatic islets from C57BL/KsJ-$lepr^{db}$/$lepr^{db}$ (db/db) mice and age-matched nondiabetic littermates by quantitative real time PCR (qRT-PCR). RNA interference was used to knockdown Lincpint expression in MIN6 cells and BALB/c mice. The effect of Lincpint on islets β cells proliferation, apoptosis and insulin secretion were assessed by MTT, flow cytometry and glucose stimulated insulin secretion (GSIS). Intraperitoneal glucose tolerance test (IPGTT), ELISA and immunohistochemistry were performed to evaluate the effect of Lincpint in vivo.

Results: Lincpint was highly expressed in pancreas compared to other tissues ($P < 0.05$) and rich in islets rather than exocrine glands from BALB/c mice ($P < 0.05$), but downregulated in db/db mice islets compared to littermates' ($P < 0.05$). Lincpint could be regulated by different concentrations of glucose in MIN6 cells ($P < 0.05$). Moreover, silencing Lincpint expression in vitro suppressed insulin synthesis and secretion ($P < 0.05$), and increased cell apoptosis ($P < 0.05$). In vivo, blood glucose, serum insulin and positive islet area were decreased after knockdown Lincpint expression ($P < 0.05$).

Conclusion: In our study, we demonstrated that Lincpint was highly expressed in nondiabetic mice pancreas and islets, but decreased in db/

db mice islet. As well as, Lincpint could affects insulin secretion and apoptosis in mouse pancreatic β cells. The present findings suggest that Lincpint may contribute to maintain β cells function, and is worthy for further investigation due to its potential for diabetes treatment.

Impact of type 2 diabetes-associated variants at the STARD10 locus on chromatin conformation and human beta cell function

M. Hu[1], P.J. Gadue[2], G.A. Rutter[3];
[1]Imperial College London, London, UK, [2]Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, USA, [3]Department of Medicine, Imperial College London, London, UK.

Background and aims: Genome-wide association studies (GWAS) have identified more than 100 *loci* in the human genome associated with type 2 diabetes. The majority of these are located in intergenic or intragenic regions suggesting that the implicated variants may alter chromatin conformation. This, in turn, is likely to influence the expression of nearby or more remotely located genes to influence beta cell function. At present, however, detailed molecular and functional analyses are still lacking for most of these variants. We recently analysed one of these loci, within the *STARD10* gene, and mapped five causal variants in an islet-specific enhancer cluster. Here, we aimed to understand how these variants affect enhancer activity and beta cell function.
Materials and methods: Human foetal pancreas-derived EndoC-βH1 cells were used throughout. Promoter-luciferase reporter, chromatin conformation capture, chromatin immunoprecipitation-qPCR, and glucose-stimulated insulin secretion (GSIS) assays were deployed to identify and assess the function of individual enhancers. CRISPR/Cas9 genome editing was used to create the required mutations or deletions.
Results: Using published ATAC-seq data, we sub-cloned 10 open chromatin regions (0.2–2 kb) at the *STARD10* locus and analysed their transcriptional activity using promoter-luciferase assays. Of these, one, termed HS1b, displayed a six-fold increase of luciferase activity [luciferase/renilla ratio: Control, 1.25 ± 0.06 *vs.* HS1b, 7.82 ± 0.17; Student's t-test, $p < 0.001$; $n = 3$]. Deletion of HS1b using CRISPR/Cas9 led to a significant reduction of *STARD10* expression (fold; Control 1 *vs.* HS1b-del, 0.486 ± 0.04; $p < 0.001$, $n = 3$) and a concomitant lowering of glucose-stimulated insulin secretion (GSIS) (15/0.5 mM glucose, fold change: control, 4.23 ± 0.41 *vs.* HS1b-del, 2.21 ± 0.06; $p < 0.05$; $n = 3$). Deletion of a 4.0 kb DNA region containing the five causal variants also reduced GSIS (15/0.5 mM glucose, fold change: Control, 1.70 ± 0.077 *vs.* SNPs-del, 1.36 ± 0.078; $p < 0.05$; $n = 3$) and lowered *STARD10* expression (fold: Control 1 *vs.* SNPs-del, 0.528 ± 0.042; $p < 0.001$, $n = 3$). Chromosome conformation capture assays (4C and 3C) identified two enhancer regions, HS1 and HS5, as interacting with the causal variants, including the indel rs140130268 with highest causal probability. Immunoprecipitation-qPCR assay using a CCCTC binding factor (CTCF) antibody confirmed the existence of multiple CTCF binding sites in both HS regions. To test the hypothesis that CTCF binding sites may create a chromatin loop defining an enhancer complex, we mutated four of the CTCF binding sites one by one. This resulted in a significant ($p < 0.05$; $n = 3$) impairment in GSIS assays [Control, 4.05 ± 0.46 *vs.* HS5-1-Mu, 2.75 ± 0.07; HS5-2-Mu, 2.66 ± 0.13; HS1-1-Mu, 3.49 ± 0.02 and HS1-2-Mu, 3.47 ± 0.57] and ~18–25% reduction in *STARD10* expression [Control, 1.0 *vs.* HS5-1-Mu, 0.82 ± 0.045; HS5-2-Mu, 0.74 ± 0.050; HS1-1-Mu, 0.82 ± 0.03; and HS1-2-Mu, 0.81 ± 0.043; $p < 0.05$; $n = 3$].
Conclusion: These data demonstrate that modification of enhancer elements at the *STARD10* locus affects beta cell function. The causal variants, which are physically associated with enhancer regions, are likely to exert their effects through the formation and activity of an enhancer-cluster complex which alters the expression of *STARD10* and possibly other genes.

Histone acetylation and transcriptome mapping reveals distinct glucose-regulated genomic regions mediated by histone acetyltransferase p300 in pancreatic beta cells

P. Bompada[1], P. volkov[1], R. Andersson[1], M. Bysani[1], S. Atanur[2], C. Luan[1], J. Omella[1], E. Renström[1], Q. Zhang[3], M. Ridderstråle[1], J. Ferrer[2], L. Groop[1], Y. De Marinis[1];
[1]Lund University, Malmö, Sweden, [2]Imperial College London, London, UK, [3]University of Oxford, Oxford, UK.

Background and aims: Histone acetylation is an essential part of gene regulation controlled by histone acetyltransferase (HAT). Previous studies showed that hyperglycemia induces histone 3 lysine 9 acetylation (H3K9ac) at gene promoters, which leads to gene expression changes. However, it is not known which genomic regions genome-wide are directly targeted by HATs at hyperglycemia, or how this may change histone acetylation and subsequently gene expression. In this study, we mapped global H3K9ac enrichment and gene expression changes induced by high glucose mediated by HAT p300 in pancreatic beta cell line INS 823/12.
Materials and methods: HAT p300 was silenced by CRISPR/Cas9 in INS1 832/13 cells. Wild-type (WT) and *Ep300* knock-out (KO) cells were treated in 5 (LG) or 25 mM (HG) glucose for 24 hours. For ChIP seq, cells were cross-linked by formaldehyde and chromatin was sonicated. DNA-protein complex was precipitated using H3K9ac antibody. Library was constructed on de-crosslinked DNA fragments and sequenced on Ilumina NextSeq 500. For RNA sequencing, mRNA was isolated by RNeasy and library was constructed using TruSeq Stranded Total RNA Library Prep Kit and sequenced on Illumina NextSeq 500.
Results: In WT cells, high glucose changed expression in 10453 genes (5042 upregulated and 5429 downregulated). When p300 KO was compared to WT at high glucose, 8943 genes were differentially expressed (4342 increased; 4600 decreased), among which 3040 genes overlapped with high glucose-sensitive genes in WT cells. The remaining 5902 genes were identified as glucose-sensitive p300-dependent genes. To understand if the gene expression changes caused by p300 KO were directly linked to histone acetylation enrichment facilitated by p300, we performed ChIP seq using H3K9ac antibody. Glucose induced changes in H3K9ac enrichment were observed in 240 genomic regions, 49% of which are in the promoter regions. Two were identified at transcription termination sites (TTS) in the Ins1 and Ins2 genes, and 32 in other intron/exon regions. When compared to WT-HG, p300 KO cells at high glucose had differential H3K9ac enrichment in 113 genomic regions, including 33% at the promoter regions. All differentially enriched H3K9ac are distributed among 21 chromosomes. Around 30% of H3K9ac changes in p300 KO (HG) were gene promoter acetylation decreases, which led to dramatic changes in respective gene expression detected by RNA seq. In the Ccnd2 (Cyclin D2) gene, H3K9ac decreased by ~5 fold at Ccnd2 promoter in p300 KO, which was associated with 600-fold decrease in the Ccnd2 gene expression. In nine genes, p300 KO led to increased H3K9ac enrichment and increased gene expression. The top gene is Stx16 (Syntaxin 16), p300 KO led to a 3-fold increase in H3K9ac at promoter, which was associated with 122-fold increase in Stx16 gene expression. Gcg (Glucagon) had 700-fold decrease in gene expression in p300 KO, but no significant H3K9ac changes were detected. This may imply that decreased Gcg gene expression may be mediated by other histone acetylation marks facilitated by p300, or this is a downstream effect via another gene expression changes.
Conclusion: Our study has revealed distinct genomic regions that are regulated by high glucose-induced H3K9ac enrichment changes mediated by HAT p300.

Role of microRNAs in the adipocyte morphology in relation to the family history of type 2 diabetes

P. Mirra[1], A. Desiderio[1], C. Nigro[1], M. Longo[1], L. Parrillo[1], R. Spinelli[1], F. Zatterale[1], F. Fiory[1], G.A. Raciti[1], U. Smith[2], F. Beguinot[1];
[1]URT GDD of the IEOS-CNR & University of Naples "Federico II", Napoli, Italy, [2]The Lundberg Laboratory for Diabetes Research at the University of Gothenburg, Gothenburg, Sweden.

Background and aims: Individuals with a family history (first-degree relatives, FDRs) of type 2 diabetes (T2D) are more likely to develop the disease, but the precise factors accounting for this increase in risk are poorly understood. However, emerging evidence suggests that epigenetic mechanisms, including microRNAs (miRNAs), may bridge genes and shared environmental components amongst family members. In euglycemic non-obese T2D-FDRs, metabolic defects have been reported and an impaired insulin sensitivity has been associated with signs of adipose tissue dysfunction and an enlarged cell size of subcutaneous adipocytes. To gain further insight into the pathogenesis of T2D, the present study aims at exploring the relationship between miRNAs and molecular mechanisms underlying the altered adipocyte morphology in euglycemic non-obese T2D-FDRs, focusing on targets that may be involved in the dysregulation of adipocyte number or size.
Materials and methods: Using the Illumina HiSeq 2000 platform, miRNA and mRNA expression profiles were examined in cultured adipose precursors from subcutaneous adipose tissue (scAT)-derived stromal vascular fractions (SVFs) of euglycemic non-obese T2D-FDRs ($n = 9$) and matched control subjects without any T2D familiarity ($n = 11$). Advanced analyses were applied to identify miRNAs and mRNAs differentially expressed between the two groups, in addition to miRNA-target interactions. Luciferase reporter assays were performed to test the proposed miRNA-target interactions.
Results: miRNA expression analysis in cultured adipose precursors from scAT-SVFs revealed 34 miRNAs differentially expressed between T2D-FDRs and controls, of which 23 are down- and 11 up-regulated. Subsequently, we confirmed that *miR-23a-5p*, *miR-193a-5p* and *miR-193b-5p* are significantly down-regulated in T2D-FDRs compared to controls. Interestingly, we observed a significant inverse correlation between the levels of each of these three miRNAs and the adipocyte cell size. Furthermore, using computational algorithms to predict miRNA targets, we realized that pathways related to adipocyte commitment/differentiation and function are enriched for these miRNAs. In addition, we integrated the mRNA expression data with the miRNA target predictions to support our proposal of new miRNA-target interactions and verified them using 3′UTR-reporter constructs and miRNA specific mimics in HEK 293 cells. Therefore, we demonstrated that the identified miRNAs may contribute to the up-regulation of IGF2 (insulin-like growth factor 2) and MXRA5 (Matrix Remodeling Associated 5), whose levels are positively and significantly correlated with the adipocyte cell size in euglycemic non-obese T2D-FDRs.
Conclusion: The decreased expression of *miR-23a-5p*, *miR-193a-5p* and *miR-193b-5p* observed in adipose precursors is a common feature of T2D-FDRs. Furthermore, our findings suggest an effective role of these miRNAs in adipocyte differentiation and/or function. Thus, they may be proposed as new biomarkers and/or targets for therapeutic interventions.

CRTC1 variants and DNA methylation in eating behaviour and adipose tissue biology in humans

L. la Cour Poulsen[1], K. Rohde[1,2], M. Keller[2], M. Stumvoll[2,3], A. Tönjes[3], P. Kovacs[2], A. Horstmann[4], A. Villringer[4,5], A. Dietrich[6], M. Blüher[2,3], Y. Böttcher[1,2];
[1]University of Oslo/Ahus, Lørenskog, Norway, [2]IFB Adiposity Diseases, Leipzig, Germany, [3]Dept. of Medicine, University of Leipzig, Leipzig, Germany, [4]Max-Planck-Institute for Human Cognitive and Brain Sciences, Leipzig, Germany, [5]Clinic of Cognitive Neurology, University of Leipzig, Leipzig, Germany, [6]Dept. of Surgery, University of Leipzig, Leipzig, Germany.

Background and aims: CREB-regulated transcription coactivator 1 (CRTC1) is involved in various biological processes including energy metabolism. Genetic variants within *CRTC1* (*e.g.* rs757318) have been related to body fat mass (BFM) and BMI in humans, while *CRTC1* knockout mice display clear changes in eating behaviour. We aimed at identifying genetic variants within *CRTC1* that are associated with eating behaviour in humans.
Materials and methods: 1,036 individuals from the Sorbs population were selected for initial analysis from which 540 completed the German 3-factor eating questionnaire. Using data obtained previously from a SNP array (blood), a total of 12 SNPs were extracted, and rs7256986 was newly genotyped. All variants were analysed for their association with eating behaviour, while only non-diabetics were included for analysis of the relation with metabolic and anthropometric variables. Analyses were done in additive, dominant and recessive modes of inheritance. Because rs7256986 introduces a CpG site, pyroseq was applied in a subcohort of $N = 42$ to test for differential methylation at this site, and its relationship to eating behaviour and to metabolic and anthropometric traits was tested. To validate our findings, a second independent German cohort with eating behaviour data was used ($N = 314$). A third cohort ($N = 77$) was used to analyse the impact of rs7256986 on *CRTC1* DNA methylation and gene expression in human adipose tissue from paired visceral (OVAT) and subcutaneous (SAT) depots. Calculations were completed using SPSS 24 and METAL. A P value over 0.05 was assumed to show correlation.
Results: Five SNP variants associate with eating behavior factors including restraint, disinhibition, and/or hunger while four relate further to alcohol or coffee intake ($P < 0.05$). Eight SNPs relate to alcohol intake only. Pyroseq at rs7256986 ($N = 42$) revealed that G-allele carriers have a 19.5 (genotype GG) or 10.7 fold (genotype GA) increase in DNA methylation as compared to homozygote A-allele carriers ($P < 0.0001$). Further, a neighboring CpG site was found to be co-methylated with higher methylation among GG carriers ($P < 0.01$). Methylation at both sites correlates with increased restraint ($P = 0.00025$). A meta-analysis on rs7256986 association with eating behavior using data from Sorbs and the second independent cohort shows the same trends for disinhibition and restraint. In the third independent cohort, G-allele carriers show increased *CRTC1* gene expression level ($P = 0.006$) and lower waist circumference ($P = 0.018$) as compared to AA-carriers. Further, *CRTC1* gene expression correlates positively with DNA methylation in OVAT ($P = 0.035$), while the latter is negatively associated with BFM ($P = 0.045$). Moreover, a negative correlation of DNA methylation ($P = 0.016$) and gene expression ($P = 0.023$) with BMI was observed.
Conclusion: Our data suggest an effect of *CRTC1* SNPs on eating behavior and DNA methylation. *CRTC1* gene expression relates to rs7256986 and DNA methylation in OVAT and, further, to BMI in an independent cohort, suggesting a potential role for *CRTC1* in adipose tissue biology.

OP 30 Retinopathy: a different look at the eyes

175

Perinatal starvation increases risk for diabetic retinopathy in adulthood

O. Fedotkina[1], R.B. Prasad[2], R. Jain[2], L. Cherviakova[3], N. Khalimon[4], T. Svietleisha[4], T. Buldenko[5], I. Artner[2], V. Kravchenko[6], A.M. Zhydenko[3], A. Vaiserman[7], M. Khalangot[6], P.M. Nilsson[2], V. Lyssenko[1,8];
[1]Department of Clinical Science, University of Bergen, Bergen, Norway, [2]Diabetes and Endocrinology, Department of Clinical Sciences, Lund University Diabetes Center, Lund, Sweden, [3]Chernihiv Regional Hospital, Chernihiv, Ukraine, [4]Chernihiv City Hospital, Chernihiv, Ukraine, [5]Public Health Authority of Chernihiv regional public administration, Chernihiv, Ukraine, [6]Komisarenko Instutute of Endocrinology and Metabolism, Kyiv, Ukraine, [7]Chebotarev Instutute of Gerontology, Kyiv, Ukraine, [8]Lund University Diabetes Center, Lund, Sweden.

Background and aims: Perinatal exposure to stressful conditions has been associated with a number of adverse consequences later in life. A recent study has demonstrated that the Ukrainian Holodomor famine in 1930'ies as associated with 1.47-fold increased risk for type 2 diabetes in adulthood. In the present study, we investigated prevalence of diabetic retinopathy as a late consequence of perinatal exposure to famine. We also studied the extent to which genetic variants associated with metabolic risk factors might influence the risk of diabetic retinopathy in a population from northern Ukraine with historical famine exposure.
Materials and methods: We obtained records on diabetes retinopathy from 101,095 patients with type 2 diabetes from Ukraine national diabetes registry, of whom 3,061 had proliferative retinopathy. We analyzed a panel of 169 SNPs in 3,634 patients with type 2 diabetes from the Chernihiv region of northern Ukraine with a history of Holodomor famine exposure to identify genetic determinants of proliferative retinopathy. Logistic regression adjusted for sex, age at visit, diabetes duration, and corrected for family relationships was used to study association of SNPs with diabetic retinopathy. We calculated crossover odds ratio for interaction between additive model of DNA variants and year of birth adjusted for sex, age, and diabetes duration using logistic regression model.
Results: There were 53,321 (34% men) patients with type 2 diabetes included from the exposed to Holodomor famine regions in Chernihiv and Kiev, and 47,774 (37% men) from unexposed regions in Volyn and Rivne, extracted from the Ukraine national diabetes registry. The odds ratio for diabetes retinopathy was increased for subjects born during Holodomor, World War II and post-war famine periods 1932–1947 ($p < 0.001$). A strong interaction between DNA variants and perinatal exposure to famine on the risk of diabetic retinopathy was observed for 11 genes (*ADRA2A*, *DCD*, *PCSK9*, *CNDP2*, *CYP2C19*2*, *MADD*, *ADCY5*, *VEGFA*, *CDKN2B*, *PIK3CG*, and *PROX1*) (odds-ratio heterogeneity test I^2 value >75, $p < 0.05$).
Conclusion: These results demonstrate an association between intrauterine exposure to famine with the risk of diabetic retinopathy in adulthood. Underlying genomic factors seem to predominantly involve mechanisms regulating neuronal functions.

Starvation induced changes in transcriptome of retinal cultures

T. Özgümüs[1], A. Fedotkina[1], M. Keindl[1], I. Artner[2], R. Jain[2], V. Lyssenko[1,2];
[1]Department of Clinical Science, University of Bergen, Bergen, Norway, [2]Department of Clinical Science, Lund University, Lund, Sweden.

Background and aims: Retinopathy is a severe complication in patients with diabetes leading to visual impairment and blindness. The prevalence of diabetes and associated complications are particularly increasing in the developing countries with histories of malnutrition and poor living conditions. Starvation is a strong exposure, which may introduce irreversible changes in the cellular physiology, even after the exposure has been eliminated. In particular, there is a limited understanding of the starvation effects on the cells in the developmental stages. The molecular understanding of the processes affected by embryonic starvation in the retina may reveal fundamental insights into novel and effective treatment strategies.
Materials and methods: In this study, the long-term effects of starvation on the RNA expression of mice embryonic retinal cultures were examined using RNA sequencing ($n = 5–6$). Cells were starved for 6 hours and subsequently cultured in a normal glucose media for 6 days before sampling. The control cells were cultured in a normal culture environment. The RNA extracts were sequenced using TruSeq Stranded Total RNA with RiboZero (Illumina). The alignment of the transcripts and differential expression analysis were done with using Kallisto 0.43.1 and edgeR 3.20.9, respectively.
Results: The retinal cell culture deconvolution analyses demonstrated downregulated expression of cell markers, such as *Glul* and *Slc1a3* (*Glast*) for Müller cells, *Tubb3* for all types of neurons, *Prkca* for bipolar neurons, *Rbfox3* for retinal ganglion cells, *Opn1sw* for photoreceptors, and *Pax6* for progenitor cells, while vasculature cell marker *Flt1* (*Vegfr1*) was upregulated in the starved samples ($p < 0.01$, FDR <0.05). No differences were observed for *Nes*, *Pecam1*, *Calb1* and *Calb2*, and *Opn3* genes. Gene ontology enrichment analyses suggested upregulation of the genes for GO terms such as response to stimulus ($p = 4.3E-23$), signalling receptor activity ($p = 4.8E-22$), blood vessel development ($p = 3.1E-18$), cell migration ($p = 2.1E-16$), immune system process ($p = 1.2E-12$) and response to stress ($p = 5.8E-8$) in the starved cells as compared to the control cultures (Figure 1). We are presently looking for the association of genetic variants in these genes with retinopathy in patients with type 2 diabetes.
Conclusion: These data demonstrate that embryonic starvation exhibits detrimental and long-term effects on the transcriptome of the neurovascular unit in the retina, and thereby could increase susceptibility for the development of retinopathy.

NSE, a novel biomarker, is elevated as an indicator of diabetic retinopathy including macular oedema

J. Li, M. Yan, Y. Zhang, M. Xie;
The First Affiliated Hospital of Nanjing Medical Univers, Nanjing, China.

Background and aims: Diabetic retinopathy (DR) has been a leading cause of legal blindness in working adults. In addition, diabetic macular edema (DME) is the most common cause of visual loss in both proliferative and non-proliferative retinopathy. Diabetic retinopathy is generally viewed as a neurovascular disease. Early DR includes a neurodegenerative component. In this regard, neuron-specific enolase (NSE), catalyzing the conversion of 2-phosphoglycerate into phosphoenolpyruvate in neurons, a new emerging biomarker of nerve deficits may be involved in retinopathy. Following nerve injury as a result of chronic exposure to ischemia or hypoxia, NSE is readily released into blood and detected in sera. We aimed to investigate the relationship between serum NSE and diabetic retinopathy including macular edema.
Materials and methods: Participants included type 1or 2 diabetes mellitus and healthy control subjects ($n = 392$). Patients with peripheral neuropathy were excluded from the study using the methods as we previously reported, i.e. through a combined assessment of clinical manifestations and functional tests of nerve deficits. Other diseases associated with possible sources of elevated NSE were also excluded. In this cross-sectional study, diabetic retinopathy status was assessed by fundus photographs. Based on International Classification of Diabetic Retinopathy or Early Treatment Diabetic Retinopathy Study (ETDRS), retinopathy and the macular edema were defined and sub-categorized, respectively. Serum neuron specific enolase (NSE) was measured using electrochemiluminescence immunoassay. Co-variables for diabetic retinopathy and NSE were obtained from fasting blood samples and interviewer- questionnaire.
Results: NSE was slightly elevated in diabetic subjects in contrast to healthy subjects and obviously increased in diabetic subjects with retinopathy compared without (8.3 (2.0) vs. 7.6 (1.5), $p = 0.037$ and 8.3 (2.0) vs. 9.5 (2.7), $p = 0.004$, respectively). In addition, NSE levels increased with and were closely correlated to the stages of retinopathy without macular edema ($r = 0.60$ (0.50–0.71), $p = 0.002$) and stages of macular edema with comparable retinopathy ($r = 0.58$ (0.46–0.69), $p = 0.006$). The association of NSE with diabetic retinopathy was independent (OR: 1.31 (1.12–1.65), $p = 0.017$), after the diabetic state and other potential confounders affecting NSE levels were considered (e.g., HbA1c, duration, age, gender, renal status, and medicines). The optimal cut-off point for serum NSE levels for differentiating patients with diabetic retinopathy including macular edema from without was 9.3 μg/l with a sensitivity of 67.5% and a specificity of 69.8%.
Conclusion: Our study demonstrated for the first time that serum neuron specific enolase levels were elevated in diabetes and independently related to diabetic retinopathy including macular edema. Our findings suggest that NSE may be a potential biomarker of diabetic retinopathy. Future prospective studies are warranted to clarify the relationship.

Improving diabetic retinopathy screening using deep learning

J.C. Mellor[1], A. Ochs[2], H.M. Colhoun[2], P. McKeigue[1];
[1]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, [2]Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK.

Background and aims: The Scottish Diabetic Retinopathy Screening programme uses manual scoring of fundus images to grade retinas on an ordinal scale from 0 to 4 and maculas on a scale from 0 to 2. The current protocol is to rescreen every 12 months, except those with R2 or M1 findings who are rescreened at 6 months. A previous study has shown that by using clinical covariates including past retinal scores it is possible to stratify patients by their risk of referable disease and thus to reduce the workload of the programme while maximizing the early detection of referable disease. The manual grading does not capture all useful information from these images relevant to a risk model for diabetic retinopathy. Deep learning, a class of machine learning algorithms based on neural networks, has produced state-of-the-art performance in learning to extract features from and classify images. The objective of this study was to establish whether using deep learning on the retinal images can improve the prediction of referable retinopathy at future examinations beyond that obtained with clinical data and manual scores alone.
Materials and methods: We used 30,604 manually graded retinal images from 3,290 people in the Scottish Type 1 Diabetes Biorecource linked to clinical data for the years 2007 to 2016. We used data from the Kaggle 2015 Diabetic Retinopathy Detection Competition to train an Inception-V4 convolutional neural network (CNN) to predict the manual grading of diabetic retinopathy. The 384 features derived from this CNN were calculated on the images obtained on the Scottish cohort. A generalised linear model (with complementary log-log link) was used to model the time to referable retinopathy. A model including only clinical covariates and manual scores was compared with models that included these variables plus the deep learning features. Two alternative approaches to limiting the effective number of deep learning variables were compared: forward-selection, and a Bayesian approach that used a "horseshoe" prior to learn the distribution of effect sizes. Predictive performance was evaluated on a test dataset not used to learn the model.
Results: The model with only clinical covariates and manual scores achieved an AUROC of 0.81 for prediction of referable retinopathy at the next examination. With deep learning features added by forward selection, the AUROC was improved to 0.88 (gain in test log-likelihood 153.5 natural log units). With deep learning features included with a horseshoe prior on the distribution of effect sizes, the AUROC was improved further to 0.91 (gain in test log-likelihood 256.1 nat log units compared with baseline model).
Conclusion: These results show that there is predictive information in the fundus images beyond the manual grading, and that this information can be extracted using deep learning. In principle this can be used in screening programmes to personalize screening schedules so as to reduce the time for which patients referable disease remain undiagnosed while also reducing the overall workload of the programme.

Association between diabetic retinopathy and Parkinson's disease: the Korean national health insurance service database

E. Koh, S. Lee, J. Jang, C. Woo, K.-U. Lee;
Asan Medical Center, Seoul, Republic of Korea.

Background and aims: Studies have shown an association between diabetes and Parkinson's disease (PD). The retina is a part of the central nervous system (CNS); it was proposed that diabetic retinopathy (DR) and PD share common pathophysiology of dopamine deficiency. However, no epidemiologic studies have investigated the relationship between these two diseases. The aim of this study was to evaluate the association between DR and incident PD using a population-based database.
Materials and methods: 14,912,368 participants who underwent regular health check-up from 2005 to 2008 in Korean National Health Insurance Service database were included. Subjects were classified into non-diabetes (non-DM), DM without DR, and DM with DR groups at baseline. These patients were followed-up until the date of the incident PD, death, or December 31, 2013. Cox proportional hazards regression analysis was used to evaluate the association between DR and incident PD.
Results: During the period, 34,834 subjects were newly diagnosed with PD. The incidence of PD was 2.74, 8.39 and 15.51 per 10,000 person-years for the non-DM, DM without and with DR groups, respectively. In multivariate Cox proportional hazard models, DR groups were associated with significantly higher risk of PD than non-DM or DM without DR groups even after adjusting for age, gender, fasting plasma glucose level, insulin usage, and other possible risk factors.

Conclusion: Concurrent DR was associated with an increased risk of incident PD. Future studies are necessary to ascertain whether increased risk of PD in DR is due to a long-lasting poor glycemic control in subjects with DR, or a dopamine deficiency in the CNS.

Proteomic analysis of retinas from patients with type 2 diabetes reveals mediators of neurodegenerative diseases

O. Simo-Servat[1], C. Hernández[1], J. Sundstrom[2], S. Weber[2], Y. Zhao[2], M. Dunklebarger[2], N. Tiberti[3], T. Laremore[4], M. Garcia-Ramirez[1], A. Barber[2], T. Gardner[5], R. Simó[1];
[1]Vall d'Hebron Research Institute, Barcelona, Spain, [2]Penn State Hershey Eye Center, Hershey, USA, [3]University of Technology, Sidney, Australia, [4]Proteomics and Mass Spectometry Core Facility, Penn State University, University Park, USA, [5]Kellog Eye Center, University of Michigan Medical School, Ann Arbor, USA.

Background and aims: Type 2 diabetic patients have a significantly higher risk of developing neurodegenerative diseases and, in particular, Alzheimer's disease than non-diabetic subjects. In addition, current evidence suggests that retinal neurodegeneration is an early event in the pathogenesis of diabetic retinopathy. Since the retina is ontogenically brain-derived tissue it could be postulated that in patients developing neurodegeneration in the brain there is a co-occurring neurodegenerative process in the retina. The main goal of the present study was to examine whether in the diabetic human retina there are common proteins and pathways shared with brain neurodegenerative diseases.
Materials and methods: A proteomic analysis was performed on three groups of postmortem retinas matched by age: non-diabetic control retinas ($n = 5$), diabetic retinas without glial activation ($n = 5$) and diabetic retinas with glial activation ($n = 5$). Retinal lysates from each group were pooled and run on an SDS-PAGE gel. Bands were analyzed sequentially by LC/MS using an Orbitrap Mass Spectrometer. Pathway enrichment analysis was performed using Ingenuity Pathway Analysis (IPA) bioinformatics platform. To identify the unique pathways related to neurodegenerative processes of each group, the Ontology and Function algorithm within IPA was used to restrict the enriched pathway dataset to those to "Neurotransmitters and Other Nervous System Signaling".
Results: A total of 2190 proteins were identified across all groups. Pathway analysis to "Neurotransmitters and Other Nervous System Signaling" revealed that 35 pathways are specifically represented in a single group (non-diabetic donors, diabetic donors without GA and diabetic donors with GA). The most relevant of these pathways were the following: "Neuroprotective Role of THOP1 in Alzheimer's Disease" and "Unfolded protein response" pathways were uniquely enriched in control retinas. By contrast, "Dopamine degradation" and "Parkinson's signaling" were enriched only in diabetic retinas with glial activation. The "Neuroregulin signaling", "Synaptic long term potentiation", and "Amyloid processing" pathways were enriched in diabetic retinas with no glial activation.
Conclusion: Proteomic analysis of diabetic retinas in early stages of diabetic retinopathy reveals mediators of neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. Our findings not only open up new therapeutic strategies against diabetes-induced retinal neurodegeneration but could be useful to further understand the neurodegenerative processes that occur in the brain of persons with diabetes.

Trajectories of estimated GFR in patients with and without albuminuria

M.E. Jørgensen[1,2], D. Vistisen[1], G.S. Andersen[1], A. Hulman[3,4], F. Persson[1], P. Rossing[1,5];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]National Institute of Public Health, Southern Denmark University, Copenhagen, [3]Aarhus University, Aarhus, [4]Danish Diabetes Academy, Odense, [5]Copenhagen University, Copenhagen, Denmark.

Background and aims: It is a common assumption that in patients with diabetes, a decline in kidney function is preceded by albuminuria. However, around one third of patients with an estimated GFR (eGFR) below 60 mL/min/1.73 m^2 have normoalbuminuria. The aim of this study was to assess the difference in the development over time in kidney function for patients with and without albuminuria from their first recording of a low eGFR.
Materials and methods: 930 patients with type 1 diabetes and 1,974 with type 2 diabetes treated in an outpatient clinic in Denmark during the period 2001–2017 were followed from their first recorded low eGFR (<60 mL/min/1.73 m^2) and onwards. Median (interquartile range) follow-up time was 4.2 years (1.5–7.6). Each patient had at least two clinical measurements with a median (interquartile range) of 7 (4–13) measurements per patient. A total of 28,288 clinical measurements were used in the analysis. GFR was estimated using the CKD-EPI formula. Albuminuria status was classified as normal (urinary albumin creatinine ratio <30 mg/g), micro (30–299 mg/g) or macro (≥300 mg/g). Trajectories of eGFR development following the first recorded low eGFR over time were estimated by mixed-effects models adjusting for sex, age at diabetes diagnosis, diabetes duration, calendar time and use of renin-angiotensin system (RAS) blockers. Interactions between time and albuminuria status and time and use of RAS blockers were included and tested. Albuminuria status and RAS blockade were included as time-varying covariates and eGFR was log-transformed prior to analysis. The analysis was stratified by diabetes type.
Results: Trajectories of eGFR development were overall similar in type 1 and type 2 diabetes (*Figure 1*). Albuminuria status significantly modified the development in eGFR ($P < 0.001$), with the steepest decline in kidney function among patients with macroalbuminuria: in patients with no RAS blockade, the annual decline was 7.0% and 6.7% in type 1 and type 2 patients respectively. RAS blockade had little effect on the trajectories. Both type 1 and type 2 diabetes patients with normoalbuminuria and who were not in RAS blockade had an estimated annual decline in eGFR of 4.2% from the adjusted model. For patients with a first recorded low eGFR of 59 mL/min/1.73 m^2 this amounted to a decline of 20 mL/min/1.73 m^2 over a 10-year period. In comparison, the average 10-year decline in eGFR in the background population age 40+ and without diabetes is around 10 mL/min/1.73 m^2.
Conclusion: Patients with type 1 or type 2 diabetes with an estimated GFR below 60 mL/min/1.73 m^2 are on average on a declining trajectory of kidney function that is increased by the presence of albuminuria.

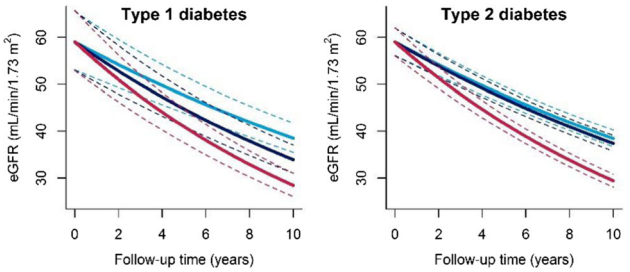

Figure 1 Estimated eGFR trajectories by diabetes type for patients with no RAS blockade and with a first recorded low eGFR of 59 mL/min/1.73/m^2. Time 0 is the first clinical visit with a recorded low eGFR. Curves are shown for patients with normoalbuminuria (light blue) microalbuminuria (dark blue) and macroalbuminuria (red)

Chronic kidney disease and risk of mortality, cardiovascular events and severe hypoglycaemia in type 2 diabetes: DEVOTE results

A. Amod[1], S.S. Emerson[2], S.P. Marso[3], D.K. McGuire[4], T.R. Pieber[5], R. Pop-Busui[6], R.E. Pratley[7], B. Zinman[8], M.V. Hansen[9], T. Jia[9], T. Mark[9], N.R. Poulter[10], on behalf of the DEVOTE Study Group;
[1]University of KwaZulu-Natal, Durban, South Africa, [2]University of Washington, Seattle, USA, [3]HCA Midwest, Kansas City, USA, [4]University of Texas Southwestern Medical Center, Dallas, USA, [5]Medical University of Graz, Graz, Austria, [6]University of Michigan, Ann Arbor, USA, [7]Florida Hospital, Orlando, USA, [8]Mount Sinai Hospital, University of Toronto, Toronto, Canada, [9]Novo Nordisk A/S, Søborg, Denmark, [10]Imperial College London, London, UK.

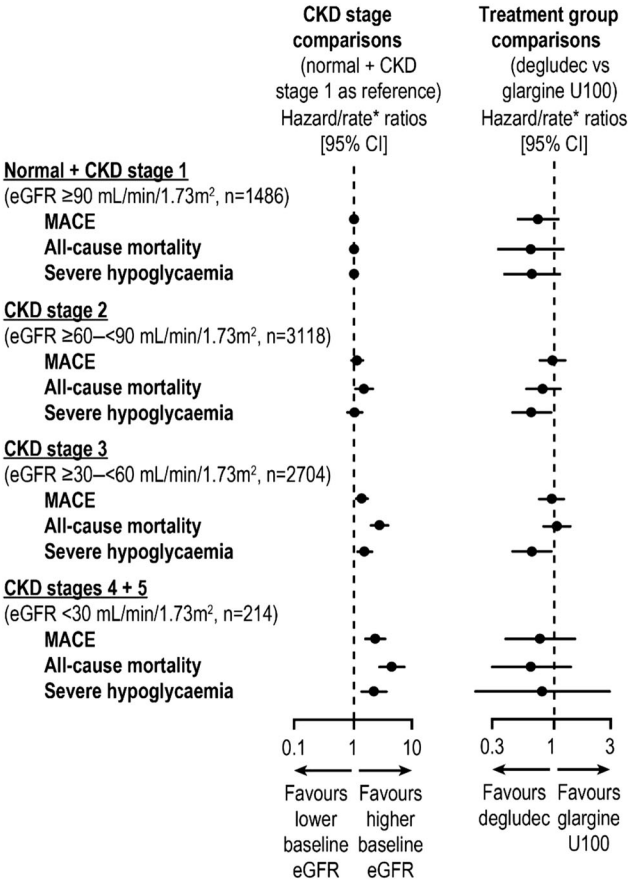
Background and aims: Type 2 diabetes (T2D) is associated with an increased risk of cardiovascular disease (CVD) and chronic kidney disease (CKD). CKD is a known risk factor for major adverse cardiovascular events (MACE), all-cause mortality and hypoglycaemia. This secondary, pooled analysis from DEVOTE examined whether baseline CKD stages were associated with an increased risk of MACE, all-cause mortality or severe hypoglycaemia in patients with T2D.

Materials and methods: DEVOTE was a treat-to-target, randomised, double-blind trial in 7637 patients with T2D at high cardiovascular (CV) risk, treated once daily with insulin degludec or insulin glargine 100 units/mL. Based on eGFR levels (mL/min/1.73 m^2), patients were divided into four CKD groups: normal + CKD stage 1 ($n = 1486$), CKD stage 2 ($n = 3118$), CKD stage 3 ($n = 2704$) and CKD stage 4 + 5 ($n = 214$). Severe hypoglycaemia was defined as an episode requiring the assistance of another person to actively administer carbohydrate or glucagon, or to take other corrective actions.

Results: According to baseline CKD stages (CKD stages 2–5), more patients had a history of CVD (CKD stages 3–5), were older and had lower HbA_{1c} versus those with normal kidney function (normal + CKD stage 1). The risk of MACE and all-cause mortality was significantly higher ($p < 0.05$) in those with a higher baseline CKD stage (Figure). There was a significantly higher rate of severe hypoglycaemia for CKD stages 3 and 4 + 5 versus CKD stage 2 or normal + stage 1. There were no significant interactions between treatment and CKD stages. Comparisons between treatment groups by CKD stage mirrored those from the primary analyses.

Conclusion: Increasing severity of baseline CKD stages was associated with a higher risk of MACE, all-cause mortality and rates of severe hypoglycaemia in patients with T2D at high CV risk.

Figure. Comparisons of effect of baseline CKD stages and basal insulin treatment (degludec vs glargine U100) on time to first MACE, all-cause mortality and severe hypoglycaemia in patients with T2D at high CV risk.



*Rate ratios only apply to the endpoint of severe hypoglycaemia, hazard ratios apply to the endpoints MACE and all-cause mortality. All endpoints reported here were externally adjudicated by the Event Adjudication Committee and pre-specified. The MACE endpoint was composed of cardiovascular mortality, non-fatal myocardial infarction, or non-fatal stroke. CI, confidence interval; CKD, chronic kidney disease; CV, cardiovascular; eGFR, estimated glomerular filtration rate; glargine U100, insulin glargine 100 units/mL; MACE, major adverse cardiovascular event; T2D, type 2 diabetes.

183

AVP gene variants, plasma copeptin and nephropathy in type 2 diabetes

G. Velho[1], L. Potier[1,2], K. Mohammedi[3], F. Fumeron[1,4], S. Hadjadj[5], M. Marre[2,4], R. Roussel[2,4];
[1]INSERM U1138, Centre de Recherche des Cordeliers, Paris, [2]Hôpital Bichat, AP-HP, Service de Diabétologie, Paris, [3]Université de Bordeaux, Faculté de Médecine Paul Broca, Bordeaux, [4]Université Paris Diderot, Sorbonne Paris Cité, UFR de Médecine, Paris, [5]CHU de Poitiers, Service d'Endocrinologie, Poitiers, France.

Background and aims: Experimental evidence supports a causal role for vasopressin (or antidiuretic hormone) in the development of chronic kidney disease and diabetic nephropathy through V2 receptor activation. Plasma copeptin, the COOH-terminal portion of pre-provasopressin and

a surrogate marker of vasopressin, was shown to be positively associated with the development and progression of diabetic nephropathy, and with end stage renal disease (ESRD) in type 1 and type 2 diabetes. To address the causality of this association, we assessed the association of *AVP* gene variants with plasma copeptin and with the risk of renal events during follow-up in a prospective cohort of people with type 2 diabetes.

Materials and methods: We studied 3077 French participants from the DIABHYCAR study (men 73%; micro- and macroalbuminuria in 76% and 24% of participants at baseline, respectively), a multicentre clinical trial on ramipril and renal and cardiovascular complications. A renal event during follow-up (median 5 years) was defined as the doubling of serum creatinine or the occurrence of ESRD (dialysis or transplantation requirement). Plasma copeptin was measured in baseline samples by an immunoluminometric assay. Six SNPs were chosen in the haplotype block containing the *AVP*gene (chr20p13): rs6084265, rs6084264, rs3761249, rs2282018, rs2770381 and rs1410713.

Results: All SNPs were significantly associated with baseline plasma copeptin. rs6084265: 8.0 ± 0.3 (CC), 8.6 ± 0.2 (TC) and 8.8 ± 0.3 pmol/L (TT; $p = 0.04$). rs6084264: 8.9 ± 0.3 (CC), 8.2 ± 0.2 (TC) and 7.7 ± 0.4 pmol/L (TT; $p = 0.005$). rs3761249: 8.4 ± 0.2 (TT), 8.6 ± 0.3 (TG) and 6.5 ± 1.0 pmol/L (GG; $p < 0.05$). rs2282018: 8.8 ± 0.3 (TT), 8.2 ± 0.2 (TC) and 7.8 ± 0.4 pmol/L (CC; $p = 0.01$). rs2770381: 7.8 ± 0.3 (AA), 8.5 ± 0.2 (AC) and 9.3 ± 0.3 pmol/L (CC; $p = 0.0002$). rs1410713: 8.7 ± 0.2 (CC), 8.5 ± 0.2 (CA) and 7.6 ± 0.4 pmol/L (AA; $p = 0.04$; ANCOVA, adjusted for sex, age, duration of diabetes, HbA1c, urinary albumin excretion and estimated glomerular filtration rate at baseline). The cumulative incidence of renal events during follow-up was 2.4% ($n = 75$). Baseline plasma copeptin was significantly associated with renal events in a Cox analysis. Hazard ratio (HR) for 1 unit of log[copeptin]: 3.12, 95% C.I. 2.18–4.42, $p < 0.0001$. Five SNPs were associated with renal events. HR (and 95% C.I.) were 2.23 (1.13–4.39), $p = 0.02$, for the T-allele of rs6084265 in a codominant model; 1.95 (1.32–2.97), $p = 0.0007$, for the C-allele of rs6084264 in a codominant model; 1.57 (1.10–2.29), $p = 0.01$, for the T-allele of rs2282018 in a codominant model; 1.80 (1.02–3.03), $p = 0.04$, for the CC-genotype (vs AX) of rs2770381; 1.77 (1.10–2.89), $p = 0.02$, for the CC-genotype (vs XA) of rs1410713 (all Cox analyses with same adjustments as above plus study treatment randomisation ramipril vs placebo).

Conclusion: We observed an association of plasma copeptin with severe renal events, and of allelic variations in the *AVP* locus with plasma copeptin and with the renal events in a cohort of people with type 2 diabetes. This pattern of mendelian randomisation supports the causality of the association of plasma copeptin (and vasopressin) with diabetic nephropathy.

Disclosure: **G. Velho:** None.

Cytosine methylation sequencing predicts the development of diabetic complications

I. Khurana[1], M. Ziemann[1], A. Kaspi[1], A.M. Syreeni[2], C. Forsblom[2], R. Ma[3], J.C.N. Chan[3], M.E. Cooper[1], P.-H. Groop[2], A. El-Osta[1];
[1]Monash University, Melbourne, Australia, [2]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, Helsinki, Finland, [3]Hong Kong Institute of Diabetes and Obesity, Hong Kong, Hong Kong.

Background and aims: While genome-wide methylation studies are typically performed using BeadChip array technology, this does not provide sufficient coverage to construct an integrated epigenetic regulatory network (ERN), important because the development of diabetic complications is considered a complex polygenic-multifactorial disorder. To address knowledge gap, we examined DNA methylation to define the ERN in the Finnish Diabetic Nephropathy (FinnDiane) cohort. Participants from FinnDiane study were selected based on the presence or absence of diabetes and diabetic kidney disease (DKD).

Materials and methods: Participants from FinnDiane study were selected based on the presence or absence of diabetes and diabetic kidney disease (DKD). Using methyl-CpG capture followed by massive parallel sequencing (methyl-seq) in leukocytes derived from 39 individuals, we detected differentially methylated regions (DMRs) associated with DKD

Results: Gene body-related regions made up >60% of the methylation differences, with <10% localised to exons. Integrative methylation analyses reveal 494 differentially methylated genes that intersect CTCF binding sites (181 genes with increased and 313 genes with reduced methylation). To determine the significance of DNA methylation changes we assessed 95 individuals using a FinnDiane validation cohort. We also assessed DKD-associated DMRs in a replication cohort from the Hong Kong Diabetes Registry. We show CTCF binding sites are sensitive to loss-of-methylation with gain-of-function in diabetes implicated in DKD involving insulin signalling, PI3K cascade, integrin cell interactions and lipid metabolism. These clinical findings were tested ex vivo using primary human diabetic vascular cells and renal derived podocytes. We confirm the transition from normal to high glucose conditions regulates insulin signalling genes mTOR, RPTOR, IRS2, FGF1 and GAB1, mediated by DNA methylation. We provide proof of concept that methylation regulates the activity of genes functionally important in signalling of insulin.

Conclusion: Not only does the epigenetic regulatory network presented here strengthen the evidence base against methylation changes merely being an epiphenomenon but the identification of core pathways and gene targets will be a useful resource and better understanding of regulatory mechanisms that contribute to the pathogenesis of diabetic kidney disease.

Whole genome sequencing of individuals with type 1 diabetes reveals novel susceptibility loci for diabetic nephropathy

J. Haukka[1,2], N. Sandholm[1,2], E. Valo[1,2], M. Parkkonen[1,2], V. Harjutsalo[3], C. Forsblom[1,2], P.-H. Groop[1,2];
[1]Folkhälsan Institute of Gemetics, Folkhälsan Research center, Helsinki, [2]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, [3]The Chronic Disease Prevention Unit, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: In recent years genome-wide association studies have yielded a few genome-wide significant common variants for diabetic nephropathy, most of them associated with end-stage renal disease. Compared to microarray chip based study designs, whole genome sequencing offers unrivalled capability to study low-frequency and rare susceptibility variants with larger effect on disease risk. Here, we performed a whole genome sequencing study in FinnDiane patients with type 1 diabetes and extreme phenotype regarding diabetic nephropathy.

Materials and methods: Altogether 599 subjects were recruited from the Finnish Diabetic Nephropathy Study (FinnDiane) cohort. The individuals represent extreme phenotypes for diabetic nephropathy: 299 cases had developed severe diabetic nephropathy (macroalbuminuria or ESRD), whereas 300 controls had retained normal AER for at least 35 years. Groups have similar age of diabetes onset (median cases: 11.7y, controls: 12.3y) but the cases had slightly higher HbA_{1c} (median cases: 9.0%, controls: 8.0%).The sequencing was conducted using Illumina HiSeq X platform by Macrogen Inc with at least 30x coverage. The short read data was processed and variants were called individually for each sample using Isaac aligner and variant caller according to Macrogen's standard pipeline. Of the 599 samples, 584 samples passed the QC and were included in the analyses.

Results: On average the participants had 3.7 million variants deviating from the reference, and in total the cohort included 22 million variants. Four variants on chromosome 22q11, in strong LD with each other,

reached the genome-wide significant p value threshold (5×10^{-8}), with the lowest p value 2.56 × 10-10. One SNP on chromosome 2p11.2 and one insertion on chromosome 5q21.1 reached suggestive p values of 1.53×10^{-7} and 8.88×10^{-7}, respectively. The intergenic chromosome 22 SNPs were close to PRDOH and several non-protein coding genes. Interestingly the same region resulted in the highest linkage peak in a previous linkage study in FinnDiane sibling pairs. However, none of the genes within 50 kb of the variants have previously been associated with any kidney diseases. Of note, these variants localize to a region of the genome with low mapping quality and require further validation.

Conclusion: This whole genome sequencing study reveals novel risk loci for diabetic nephropathy. However, the chromosome 22 findings need to be validated with more robust read processing and variant calling. Joint variant calling using Broad Institute's best practices guidelines with Genome Analysis Toolkit is in progress.

Cooperative regulation of insulin signalling genes by DNA methylation in human podocytes

A. Jørgensen[1,2], I. Khurana[1], A. El-Osta[1];
[1]Department of Diabetes, Monash University, Melbourne, Australia, [2]Metropolitan University College, Copenhagen, Denmark.

Background and aims: Diabetic kidney disease (DKD) is the most common cause of end stage renal disease (ESRD). DKD is associated with abnormal changes in tubular and glomerular cells in the kidney. Podocyte injury, dysfunction, and loss are central to the development and progression of DKD, however, the precise mechanism remains poorly understood. While the pathogenesis of DKD is complex we now appreciate that seemingly disconnected pathways mediated by hyperglycemia are integrated by genetic and environmental determinants. Nowhere is this more evident than in type 1 diabetes (T1D). For instance, while some patients with T1D develop DKD after many years of disease, the majority do not, despite similar levels of hyperglycemia. We postulate glucose-induced DNA methylation changes activate insulin signaling pathways in the human podocyte.

Materials and methods: We cultured human podocytes in normo-glucose (NG) and high-glucose (HG) for 15 days. DNA methylation patterns were assessed using methyl-binding-domain capture (MBDCap) followed by qPCR. Transcription factor binding was monitored by chromatin immunoprecipitation (ChIP) assay. Quantitative real-time PCR (qPCR) was used to assay gene expression and high throughput protein arrays to detect changes in insulin signaling.

Results: We found changes in DNA methylation patterns and gene activity of mechanistic target of rapamycin (mTOR), regulatory-associated protein of mTOR (RPTOR), insulin receptor substrate 1 (IRS-2), GRB2 associated binding protein 1 (GAB1) and fibroblast growth factor 1 (FGF1) were associated with insulin signaling in hyperglycemic podocytes. For example, mTOR DNA methylation was significantly reduced (~60% for HG) and inversely correlated with CTCF transcription factor binding. Furthermore, increased gene expression levels are consistent with mTOR protein activity in human podocytes under hyperglycemic conditions.

Conclusion: Hyperglycemic podocytes undergo dramatic changes in DNA methylation that regulate the expression of genes such as mTOR implicated in the regulation of insulin signaling pathways. The regulatory capacity of CTCF that we have identified suggests other methylation sites could also be prime candidates for gene control in human podocytes.

Determinants and pathological role of insulin hypersecretion in non-diabetic adults and adolescents

D. Tricò[1], A. Natali[1], S. Arslanian[2], A. Mari[3], E. Ferrannini[4];
[1]University of Pisa, Pisa, Italy, [2]University of Pittsburgh Medical Center, Pittsburgh, USA, [3]National Research Council, Padua, Italy, [4]National Research Council, Pisa, Italy.

Background and aims: The prevailing view of the natural history of type 2 diabetes (T2D) is that an early loss of insulin sensitivity precedes and causes a progressive increase of β cell insulin secretion, which would initially compensate for the insulin resistance to maintain glucose homeostasis. However, mechanisms underlying insulin hypersecretion are not fully understood, and growing evidence suggests that an inappropriate increase of insulin secretion may be the first event leading to T2D. Our aim was to identify insulin hypersecretion, independent of insulin resistance, and its role in the early derangements of glucose homeostasis.

Materials and methods: In 1,287 non-diabetic adults followed up for 3 years, insulin secretion rate (ISR) and β cell function parameters were estimated by C-peptide modelling during an OGTT. Insulin sensitivity (M/I) was measured by a hyperinsulinaemic-euglycaemic clamp. After regressing ISR on M/I, subjects in the upper tertile of the distribution of residuals were defined as hypersecretors (HyperS), while the other subjects as normosecretors (NormoS). This analysis was repeated in a multiethnic cohort of 182 obese adolescents.

Results: HyperS were more likely to be females ($p = 0.001$) and to have family history of T2D ($p = 0.02$) than NormoS. Furthermore, HyperS showed older age ($p = 0.0003$), higher fasting ($p = 0.005$) and post-OGTT glucose levels ($p < 0.0001$), BMI ($p = 0.03$), percent fat mass ($p < 0.0001$), LDL cholesterol ($p = 0.001$), fasting triglycerides ($p < 0.0001$), insulin-suppressed NEFA ($p < 0.0001$), γ-glutamyl-transferase ($p = 0.001$), as well as lower physical activity ($p = 0.005$) and HDL cholesterol ($p = 0.002$), compared to NormoS, despite similar M/I ($p = 0.10$). Among β cell function parameters, HyperS had higher β cell glucose sensitivity ($p < 0.0001$) and ISR at 5 mmol/L glucose ($p < 0.0001$), after adjustments for age, sex, and BMI. In multiple logistic analysis, significant predictors of HyperS were female sex (OR 3.62[0.13–0.57], $p = 0.0004$), post-OGTT glucose (OR 1.81[1.45–2.26], $p < 0.0001$), triglycerides (OR 2.03[1.28–3.20], $p = 0.002$), physical activity (OR 0.82[0.67–0.99], $p = 0.04$), and HDL cholesterol (OR 0.52[0.30–0.93], $p = 0.02$). Similarly defined HyperS adolescents showed higher fasting glucose ($p = 0.01$), post-OGTT glucose ($p < 0.0001$), LDL cholesterol ($p = 0.04$) and fasting triglycerides ($p = 0.01$) compared to NormoS. Furthermore, HyperS adolescents were more likely to be African Americans than American Whites ($p = 0.003$). At follow up, HyperS had increased odds of developing altered glucose tolerance or T2D (OR 1.49 [1.01–2.21], $p = 0.046$), after adjusting for age, sex, BMI, and fasting glucose.

Conclusion: We identified the phenotype of HyperS, where sex, race, post-OGTT glucose levels, triglycerides, HDL cholesterol, and physical activity were main determinants of insulin secretion fully independently of insulin sensitivity in both non-diabetic adults and adolescents. Furthermore, we found that inappropriately elevated insulin secretion relative to insulin sensitivity predicts deteriorations of glucose control over time. This evidence challenges the traditional view of insulin secretion as a mere adaptive mechanism to insulin resistance, and warrants further studies to identify the mechanisms of primary insulin hypersecretion and potential approaches to its prevention and treatment.

Quantifying beta cell mass non-invasively with PET probe: ^{18}Fluorine-labelled Exendin4

N. Fujita[1], H. Fujimoto[1], K. Hamamatsu[1], T. Murakami[1], H. Kimura[2], K. Toyoda[1], H. Saji[3], N. Inagaki[1];
[1]Diabetes, Endocrinology and Nutrition, Graduate School of Medicine, Kyoto University, Kyoto, [2]Analytical and Bioinorganic Chemistry, Kyoto Pharmaceutical University, Kyoto, [3]Patho-Functional Bioanalysis, Graduate School of Pharmaceutical Sciences, Kyoto University, Kyoto, Japan.

Background and aims: β-cell function and β-cell mass (BCM) play important roles in insulin secretion. Cross-sectional studies on harvested pancreas have reported that BCM decreases in patients with type 2 diabetes. Thus, a method to quantify BCM non-invasively and repeatedly will enable us to improve our understanding on the pathophysiology of diabetes. However, the method has not been established yet. Therefore, we aim to examine whether BCM can be quantified non-invasively using a glucagon-like polypeptide-1 (GLP-1) receptor targeting probe, ^{18}Fluorine-labeled Exendin4 (^{18}F-Ex), with positron emission tomography (PET).
Materials and methods: The specificity of ^{18}F-Ex to GLP-1 receptors was assessed by a binding assay with a membrane-prepared recombinant human GLP-1. Specific accumulation to β-cells was evaluated by autoradiography with pancreatic sections of transgenic MIP-GFP mice after intravenously injecting ^{18}F-Ex. A blocking study was also performed with a pre-injection of excess non-radiolabeled Exendin(9-39). Organ specificity was investigated by a bio-distribution study with 6-week-old male BL6 mice. PET images of 12-week-old female NOD mice (4 hyperglycemic and 6 euglycemic) were taken at 30 min after injecting ^{18}F-Ex intravenously. Pancreata of the 10 NOD mice were harvested after obtaining PET images. The percentage of ^{18}F-Ex uptake in the pancreas was calculated by measuring the radioactivity of injected ^{18}F-Ex and harvested pancreas using a gamma counter. Pancreatic sections were stained with an anti-insulin antibody. BCM was calculated by multiplying the relative insulin-positive area by pancreatic weight. The percentage of ^{18}F-Ex uptake in the pancreas was compared between hyperglycemic and euglycemic NOD mice. The correlation between BCM and the percentage of ^{18}F-Ex uptake in the pancreas was also examined.
Results: A similar IC_{50} of ^{18}F-Ex and GLP-1(7-36) amide was confirmed in the binding assay analysis (0.070 nM and 0.045 nM, respectively). Radioactive signals in autoradiography were co-localized with fluorescent signals that are detected in insulin-producing β-cells on the pancreatic sections of MIP-GFP mice. The radioactive signals were blocked with the pre-injection of excess non-radiolabeled Exendin(9-39). In the bio-distribution study, the pancreatic uptake of ^{18}F-Ex was the highest at 30 min after injection (23.8%ID/g) and was retained for 2 h (17.5%ID/g). On the PET image, the pancreas was able to be identified and was distinguishable from other surrounding organs. *In vivo* radioactive signals from the pancreas were apparently weaker in the hyperglycemic NOD mice than in the euglycemic NOD mice. A significant difference was found between the hyperglycemic and euglycemic NOD mice in the percentage of ^{18}F-Ex uptake in the harvested pancreas (10.8%ID/g vs 18.4%ID/g, $p = 0.02$). The percentage of ^{18}F-Ex uptake in the harvested pancreas significantly correlated to BCM ($R = 0.72$).
Conclusion: ^{18}F-Ex was proven to specifically accumulate to β-cells. BCM significantly correlated with ^{18}F-Ex uptake in the harvested pancreas that can be non-invasively quantified using PET. Therefore, BCM could be non-invasively estimated by PET with ^{18}F-Ex *in vivo*.

Glucose homeostasis, insulin secretion and beta cell transcriptomics of mice with beta cell specific insulin resistance

S. Skovsø[1], D.A. Dionne[1], E. Panzhinskiy[1], H. Modi[1], J. Kolic[1], P. Overby[1], D. Hutchinson[1], S. Marcil[1], X. Hu[1], H.L. Noh[2], S. Suk[2], S. Flibotte[3], L.C. Alonso[4], J.K. Kim[4,2], J.D. Johnson[1];
[1]Diabetes Research Group, Life Sciences Institute, Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada, [2]Program in Molecular Medicine, Department of Medicine, University of Massachusetts Medical School, Worcester, USA, [3]Department of Zoology, University of British Columbia, Vancouver, Canada, [4]Division of Diabetes, Department of Medicine, University of Massachusetts Medical School, Worcester, USA.

Background and aims: The potential role of β-cell insulin resistance in diabetes remains somewhat enigmatic. Previously, autocrine insulin action has alternately been proposed to decrease or increase its own secretion, and the consequences of β-cell insulin resistance would differ in each scenario. The *Ins1*^{Cre} mouse model has become available and permits gene deletion specifically in the β-cells, but not in the brain. Our aim was to examine insulin release and gene expression on β-cells from mice lacking one or both alleles of the insulin receptor (*Insr*) gene.
Materials and methods: Male and female knockout *Insr*$^{f/f}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ mice, heterozygous *Insr*$^{f/wt}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ mice, and *Insr*$^{wt/wt}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ mice littermate controls were fed a low fat diet (LFD) or a high fat diet (HFD). Glucose tolerance, insulin tolerance, and insulin secretion (all *i.p.*) were assessed at multiple ages. Insulin secretion was also examined using the hyperglycemic clamp technique. RNAseq was conducted on FACS-purified, recombined β-cells, with Reactome analysis of differentially expressed pathways.
Results: Glucose homeostasis was significantly ($p < 0.05$) improved in LFD female *Insr*$^{f/f}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ and *Insr*$^{f/wt}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ mice when compared to controls at 9, 21 and 39 weeks. There were no significant differences between groups of male mice, or between groups of HFD-fed mice, suggesting the possibility that global insulin resistance may obscure these effects and prompting us to focus on female LFD-fed mice to understand the mechanisms of improved glucose tolerance. In these mice, no difference in insulin tolerance was observed at 10, 22 or 40 weeks. However, plasma insulin levels were higher following *i.p.* glucose challenge ($p = 0.055$), explaining their improved glucose tolerance. Similarly, insulin levels were exaggerated while plasma glucose levels were maintained at ~350 mg/dl in hyperglycemic clamp experiments. The glucose infusion rates required to maintain hyperglycemia during clamp trended higher in *Insr*$^{f/f}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ versus littermate controls likely due to a higher insulin secretion occurring during β-cell specific insulin resistance. Together, these data support the hypothesis that glucose stimulated insulin release inhibits its own secretion during hyperglycemic conditions. Reactome analysis of RNAseq data pointed to significant differences in genes regulating β-cell function in *Insr*$^{f/f}$:*Ins1*$^{cre/wt}$:nTnG$^{+/-}$ versus controls.
Conclusion: Loss of β-cell *Insr* increases insulin levels during glucose challenge thereby improving glucose homeostasis in young mice, consistent with the concept that glucose stimulated insulin release normally inhibits its own secretion during hyperglycemic conditions. By contributing to hyperinsulinemia, β-cell specific insulin resistance may play an early role in the initiation of type 2 diabetes pathogenesis.

FGF family members may represent novel drivers of beta cell dedifferentiation in type 2 diabetes

S. Knight[1], N. Mullooly[1], B.J. Isherwood[1], L. Holmberg-Schiavone[2], C. Wennberg.Huldt[3], G. O'Mahony[3], S. Gopel[3];
[1]Discovery Sciences, IMED Biotech Unit, AstraZeneca, Cambridge, UK, [2]Discovery Sciences, IMED Biotech Unit, AstraZeneca, Gothenburg, Sweden, [3]Cardiovascular, Renal and Metabolic Disease, IMED Biotech Unit, AstraZeneca, Gothenburg, Sweden.

Background and aims: Recent evidence suggests β-cell dedifferentiation as a key driver for the loss of pancreatic β-cell function. We adapted a previously established model of dedifferentiation using the human β-cell line, EndoC-βH1 to (i) enable high-throughput systematic investigation of the pathways involved in dedifferentiation in Type 2 diabetes (T2D) and (ii) identify small molecules capable of reversing the dedifferentiated phenotype.
Materials and methods: We performed a phenotypic screen using the EndoC-βH1 model of dedifferentiation to monitor the ability of 916 proteins of the secretome to alter the differentiation status of the human pancreatic β-cell line. Dedifferentiation was monitored by measuring changes in the subcellular location and expression of the β-cell marker MAFA (key regulator of glucose stimulated-insulin secretion) and the pancreatic progenitor marker SOX9. We further profiled small molecules in an FGF2-driven model of EndoC-βH1 dedifferentiation to assess the potential to reverse the effect.
Results: FGF9, FGF18 and FGF4 were identified as novel biological modulators of the dedifferentiation phenotype, along with previously established FGF1 and FGF2. FGF9 induced the strongest phenotypic effect with a 2 fold increase in SOX9 nuclear intensity and a 1.5 fold reduction in MAFA nuclear/cytoplasmic localisation compared to FGF2 control. The unique ability of the FGF family members from 916 secreted proteins to alter the dedifferentiation phenotype suggests that FGF signalling may be an important player in dedifferentiation. 13 of the 18 secreted FGFs were constituents of the tested library, however many members including FGF7 and FGF10 from the FGF7 subfamily and FGF23, FGF21 and FGF19 from the endocrine FGF subfamily did not induce dedifferentiation indicating that specific FGF-FGFR or FGF+co-factor-FGFR interactions are likely to govern the dedifferentiation phenotype. Indeed further studies indicate that a FGFR1c antibody is capable of partially inhibiting FGF2 induced changes in MAFA and SOX9 in both EndoC-βH1 and human primary islets. Using single cell RNA sequencing, FGFR1, FGF2 and FGF9 were found to have increased expression in pancreatic cells from T2D, with FGF9 and FGFR1 showing increased expression in β-cells. The FGF2-driven dedifferentiation of the EndoC-βH1 cell line was found to be reversible through treatment with small molecule inhibitors of MAPK/ERK and TGFβ signalling. For example, a MEK1 inhibitor (pEC50 = 5.5, pIC50 = 6.9), and a TGFβR1/TGFβR2 inhibitor (pEC50 = 5, pIC50 = 5.2) restored MAFA and reduced SOX9 protein expression to dedifferentiated cells to similar levels as that observed for undifferentiated cells.
Conclusion: We identified members of FGF family that may represent novel drivers of dedifferentiation in T2D. We further show increased transcriptional expression of FGF9 in pancreatic β-cells from T2D patients. We demonstrated reversibility of the phenotype through pharmacological intervention, supporting the pharmacological targeting of redifferentiation for therapeutic intervention in T2D. To our knowledge this is the first example of small molecule driven reversibility of a dedifferentiated phenotype in a human-based pancreatic β-cell model.

Hyperglycaemia adversely affects mitochondrial function in pancreatic islets

E. Haythorne[1], A.I. Tarasov[2], F.M. Ashcroft[1];
[1]Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, [2]OCDEM, University of Oxford, Oxford, UK.

Background and aims: Glucose metabolism is essential for glucose-stimulated insulin secretion from pancreatic β-cells. Metabolically generated ATP causes ATP-sensitive potassium (K_{ATP}) channel closure, membrane depolarisation and calcium influx, which stimulates exocytosis. There is accumulating evidence to suggest that β-cell mitochondrial metabolism is impaired in type 2 diabetes mellitus (T2DM), and contributes to reduced insulin secretion. As hyperglycaemia is common to all forms of diabetes, we aimed to determine if hyperglycaemia adversely affects mitochondrial function and thereby ATP production in pancreatic islets.
Materials and methods: In human patients and animal models of T2DM, hyperglycaemia often occurs in conjunction with elevated levels of circulating lipids, making it difficult to distinguish between the deleterious effects of glucose and lipids. We therefore used the βV59M mouse model in which hyperglycaemia is not accompanied by dyslipidaemia. In these mice, tamoxifen-inducible expression of a constitutively open K_{ATP} channel specifically in pancreatic β-cells inhibits insulin secretion and rapidly elevates blood glucose (>20 mmol/l). Diabetes was induced at 12 weeks of age and islets isolated 2 weeks later. Non-diabetic littermates were used as controls. Cellular Oxygen Consumption Rate (OCR) was monitored in real-time using the XF-24 extracellular flux analyser (Seahorse Bioscience, Inc.). Imaging the kinetics of ATP in β-cells was performed on a zoom microscope AxioZoom.V16 (Carl Zeiss) and utilised fluorescent sensor for Mg^{2+} (Mg-Green, ThermoFisher) as a surrogate for ATP.
Results: In comparison to islets from control mice, islets from diabetic mice showed a significant reduction in the % increase in OCR when ambient glucose was raised from 2 to 20 mmol/l (diabetic = 48.44 ± 8.98 ± vs. control = 91.29 ± 7.26% increase in OCR, $p < 0.005$; $n = 9$–12, 6 animals/genotype). Sequential addition of the ATP-synthase inhibitor oligomycin produced significantly less inhibition of OCR in islets from diabetic mice compared to control, indicating hyperglycaemia reduces the activity of ATP-synthase (diabetic = 88.72 ± 6.43 vs control = 123.05 ± 5.59% decrease in OCR, $p < 0.05$; $n = 5$–7, 3 animals/genotype). Subsequent addition of rotenone and antimycin A, which inhibit complex 1 and 3 of the electron transport chain respectively, supressed OCR to the same degree in both diabetic and control islets, indicating no difference in the level of mitochondrial leak. ATP increase in response to 20 mmol/l glucose was reduced in hyperglycaemic islets by 56 ± 6% (control = 1147 islets, diabetic = 423 islets).
Conclusion: Our results demonstrate that hyperglycaemia, independent of changes in circulating lipids, leads to impaired mitochondrial respiration and ATP production in pancreatic islets. Mitochondrial metabolism is essential for the stimulation of insulin secretion by glucose and therefore hyperglycaemia-induced mitochondrial dysfunction is likely to contribute to β-cell failure in T2DM. It remains to be determined if the deleterious effects of hyperglycaemia are limited to β-cells or if they occur in all islet cell types.

The liver-alpha-cell axis during weight loss in type 2 diabetes

J. Otten, A. Stomby, M. Waling, E. Chorell, M. Ryberg, M. Svensson, J.J. Holst, T. Olsson;
Umeå University, Umeå, Sweden.

Background and aims: The concept of a *liver-alpha-cell axis* has recently been described: increasing levels of amino acids stimulate glucagon secretion which, in turn enhances amino acid turnover in the liver by increasing ureagenesis. Thus, alpha cell function is essential for maintaining normal amino acid levels. Alanine and glutamine in particular are reported to stimulate glucagon secretion and alpha cell proliferation, respectively. We aimed to investigate the effect of weight loss by a Paleolithic diet with/without exercise on fasting amino acids, endogenous glucose production (EGP) and glucagon levels during a mixed meal to elucidate the *liver-alpha-cell* axis.
Materials and methods: Thirty-two overweight patients with type 2 diabetes were randomized to either a Paleolithic diet (PD) or a Paleolithic diet combined with supervised exercise (PD-EX). Subjects were served a solid mixed meal test at baseline and after 12 weeks. Glucose, insulin and glucagon were measured at 0, 30, 60, 120 and 180

min with calculation of the total area under the curve for the response. On another study day, fasting glutamine and alanine were measured with GC-MS and suppression of EGP was examined with the hyperinsulinemic euglycemic clamp technique with [6,6-$^2H_2$]glucose as a tracer and with an insulin infusion of 40 mU/m^2/min.

Results: Median weight loss was 7 kg in both study groups. Fasting glucagon tended to decrease in both study groups. Postprandial glucagon decreased by 22% in the PD-group ($P < 0.01$) and by 21% in the PD-EX group ($P = 0.13$). Fasting alanine decreased in the PD group ($P < 0.01$). Fasting glutamine increased non-significantly in both groups. Suppression of EGP increased by 26% in the PD group ($P < 0.05$) and by 10% in the PD-EX group ($P = 0.75$). The increased suppression of EGP during the intervention, was associated with a) reduction of postprandial glucagon levels ($r_S = -0.65$, $P < 0.01$), b) decreasing fasting glucagon levels ($r_S = -0.51$, $P < 0.05$) and c) the increasing fasting glutamine levels ($r_S = 0.51$, $P < 0.05$).

Conclusion: Weight loss decreases glucagon levels in concert with improved suppression of endogenous glucose production of the liver/kidney. The latter is associated with increasing glutamine levels, which may be involved in the regulation of the *liver-alpha-cell axis*.

Integration of half-day carbohydrate restriction into a hypocaloric Mediterranean-type diet in overweight and obese subjects: an open label, randomised, controlled trial

D. Tsilingiris, D. Dellis, I. Eleftheriadou, A. Tentolouris, M. Karanasiou, A. Meimari, G. Dellis, C. Dimosthenopoulos, S. Lazarou, A. Kokkinos, P.P. Sfikakis, N. Tentolouris;

1st Department of Propaedeutic Internal Medicine, Medical School, National and Kapodistrian University of Athens, Greece, Athens, Greece.

Background and aims: Among available modalities for weight loss, carbohydrate restriction diets achieve rapid weight decline with concomitant improvements in metabolic risk factors. Adherence to a strict carbohydrate restriction regimen is often hard to achieve. Aim of the present study was to investigate the effect of a half-day (morning) carbohydrate restriction diet (HCR-D) on weight loss and metabolic risk factors in overweight and obese subjects.

Materials and methods: A total of 70 overweight and obese individuals [41 (58.6%) females, 24 (34%) with type 2 diabetes, mean age 49.9 ± 10.7 years, mean body mass index-BMI 33.7 ± 3.9 kg/m^2)] were randomly allocated between two hypocaloric dietary regimens: HCR-D and a Mediterranean-type diet that served as control. Participants in the HCR-D group were permitted a minimum of 300 kcal of very low carbohydrate breakfast and a mid-morning snack, while a maximum of 300 kcal of typical Mediterranean early daily meals were allowed in the control group. Both diets were identical from midday thereafter. Participants were followed up over a period of 2 months. Somatometric and laboratory data were collected at screening and at follow-up completion.

Results: Baseline clinical and laboratory characteristics were comparable between the two groups. As compared to baseline, individuals in both groups achieved significant and clinically meaningful reductions in body weight, BMI, waist circumference and body fat mass. However, reductions were more pronounced in the HCR-D compared to the control group in weight, BMI, waist circumference and fat mass (mean differences between groups 3.45 kg, 1.52 kg/m^2, 3.21 cm, 1.45 kg, respectively, all $p < 0.001$). Furthermore, compared to the control group more participants in the HCR-D achieved loss of 5–10% of body weight by the end of the 1st month (77.1 vs 31.4%, $p < 0.001$), as well as 5–10% and >10% of weight by the end of the 2nd month (65.7 vs. 57.1% and 34.3 vs. 8.6% respectively, $p < 0.001$). All individuals in the HCR-D group achieved loss of ≥5% baseline weight by the end of the intervention as compared to 65.7% in the control group ($p < 0.001$). Participants in both groups achieved similar reductions in fasting serum glucose (FSG) and HbA_{1c} (−4.23 vs. −6.40 mg/dl, and 0.26% vs. −0.24%, respectively all $p > 0.05$) as well as improvements in the homeostatic model assessment index for insulin resistance (HOMA-IR) (−0.91 vs. −0.78, $p > 0.05$). Among individuals with type 2 diabetes, weight loss, BMI and weight circumference reductions from baseline were significantly greater for those allocated to the HCR-D than the control group (mean differences between groups 3.76 kg $p = 0.002$, 1.21 kg/m^2 $p = 0.005$, 3.49 cm $p = 0.002$ respectively). Loss of fat mass and improvements in FSG, HbA_{1c} and HOMA-IR were similar for participants with diabetes in both groups.

Conclusion: Application of morning carbohydrate restriction on a Mediterranean diet resulted in greater and more rapid weight loss while retaining metabolic benefits regarding glycemia-related parameters. Such strategies may combine the beneficial effects of carbohydrate restriction diets with improved adherence.

Three meals diet with high energy breakfast is an effective strategy for weight loss, reduction of glucose variability and of total daily insulin dose in type 2 diabetes

D. Jakubowicz[1], O. Froy[2], S. Tsameret[2], J. Wainstein[1], I. Raz[3], M. Menaged[1], Y. Bar-Dayan[4], N. Mor[4], T. Ganz[4], Z. Landau[4];
[1]Wolfson Medical Center, Tel Aviv University, [2]Institute of Biochemistry, The Hebrew University of Jerusalem, [3]Diabetes Unit, Hadassah University Hospital, The Hebrew University of Jerusalem, [4]Wolfson Medical Center, Holon, Israel.

Background and aims: Obese patients with uncontrolled type 2 diabetes (T2D) and insulin resistance (IR), often require high total daily insulin dose (TDID), which leads to weight gain, worsening IR and hyperglycemia, requiring further increase of TDID, a vicious cycle ever-increasing TDID, weight gain, persistent hyperglycemia and high risk for diabetes complications. We have previously shown that a 3-meal diet (3Mdiet) with timing schedule, consisting of high energy breakfast (B) and Lunch (L) and low-energy dinner (D), can improve glycemic control, overall glycemia, reduce appetite and promote weight loss (WL) in obese and orally treated patients with T2D. Our aim was to compare the effects of 3Mdiet vs. 6-meals diet evenly distributed throughout the day (6Mdiet) on WL, overall glycemia, glucose variability (GV), appetite and TDID reduction in uncontrolled insulin treated T2D.
Materials and methods: Twenty-eight T2D (age 69 ± 7 yrs; BMI: 32.2 ± 5 kg/m^2; since 19.9 ± 8 yrs) were randomly assigned to12 weeks of isocaloric nutritional intervention with either 3Mdiet (1600 ± 200 kcal, B:L:D: 50:33:17%) or 6Mdiet (1600 ± 200 kcal, B:L:D: 20:25:25% + 3 snacks 10% each). Overall glycemia and GV including Daily-Risk-for Hyperglycemia (HBGI) and Average-Daily-Risk-Range (ADRR), were assessed for 14 days by continuous glucose monitoring (CGM) at baseline and at 12 weeks. Insulin dose was titrated biweekly.
Results: After 12 weeks improvement of the following parameters demonstrated in 3Mdiet compared to 6Mdiet, respectively: WL (−5.0 ± 0.9 kg vs. +0.26 ± 0.3 kg, $p < 0.05$). HbA1c decreased by −1.2 ± 0.3% (8.2 ± 1% to 7.0 ± 0.3%) vs −0.2 ± 0.4% (7.96 ± 1% to 7.7 ± 0.4%) ($p < 0.05$). Overall glycemia decreased in 3Mdiet by −40 ± 10 mg/dl (169 ± 23 to 129 ± 11 mg/dl) vs. −18 ± 16 mg/dl (174 ± 24 to 156 ± 20 mg/dl) in 6Mdiet ($p < 0.05$). There was no correlation between Δ body weight and Δ overall glycemia in neither of the groups ($R^2 = 0.0363$ for 3Mdiet, and $R^2 = 0.0135$ for 6Mdiet). GV indices were reduced in 3Mdiet by 62% for HBGI and by 55% for ADRR compared to 6Mdiet ($P < 0.05$). Overall VAS_{100} hunger scores were reduced by −18 ± 3 in 3Mdiet, but increased by 2 ± 1.7 in 6Mdiet ($p < 0.05$). Similarly, craving scores (especially for carbohydrates/starches) were augmented by 4 ± 5.1 with 6Mdiet, while in 3Mdiet were significantly reduced by −36 ± 7.7 ($p < 0.05$). At the end of the intervention, TDID increased by 4.9 ± 14 units/day (from 70.6 ± 17 to 75.5 ± 11 units/day) in 6Mdiet, whereas was significantly reduced by −27 ± 16 units/day (from 73.5 ± 16 to 33.8 ± 15.2 units/day) in 3Mdiet ($p < 0.05$).
Conclusion: In uncontrolled insulin treated T2D, the 3Mdiet with high energy breakfast was shown to be more effective than the traditional diet with six small meals evenly distributed throughout the day, for WL, overall glycemia, HbA1c, glucose variability, appetite and for the reduction of insulin requirements. Importantly, the reduction of overall glycemia and glucose variability, was independent of weight loss suggesting beneficial effect of meal timing schedule consisting on 3Mdiet. Therefore, meal timing with 3Mdiet with high-energy-breakfast should be strategy to improve diabetes control and outcome with less daily insulin dose.

The incretin effect of essential amino acids (EAA) in youth and ageing

H. Abdulla[1], J.J. Bass[1], T. Stokes[2], S.H. Gorissen[2], S.M. Phillips[2], B.E. Phillips[1], K. Smith[1], I. Idris[1], P.J. Atherton[1];
[1]Molecular, Metabolic and Clinical Physiology Group, MRC-ARUK Centre for Musculoskeletal ageing research - School of Medicine - University of Nottingham, Derby, UK, [2]Department of Kinesiology, Mcmaster University, Hamilton, Canada.

Background and aims: The oral ingestion of glucose triggers greater insulin release than a comparable glucose challenge delivered intravenously. However, whether this phenomenon - known as the 'incretin effect' - applies to ingested volumes of dietary essential amino acids (EAA) during intake of meals is ill-defined. Furthermore, since EAA (and insulin) are important components of skeletal muscle protein anabolism and muscle loss is accelerated with ageing, exploration of how ageing impacts any incretin effect of EAA is warranted. We thus explored: i) whether EAA could induce an incretin effect, and ii) whether ageing impacted this incretin effect.
Materials and methods: A 15 g mixed EAA beverage was administered orally to two groups of younger ($N = 8$; mean age 25.6 ± 1.5 y) and older ($N = 8$; mean age 69.1 ± 1 y) healthy volunteers. Another group of younger volunteers ($N = 9$; mean age 21 ± 1 y) were given an equivalent intravenous (IV) beverage aiming to achieve matched plasma AA profiles. Oral EAA were given as a drink dissolved in an aqueous solution and consumed over 2 min. For IV delivery, 15 g of mixed EAA were infused at a rate of 133 mg.min^{-1} for 15 min followed by a rate of 289 mg.min^{-1} for a further 45 min. Plasma concentrations of AA, insulin, glucagon like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) were quantified over a period of 120 min. Analytically, AA were derivatised as their N-acetyl-N-propyl esters and their concentrations determined against a standard curve of known concentrations using gas chromatography mass spectrometry (GC-MS). Milliplex Map, commercial ELISA kits, were used to determine insulin and gut hormone abundance. Statistical analyses was performed in Graphpad Prism 7 via ANOVA and t-tests as appropriate.
Results: EAA produced rapid insulinaemia and aminoacidaemia with total AA, sum EAA and sum branched-chain AA matched between oral and IV groups. Insulin levels peaked at 1353.37 pmol l^{-1} at 30 min following oral feeding compared to 782.4 pmol l^{-1} at 60 min following IV feeding. EAA peaked at 3395.39 μM at 45 min during IV infusion compared to 2891.73 μM following oral intake (*p*: NS). There was an approximate 45% incretin effect on calculating insulin response in the first 60 min. GIP increased following oral intake (452.28 pmol l^{-1} vs 232 pmol l^{-1} , $p < 0.05$) coinciding with insulin elevations, while no significant changes were observed with GLP-1. No differences were observed between younger and older groups in the profile of insulin or incretins following oral EAA intake (Figure. 1)
Conclusion: In response to oral vs. IV plasma essential aminoacidemia, oral EAA intake induced an incretin effect associated with augmented GIP, but not GLP-1. No ageing effects were observed on EAA stimulated incretin hormone release. Thus, postprandial levels of EAA induce a GIP-mediated incretin effect, unaffected by age, supporting the notion of EAA as *acute* nutritive therapeutics in Diabetes and ageing.

Long-term effects of weight loss on muscle strength and bone mineral density in adults with overweight or obesity: a PREVIEW sub-study

R.V. Seimon[1], S. McClintock[1], J. Dodds[1], R. Muirhead[1], S. Brodie[1], J. Zibellini[1], A. Das[1], A.L. Wild-Taylor[1], J. Honeywood[1], M. Fogelholm[2], A. Raben[3], J. Brand-Miller[1], A. Sainsbury[1];

[1]The University of Sydney, Camperdown, Australia, [2]University of Helsinki, Helsinki, Finland, [3]University of Copenhagen, Copenhagen, Denmark.

Background and aims: Low energy diets, using meal replacement products, are an effective weight loss tool. However, little is known about changes in musculoskeletal integrity with these diets, particularly in people with overweight/obesity of different age or sex. Therefore, we aimed to determine the effect of a low energy (total meal replacement) diet on muscle strength and bone mineral density (BMD) in specific populations of adults.

Materials and methods: This sub-study is part of the PREVIEW randomised controlled trial (www.previewstudy.com). In total, 155 younger (27–45 years) and older (46–70 years) men and women with overweight/obesity (BMI >25 kg/m^2) and pre-diabetes were recruited and underwent a total meal replacement diet (~3400 kJ/day) for 2 months using Cambridge Weight Plan products, followed by a weight maintenance program until 36 months. At 0 (baseline), 2, 12 and 36 months, dominant handgrip strength were measured via hand dynamometry, and BMD was measured at the hip and spine using dual-energy X-ray absorptiometry. An intention-to-treat (ITT) analysis was conducted using a generalized linear mixed-model, with time and group as factors.

Results: Body weight was significantly reduced (by 5.8–12.4%) compared to baseline values in all groups at 2, 12 and 36 months, except in younger women, where body weight returned to values not significantly different from baseline by 36 months (Table 1). At 36 months, all groups showed significant reductions from baseline in dominant handgrip strength (Table 1). These reductions represented 6.8–11.8% of baseline handgrip strength, which is on par with the amount of muscle strength lost per decade (8–10%) in adults >40 years. In addition, at 12 months, older but not younger men and women exhibited significant reductions from baseline in dominant handgrip strength. Older women also showed decreases from baseline in hip BMD at 12 months (-0.02 ± 0.004 g/cm^3, $P < 0.001$), and decreases in spine BMD at 12 (-0.014 ± 0.006 g/cm^3) and 36 months (-0.035 ± 0.006 g/cm^3; $P < 0.05$ for both), with no significant change from baseline in any other group at 2, 12 or 36 months.

Conclusion: Strategies to monitor and protect against loss of muscle strength and BMD during use of low energy (total meal replacement) diets are called for, particularly in older women. However, given the known gravity of obesity-related health complications, concerns about potential effects of low energy diets on muscle strength and BMD should not deter clinicians from using these diets to manage overweight/obesity, with due care to monitor and protect musculoskeletal integrity before, during and after the diet.

Table 1: Changes in body weight and handgrip strength in younger and older men and women

Outcome	Time (months)	Younger men	Younger women	Older men	Older women
Body weight (kg)	0	108.2±4.8 (n=14)	102.3±3.4 (n=28)	102.9±3.2 (n=32)	96.3±2.0 (n=81)
	2	95.5±4.7* (n=14)	91.8±3.3* (n=25)	90.0±3.1* (n=32)	86.2±1.9* (n=81)
	12	97.6±5.1* (n=11)	92.7±3.6* (n=18)	92.5±3.4* (n=26)	86.5±2.1* (n=77)
	36	101.7±5.1* (n=10)	99.5±3.7 (n=14)	95.1±3.3* (n=25)	90.9±2.1* (n=61)
Dominant handgrip strength (kg)	0	43.9±2.9	38.0±2.0	39.1±1.9	36.3±1.2

High dietary glycaemic load is associated with increased levels of plasma and urinary methylglyoxal hydroimidazolones (MG-H1) in type 2 diabetes: the CODAM study

K. Maasen[1,2], M.M. van Greevenbroek[1,2], C.J.H. van der Kallen[1,2], C.D.A. Stehouwer[1,2], C.G. Schalkwijk[1,2];
[1]CARIM School for Cardiovascular Diseases, Maastricht University Medical Centre, Maastricht, [2]Department of Internal Medicine, Maastricht University Medical Centre, Maastricht, Netherlands.

Background and aims: Accumulation of advanced glycation endproducts (AGEs) and AGE-precursors (dicarbonyls) contributes to the development of diabetic complications. We previously found increased circulating levels of the dicarbonyls methylglyoxal (MGO), glyoxal (GO), and 3-deoxyglucosone (3-DG) after an oral glucose tolerance test and mixed meal test. Glycaemic Index (GI) is a value assigned to foods based on how quickly they affect blood glucose and Glycaemic Load (GL) represents carbohydrate quality and quantity in a serving of that food. In this study, we examined associations of dietary GI and GL with dicarbonyls and AGEs.

Materials and methods: Cross-sectional analyses were performed in the Cohort on Diabetes and Atherosclerosis Maastricht (CODAM [$n = 574$, 25% Type 2 Diabetes (T2DM), 59 ± 7 years]). GI and GL were derived from a Food Frequency Questionnaire. Dicarbonyls and AGEs were measured in fasting state by UPLC-MS/MS. MGO, GO and 3-DG were measured in plasma and free forms of hydroimidazolone (MG-H1), N^{ε}-(carboxymethyl)lysine (CML), N^{ε}-(carboxyethyl)lysine (CEL) were measured in both plasma and urine. Protein-bound CML, CEL and pentosidine were measured in plasma. Multiple linear regression was performed with log-transformed and standardized dicarbonyls and AGEs (dependent variables), and standardized dietary GI or GL content (main independent variables). Models were adjusted for age, sex, glucose metabolism status, BMI, smoking, physical activity, medication, kidney function, alcohol intake, and dietary fat and fibre.

Results: GI was not significantly associated with dicarbonyl or AGE levels ($-0.070 < \beta < 0.051$, $0.1 < p$ value < 0.8). GL was associated with plasma MG-H1 after adjustment for age and sex ($\beta = 0.137$, 95%CI [0.048; 0.227], $p = 0.003$). Statistical significance was just lost in the fully adjusted model ($\beta = 0.133$, 95%CI [−0.018; 0.284], $p = 0.084$). A similar positive association was observed between GL and urinary MG-H1 ($\beta = 0.168$, 95%CI [−0.001; 0.338], $p = 0.052$). Significant interaction with glucose metabolism status was found for the association between GL and plasma MG-H1, urinary MG-H1 and plasma CEL (all $p < 0.1$). After stratification by glucose metabolism status, GL was most strongly associated with circulating and urinary MG-H1 in T2DM individuals ($\beta = 0.369$, 95%CI [0.038; 0.700], $p = 0.029$ and $\beta = 0.367$, 95%CI [0.014; 0.721], $p = 0.042$ respectively). In addition, GL was in the total cohort inversely associated with GO ($\beta = -0.174$ 95%CI [−0.327; −0.021], $p = 0.026$) and protein-bound pentosidine ($\beta = -0.184$, 95%CI [−0.335; −0.033], $p = 0.017$) in the fully adjusted model.

Conclusion: Circulating and urinary levels of MG-H1 were higher in individuals who had a higher glycaemic load in their habitual diet. These associations remained statistically significant after adjustments for potential confounders in T2DM but not in the total cohort. The lack of association with GI suggests that dietary carbohydrate quantity rather than quality is important for the effect of diet on circulating AGEs. The fact that the most consistent and positive association was observed for MG-H1 suggests that dietary GL induces MG-H1 via transient increases in MGO.

Effects of the bitter taste receptor agonist, denatonium benzoate, on postprandial glycaemia, gastric emptying and energy intake in type 2 diabetes

C. Xie, X. Wang, M.J. Bound, J. Grivell, R.L. Young, K.L. Jones, M. Horowitz, C.K. Rayner, T. Wu;
Adelaide Medical School, University of Adelaide, Adelaide, Australia.

Background and aims: The gastrointestinal tract, like the tongue, has the capacity to "taste" nutrients through activation of G protein coupled-receptors (GPCRs). Emerging evidence from preclinical models and healthy humans has linked activation of gastrointestinal bitter taste receptors (BTRs) to stimulation of gastrointestinal hormones and altered gut motility in association with suppression of energy intake and a reduction in postprandial glycaemic excursions. We have evaluated the effects of the BTR agonist, denatonium benzoate (DB), on gastric emptying, postprandial glycaemia and energy intake in type 2 diabetes (T2DM).
Materials and methods: 16 T2DM patients managed by diet ± metformin (7 male and 9 female; mean age 66.6 ± 1.0 years; BMI 31.3 ± 1.1 kg/m^2; HbA1c 6.6 ± 0.1%; duration of known diabetes 6.4 ± 1.2 years), were studied on 4 occasions (Parts A and B; 2 days each) in double-blind, randomised fashion. In Part A, subjects consumed a gelatin capsule containing either 30 mg DB (a dose shown to reduce energy intake in healthy subjects in our unpublished study) or sodium chloride (control) with 150 mL water and 30 min later consumed a standardised mashed potato meal (1541.8 kJ) labelled with 100 μL ^{13}C-octanoic acid to evaluate gastric emptying and postprandial glycaemia. In Part B, subjects consumed the capsule containing DB or control and were offered a standardised *ad libitum* buffet meal after 30 min, to evaluate energy intake. In part A, "Arterialised" venous blood was sampled every 30 min for measurement of plasma glucose and breath samples collected for the determination of the gastric half-emptying time (T50). Energy intake was quantified using Foodworks software. Data are means ± SEM. $P < 0.05$ was considered statistically significant.
Results: Subjects tolerated the studies well, without nausea. Compared with control, DB had no effect on gastric emptying (T50: DB 176 ± 10 min vs. control 178 ± 12 min) or plasma glucose after the standardised mashed potato meal, but reduced both energy intake (DB 3254 ± 377 kJ vs. control 3695 ± 467 kJ, $P = 0.046$) and the weight of food intake (DB 935 ± 78 g vs. control 1034 ± 93 g, $P = 0.027$) at the buffet meal.
Conclusion: In relatively well controlled T2DM, oral administration of the BTR agonist, DB, has no effect on gastric emptying or postprandial glycaemia, but suppresses energy intake. Stimulation of intestinal BTRs may represent a novel approach to the management of obesity in T2DM.

Chronic hyperadiponectinaemia ameliorates bone quality in aged mice by promoting osteogenesis rather than inhibiting bone resorption

S. Otabe[1], Y. Xiaohong[1], T. Ohki[1], T. Hashinaga[1], N. Wada[1], H. Nakayama[1], N. Tohgi[2], M. Nomura[1], K. Yamada[3];
[1]Department of Medicine, Kurume University School of Medicine, Fukuoka, [2]Department of Medicine, Yamada Memorial Hospital, Mihara, [3]Department of Medicine, Asakura Medical Association Hospital, Asakura, Japan.

Background and aims: Fragility bone fractures, caused by osteoporosis, are an important global concern, particularly among our aging population. Furthermore, alterations in bone quality are the underlying basis for fragility fractures in patients with diabetes. We previously demonstrated that adiponectin—a physiologically active substance secreted specifically by adipocytes—possesses anti-aging effects in mammals. Here, we used transgenic mice to investigate the effects of adiponectin at the third vertebral body and femoral bone, as two common sites of bone fracture in older persons.
Materials and methods: Transgenic mice with hyperadiponectinemia *derived from only hepatocytes* from birth and C57BL6 mice (control) were fed with normal chow ad libitum and were sacrificed at the age of 60 weeks ($n = 4$ per group, males and females). The serum levels of human and mouse adiponectin were measured using ELISA kits for human adiponectin (Otsuka, Japan) and mouse adiponectin (AdipoGen, Korea), respectively, without detectable cross-reactivity. Mice were injected with calcein and tetracycline labels before sacrifice, and samples were assayed for various measures of *bone histo*morphometry evaluated by the Bone Ito Histomorphometry Institute (Nigata, Japan).
Results: There was no significant difference in the bodyweight of C57BL/6N and transgenic mice in males (36.1 ± 4.8 g vs. 30.4 ± 1.5 g) or females (27.1 ± 4.7 g vs. 31.5 ± 3.3 g). The concentration of hepatocyte-derived exogenous human adiponectin in male and female transgenic mice was high: 686.3 ± 287.7 μg/mL and 596.3 ± 302.1 μg/ml, respectively. Adipocyte-secreted endogenous mouse adiponectin was significantly higher in the transgenic mice (203.1 ± 45.3 μg/mL and 221.7 ± 76.2 μg/mL) than in C57BL/6N mice (31.5 ± 11.2 μg/mL and 33.0 ± 11.7 μg/mL) in males and females, respectively. Cancellous bone volume at the third lumbar vertebra was not significantly different between C57BL/6N and transgenic mice, respectively, in females (16.86% ± 4.00% vs. 16.19% ± 0.45%), but was significantly different in males, with higher values in the transgenic mice (11.33% ± 0.54% vs. 18.63% ± 0.30%, respectively; $P < 0.001$). Mineral apposition rates at the third lumbar vertebra and the femoral shaft were significantly higher in transgenic mice than in C57BL6 mice in both males (2.15 ± 0.20 vs. 1.39 ± 0.11; $P < 0.001$, 1.47 ± 0.20 vs. 0.59 ± 0.16 μm/day; $P < 0.0005$) and females (2.86 ± 0.13 vs. 1.67 ± 0.37; $P < 0.0009$, 1.62 ± 0.06 vs. 0.96 ± 0.09 μm/day; $P < 0.0001$). Moreover, bone formation rates at the bone surface at both the third lumbar vertebra and femoral shaft were significantly higher in transgenic mice as compared with C57BL6 mice in males (0.198 ± 0.056 vs. 0.096 ± 0.022; $P < 0.02$, 0.157 ± 0.055 vs 0.029 ± 0.030 mm^3/mm^2/year; $P < 0.006$) and in females (0.357 ± 0.014 vs 0.188 ± 0.021; $P < 0.0001$, 0.417 ± 0.171 vs 0.126 ± 0.015 mm^3/mm^2/year; $P < 0.02$). There were no differences in eroded surface/bone surface (%), or osteoclast number/bone surface (N/mm) between C57BL/6N and transgenic mice in both sexes.
Conclusion: Chronic hyperadiponectinemia significantly promotes osteogenesis in aged mice. Maintaining high adiponectin serum levels or administering an analogue could prevent diabetes-associated bone fracture.

The dual PPARα/γ-agonist tesaglitazar robustly induces browning of white fat in vitro and in vivo

T. Kroon[1], M. Harms[1], D. Nilsson[2], A. Lindblom[1], P. Gennemark[1], G. O'Mahony[1], V. Osinski[3], C. MacNamara[3], J. Boucher[1,2];
[1]Cardiovascular, Renal and Metabolism, IMED Biotech Unit, AstraZeneca, Gothenburg, Sweden, [2]Wallenberg Centre for Molecular and Translational Medicine, The Lundberg Laboratory for Diabetes Research, University of Gothenburg, Gothenburg, Sweden, [3]Department of Medicine, Cardiovascular Research Center, University of Virginia, Charlottesville, USA.

Background and aims: Peroxisome proliferator-activated receptors (PPARs) are key transcription factors that regulate both white and brown fat development and function, and the conversion of white into brown-like adipocytes. Here we investigated whether PPARα and PPARγ possess a synergistic ability to induce browning of white fat.
Materials and methods: *In vitro* experiments were performed in primary mouse white preadipocytes and *in vivo* studies were conducted in lean and diet-induced obese C57bl/6 mice, treated with various selective PPARα, selective PPARγ or dual PPARα/γ agonists. Cell and tissue gene expression was measured by qPCR. Body and tissue weight, food intake, energy expenditure, liver lipid content and plasma glucose, insulin and lipids were quantified.
Results: *In vitro* testing of structurally diverse dual PPARα/γ agonists in mouse preadipocytes identified tesaglitazar as the most robust inducer of uncoupling protein 1 (*Ucp1*), increasing *Ucp1* by several hundred fold after an 8-day treatment. Tesaglitazar increased expression of a broad range of brown fat-related genes, including the key transcriptional regulators *Pgc1α* and *Prdm16*, and was associated with increased mitochondrial content. Importantly, tesaglitazar also strongly induced browning *in vivo* in both lean and obese mice. Tesaglitazar increased *Ucp1* mRNA levels >200-fold in the inguinal fat of obese mice, largely exceeding the 5-fold increase observed with rosiglitazone treatment. Tesaglitazar-induced browning was associated with increased energy expenditure, enhanced insulin sensitivity, reduced liver steatosis and an overall improved metabolic profile compared to rosiglitazone and vehicle control groups. I*n vitro* however, rosiglitazone and tesaglitazar were found to be equally potent *Ucp1* inducers, and combining rosiglitazone with the selective PPARα agonist WY14643, did not result in any further increase in *Ucp1*. Fibroblast growth factor 21 (FGF21) is a hormone mostly produced by the liver, which has been shown to induce browning of white fat in rodent models and is under PPARα control. Following tesaglitazar treatment, FGF21 liver expression and circulating levels were increased 3- and 8-fold, respectively, but were not changed with rosiglitazone treatment. Moreover, linear regression revealed a strong correlation between circulating FGF21 levels and inguinal fat *Ucp1* mRNA expression ($r^2 = 0.75$, $P < 0.001$), suggesting that FGF21 plays a role in the browning effect of tesaglitazar.
Conclusion: PPARγ agonism alone is sufficient for the conversion of white into brown-like adipocytes *in vitro,* but dual PPARα/γ agonism is superior to PPARγ agonism alone at inducing white fat browning *in vivo*, through additional PPARα-mediated increase in FGF21. Together, these findings identify a novel opportunity to develop compounds with robust browning of white fat, through modulation of multiple PPARs.

AAV-mediated overexpression of BMP7 induces white adipose tissue adipogenesis and reverses insulin resistance

E. Casana, V. Jimenez, V. Sacristan, S. Muñoz, C. Jambrina, J. Rodo, S. Darriba, C. Mallol, M. Garcia, X. Leon, I. Grass, S. Franckhauser, F. Bosch;
Universitat Autonoma de Barcelona, Bellaterra, Spain.

Background and aims: Obesity and type 2 diabetes are strongly associated and a major health problem because of their alarmingly growing prevalence worldwide. The hypertrophic expansion of white adipose tissue (WAT) promotes ectopic fat accumulation and development of insulin resistance whereas WAT hyperplasia is associated with preservation of insulin sensitivity. Several members of the Bone Morphogenetic Protein (BMP) family have been shown to play a role in white and/or brown adipogenesis and energy homeostasis. Although BMP7 has extensively been reported to induce brown adipogenesis in vitro, its role on WAT expandability and its potential contribution to insulin sensitivity remains to be elucidated.
Materials and methods: Specific overexpression of BMP7 in WAT was obtained by means of intra-depot administration of adeno-associated viral (AAV) vectors encoding for a murine optimized BMP7 coding sequence under the control of the CAG promoter in conjunction with target sequences of the liver-specific microRNA122a and the heart-specific microRNA1. To achieve specific overexpression of BMP7 in the liver, intravenous administration of AAV vectors bearing a murine optimized BMP7 coding sequence and the liver-specific hAAT promoter was carried out.
Results: Local administration of AAV vectors encoding BMP7 in WAT resulted in hyperplasic expansion of WAT together with reduced liver steatosis and amelioration of insulin sensitivity in both HFD-fed and ob/ob obese mice. In contrast, the AAV-mediated overexpression of BMP7 specifically in the liver did not promote WAT hyperplasia although the circulating levels of BMP7 achieved were similar to those obtained after intra-WAT administration of AAV vectors. Nevertheless, when liver-derived BMP7 circulating levels were further increased, body weight and insulin sensitivity were normalised in HFD-fed as well as in ob/ob mice.
Conclusion: Altogether, the results of this study unravel a new role of BMP7 on white adipogenesis. In addition, this study highlights the therapeutic potential of AAV-mediated BMP7 gene therapy to ameliorate obesity and insulin resistance.

PCSK9 deficiency results in altered insulin secretion and glucose intolerance: the role of the LDL receptor

G. Norata, L. Da Dalt, M. Ruscica, C. Perego, A. Catapano;
University of Milan, Milan, Italy.

Background and aims: *PCSK9* loss of function genetic variants are associated with lower LDL cholesterol but also with higher plasma glucose levels and increased risk of type 2 diabetes mellitus. Here we investigated the molecular mechanisms underlying this association.
Materials and methods: *Pcsk9* KO, WT, *Pcsk9/Ldlr* DKO, *Ldlr* KO, albumin *AlbCre+/Pcsk9*$^{LoxP/LoxP}$ (liver selective *Pcsk9* knock-out mice) and *AlbCre-/Pcsk9*$^{LoxP/LoxP}$ mice were used. GTT, ITT, insulin and C-peptide plasma levels, pancreas morphology and cholesterol accumulation in pancreatic islets were studied in the different animal models.
Results: Glucose clearance was significantly impaired in *Pcsk9* KO mice fed a standard or a high fat diet for 20 weeks compared to WT animals, insulin sensitivity however was not affected. A detailed analysis of pancreas morphology of *Pcsk9* KO mice vs controls revealed larger islets with increased accumulation of cholesteryl esters, paralleled by increased insulin intracellular levels and decreased plasma insulin and C-peptide levels. This phenotype was completely reverted in *Pcsk9/Ldlr* DKO mice implying the LDLR as the PCSK9 target responsible for the phenotype observed. Further studies in albumin *AlbCre+/Pcsk9*$^{LoxP/LoxP}$, which lack detectable circulating PCSK9, also showed a complete recovery of the phenotype, thus indicating that circulating, liver-derived PCSK9, the principal target of monoclonal antibodies, does not impact beta cells function and insulin secretion.

Conclusion: PCSK9 critically controls LDLR expression in pancreas perhaps contributing to the maintenance of a proper physiological balance to limit cholesterol overload in beta cells. This effect is independent of circulating PCSK9, and is probably related to locally produced PCSK9. These data suggest that anti-PCSK9 therapies, which target mainly circulating PCSK9, might have a limited impact on beta cell dysfunction and the incidence of diabetes in contrast to Mendelian randomization analysis where the effect of global PCSK9 deficiency was investigated.

Newly discovered regulator of lipid metabolism: pyruvate dehydrogenase kinase 1

C.L.K. Leung, S. Karunakaran, B.X. Hu, J. Dong, L. Tang, S. Wei, Z. Rajwani, J.D. Johnson, S.M. Clee;
Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada.

Background and aims: Pyruvate dehydrogenase kinases (PDKs) are a family of enzymes with isoforms 1–4 that have been studied as a therapy for diabetes and cancers. PDKs are mitochondrial proteins that inactivate pyruvate dehydrogenase, which regulates the entry of pyruvate into the Kreb's Cycle. This generates acetyl-CoA that can either be oxidized or used for lipid synthesis. Previous studies have shown that PDK2 and 4 knockout mice have improved glucose tolerance and glucose oxidation. Downregulation of PDK2 and 4 has been shown to ameliorate diabetes. However, PDK1 is regulated differently and its role in whole body glucose and lipid metabolism has not been directly tested. We hypothesized that decreasing PDK1 would increase glucose tolerance and lipid metabolism.
Materials and methods: We studied PDK1 knockout (KO) and wildtype (WT) littermate mice fed a high fat diet (60% fat, with sucrose) from weaning. Body weights were measured weekly. At 10 weeks, we conducted insulin tolerance test (ITT) using 1 U/kg intraperitoneal insulin dose. At 6 and 11 weeks, we conducted glucose tolerance tests (GTT) using 1 g/kg intraperitoneal glucose. At 12 weeks, we collected 4 hour fasted cardiac bleeds. We used enzymatic colorimetric assays to measure triglyceride, cholesterol and glucose levels in plasma samples. Insulin from GTT and cardiac bleeds were measured using ELISAs. We conducted a chloroform methanol lipid extraction on 12 week old flash frozen heart and livers from PDK1 KO mice to determine cholesterol and triglyceride content. We isolated primary islets and conducted perifusion of KO and WT mice using 120 matched islets from each. Perifusion solutions were made of 3 mM glucose (basal), 20 mM glucose or basal glucose with 30 mM KCl in Krebs Ringer Bicarbonate buffer and were flowed through at a rate of 1 mL/minute for 20–30 minutes for each secretagogue with 30 minutes basal glucose in between each. Perifusion fractions (1.7 mL) were collected every 5 minutes and measured for insulin using radioimmunoassay.
Results: Mice with reduced PDK1 had body weights similar to WT littermates ($p > 0.05$). We found modestly improved glucose tolerance in mice lacking PDK1 ($p = 0.2$), but no difference in fasting glucose and insulin levels ($p > 0.05$). We also conducted insulin tolerance tests and were unable to detect a difference between WT and KO ($p > 0.05$). From perifusion of isolated primary islets, we were also unable to detect a difference in insulin secretion between WT and KO ($p > 0.05$). However, we found a larger role of PDK1 on lipid metabolism that was not previously shown in other PDKs. We did not observe effects on fasting cholesterol levels, but found mice with reduced PDK1 had a 68% reduction in triglyceride levels ($p = 0.02$). We have found no changes in cholesterol levels in liver and heart ($p > 0.05$). We also found no evidence for altered hepatic triglyceride contents. However, PDK1 KO hearts had a 43% increase in triglyceride levels ($p = 0.0003$).
Conclusion: Our data suggest reduced PDK1 is associated with a modest improvement in glucose tolerance, no changes in insulin sensitivity. Importantly, we found a significant reduction of plasma triglycerides, but increased triglyceride concentrations in hearts. Together these data suggest an important and previously unknown role of PDK1 in metabolism and of PDKs in lipid metabolism, and that reducing PDK1 may have significant effects on glucose and lipid metabolism.

Evaluation of changes in serum lipid intermediate oxidation products in the progress of type 2 diabetes development

M. Ciborowski[1], J. Godzien[2], J. Siroka[3], F. Traldi[2], M. Gorska[1], C. Barbas[2], A. Kretowski[1];
[1]Medical University of Bialystok, Bialystok, Poland, [2]Universidad CEU San Pablo, Madrid, Spain, [3]Palacký University in Olomouc, Olomouc, Czech Republic.

Background and aims: Oxidative stress is considered as one of the factors underlying the development of insulin resistance and type 2 diabetes mellitus (T2DM). A major mechanism responsible for increased oxidative stress is hyperglycemia-induced production of reactive oxygen species (ROS). Formation of the final products of lipid peroxidation: 4-hydroxynonenal (HNE) and malondialdehyde (MDA) is proceeded by appearance of lipids with fatty acids oxidized to their hydroxyl -OH, dihydroxyl -$(OH)_2$, peroxyl-OOH, keto- and epoxy forms. In case of phosphatidylcholines (PCs), these intermediate oxidation products are important signalling molecules associated with platelet aggregation, proliferation and migration of vascular smooth muscle cells, inflammatory response, endoplasmic reticulum stress and apoptosis. In this study changes in serum oxidized fatty acids (oxFAs) and oxidized PCs (oxPCs) were evaluate during the progress of T2DM development.
Materials and methods: The study group consisted of 204 individuals divided into 4 age and sex-matched groups: healthy controls (52 ± 11 years, BMI = 28 ± 5), subjects with IR but without dysglycemia (47 ± 11 years, BMI = 30 ± 8), with prediabetes (PD) (53 ± 9 years, BMI = 30 ± 7), and type 2 diabetes (T2DM) (53 ± 10 years, BMI = 32 ± 7). Serum samples were fingerprinted using LC-QTOF-MS. The analytical standard mixture of oxPCs was used to evaluate MS/MS fragmentation pattern characteristic to different PCs oxidation products (hydroxyl -OH, dihydroxyl -(OH)2, peroxyl -OOH, keto =O and epoxy forms). Based on that information we searched for oxFAs and oxPCs in the fingerprinting data. Differences in the level of found oxidized lipids between control, IR, PD and T2DM individuals were evaluated by Welch's t-test.
Results: In the studied samples we have found hydroxyl-FAs and hydroxyl-PCs as well as -OOH, -$(OH)_2$ and =O modified PCs; e.g.: hydroxyl docosahexaenoic and hydroxyl arachidonic acids, PC (34:2-OH), PC (34:2-OOH), PC (36:6-$(OH)_2$) or PC (36:2=O). There was a characteristic pattern of changes in oxidized lipid species related to T2DM development. In comparison to healthy controls increase in IR (+44–78%, $p = 0.02$–0.05) and PD groups (+50–101%, $p = 0.05$) was observed. Surprisingly, in subjects with overt type 2 diabetes serum lipid intermediate oxidation products levels were decreased (−25–85%, $p = 0.001$–0.04) in comparison to controls.
Conclusion: To our knowledge this is the first study identifying serum lipid intermediate oxidation products and evaluating their change in the course of T2DM development. A decrease of oxidized lipids in T2DM patients is probably due to the formation of lipid peroxidation end-products (HNE and MDA).

Physical activity and the risk of LADA, results from a Swedish case-control study and the Norwegian HUNT Study

R. Hjort[1], E. Ahlqvist[2], L. Alfredsson[1], V. Grill[3,4], L. Groop[2], A. Rosengren[2], T. Tuomi[5,6], B.O. Åsvold[3,7], S. Carlsson[1];
[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, [2]Department of Clinical Sciences in Malmö, Clinical Research Centre, Lund University, Malmö, Sweden, [3]Department of Endocrinology, St. Olavs Hospital, Trondheim University Hospital, Trondheim, Norway, [4]Department of Clinical and Molecular Medicine, NTNU, Norwegian University of Science and Technology, Trondheim, Norway, [5]Abdominal Center, Endocrinology, Helsinki University Central Hospital, Research Program for Diabetes and Obesity, University of Helsinki, Helsinki, Finland, [6]Folkhälsan Research Center, Helsinki, Finland, [7]K.G. Jebsen Center for Genetic Epidemiology, Department of Public Health and Nursing, NTNU, Norwegian University of Science and Technology, Trondheim, Norway.

Background and aims: Physical activity (PA) has been linked to a reduced risk of type 2 diabetes (T2D) by ways of improving insulin sensitivity in key metabolic organs. We set out to investigate if PA was associated with a reduced risk of latent autoimmune diabetes in adults (LADA), and whether the association was modified by HLA genotype.
Materials and methods: We used data from a Swedish population-based case-control study with incident cases of LADA ($n = 474$, GADA-positive) and T2D ($n = 1593$ GADA-negative) and matched controls ($n = 3032$), and prospective data from the Norwegian HUNT Study, including 1,012,957 person-years of follow-up (1986–2008) and incident cases of LADA ($n = 147$) and T2D ($n = 2002$). We estimated odds ratios (OR) and hazard ratios (OR) of diabetes in relation to self-reported leisure time PA in four (high, moderate, low vs. sedentary) and two categories (active vs. sedentary) and adjusted for age, sex, family history of diabetes, smoking and BMI (kg/m^2). Analyses of the Swedish data were stratified by HLA DR-DQ genotypes.
Results: High PA was associated with a reduced risk of LADA in both the Swedish (OR 0.66, 95% CI 0.45–0.97) and Norwegian (HR 0.45, 95% CI 0.23–0.90) data (Table 1). The association did not persist after adjustment for BMI. High PA was also associated with a reduced risk of T2D, which was attenuated but remained after adjustment for BMI. Stratification by HLA genotype indicated that PA was associated with LADA only among those with low-risk genotypes. Sedentary compared to active LADA patients had higher mean BMI (31.2 vs. 27.6, $p < 0.0001$), were more insulin resistant (HOMA 3.60 vs. 2.60, $p = 0.0032$), had better beta-cell function (HOMA 51.1 vs. 36.6, $p = 0.0113$) and higher proportion of HLA low-risk genotypes (31.9 vs. 20.4, $p = 0.0372$).
Conclusion: These findings indicate that physical activity is associated with a reduced risk of LADA, which is mediated by beneficial effects on body weight and likely involve insulin sensitivity. A protective effect does not seem to apply to individuals with high-risk HLA genotypes, in whom a beneficial effect from physical activity on body weight and insulin sensitivity may not be enough to prevent or postpone onset of LADA.

Genetic discrimination between LADA and type 1 diabetes within the MHC

R. Mishra[1], J.P. Bradfield[2], D.L. Cousminer[1], A. Chesi[1], K.M. Hodge[1], H. Hakonarson[2], BMDCS, D. Mauricio[3], N.C. Schloot[4], K.B. Yderstræde[5], B.F. Voight[6], S. Schwartz[7], B.O. Boehm[8,9], R.D.G. Leslie[10], S.F.A. Grant[1];
[1]Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, USA, [2]Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, USA, [3]Hospital Universitari Germans Trias i Pujol, Badalona, Spain, [4]German Diabetes Center, Düsseldorf, Germany, [5]Odense University Hospital, Odense, Denmark, [6]Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, USA, [7]Main Line Health System, Wynnewood, USA, [8]Department of Internal Medicine I, Ulm University Medical Centre, Ulm, Germany, [9]LKC School of Medicine, Nanyang Technological University, Singapore and Imperial College London, London, UK, [10]ActionLADA/Department of Immunobiology, Barts and the London School of Medicine and Dentistry, Queen Mary University of London, London, UK.

Background and aims: Studies on type 1 diabetes (T1D) and type 2 diabetes have revealed significant insights into novel biological mechanisms underlying diabetes, yet the genetic etiology of latent autoimmune diabetes in adults (LADA) remains largely unknown; furthermore, improved biomarkers of LADA are required to optimize diagnosis. Our genome-wide association assessment shows that the major histocompatibility complex (MHC) harbors the strongest association with LADA; however, the association is clearly attenuated compared to observations in T1D cohorts. While T1D susceptibility has long been known to be principally harbored within the MHC Class II genes *HLA-DQB1* and *HLA-DRB1*, variation in the MHC class I genes *HLA-A* and *HLA-B* have been subsequently shown, through conditional analysis, to increase T1D risk further. Given that MHC Class I markers have also been shown to be associated with lower age-at-diagnosis in T1D, the adult-onset disease of LADA is well placed to shed further light on this association.
Materials and methods: To investigate potential genetic discriminators at the MHC between LADA and T1D, we attempted recapitulation of findings in Nejentsev et al using an imputation-based approach and performing forward stepwise conditional logistic regression of the MHC region in T1D cases ($n = 1990$) and controls ($n = 2856$) from the Wellcome Trust Case Control Consortium (WTCCC), and in a well-phenotyped LADA cohort ($n = 978$) using population-based controls ($n = 1057$).
Results: We confirmed the strongest T1D associations at *HLA-DRB1* and *HLA-DQB1* ($P = 6.10 \times 10^{-175}$ and $P = 2.90 \times 10^{-219}$, respectively), as well as the independent effect of *HLA-B* ($P = 1.67 \times 10^{-14}$) and *HLA-A* ($P = 5.25 \times 10^{-8}$) to T1D. We then performed the conditional analysis in the LADA and population-based controls cohort, observing significant association at *HLA-DRB1* and *HLA-DQB1* ($P = 5.93 \times 10^{-22}$ and $P = 4.68 \times 10^{-13}$, respectively), although of diminished effect size when compared to T1D. Notably, we did not observe significant independent effects in *HLA-B* or *HLA-A* for LADA. After sensitivity analyses through the systematic decreasing of the sample size of T1D and WTCCC controls in order to contrast with the LADA vs controls sample size, the independent effects of *HLA-B* and *HLA-A* consistently remained.
Conclusion: Despite significant association at *HLA-DQB1* and *HLA-DRB1* with LADA, we did not observe independent effects of *HLA-B* and *HLA-A*. These results highlight a potential use for MHC Class I markers in differentiating T1D from LADA.

Development and validation of a clinical prediction model to identify adult patients (aged 18–50) with type 1 diabetes requiring early insulin therapy

A.L. Grubb[1], K. Patel[1], R.A. Oram[1,2], A.V. Hill[1], C. Angwin[1], T.J. McDonald[1,2], M.N. Weedon[1], A.T. Hattersley[1,2], K.R. Owen[3,4], B.M. Shields[1], A.G. Jones[1,2];
[1]National Institute for Health Research Exeter Clinical Research Facility, Exeter, [2]Royal Devon and Exeter NHS Foundation Trust, Exeter, [3]Oxford Centre for Diabetes Endocrinology and Metabolism, Oxford, UK, [4]Oxford NIHR Biomedical Centre, Oxford, UK.

Background and aims: Correctly determining diabetes subtype at diagnosis is important to ensure optimal treatment and education, but is often difficult, particularly in young adults, where misclassification is common. We aimed to develop a clinical prediction model combining clinical features and GAD islet-autoantibodies to accurately identify patients with type 1 diabetes.
Materials and methods: We studied 1,352 participants in Exeter-based cross-sectional cohorts diagnosed with diabetes between the ages of 18 and 50. Our study outcome was type 1 diabetes, which was robustly defined as the presence of both severe endogenous insulin deficiency (C-peptide <200 pmol/L) and rapid insulin requirement (≤3 years). We examined the relationship between clinical features (age at diagnosis and BMI), GAD islet-autoantibodies and the presence of type 1 diabetes using logistic regression. We developed two prediction models based on; 1) clinical features 2) clinical features and GAD islet-autoantibodies. External validation of the models was performed using 701 participants taken from the Young Diabetes in Oxford study (UK).
Results: Type 1 diabetes was present in 13% of participants in the Exeter cohort ($n = 179/1352$). Participants with type 1 diabetes were younger at diagnosis (median 30 years versus 44 years, $p < 0.001$), had a lower BMI (median 26 kg/m^2 versus 34 kg/m^2, $p < 0.001$) and a higher percentage of them were GAD positive (62% versus 5%, $p < 0.001$). Age of diagnosis, BMI and GAD islet-autoantibodies were discriminative and independent predictors of type 1 diabetes ($p < 0.001$ for all). The model combining clinical features was highly discriminative (AUC ROC 0.90 [95% CI 0.88, 0.93]); adding GAD improved discrimination (AUC ROC 0.96 [0.95, 0.97] $p < 0.001$). Type 1 diabetes was present in 19% of the participants in the Young Diabetes in Oxford study ($n = 134/701$). In the external validation, both models still showed excellent discrimination (clinical features AUC ROC 0.86 [0.82, 0.89]; clinical features + GAD AUC ROC 0.92 [0.89, 0.95] $p < 0.001$).
Conclusion: This is the first study to show that a clinical prediction model combining age at diagnosis, BMI and GAD islet-autoantibodies can accurately identify type 1 diabetes in a group of patients where misclassification is most common. GAD islet-autoantibodies add additional discrimination over and above clinical features, and may be helpful where clinical features are inconclusive. Our model has excellent discrimination and routine use of this model in clinical practice is likely to reduce misclassification.

Genetic determinants of type 1 diabetes

A. Spiliopoulou[1], S.J. McGurnaghan[2], C.N.A. Palmer[3], P.M. McKeigue[1], H.M. Colhoun[2,4], on behalf of the SDRNT1BIO Investigators;
[1]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, [2]Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, [3]Ninewells Hospital and Medical School, University of Dundee, Dundee, [4]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: The Scottish Diabetes Research Network Type 1 Bioresource (SDRNT1BIO) study is a nationally representative cohort of 6127 patients with a clinical diagnosis of T1DM (time to insulin use within 12 months) without restriction on age of onset. We performed a case-control GWAS of T1DM using the SDRNT1BIO cohort and non-diabetic controls from the background population; the Generation Scotland Family Health Study (GS).
Materials and methods: The study included 5172 unrelated T1DM cases from SDRNT1BIO and 7497 unrelated controls from GS. Samples were genotyped using the Illumina Human CoreExome and the OmniExpressExome arrays, and imputed using the online service of the Sanger Institute. GWAS was performed with SNPTEST, adjusting for age, sex and three principal components. Replication was sought in UK Biobank (UKBB). The Immunobase platform was used to define known genetic regions associated with T1DM. The ENSEMBL-VEP and GENOSCORES platforms were used to annotate GWAS findings.
Results: From 54 autosomal regions reported as genome wide significant for T1DM in Immunobase, 50 were replicated at the Bonferroni corrected p value threshold ($p < 0.01/54$), with 20 regions reaching significance below 2×10^{-6}. We confirmed a previously suggested genetic association at the *TNFRS11B* locus (strongest association with intronic SNP rs4242592, $p = 6 \times 10^{-9}$) and identified a novel association for T1DM at the *NOTCH2/ADAM30* locus (strongest association with intronic SNP rs406767, $p = 6 \times 10^{-11}$). The latter was stronger in cases diagnosed after age 25 (OR = 1.34, 95% CI = 1.22–1.49) than in cases diagnosed before age 25 (OR = 1.19, 95% CI = 1.09–1.30). *NOTCH2* has been reported as a genetic locus for type 2 diabetes mellitus (T2DM) in a large GWAS meta-analysis but has not been previously detected as a T1DM locus. The association with rs406767 was replicated for T1DM in UKBB ($p = 4 \times 10^{-4}$). rs406767 is in linkage disequilibrium ($R = 0.89$) with a quantitative trait locus (QTL) of *NOTCH2* expression in whole blood ($p = 2 \times 10^{-9}$), and the allele associated with lower *NOTCH2* expression is associated with higher T1DM risk in SDRNT1BIO and UKBB and higher T2DM risk in UKBB ($p = 2 \times 10^{-6}$). The *TNFRSF11B* locus was reported as a suggestive association in a large T1DM GWAS meta-analysis. Our study confirms this association at genome-wide significance. The direction of effect on T1DM is consistent in UKBB, but the association does not reach replication significance. The allele associated with higher T1DM risk at the *TNFRSF11B* locus is also associated with lower methylation of *TNFRSF11B* in whole blood ($p = 3 \times 10^{-76}$) and with increased bone mineral density ($p = 2 \times 10^{-17}$). *TNFRSF11B* encodes osteoprotegerin, a decoy receptor for the receptor activator of nuclear factor kappa B ligand, which is implicated in inflammation, innate immunity and bone resorption.
Conclusion: We confirm a previously suggested effect of the *TNFRSF11B* locus on T1DM, and identify a novel T1DM association at the *NOTCH2* locus. Although this association, reported previously for T2DM, is stronger for late-onset than early-onset T1DM, it is still detectable in early-onset cases. This adds to the evidence that T1DM and T2DM are part of a continuum, with some genetic features in common.

Antibodies to oxidised insulin improve prediction of type 1 diabetes in children with positive standard islet-autoantibodies

R. Strollo[1], C. Vinci[2], N. Napoli[1], E. Fioriti[1], E. Maddaloni[1], L. Åkerman[3], R. Casas[3], P. Pozzilli[1], J. Ludvigsson[3], A. Nissim[2];
[1]Universitá Campus Bio-Medico, Rome, Italy, [2]Queen Mary, University of London, London, UK, [3]Linköping University, Linköping, Sweden.

Background and aims: We have shown that insulin post-translationally modified by reactive oxidants (oxPTM-INS) is a neoantigen in type 1 diabetes (T1D). Most of T1D subjects or prediabetic children have autoantibodies to oxPTM-INS (oxPTM-INS-Ab). However, it is not clear whether oxPTM-INS-Ab can improve early diagnosis and prediction in association with the standard islet-AAB. Here, we evaluated whether oxPTM-INS-Ab can improve T1D prediction in children with positive islet-autoantibodies (AAB).
Materials and methods: We evaluated sensitivity, specificity, accuracy and risk for progression to T1D associated with oxPTM-INS-Ab and the standard islet-AAB that include insulin (IAA), GAD (GADA), and tyrosine-phosphatase 2 (IA-2A) in a cohort of islet-AAB positive (AAB^+) children (median follow-up 8.8 years) from the 'All Babies in Southeast Sweden' (ABIS), a large prospective birth cohort study in the general population. oxPTM-INS-Ab to insulin modified by hydroxyl radical (•OH) were measured by our developed ELISA platform.
Results: oxPTM-INS-Ab was the most sensitive and specific autoantibody-biomarker (74% sensitivity, 91% specificity), followed by IA-2A (71% sensitivity, 91% specificity). GADA and IAA showed lower sensitivity (65%, and 50%, respectively) and specificity (66%, and 68%, respectively). Accuracy (AUC of ROC) of oxPTM-INS-Ab was higher than GADA and IAA ($p = 0.003$ and $p = 0.017$, respectively), and similar to IA-2A ($p = 0.896$). Risk for diabetes was higher ($p = 0.03$) among multiple AAB^+ who were also oxPTM-INS-Ab^+ compared with those who were oxPTM-INS-Ab^-. Importantly, when replacing IAA with oxPTM-INS-Ab diabetes risk increased to 100% in children with oxPTM-INS-Ab^+ in combination with $GADA^+$, and IA-$2A^+$, compared to 84.37% in those with IAA^+, $GADA^+$, and IA-$2A^+$ ($p = 0.04$).
Conclusion: Antibodies to oxidised insulin (oxPTM-INS-Ab), compared to IAA which measure autoantibodies to native insulin, improve T1D risk assessment and prediction accuracy in AAB^+ children.

Mutations in YIPF5 are a novel cause of neonatal diabetes, highlighting the critical role of endoplasmic reticulum-to-Golgi trafficking in human beta cell survival

E. De Franco[1], M. Lytrivi[2], K. Patel[1], M. Igoillo-Esteve[2], M. Wakeling[1], B. Haliloglu[3], E. Unal[4], T. Godbole[5], M. Yildiz[6], S. Ellard[1], M. Cnop[2], A.T. Hattersley[1];
[1]University of Exeter Medical School, Exeter, UK, [2]ULB Center for Diabetes Research, Bruxelles, Belgium, [3]Yeditepe University Hospital, Istanbul, Turkey, [4]Dicle University, Diyarbakır, Turkey, [5]Harmony Health Hub, Nashik, India, [6]Kanuni Sultan Suleyman Training and Research Hospital, Istanbul, Turkey.

Background and aims: Neonatal diabetes (NDM) diagnosed before 6 months is caused by mutations that reduce β cell number (reduced formation/increased destruction) or impair β cell function. Understanding the genetic basis of rare NDM subtypes highlights fundamental biological processes in β cells. We investigated the genetic cause of a syndrome characterised by NDM, microcephaly and epilepsy.
Materials and methods: We performed whole genome sequencing for 2 unrelated patients with NDM (diagnosed aged 5 and 9 weeks), epilepsy and microcephaly, born to consanguineous parents. Replication studies were performed in 394 patients with NDM (16 with microcephaly) using a targeted next generation sequencing assay. YIPF5 was silenced in the human β cell line EndoC-βH1 using RNA interference. Cells were exposed to the endoplasmic reticulum (ER) stressors thapsigargin and brefeldin A. Apoptosis was evaluated by staining with DNA-binding dyes or real-time annexin V binding assay. mRNA expression was assessed by qPCR.
Results: The two patients had homozygous likely deleterious variants (missense, p.(Ala181Val) and in-frame deletion p.(Lys106del)) in *YIPF5*. Replication studies identified 2 homozygous *YIPF5* mutations (p.(Trp218Arg) and p.(Ile98Ser)) in 3 patients (2 siblings) with insulin treated diabetes diagnosed before the age of 12 months. All patients had epilepsy and microcephaly. YIPF5 mRNA showed abundant expression in pancreas and islets. As YIPF5 is thought to be key in trafficking between ER and Golgi compartments, we examined the impact of YIPF5 deficiency on β cell survival during ER stress. YIPF5 knockdown did not affect basal β cell survival, but it sensitized β-cells to thapsigargin and brefeldin A (respectively $44 \pm 2\%$ and $29 \pm 5\%$ apoptosis vs $24\text{-}25 \pm 3\%$ in control siRNA-transfected cells, $p < 0.05$, $n = 4$). In time course experiments, ER stressed YIPF5-depleted cells showed increased expression of CHOP, BiP and spliced XBP1 ($p < 0.001$ at 24 h, $n = 5$), indicating activation of the 3 canonical branches of the ER stress response. CHOP silencing protected YIPF5-depleted cells from thapsigargin-induced apoptosis ($p < 0.001$, $n = 3$). Expression of the proapoptotic proteins PUMA and DP5 was enhanced by YIPF5 silencing ($p < 0.001$ at 24 h, $n = 5$). Treatment with forskolin, a potent cAMP inducer, abolished apoptosis induced by thapsigargin in YIPF5-depleted cells ($p < 0.001$, $n = 5$).
Conclusion: Homozygous loss of function mutations in *YIPF5* are a novel cause of a syndrome of microcephaly, epilepsy and NDM, which we suggest is termed MEND syndrome. Functional studies show that YIPF5 deficiency reduces β cell survival by enhancing the ER stress response and sensitizing human β cells to ER stress-induced apoptosis. This is the first report of mutations in a gene affecting ER-to-Golgi trafficking resulting in NDM by increasing β cell ER stress. This study highlights an unexpected critical role of *YIPF5* in the human β cell.

Functional state of muscle mitochondria reflects exercise-induced changes in insulin sensitivity and cognitive performance in elderly

J. Ukropec[1], M. Nemec[1], D. Maderova[1], V. Tirpakova[2], P. Krumpolec[1], L. Slobodova[1,3], M. Vajda[4], M. Schon[1,3], J. Cvecka[4], Z. Sumbalova[5,6], M. Sedliak[4], B. Ukropcova[1,3];
[1]Institute of Experimental Endocrinology, Biomedical Research Center, Bratislava, Slovakia, [2]Slovak Health University, Bratislava, Slovakia, [3]Institute of Pathological Physiology Faculty of Medicine Comenius University, Bratislava, Slovakia, [4]Faculty of Physical Education and Sport Comenius University, Bratislava, Slovakia, [5]Faculty of Medicine Comenius University, Bratislava, Slovakia, [6]Medical University of Innsbruck, Innsbruck, Austria.

Background and aims: Sedentary ageing accelerates the risk of chronic metabolic and neurodegenerative diseases, while regular exercise could effectively support healthy ageing. Here we report results of the 3-month supervised aerobic/strength training intervention in seniors with/without mild cognitive impairment and prediabetes.
Materials and methods: Fourteen non-obese sedentary seniors with/without mild cognitive impairment and prediabetes were subjected to 3-month training (3x1h/week), consisting of intensive whole-body aerobic (60–70% HRmax) and resistance exercises (60–70% 1RM) of major muscle groups. Whole-body glucose metabolism (oGTT), insulin sensitivity (euglycemic hyperinsulinemic clamp), resting energy expenditure/REE, metabolic substrate preference/RQ and metabolic flexibility/ΔRQ (indirect calorimetry), daily ambulatory activity (accelerometers/Activinsights) and physical fitness/VO_2max (Rockport Test) were determined. Cognitive functions were assessed with a battery of validated cognitive tests (MMSE/ACE-R/CogState/Memtrax). Biopsy of *m. vastus lateralis* was performed in local anesthesia using Bergström needle technique. Functional state of muscle mitochondria was determined by O_2k high-resolution respirometry, applying SUIT protocols RP1&RP2 (Oroboros). Oxygen consumption rate (pmol/s/mg tissue wet weight) was evaluated in saponin-permeabilized muscle fibers.
Results: Exercise intervention increased propensity to voluntary physical activity, insulin sensitivity, metabolic flexibility, mitochondrial ETC complex I activity, as well as memory and executive functions ($p < 0.05$ for all). Muscle mitochondrial oxidative phosphorylation capacity was negatively associated with BMI ($R = -0{,}548$; $p = 0{,}042$) and mitochondrial fatty acid oxidation rate was positively associated with short-term memory (CogState, $R = 0{,}616$; $p = 0.019$). Improvements in physical fitness were associated with cognitive tests' scores (ACE-R; $R = 0.671$, $p = 0.0002$, CogState; $R = 0.561$, $p = 0.003$) and metabolic flexibility (ΔRQ) with the baseline/leak respiration of muscle mitochondria ($R = 0.440$, $p = 0.05$) as well as with the memory and executive functions ($R = 0.721$, $p = 0.001$). Moreover, non-coupled respiration rate of muscle mitochondria correlated positively with learning/working memory (CogState, $R = 0.412$, $p = 0.032$) and with the psychomotor attention score (CogState, $R = 0.471$, $p = 0.011$).
Conclusion: Our preliminary results showed that exercise-induced changes in functional state of muscle mitochondria are tightly linked to BMI, whole-body metabolic flexibility and cognitive performance in seniors with/without mild cognitive impairment and prediabetes. We are extending the population to investigate the exercise-related links between muscle metabolic and functional state, whole-body metabolism and cognition in prediabetic and metabolically healthy seniors.

Local-tissue hyperinsulinaemia is a greater risk factor for insulin resistance than hyperglycaemia in type 1 diabetes and MODY2

J.M. Gregory, T.J. Smith, N.N. Abumrad, A.D. Cherrington;
Vanderbilt University, Nashville, USA.

Background and aims: Insulin resistance (IR) is strongly associated with macrovascular disease and occurs consistently in type 1 diabetes (T1DM). Mechanisms underpinning T1DM IR are unclear, however. We hypothesized that hyperinsulinemia resulting from peripheral circulation insulin delivery is a greater contributor to tissue-specific IR than hyperglycemia in T1DM.
Materials and methods: Insulin sensitivity was assessed in 3 cohorts with differing conditions for glycemia and insulinemia: healthy controls (euinsulinemia + euglycemia, $n = 10$), MODY2 (euinsulinemia + hyperglycemia, $n = 9$) and T1DM (hyperinsulemia + hyperglycemia equivalent to MODY2, $n = 9$). A 2-step, hyperinsulinemic, euglycemic, pancreatic clamp and isotopic tracer techniques were used to assess tissue-specific IR. Hyperglycemia's contribution to IR was indicated by differences in insulin sensitivity between control and MODY2. Hyperinsulinemia's effect on IR was shown by differences in insulin sensitivity between MODY2 and T1DM. Insulin sensitivity of the liver and fat were quantified by how much a 12 mU/m^2/min insulin infusion (step 1) suppressed glucose production (ΔR_a) and NEFA levels, respectively, from baseline. Muscle insulin sensitivity was determined by quantifying glucose uptake (R_d) during high insulin infusion (40 mU/m^2/min, step 2). Cohorts were matched for age and BMI. T1DM participants received a variable IV insulin infusion overnight to match glucose with the MODY2 group at the start of the clamp.
Results: Risk factors for IR (BMI, age, etc.) were similar between groups. HbA_{1c} was 4.8 ± 0.1, 6.7 ± 0.2 and 6.1 ± 0.1% for control, T1DM and MODY, respectively. Arterialized plasma insulin concentrations (μU/mL) for control, T1DM and MODY2, respectively, were 8.7 ± 0.5, 20.7 ± 2.1 and 8.7 ± 0.9 at baseline; 21.1 ± 0.8, 28.4 ± 1.5 and 21.0 ± 0.8 during step 1; and 80.5 ± 3.2, 76.6 ± 3.3 and 76.3 ± 2.0 during step 2. Somatostatin infusion suppressed c-peptide to T1DM levels in control and MODY2. Glucagon, epinephrine, norepinephrine and cortisol levels remained basal and equal between cohorts. ΔR_a (mg/kg FFM/min) in step 1 was minimally different between groups (1.7 ± 0.1, 1.8 ± 0.2 and 2.1 ± 0.2 for control, T1DM and MODY2). ΔNEFA (mmol/L) was virtually identical between control and MODY2 (393 ± 52 vs 382 ± 69) but less in T1DM (124 ± 87, $p = 0.02$ vs control, $p = 0.03$ vs MODY2). R_d (mg/kg FFM/min) in step 2 was similar between control and MODY2 (15.4 ± 1.1 vs 13.8 ± 0.8, Δ = 1.6, 95% CI −1.3 to 4.6) but lower for T1DM (11.3 ± 1.3; vs control: $p = 0.03$, Δ = 4.1, 95% CI of Δ 0.6 to 7.7; vs MODY2: $p = 0.1$, Δ = 2.5, 95% CI of Δ −0.6 to 5.7).
Conclusion: Iatrogenic local tissue hyperinsulinemia occurs chronically at muscle and fat in T1DM but not in MODY2 nor control and is associated with tissue-specific IR. Despite having hyperglycemia, when MODY2 is compared with control, insulin sensitivity at fat was nearly identical and insulin sensitivity at muscle was minimally different. The T1DM group had lower insulin sensitivity at fat and muscle than control and MODY2, despite having similar hyperglycemia to MODY2. Based on arterialized insulin concentrations, each group had the same estimated chronic hepatic insulin levels and differences in hepatic insulin sensitivity were indistinguishable. This suggests iatrogenic hyperinsulinemia confers more risk for IR at these tissues than hyperglycemia. Approaches to restore the physiologic insulin distribution between the portal and peripheral circulations should mitigate IR in T1DM.

AAV-mediated FGF21 overexpression in skeletal muscle expands healthspan and counteracts insulin resistance

V. Sacristan Fraile[1], C. Jambrina[2], E. Casana[2], S. Muñoz[2], J. Rodo[1], S. Darriba[1], M. Garcia[2], X. Leon[2], I. Grass[1], V. Jimenez[2], F. Bosch[2];
[1]Center of Animal Biotechnology and Gene Therapy, Universitat Autònoma de Barcelona, Bellaterra, [2]Center of Animal Biotechnology and Gene Therapy, Universitat Autònoma de Barcelona and Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabolicas Asociadas (CIBERDEM), Bellaterra, Spain.

Background and aims: Insulin resistance and weight gain increases with aging, resulting in increased risk of cardiovascular disorders. Fibroblast growth factor 21 (FGF21) has been described as a potential factor that could exert benefitial effects to treat these age-related diseases. The aim of this study was to evaluate the potential of extending healthspan of the long-lasting secretion of FGF21 into the bloodstream following a single administration of adeno-associated viral (AAV) vectors to the skeletal muscle (Skm). Moreover, the anti-obesogenic and anti-diabetic effects of this treatment were also assessed.
Materials and methods: AAV vectors with high tropism for skeletal muscle carrying a murine FGF21 coding sequence (AAV-FGF21) or non-coding AAV-Null vectors were administered into the quadriceps, gastrocnemius, and tibialis cranialis muscles of each hind limb of adult (8- or 19-week-old) or old (1-year-old) C57Bl6 mice. To induce obesity and insulin resistance, 8-week-old C57Bl6 mice were fed a HFD for 12 weeks and afterwards administered intramuscularly with AAV-FGF21 vector. After treatment, mice were maintained on HFD feeding.
Results: Animals treated with FGF21-encoding vectors at 8 weeks of age and fed a chow diet showed a marked increase in circulating FGF21, which was parallel to high levels of expression of vector-derived FGF21 in the 3 injected muscles. At the end of the 10-month follow-up period (12 months of age) mice injected intramuscularly with AAV-FGF21 maintained the body weight they had at the initiation of the study and were slimmer than controls, which steady increased their weight as animals aged. While the weight of the muscles was barely affected by FGF21 gene transfer, the weight of the white and brown depots as well as the liver were considerably reduced. In contrast to null-injected animals, mice treated with AAV-FGF21 showed reduced insulinemia and markedly improved insulin sensitivity. In addition, assessment of improvements in healthspan in a new cohort of mice treated with AAV-FGF21 vectors when aged 1-year is ongoing. Moreover, when Skm was used as source of circulating FGF21 in HFD-fed mice, counteraction of obesity and increased insulin sensitivity were also observed.
Conclusion: Altogether, these results demonstrate that intramuscular administration of AAV vectors that lead to therapeutically-relevant levels of circulating FGF21 is safe in the long-term and highlight the therapeutic potential of this approach to expand healthspan as well as to treat T2D and obesity in the future.

Insulin and muscle contraction regulate TBC1D1 through phosphorylation and interaction with the cytosolic tail of insulin-regulated aminopeptidase

S. Mafakheri[1,2], R.R. Flörke[1,2], S. Kanngießer[1], S. Hartwig[1,2], T. Schönberger[1], N. Hamker[1], S. Lehr[1,2], A. Chadt[1,2], H. Al-Hasani[1,2];
[1]Institue of Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Düsseldorf, [2]German Center for Diabetes Research (DZD), Düsseldorf, Germany.

Background and aims: In skeletal muscle, the ~1200 aa Rab GTPase-activating (GAP) protein TBC1D1 is phosphorylated by AKT and AMPK in response to insulin and contraction. Mutation of phosphorylation sites for AKT and AMPK impairs GLUT4 translocation from storage vesicles (GSVs) to the plasma membrane. However, the exact phosphorylation pattern and the mechanism how the signal is transmitted to GSVs is unclear.
Materials and methods: We expressed and purified recombinant full-length His6-TBC1D1 in *Sf*9 insect cells via the Baculovirus system. We characterized the enzymatic activity of purified TBC1D1 under various conditions by adding recombinant Rab GTPases and measuring of Gamma-32P-GTP hydrolysis, *in vitro*. Mapping of the phosphorylation sites of TBC1D1 after *in vitro* phosphorylation using purified AKT/AMPK was performed by mass spectrometry and phospho-specific antibodies.
Results: Size-exclusion chromatography of the purified protein reveals a molecular mass of approx. 600 kDa, consistent with formation of TBC1D1 trimers. Similar to the truncated 50 kDa C-terminal GAP domain, full-length TBC1D1 shows RabGAP activity towards GLUT4-associated Rab8a, Rab10 and Rab14 but with a 200-fold increase in velocity compared to the GAP domain expressed in *E. coli*. Full-length TBC1D1 is phosphorylated at Ser^{231} in response to AMPK and at Thr^{590} in response to both AMPK and AKT. While *in vitro* phosphorylation of TBC1D1 by AKT or AMPK increased 14-3-3 binding, it did not alter the RabGAP activity. However, we found that full-length TBC1D1 interacts with the 110 aa cytoplasmic domain of the insulin-regulated aminopeptidase (IRAP), a resident protein in GLUT4 storage vesicles, and this binding is disrupted by phosphorylation of TBC1D1 by AKT or AMPK.
Conclusion: For the first time, we purified and characterized active full-length TBC1D1. Our data indicate that insulin and contraction-mediated activation of AKT/AMPK alters the recruitment of TBC1D1 to GSVs via phosphorylation and interaction with IRAP. In response to insulin/contraction, this makes phosphorylated TBC1D1 unavailable for its Rab substrates, and consequently increases the activation state, i.e., the active GTP-bound form of the Rabs that subsequently triggers GLUT4 translocation from GSVs to the plasma membrane.

Diabetes modulates microRNAs 29b-3p, 29c-3p, 199a-5p and 532-3p expression in muscle: potential participation in GLUT4 repression

J. Esteves[1], C.Y. Yonamine[1], F. Gerlinger-Romero[1,2], D.C. Pinto-Junior[1], F.J. Enguita[3], U.F. Machado[1];
[1]University of São Paulo, São Paulo, Brazil, [2]Deakin University, Geelong, Australia, [3]Instituto de Medicina Molecular, Universidade de Lisboa, Lisboa, Portugal.

Background and aims: Diabetes is a metabolic disease characterized by hyperglycemia associated with impaired glucose uptake, in which reduced GLUT4 protein expression (encoded by the *SLC2A4* gene) plays an essential role. MicroRNAs (miRNAs), which are small noncoding RNA molecules that regulate gene expression at the posttranscriptional level, have been described as involved in the pathophysiology of diabetes. However, the miRNAs involvement upon skeletal muscle GLUT4 repression in diabetes, consequently impairing the glucose uptake, is unclear. Therefore, the aim of this study was to evaluate the expression of miRNAs potentially involved in the *Slc2a4*/GLUT4 repression in skeletal muscle of diabetic rats.
Materials and methods: Male Wistar rats (70-day old) were rendered diabetic by receiving streptozotocin (50 mg/kg, i.v.). After 13 days, three groups were formed: non-diabetic (ND), and diabetic treated with placebo (D) or with NPH insulin (ID) (6 U/day). Treatments were conducted for 7 days, totalizing 21 days of diabetes. At the end of the experimental period, the animals were anesthetized, blood was collected, and the soleus

skeletal muscles were harvested for evaluation of different mRNAs and miRNAs by RT-qPCR, and proteins by Western blotting. *In silico* analysis was used to select miRNAs predicted as potential regulators of *Slc2a4*/GLUT4 in rat. The comparison among groups was performed by analysis of variance followed by Bonferroni post-test. Correlations analysis were performed by Pearson or Spearman correlation coefficient.

Results: Diabetic rats reduced body and skeletal muscle mass development, and shown hyperglycemia, glycosuria and increased plasma fructosamine; insulin treatment improved these parameters. Diabetes reduced ($P < 0.001$) by ~55% and ~77% the *Slc2a4* mRNA and GLUT4 protein; insulin treatment restored these variables completely. *In silico* analysis revealed that 651 miRNAs were predicted as potential regulators of *Slc2a4*/GLUT4 expression, from these, 16 miRNAs were selected for analysis. Seven miRNAs were modulated by diabetes ($P < 0.05$ to $P < 0.001$), being two upregulated, miR-29b-3p (~118%) and miR-29c-3p (~51%,); and five downregulated (~30%), miR-93-5p, miR-150-5p, miR-199a-5p, miR-345-3p e miR-532-3p. Except for miR-150-5p, insulin treatment reverted these changes. Besides, GLUT4 protein content correlated negatively ($P < 0.05$) with miR-29b-3p and miR-29c-3p, suggesting a causal relationship, and positively with miR-199a-5p and miR-532-3p, suggesting an indirect relationship. Correlations were also detected between these miRNAs and blood glucose, glycosuria and plasma fructosamine, and insulin therapy reversed most of the alterations.

Conclusion: In summary, diabetes leads to upregulation of miR-29b-3p and miR-29c-3p expression and downregulation of miR-199a-5p and miR-532-3p expression in skeletal muscle. These miRNAs are predicted to regulate *Slc2a4*/GLUT4 expression, and their regulations correlated significantly with GLUT4 content variations. The results make these miRNAs as potential targets to control GLUT4 expression in muscle and, consequently, the tissue glucose disposal and blood glucose control in diabetes.

Human skeletal muscle mitochondrial dynamics in relation to insulin sensitivity and oxidative capacity

A. Houzelle, J.A. Jörgensen, G. Schaart, S. Daemen, E. Phielix, M.K.C. Hesselink, P. Schrauwen, J. Hoeks;
Nutrition and Movement Sciences, Maastricht University, Maastricht, Netherlands.

Background and aims: Recent insights indicate that mitochondria operate in a highly dynamic network, constantly remodeling itself via fusion and fission mechanisms, termed mitochondrial dynamics, rather than acting as single organelles. Recent studies have started to unravel the link between mitochondrial dynamics regulatory proteins, such as mitofusin-2 (MFN2) and dynamin-related protein 1 (DRP1), mitochondrial function and metabolic diseases. Moreover, manipulation of these proteins via gain or loss-of function studies in animal models resulted in alterations in mitochondrial function. Here, we aim to investigate the relation between mitochondrial dynamics and oxidative capacity and insulin sensitivity in human skeletal muscle over a wide range in insulin sensitivity.

Materials and methods: We collected muscle biopsies from 45 well-phenotyped subjects recruited from 4 metabolically distinct populations (T2DM patients, healthy obese subjects, lean sedentary subjects and endurance-trained athletes) and measured content of proteins involved in regulating mitochondrial dynamics (MFN1/2, OPA1, Fis1 and DRP1) and -quality control (HSP60, PINK1 and LC3) via western blotting. In addition, muscle tissues from a subgroup of athletes and Type 2 diabetes subjects ($n = 3$ in both groups) were used to investigate mitochondrial network morphology and fragmentation using confocal microscopy. Correlation analysis was performed to determine relationship between mitochondrial dynamics and VO_2max or Glucose Infusion Rate (GIR) as assessed by a hyperinsulinemic-euglycemic clamp.

Results: Fis1, involved in mitochondrial fission, and OPA1, promoting fusion of the inner mitochondrial membrane, were 57% and 42% lower in type 2 diabetes when compared to endurance-trained athletes ($p < 0.01$ and $p = 0.01$ respectively). HSP60 protein levels, involved in mitochondrial quality control, were also reduced by 54% in T2DM as compared to athletes ($p < 0.001$). Although it did not reach statistical significance, assessed via Tukey's post-hoc test, obese and lean individuals showed an intermediate phenotype for these proteins. Confocal images showed a higher mitochondrial network fragmentation index in T2DM compared to athletes. This observation was independent of fiber type, as fragmentation was 21% higher in type I fibers and 27% higher in type 2 fibers in T2DM compared to athletes. Finally, in the entire cohort, Fis1 and HSP60 protein levels correlated positively with VO_2max ($n = 45$, $r = 0.57$, $p < 0.001$, and $r = 0.33$, $p = 0.02$). Furthermore, Fis1 protein levels correlated positively with the GIR obtained after the high-insulin phase of a hyperinsulinemic-euglycemic clamp ($n = 45$, $r = 0.45$, $p < 0.01$).

Conclusion: Impaired mitochondrial function has been reported multiple times in type 2 diabetes. Here, we report disturbance in skeletal muscle mitochondrial dynamics. We show, in diabetes patients, that skeletal muscle mitochondrial network and its regulatory proteins point toward a more fragmented mitochondrial network and correlate with oxidative metabolism and insulin sensitivity. Whether this is a mere consequence, or a potential contributing factor, to the development of type 2 diabetes remains to be elucidated.

Background and aims: Adipose tissue capillarization is correlated with insulin sensitivity and metabolic homeostasis. Methylglyoxal was shown to impair adipose tissue capillarization and insulin sensitivity in obese rats leading to the onset of metabolically unhealthy obesity. We hypothesized that decreased glyoxalase 1 (GLO-1) activity in adipose tissue may be correlated with impaired insulin sensitivity in obese patients, thus being a promising therapeutic target in obesity and type 2 diabetes. Given that bariatric surgery was observed to increase adipose tissue angiogenesis and GLP-1 is known to promote angiogenesis, we hypothesized that glyoxalase could be a target of GLP-1 favoring adipose tissue angiogenesis.
Materials and methods: In a cohort of obese patients (diabetic and non-diabetic), we collected samples of visceral adipose tissue, determined insulinemia and calculated insulin resistance indexes. Glyoxalase activity in human visceral adipose tissue was determined using an enzymatic assay. The role of GLP-1 in adipose tissue angiogenesis and glyoxalase modulation was assessed using the adipose tissue angiogenic assay and HUVEC cell line. In order to evaluate the role of GLP-1 *in vivo*, type 2 diabetic GK rats were submitted to sleeve gastrectomy (surgical model) or Liraglutide administration (pharmacological model). The activation of glyoxalase and angiogenic and vasoactive mechanisms were evaluated in the epididymal adipose tissue of GK rats.
Results: Glyoxalase activity in visceral adipose tissue of obese patients was inversely correlated ($n = 82$, Pearson correlation) with plasma insulin levels ($r = -0.27$, $p = 0.013$), HOMA-IR ($r = -0.277$, $p = 0.019$) and HOMA2-IR ($R = -0.276$, $p = 0.012$) indexes, while directly correlated with the insulin sensitivity index QUICKI ($r = 0.248$, $p = 0.024$). GLP-1 increased adipose tissue capillarization in the adipose tissue angiogenic assay in a glyoxalase-dependent manner and increased glyoxalase expression in HUVECs. Moreover, glyoxalase expression in epididymal adipose tissue was increased in both rats submitted to sleeve gastrectomy and treated with Liraglutide, surgical and pharmacological models of increased GLP- 1 levels. Increased glyoxalase activity in Liraglutide-treated rats was associated with increased expression of angiogenic and vasoactive factors, such as VEGF, VEGFR2, FGFR, HIF-2alpha and eNOS, as well as increased insulin receptor phosphorylation (Tyr1163).
Conclusion: Lower adipose tissue glyoxalase is correlated with insulin resistance and may be a target of GLP-1 in order to improve adipose tissue capillarization and insulin sensitivity, which may be a promising therapeutic approach to prevent metabolic dysregulation in obesity and type 2 diabetes.

Background and aims: Obesity-related insulin resistance (IR) may develop in key metabolic organs, representing different etiologies towards cardiometabolic diseases. This study aimed to identify distinct transcriptome profiles of abdominal subcutaneous adipose tissue (ScAT) in relation to muscle or liver IR.
Materials and methods: Overweight/obese non-diabetic participants of the European DiOGenes project (BMI >27 kg/m^2, $n = 368$) were classified at baseline into 4 groups: i) no-IR ($n = 186$), ii) muscle-IR ($n = 69$), iii) liver-IR ($n = 53$), iv) muscle/liver-IR ($n = 60$). The IR phenotype was based on tertiles of the muscle insulin sensitivity index (MISI) and the hepatic IR index (HIRI), derived from a 5-point OGTT. ScAT RNA sequencing data were compared between groups using DESeq2, adjusted for study center, sex, BMI and waist-to-hip ratio. Based on DiOGenes outcomes, the relationship between systemic low-grade inflammation and IR phenotype was subsequently studied in overweight/obese non-diabetic individuals of the Cohort on Diabetes and Atherosclerosis Maastricht (CODAM, BMI >25 kg/m^2, $n = 325$) and Maastricht study (BMI >27 kg/m^2, $n = 792$), using linear regression analyses.
Results: In DiOGenes, ScAT extracellular matrix organization genes (e.g. collagens) were significantly upregulated in the liver-IR *vs* no-IR comparison (Fold change (FC) >1.2, $p < 0.05$). In muscle-IR *vs* no-IR comparison, inflammatory pathways were significantly changed with pronounced upregulation of chemokine and complement genes (FC >1.2, $p < 0.05$). Plasma low-grade inflammation was inversely associated with MISI (CODAM: standardized-ß [95%CI]: −0.108 [−0.205; −0.011] $p = 0.028$; Maastricht Study: −0.131 [−0.193; −0.068] $p < 0.001$), while no association was observed with HIRI (CODAM std-ß [95% CI]: 0.066 [−0.032; 0.165] $p = 0.184$; Maastricht Study: 0.000 [−0.064; 0.064] $p = 0.995$). The association between low-grade inflammation and MISI was adjusted for HIRI, and vice versa.
Conclusion: Muscle and hepatic IR were characterized by distinct abdominal ScAT transcriptome profiles. Extracellular matrix remodeling genes were upregulated in individuals with primarily hepatic IR, whilst inflammatory genes were significantly upregulated in primarily muscle IR individuals. An increased systemic low-grade inflammation profile was specifically related to muscle IR. We propose that increased abdominal ScAT inflammatory gene expression in the muscle IR phenotype may translate into an increased systemic inflammatory profile, putatively linking abdominal ScAT inflammation to muscle IR.

New insights in adipose tissue dysfunctions in diabetic obese patients: a new PPARγ truncated isoform mimicking PPARG dominant negative mutations

M. Aprile[1], S. Cataldi[1], M. Blüher[2], A. Ciccodicola[1], V. Costa[1];
[1]Institute of Genetics and Biophysics "A. Buzzati-Traverso" (IGB-CNR), National Research Council, Naples, Italy, [2]Department of Medicine, University of Leipzig, Leipzig, Germany.

Background and aims: Adipose tissue (AT) dysfunctions are hallmark of insulin resistance and contribute to type 2 diabetes (T2D) onset. PPARγ is a ligand-dependent transcriptional factor essential for differentiation of insulin-sensitive adipocytes and maintenance of whole body insulin sensitivity. *PPARG* loss of function mutations are associated with lipodistrophy, increased BMI, insulin resistance, and dominant negative mutations also block adipocyte differentiation. We identified a new dominant negative PPARγ isoform lacking LBD (PPARγΔLBD) highly expressed in human AT. Its overexpression interferes with the transcription of PPARγ-induced genes involved in lipid, glucose and insulin homeostasis. Our aim is to investigate whether PPARγΔLBD functionally mimics dominant negative mutations and to verify its relevance in the context of human metabolic diseases.
Materials and methods: PPARγΔLBD over-expression (assessed by qPCR, western blot and immunofluorescence) was induced by electroporation in the early stages of adipogenesis of hTERT-immortalized adipose-derived mesenchymal stem cells (AdMSCs), used as *in vitro* model. Terminal differentiation was assessed by Oil Red O staining and expression analysis of specific markers (qPCR). Subcutaneous AT biopsies were obtained from a German cohort of patients ($n = 95$; mean age = 55.5 ± 16.5 y.o.; mean BMI = 35.4 ± 11.8) undergoing bariatric surgery. According to fasting glucose levels and after OGTT, patients were classified as diabetic (T2D, $n = 32$), with impaired glucose tolerance (IGT, $n = 15$) and with normal glucose tolerance (NGT, $n = 47$). Patients were also stratified in lean (BMI <25) and overweight/obese (BMI >25). Gene expression differences were analyzed by Student's t test or Kolmogorv-Smirnov test, and linear models implemented in R language were used for correlation analysis.
Results: PPARγΔLBD over-expression in pre-adipocytes significantly impairs their adipogenic potential, resembling the effects of *PPARG* mutations. PPARγΔLBD has variable expression in human subcutaneous AT. Interestingly, T2D patients display increased PPARγΔLBD/PPARγ ratio ($p < 0.01$) compared to NGT. Additionally, PPARγΔLBD/PPARγ ratio positively correlates with BMI ($n = 95$, $r = 0.37$; $p = 0.0002$), regardless of diabetic state (T2D $r = 0.394$; $p = 0.025$ and NGT $r = 0.33$; $p = 0.02$). Accordingly, significantly higher PPARγΔLBD/PPARγ ratio was measured in the overweight/obese group *vs* lean patients ($p < 0.01$). Indeed, PPARγΔLBD/PPARγ ratio had a positive correlation with BMI only in the overweight/obese group ($r = 0.28$; $p = 0.020$; lean $r = 0.03$; $p = 0.873$). These data reveal for the first time the presence of high levels of a dominant negative isoform of PPARγ, PPARγΔLBD, in AT of diabetic and obese patients, suggesting a role in the impairment of PPARγ that is functionally related to obesity-associated AT dysfunctions.
Conclusion: The new naturally-occurring truncated isoform of PPARγ identified by our group, PPARγΔLBD, is capable to impair the adipogenic potential of precursor cells mimicking the effects of dominant negative mutations in *PPARG* gene. Its increased levels in AT of T2D patients and overweight/obese individuals and its positive correlation with BMI strongly suggest its contribution to the impairment of PPARγ activity in the AT of diabetic obese patients.

Elevated plasma proneurotensin levels predict NAFLD and visceral adipose tissue inflammation in adults with and without type 2 diabetes

I. Barchetta[1], F.A. Cimini[1], F. Leonetti[1], D. Capoccia[1], L. Bertoccini[1], V. Ceccarelli[1], G. Silecchia[1], M. Orho-Melander[2], O. Melander[2], M.G. Cavallo[1];
[1]Sapienza University of Rome, Rome, Italy, [2]Lund University, Malmo, Sweden.

Background and aims: Neurotensin (NT) is an intestinal peptide released by fat ingestion and promoting lipids absorption; higher circulating NT levels are associated with the incidence of type 2 diabetes (T2D), cardiovascular disease, breast cancer, and with total and cardiovascular mortality. Reduced intestinal fat absorption, along with protection from obesity and fatty liver, have been shown in NT-deficient mice fed with high-fat diet. NT was also demonstrated to take part to visceral adipose tissue (VAT) inflammation -a leading cause of non-alcoholic fatty liver disease (NAFLD) and steatohepatitis (NASH)- in experimental colitis, by enhancing the preadipocyte-dependent macrophage migration. Whether NT is related to NAFLD and NASH in humans has not been explored. This study aimed at investigating the relationship between plasma proneurotensin1-117 (pro-NT), a stable fragment of the NT precursor hormone, and the presence/severity of NAFLD and NASH and to unravel correlates of increased pro-NT levels.
Materials and methods: For this cross-sectional study, we recruited 320 consecutive individuals (M/F: 158/162; mean ± SD age: 50.7 ± 11.2 years), with and without T2D ($n = 110/210$), referring to the Endocrinology and Diabetes outpatient clinics at Sapienza University of Rome, Italy, for metabolic evaluations. A first cohort (i) of sixty obese patients underwent bariatric surgery for clinical purposes and intraoperative liver biopsies were performed for diagnosing NAFLD/NASH. Moreover, we explored the presence of VAT inflammation in VAT biopsies available for 40 out of these 60 subjects. In the cohort (ii) of individuals not candidate to surgery ($n = 260$), NAFLD was evaluated through liver ultrasonography (US). Circulating pro-NT levels were measured by a chemiluminometric sandwich immunoassay on plasma frozen immediately after separation and stored at −80°C.
Results: Subjects with biopsy-proven NAFLD ($n = 32/60$, 53%) had significantly higher plasma pro-NT than those without NAFLD (183.6 ± 81.4 vs 86.7 ± 56.8 pmol/L, $p < 0.001$). Greater pro-NT correlated with the presence of NASH ($p < 0.001$), higher NAS and SAF score (both $p < 0.001$), age, female gender, T2D and insulin-resistance. Notably, pro-NT positively associated with signatures of VAT inflammation (greater CD68+ macrophage infiltration, reduced microvessel density, higher HIF-1α, WISP-1 and UNC5B expression in VAT; all $p < 0.05$). Higher pro-NT predicted NAFLD with AUROC = 0.836 (C.I.95%:0.73–0.94; $p < 0.001$). At the multivariate logistic regression analysis, pro-NT levels were associated with biopsy-proven NAFLD independently from all the confounders. The positive association between pro-NT and presence of NAFLD was confirmed in the second cohort (US-NAFLD+: $n = 103/260$; 40%), regardless of age and other determinants of greater pro-NT in this population, such as female gender, metabolic syndrome and T2D.
Conclusion: Increased plasma pro-NT levels identify the presence and severity of NAFLD/NASH and are associated with signatures of VAT inflammation; in dysmetabolic individuals, NT may specifically promote hepatic fat accumulation though mechanisms likely related to metabolic impairment and increased insulin-resistance.

OP 38 Novel actions of metformin and pioglitazone

221

Metformin attenuates the fall in postprandial blood pressure and slows gastric emptying in type 2 diabetes

M.J. Borg, C.K. Rayner, M. Horowitz, K.L. Jones, T. Wu;
Adelaide Medical School, University of Adelaide, Adelaide, Australia.

Background and aims: There is evidence that metformin has cardioprotective benefits in type 2 diabetes (T2DM) independent of improvements in glycaemic control. It is now recognised that exposure of the small intestine to nutrients (determined by the rate of gastric emptying), and the concomitant increase in splanchnic blood flow, may be associated with a reduction in BP and, in some cases, postprandial hypotension. The latter, defined by a fall in systolic BP (SBP) of ≥20 mmHg within 2 hours of a meal, occurs frequently in T2DM, and is associated with syncope, falls, stroke and increased mortality. We recently reported that metformin modulates the cardiovascular response to intraduodenal (ID) glucose in patients with T2DM. We have now evaluated the acute effects of metformin (administered by ID infusion in order to standardise small intestinal exposure) on SBP, diastolic BP (DBP), heart rate (HR) and gastric emptying following oral glucose in T2DM.
Materials and methods: 10 T2DM patients managed by diet alone (5 male and 5 female; 65.6 ± 3.1 years; BMI 30.1 ± 1.7 kg/m^2; HbA1c 6.4 ± 0.2% [45.8 ± 1.6 mmol/mol]; duration of known T2DM 5.5 ± 1.0 years), were studied on two occasions in a double-blind, randomised, crossover design. Participants received either metformin 1 g, or saline control, via an ID catheter ($t = -60$ to -55 min), before ingesting a 50 g glucose drink labelled with ^{13}C-acetate ($t = -2$ to 0 min). SBP, DBP and HR were assessed every 5 min by automatic sphygmomanometer, and breath samples taken at regular intervals to determine the gastric half-emptying time (T50). Data are mean values ± SEM. $P < 0.05$ was considered significant.
Results: The studies were all tolerated without nausea. Basal SBP (control 136 ± 6 mmHg vs. metformin 129 ± 4 mmHg), DBP (control 74 ± 3 mmHg vs. metformin 71 ± 4 mmHg) and HR (control 67 ± 4 beats/min vs. metformin 68 ± 3 beats/min) did not differ between the two days. On both days, SBP and DBP decreased, while HR increased, following oral glucose ($P < 0.01$ for each). The fall in SBP was less after metformin than control (treatment effect: $P = 0.036$, treatment by time interaction: $P < 0.001$; Figure) without any differences in either DBP or HR. Four participants exhibited a sustained fall in SBP ≥20 mmHg with control, and only two with metformin. Metformin also slowed gastric emptying (T50: 183 ± 51.6 vs. 130 ± 21.1 min; $P = 0.008$).
Conclusion: Acute administration of metformin attenuates the hypotensive response to, and slows the gastric emptying of, oral glucose in T2DM. These effects may contribute to both postprandial glucose lowering by metformin, and its favourable cardiovascular profile.

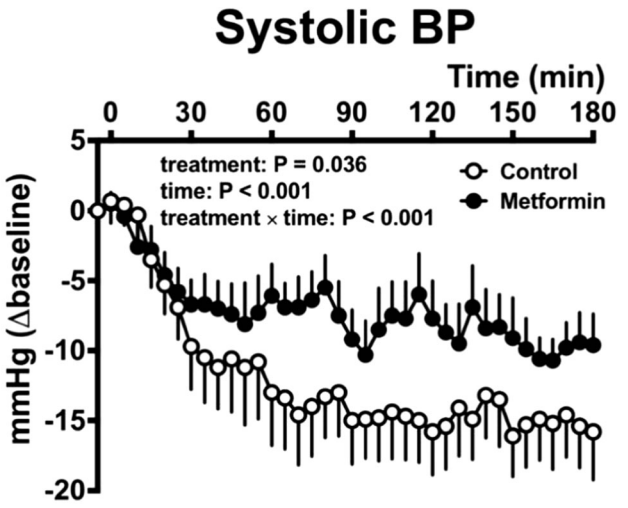

Figure: Effect of metformin 1g, administered acutely by intraduodenal infusion, on the systolic BP response to an oral glucose drink (50g) in patients with type 2 diabetes. Two-factor repeated measures ANOVA, with treatment and time as factors, was used to determine statistical significance. Data are mean values ± SEM.

Comparative effects of proximal and distal small intestinal administration of metformin on plasma glucose and GLP-1, and gastric emptying after oral glucose in type 2 diabetes

T. Wu, M. Borg, K.L. Jones, M. Horowitz, C.K. Rayner;
Adelaide Medical School, The University of Adelaide, Adelaide, Australia.

Background and aims: The gastrointestinal tract is increasingly recognised as key to the anti-diabetic action of metformin. Emerging evidence indicates a substantial role for glucagon-like peptide-1 (GLP-1), which has pleiotropic glucose-lowering effects, including slowing of gastric emptying (GE). Given that GLP-1 is released predominantly from the ileum and colon, the distal gut may be of greater relevance for the action of metformin, compared with the proximal gut. Accordingly, we evaluated the comparative effects of metformin administered into the proximal and distal small intestine on plasma glucose and GLP-1, and GE, after oral glucose in type 2 diabetes (T2DM).
Materials and methods: 10 diet-managed T2DM patients (5 male; 65.6 ± 3.1 years; BMI 30.1 ± 1.7 kg/m^2; HbA1c 6.4 ± 0.2%; duration of known diabetes 5.5 ± 1.0 years), were studied on three occasions in a double-blind, randomised, crossover design. On each study day, a transnasal multilumen catheter was positioned with proximal and distal infusion ports located at 13 and 190 cm beyond the pylorus, respectively. On separate days, participants received infusions of (i) proximal saline + distal saline (control), (ii) proximal metformin (1000 mg) + distal saline, or (iii) proximal saline + distal metformin (1000 mg), each in a volume of 40 mL over 5 min, followed 60 min later by a 200 mL glucose drink, containing 50 g glucose and 150 mg ^{13}C-acetate. "Arterialised" venous blood was sampled at frequent intervals over 3 hours after the drink for measurements of plasma glucose, GLP-1, insulin and glucagon. Breath samples were collected for the measurement of GE by calculating the half-emptying time (T50).
Results: There were significant treatment effects of metformin on the peak glucose concentrations ($P < 0.001$), the incremental areas under the curves (iAUCs) for plasma glucose ($P < 0.001$) and total GLP-1 ($P = 0.03$), and the T50 ($P = 0.01$), but not on the iAUC for plasma insulin

or glucagon. Compared with control, both proximal and distal metformin reduced the peak and iAUC for plasma glucose ($P < 0.05$ each), with no difference between them. Proximal metformin augmented the iAUC for GLP-1 and slowed GE ($P < 0.05$ each), while the distal metformin was associated with numerically, but not statistically, greater GLP-1 concentrations and longer T50 than control. However, plasma GLP-1 concentrations and the T50 did not differ between proximal and distal metformin.
Conclusion: In diet-controlled T2DM patients, glucose-lowering, resulting from a single dose of metformin administered to the proximal and distal small intestine, was comparable, despite the stimulation of GLP-1 secretion and slowing of GE being modestly greater when metformin was administered to the proximal small intestine. These observations suggest that the site of gastrointestinal administration is not critical to the capacity of metformin to reduce blood glucose.

	Control	Proximal metformin	Distal metformin	P value
Peak glucose (mmol/L)	12.2 ± 0.4	10.8 ± 0.4**	10.9 ± 0.7*	0.007
Glucose iAUC (mmol/L*min)	788.1 ± 48.4	610.6 ± 34.7***	644.1 ± 73.3*	< 0.001
Insulin iAUC (mU/L*min)	4136.3 ± 777.8	3612.6 ± 728.1	3550.5 ± 799.8	0.29
Glucagon iAUC (pg/mL*min)	-2051.3 ± 487.7	-1271.3 ± 445.6	-1590.5 ± 534.7	0.19
Total GLP-1 iAUC (pmol/L*min)	491.2 ± 291.4	1255.9 ± 339.0*	1012.0 ± 368.4	0.03
Gastric emptying T50 (min)	130 ± 21	183 ± 52*	160 ± 47	0.01

One-factor ANOVA, with Bonferroni's correction for post hoc comparisons, was used for statistical analysis. *P < 0.05, **P < 0.01 and *** P< 0.001 for proximal or distal metformin vs. control. Data are means ± SEM.

Pioglitazone treatment reverts diabetes-related abnormalities in mitochondrial proteomic profile of skeletal muscle

T.V. Fiorentino[1], A. Monroy[2], S. Kamath[2], C. Carroll[2], K. Hakala[2], R. Sotero[1], G. Daniele[2], M. Abdul-Ghani[2], M.L. Hribal[1], D. Tripathy[2], G. Sesti[1], R.A. DeFronzo[2], F. Folli[3,2];
[1]University Magna Graecia of Catanzaro, Catanzaro, Italy, [2]University of Texas Health Science Center, San Antonio, USA, [3]University of Milan, Milano, Italy.

Background and aims: Several studies have demonstrated that type 2 diabetes (T2DM) is associated with skeletal muscle (SKLM) mitochondrial dysfunction. Pioglitazone (PIO) is a hypoglycemic agent which improves insulin sensitivity through several and incompletely understood mechanisms, including the promotion of mitochondrial oxidative metabolism. In this study, we aimed to identify the determinants of mitochondrial dysfunction in SKLM of subjects with T2DM and to evaluate whether PIO treatment is able to modulate the SKLM mitochondrial proteomic pattern.
Materials and methods: Two different groups of adults were studied. Group 1 was composed of 16 individuals, 8 with normal glucose tolerance (NGT) and 8 with T2DM, subjected to analysis of SKLM mitochondrial proteome by 2D-gel electrophoresis followed by mass spectrometry-based protein identification. Group 2 included 48 individuals, 24 with NGT and 24 with T2DM. SKLM biopsies of these subjects were lysed and subjected to immunoblot analysis. Of 24 subjects with T2DM, 20 were randomized to receive placebo or PIO (15 mg daily) for 6 months. After 6 months of treatment, SKLM biopsy was repeated.
Results: By performing mitochondrial proteomic analysis on study group 1, we identified ten mitochondrial proteins involved in oxidative metabolism which were differentially expressed between T2DM and NGT groups, with a downregulation of ATP synthase alpha chain (ATPA), electron transfer flavoprotein alpha-subunit (ETFA), cytochrome c oxidase subunit VIb isoform 1 (CX6B1), pyruvate dehydrogenase protein X component (ODPX), dihydrolipoamide dehydrogenase (DLDH), dihydrolipoamide-S-succinyltransferase (DLST), and mitofilin, and an up-regulation of hydroxyacyl-CoA-dehydrogenase (HCDH), 3,2-trans-enoyl-CoA-isomerase (D3D2) and delta3,5-delta2,4-dienoyl-CoA-isomerase (ECH1) in T2DM as compared to NGT subjects. To extend these findings we performed immunoblot analysis on SKLM lysates obtained from a separate, and more numerous, study group (group 2). In comparison to NGT subjects, T2DM exhibited lower SKLM protein levels of ATPA (−30%, $P = 0.006$), ETFA (−50%, $P = 0.02$), CX6B1 (−30%, $P = 0.03$), key factors for mitochondrial ATP biosynthesis, and mitofilin (−30%, $P = 0.01$), a structural protein essential for normal mitochondrial function. Individuals with T2DM displayed reduced expression of the enzymes involved in the Krebs cycle DLST and ODPX (−20%, $P \leq 0.05$) and increased expression of HCDH and ECH1, enzymes implicated in the fatty acid catabolism (+30%, $P \leq 0.05$) in comparison to NGT subjects. Notably, subjects with T2DM treated with PIO for 6 months exhibited increased expression of ATPA (+33%, $P \leq 0.05$), ETFA (+60%, $P \leq 0.05$), CX6B1 (+33%, $P = 0.01$), mitofilin (+20%, $P \leq 0.05$) and DLST (+10%, $P = 0.08$) in comparison to baseline, whereas no change was observed in placebo treated T2DM patients. Furthermore, HCDH and ECH1 protein levels, which were upregulated in SKLM of subjects with T2DM in comparison to NGT individuals, were reduced by −10% and −15% respectively ($P \leq 0.05$ for both) after PIO treatment.
Conclusion: Treatment with PIO exerts positive effects on the abnormal expression of several mitochondrial proteins involved in oxidative metabolism in the SKLM of subjects with T2DM.

Comparison of ipragliflozin and metformin for bone density and muscle in type 2 diabetes: a prospective, blinded-endpoint, randomised controlled study

K. Ishikawa[1,2], M. Koshizaka[1,2], R. Ishibashi[2], K. Sakamoto[2], A. Kobayashi[1,2], H. Yokoh[1,2], M. Shoji[1,2], S. Ide[1,2], K. Ide[1,2], Y. Baba[1,2], T. Ishikawa[1,2], Y. Maezawa[1,2], T. Horikoshi[3], K. Yokote[1,2];
[1]Division of Metabolism and Endocrinology, Chiba university hospital, CHIBA, [2]Clinical cell biology and medicine, Chiba university graduate school of medicine, Chiba, [3]Diagnostic Radiology and Radiation Oncology, Chiba university graduate school of medicine, CHIBA, Japan.

Background and aims: Sodium glucose transporter 2 (SGLT2) inhibitors are glucose-lowering agents that cause a reduction in body weight and prevent the recurrence of cardiovascular disease. We have reported that ipragliflozin (SGLT2 inhibitor) reduces visceral fat compared with metformin in patients with type 2 diabetes who received dipeptidyl peptidase-4 (DPP-4) inhibitor as a first-line medication for diabetes. The effects of SGLT2 inhibitors on bone and skeletal muscle are not well understood. In this study, we investigated the influence of ipragliflozin on bone mineral content and skeletal muscle in Asian patients with type 2 diabetes that cannot be sufficiently controlled with DPP-4 inhibitors.
Materials and methods: This was a randomized, multicenter, 24-week, open-label, and blinded-endpoint study. Overall, 103 patients with type 2 diabetes treated with sitagliptin 50 mg/day were assigned to receive either ipragliflozin 50 mg/day ($n = 51$) or metformin 1000–1500 mg/day ($n = 52$). The primary outcome was the change in rate of visceral fat area (obtained by computed tomography at the fourth lumbar level and measured by two radiologists blinded to the clinical information) in the two groups at 24 weeks. The secondary outcome was the change in the rate of bone-specific alkaline phosphatase (BAP), tartrate-resistant acid phosphatase-5b (TRACP-5b), grip strength, bone mineral density, and muscle measurements in the same slice of the visceral fat image.
Results: The rate of reduction in visceral fat area in the ipragliflozin-treated group was greater than that in the metformin-treated group after 24 weeks (−12.06% vs. −3.65%, group difference [95% CI] −8.40% [−16.4 to −3.38], $P = 0.040$). BAP and TRACP-5b in the ipragliflozin-treated group were significantly higher than those in the metformin-treated group at 24 weeks (BAP; −0.71% vs. −10.4%, group difference [95% CI] 14.76% [6.31 to 23.05], $P = 0.0004$: TRACP-5b; 11.94% vs.

−10.3%, group difference [95% CI] 25.47% [17.46 to 34.19], $P < 0.0001$). There were no differences in bone mineral density, grip strength, and muscle area between ipragliflozin and metformin. Bone fracture was not observed in either group.

Conclusion: The bone mineral density was the same after ipragliflozin and metformin treatment. However, the osteogenic marker BAP and the osteolytic marker TRACP-5b were higher in the ipragliflozin-treated group than in the metformin-treated group; therefore, the bone metabolism in the ipragliflozin-treated group was of the "high turnover" type. No effect of ipragliflozin on skeletal muscle was identified.

Table

		Ipragliflozin		Metformin		Difference between groups		
	Weeks	Rate of change (%)	95% CI	Rate of change (%)	95% CI	Rate of change (%)	95% CI	p value
Visceral fat area	24	-12.06	-20.55, -3.56	-3.65	-11.78, 4.48	-8.4	-16.43, -3.38	0.04
BAP *	12	-4.47	-7.87, 4.88	-10.48	-13.55, -1.5	5.81	-0.42, 13.56	0.064
	24	-0.71	-5.88, 10.24	-10.4	-18.92, -5	14.76	6.31, 23.05	0.0004
TRACP-5b *	12	12.21	1.18, 20.22	-9.3	-15.49, -6.22	21.4	13.5, 29.28	<0.0001
	24	11.94	7.56, 20.08	-10.3	-21.68, -7.17	25.47	17.46, 34.19	<0.0001
Bone density in CT	24	-1.58	-5.38, 2.21	-3.09	-5.54, -0.64	1.51	-2.95, 5.96	0.504
Muscle area in CT	24	-2.59	-3.75, -1.44	-1.71	-3.01, -0.42	-0.88	-2.59, 0.83	0.31
Grip strength	12	1.04	-1.31, 3.39	3.53	-0.51, 7.58	-2.49	-7.1, 2.12	0.285
	24	1.86	-0.35, 4.06	2.81	-1.06, 6.67	-0.95	-5.36, 3.47	0.671

Rate of change is shown as means unless otherwise indicated.
*: The data were not normally distributed and had outliers; nonparametric analysis (Wilcoxon rank sum test and group difference confidence interval by Hodges-Lehmann estimator) was performed. Rate of change are shown as median.
CI, Confidential interval; BAP, bone alkaline phosphatase; CT, computed tomography.

Distinct trajectory patterns of HbA_{1c} in adults with type 2 diabetes: a longitudinal group-based modelling approach based on the DPV registry

K. Laubner[1], A. Schwandt[2,3], W. Rathmann[4,3], O. Kuss[4,3], F. Best[5], S. Ebner[6], M. Paulmann[7], R.W. Holl[2,3], DPV initiative and the DZD;
[1]Department of Medicine II, Division of Endocrinology and Diabetology, Freiburg, Germany, [2]Institute of Epidemiology and Medical Biometry (ZIBMT), Ulm, Germany, [3]German Centre for Diabetes Research (DZD), Munich-Neuherberg, Germany, [4]Leibniz Institute for Diabetes Research at Heinrich-Heine-University Düsseldorf, Institute for Biometrics and Epidemiology, Düsseldorf, Germany, [5]Diabetes practice Dr. Best, Essen, Germany, [6]Kepler University Hospital, Medical Campus III, Linz, Austria, [7]Specialist diabetes practice Hannover, Hannover, Germany.

Background and aims: Metabolic control is essential in the management of type 2 diabetes (T2D). This study aimed to identify groups of heterogeneous HbA1c trajectories over time in a large adult T2D cohort.
Materials and methods: A total of 6,470 adults with T2D (≥40 years, 55% males) were selected from the German/Austrian multicenter diabetes prospective registry DPV. Subjects were examined during the first five years after T2D onset (with at least three aggregated HbA1c values per year diabetes duration). Latent class growth modeling as trajectory approach (SAS PROC TRAJ) was applied to determine distinct groups following similar HbA1c patterns over time. The number of groups was determined by BIC and cluster size.
Results: Four longitudinal trajectories of HbA1c were found (Figure). The largest group maintained *good metabolic control* over time, whereas participants within the second group were characterized as *medium metabolic control*. Another group showed initially severe hyperglycemia, but reached good metabolic control after one year diabetes duration (*improving HbA1c*). High HbA1c over time was observed in the fourth group (*poor metabolic control*). Significant differences were observed for age at T2D onset, gender, glucose-lowering therapy, and BMI among all HbA1c groups (all $p < 0.01$). As compared to the *good metabolic control* group, the *improving HbA1c* group comprised more males, younger age at onset, more intensive glucose-lowering treatment and less often nonpharmacological therapy, whereas in the *medium* or *poor metabolic control* group, higher BMI, lower frequency of treatment with glucose-lowering drugs only and higher frequency of nonpharmacological treatment was observed.
Conclusion: Among this large T2D cohort of adults from Germany/Austria, four trajectories with heterogeneous HbA1c patterns over time were found. Glucose-lowering treatment, demographics, and BMI were related to distinct HbA1c trajectories.

Costs of prevalent and incident cardiovascular disease in patients with type 2 diabetes in Scotland using routinely collected data

P. McMeekin[1], C. Geue[1], O. Wu[1], E. Mocevic[2], C. Stentoft Hoxer[3], A. Ochs[4], S. McGurnaghan[4], H. Colhoun[4], Scottish Diabetes Research Network Epidemiology Subgroup;
[1]HEHTA, University of Glasgow, Glasgow, UK, [2]Novo Nordisk A/S, Søborg, Denmark, [3]Novo Nordisk, West Sussex, UK, [4]MRC Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK.

Background and aims: Patients with type 2 diabetes mellitus (T2DM) are disproportionately affected by cardiovascular disease (CVD). Morbidity associated with CVD places a burden on health services and the wider economy. We estimated annual average cost per patient to the healthcare system and wider economy of treating T2DM patients with established CVD, patients at high risk of CVD, but without established CVD and patients without CVD (Analysis A). We also estimated for patients with established CVD total average costs in the first, second and third year after CVD was diagnosed compared to patients with no CVD (Analysis B).
Materials and methods: Data about all T2DM patients in Scotland were obtained from the Scottish Care Information Diabetes Collaboration (SCI DC) registry: i) for those alive at 1 July 2015 (Analysis A) and ii) those alive between 1 January 2010 and 30 June 2015 (Analysis B). For analysis B, a 10year look-back was used from patient entry to exclude patients with prior CVD. Data linkage was used to retrieve information on secondary care admissions and day cases (Scottish Morbidity Records (SMR01)), prescribed medications (Prescribing Information System) and deaths (National Records for Scotland). Hospital costs were estimated from length of stay using per diem costs by Health Board and Speciality. Prescription costs were estimated using British National Formulary codes. Care home utilisation was determined from SMR01 recorded discharge destination and costs from the Scottish Care Home Census. Indirect costs where estimated for those of non-pensionable age using time in hospital and residential care and average wages. Primary care use and cost were estimated accounting for comorbidities, age and sex.
Results: Analysis A included 73,037 T2DM patients with established CVD, 141,428 at high risk of CVD and 30,287 with no CVD. The annual cost per T2DM patient with established CVD was £6,890 (95% CI; £1,567, £29,705), per T2DM patient with no CVD £2,456 (95% CI; £704, £7,999) and per patient at high risk of CVD £3,346 (95% CI; £1,000, £16,077). Hospital admissions made up the majority of costs in each patient category. Those with established peripheral arterial diseases and hypertensive diseases incurred the largest costs, those with ischaemic heart disease and needing revascularisation the smallest. Costs for each CVD category increased with age. Analysis B included 245,428 T2DM patients, 35,322 of whom had established CVD. By year three the total cost of treating a person with incident CVD was £31,910 (95% CI: £13,449, £76,066) compared to a patient without CVD (£6,863 (95% CI: £2,960, £21,561)). Over two years the cost was £26,024 (95% CI £10,881, £62,983) and £4,874 (£2,130, £15,272) respectively and during the first year £18,927 (95% CI: £7,725, £47,603) and £2,422 (95% CI £1,025, £7,983). Costs increased with age, and cerebrovascular events and hypertensive diseases were associated with the greatest cost.
Conclusion: CVD in T2DM patients places a significant financial burden on health and social care services. The highest costs are incurred during the incident CVD event. Cost differentials between patient groups continue to show beyond the incident event.

2016/17 national diabetes audit: certain newer to market agents impact positively on glycaemic control at a population level

A. Heald[1], A. Fryer[2], S.G. Anderson[1], S. Farman[3], M. Livingston[1], M. Davies[4], G. Moreno[5], R. Gadsby[6], M. Stedman[4];
[1]The School of Medicine and Manchester Academic Health Sciences Centre, University of Manchester, Manchester, UK, [2]Institute for Applied Clinical Sciences, Keele University, Keele, Keele, UK, [3]Mersey Deanery Psychiatry Rotation, Liverpool, UK, [4]RES Consortium, Andover, UK, [5]High Specialty Regional Hospital of Ixtapaluca, Mexico City, Mexico, [6]University of Warwick, Warwick, UK.

Background and aims: Spend on Type 2 diabetes mellitus (T2DM) medication is increasing, proportion of people with T2DM achieving target glycaemia outcomes is static or declining. Aim was to determine using public published General Practitioner Practice (GPP) level data, how differences in T2DM prescribing patterns including newer agents relate to achieving glycaemic target levels.
Materials and methods: Multiple linear regression modelling was applied to data from GPP in 2015/16 and latest 2016/17 National Diabetes Audit (NDA) with >100 patients on T2DM register. GPP data included epidemiology, level of diabetes service, and prescribing using defined daily dose (DDD) both by class and BNF chemical including Glucagon-like peptide-1 (GLP1), and Dipeptidyl peptidase-4 inhibitors (DPP4i) and SGLT2i, was linked to proportion achieving target glycaemic control (TGC; HbA1c ≤7.5%, 58 mmol/mol) and at high glycaemic risk (HGR; HbA1c >10.0%, 86 mmol/mol).
Results: T2DM register (5,488 GP practices) grew 6.2% to 2.26 million. Most new patients came in <64 age which grew from 44.4% to 46.7%. %Patients <65 was found to have negative impact on both TGC & HGR. Level of service as % completion of 8 checks fell by 12% from 54.1% to 47.8%. T2DM medication/patient fell by 1.7%, 15% less glitazones (TZD) (0.03DDD/T2 register), 6% less sulphonylurea (SU) (0.61), 2% less insulin and 1% less metformin (0.51). 3% growth in GLP1 (0.03 DDD/T2 register), 12% DPP4i (0.13) and 65% in SGLT2i (0.04). Specifically Dulaglutide grew by 880%, Empagliflozin 440%, Canagliflozin 100%, Alogliptin 175%, and Linagliptin 30%. Vildagliptin declined by 17%, Exenatide 15% and Saxagliptin 10%. Liraglutide and Sitagliptin prescriptions were relatively static. Wide variations were observed between GPP. % TGC increased by 1.4% of total (20,507) to 66.8% and HGR increased by 2.1% of total (3125) to 6.7%. Linking annual change by factor to change in TGC and HGR numbers (Figure) showed a fall in diabetes check completion by 142,430 patients & TZD prescribing by 11,940 patients with associated reduced TGC by 6,107 & increased HGR by 6,114 patients. Provision of various DPP4i

and SGLTi to at least 55,500 patients brought 12,200 into TGC and 6400 out of HGR.

Conclusion: GPP type and service are significant to outcomes. SU use is falling but continues to deliver poor outcomes. Certain newer agents are linked to improved outcome (Figure). The SGLTIs empagliflozin and canagliflozin show benefits in TGC and all SGLTis reduce numbers at HGR. GLP1 seem to have peaked in some practices. There is considerable variation in impact of different DPP4i. TZD still seem to offer some benefits.

Figure 1: Applying Regressions Coefficient from Longitudinal Analysis to the numbers of patients being treated to show the impact of factors with p score <0.01 on overall change in numbers of achieving target Glycaemic control (TGC) or at Higher Glycaemic Risk (HGR)(numbers in bars with orange denoting deterioration and green denoting improvement).

Are neighbourhood factors associated with diabetes progression in prediabetes patients? Using census data to predict patient-centered health outcomes

J.A. Schmittdiel[1], W. Dyer[1], C. Marshall[1], R. Bivins[2];
[1]Kaiser Permanente Northern. California, Oakland, USA, [2]University of Warwick, Coventry, UK.

Background and aims: Existing prediction models that examine factors associated with developing diabetes are commonly focused on individual level patient factors such as weight, blood sugar levels, and race/ethnicity. Data regarding patient social context at the area level are rarely assessed as predictors in these models, despite the known relationship between a patient's neighborhood environment (*e.g.* the "zip code effect") and a wide range of health outcomes. The purpose of this study is to determine whether United States Census variables on income, education, and receipt of food assistance at the area level are associated with developing diabetes after adjustment for traditional demographic and clinical factors.

Materials and methods: Kaiser Permanente Northern California (KPNC) is an integrated delivery system that provides comprehensive health care to more than 4 million patients in the United States. This retrospective cohort study included adult patients aged ≥18 from KPNC the with laboratory-defined prediabetes (fasting plasma glucose [FPG] 100–125 mg/dL and/or glycated hemoglobin [A1c] 5.7–6.4%) between 1/1/2006 and 12/31/2010. To create an incident prediabetes cohort, we excluded all patients who had tested in this range in the 2 years prior, as well as those with a pre-existing diagnosis of diabetes or prediabetes during this period. The primary outcome was progression to diabetes within 36 months of prediabetes identification. To assess predictors of progression to diabetes, we employed logistic regression using age, gender, race/ethnicity, baseline blood sugar levels, baseline body mass index (BMI), Census block group level education and income, and Census track level percentage of households receiving benefits through the governmental food assistance 'Supplemental Nutrition Assistance Program' (SNAP).

Results: The cohort included 157,752 patients, with a mean age of 57.2 (SD 13.6), 50% female, and 59% non-Hispanic White. In the multivariate regression model greater age, having overweight or obesity, and having a blood sugar value of FPG >110 or A1c >6.0 at baseline were all significantly associated with developing diabetes within 36 months of prediabetes identification. After adjusting for these demographic and clinical variables, patients were also more likely to progress to diabetes if they lived in an area where <50% of the adult population aged ≥25 had obtained a bachelor's degree or higher (OR = 1.2, 95% CI = 1.1, 1.3), or if they lived in an area where SNAP benefits were received by 10% or more of households (OR = 1.2, 95% CI = 1.1, 1.4). Higher median household income at the area level had a protective effect against diabetes progression (OR = 0.98, 95% CI = 0.97, 0.99).

Conclusion: Census information on neighborhood and tract-level education, income, and receipt of food assistance are significant predictors of developing diabetes within a prediabetes population, even after adjusting for traditional individual demographic and clinical factors. Clinical interventions should take these factors into account, and health care systems should consider addressing neighborhood-level resources and social needs as a path to improving community and population-level health outcomes.

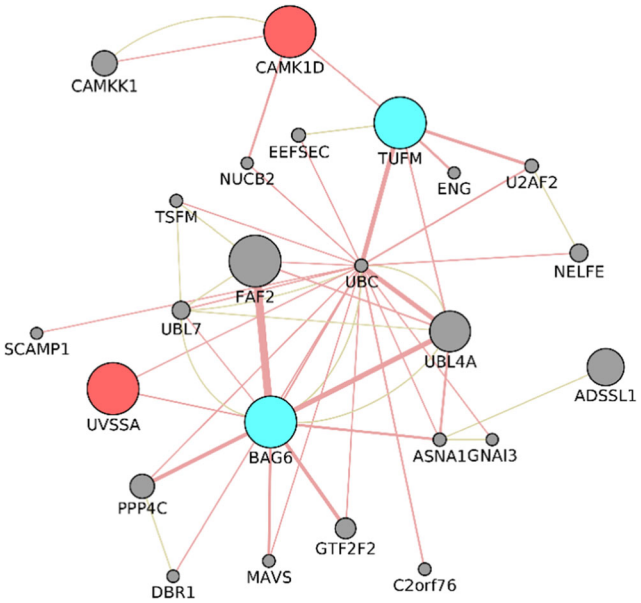
OP 40 Innovation in genetics

229

A common regulatory network for type 1 and type 2 diabetes susceptibility genes in human pancreatic islets

S. Kaur[1], A.H. Mirza[2], F. Pociot[1], J. Størling[1];
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]Weill Cornell Medicine, New York, USA.

Background and aims: Genetic risk factors contribute significantly to the etiology of type 1 diabetes (T1D) and type 2 diabetes (T2D) and genome-wide association studies (GWAS) have identified >50 loci for both diseases. Despite the clinical and phenotypical similarities between the two forms of diabetes, there is basically no overlap at the genetic level between the two diseases. Since pancreatic β-cell dysfunction is the principal cause of both forms of diabetes, we hypothesized that a proportion of the risk genes for T1D and T2D interact in common networks and pathways in islets to affect β-cell fragility. In this study, we aimed to identify common functional interaction networks between T1D and T2D risk loci-associated genes by integrating GWAS, human islet gene expression and islet-specific expression quantitative trait locus (eQTL) data.
Materials and methods: The T1D and T2D GWAS data was retrieved from T1Dbase v.4.16 and DIAGRAMv3. All genes located ±100 kb from genome-wide associated significant SNPs were extracted. Publically available human pancreatic islet RNAseq data consisting of 118 islet preparations was used to identify islet expressed genes and islet *cis*-exon eQTLs. ToppGene suite and CytoScape were used to create interaction networks. The interactions between T1D and T2D loci genes were further extended to include neighboring genes (max $n = 20$) based on physical interactions and shared protein domains in GeneMania. Functional annotation based on gene ontology terms and pathways was performed using ClueGO.
Results: In total, 27,772 protein-coding and non-coding transcripts were found expressed in 118 human islet samples, of which 2,339 genes had at least one significant islet exon-eQTL (p value <0.05). Out of the 2,339 islet eQTL genes, 66 and 27 genes were located in T1D and T2D GWAS loci, respectively. These two groups (66 T1D and 27 T2D genes) were further subjected to network analysis. The T1D/T2D islet gene network identified interactions between TUFM ~ CAMK1D and BAG6 ~ UVSSA. The functional annotation analysis of the extended T1D/T2D interaction network identified 3 clusters of significantly-enriched gene ontology terms related to regulation of tumor necrosis factor-mediated signaling pathway, regulation of cell death and cell cycle-related processes.
Conclusion: This study identified a shared islet network consisting of T1D and T2D candidate genes. This network highlighted plausible roles of novel genes associated with cell cycle processes and cell-death regulation that might contribute to pancreatic β-cell impairment in both T1D and T2D.



Disclosure: **S. Kaur:** None.

Type 2 diabetes-induced beta cell gene regulatory networks identified using single-cell RNA-sequencing of human islets

N. Wierup[1], J.A. Martínez-López[2], A. Lindqvist[1], R.G. Fred[1], A.B. Muñoz-Manchado[2], S. Chriett[1], L. Shcherbina[1], J. Hjerling-Leffler[2];
[1]Lund University, Malmo, [2]Laboratory of Molecular Neurobiology, Department of Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Deranged islet function is a culprit in type 2 diabetes (T2D). Currently, major focus is on assessing differential expression of genes in T2D vs. nonT2D whole-islet preparations. This strategy is limited by the fact that the islets are composed of at least five different cell types. Therefore, single-cell information on disease vs. control cells is warranted. Single-cell RNA-sequencing has been successfully performed in human islets, but the available data is contradictory, and rely on simple differential expression analysis. We aimed at understanding, and to functionally test, gene regulatory changes in relevant biological processes in beta cells of T2D patients.
Materials and methods: Handpicked islets (100/donor) from cadaver donors were dissociated into single cell suspensions using Accutase. Cells were isolated by unbiased FACS and Smart-seq2 single-cell transcriptomics was used to sequence cells from 6 nonT2D- and 4 T2D donors (obtaining transcriptomes of 3075 cells). Cell identity was determined using the two way unsupervised clustering algorithm BackSPIN and t-SNE technique. We identified affected biological pathways using differential gene correlation network analysis. Insulin secretion and gene expression after siRNA silencing was assessed in INS-1 (832/13) and EndoC-BH1 cells.
Results: BackSPIN identified 12 distinct pancreatic cell populations, including alpha-, beta-, delta-, PP- and ghrelin cells. Clustering was verified manually by comprehensive analysis of differential expression of established markers for each cell type. Numerous genes were differentially regulated in every cell population in T2D donors. To understand the biological processes that fail in T2D beta cells, we assessed networks of genes. Using novel bioinformatic tools we identified 12 gene regulatory networks (GRNs), representing established (e.g. mitochondria function and ER-stress), as well as hitherto unknown biological processes that were affected in T2D beta cells. The GRNs included genes with

established roles in T2D, e.g. NEUROD1, PDX1, NKX6.1, and GLP1R, and our analysis put them in a new disease context. We also identified node genes, i.e. genes potentially regulating many other genes, in the GRNs. Most of the node genes have not been described in beta cell biology and their significance was validated in beta cell lines. 12 out of 14 of the uncovered T2D-genes were found to affect insulin expression and/or glucose- and cAMP-stimulated, but not basal insulin secretion. We also tested selected GRNs functionally by siRNA targeting of node genes, followed by bulk RNAseq of INS-1 (832/13) cells. Immunohistochemistry in pancreatic sections from the same donors confirmed protein expression of the node genes in human beta cells.

Conclusion: We have identified 12 distinct biological processes that are affected in T2D beta cells and identified and functionally tested node genes, many of them with previously unknown function, that are key regulators of each process. This is a major leap forward for the understanding of the deranged characteristics of beta cells in T2D.

Dietary fat quality and genetic risk of type 2 diabetes

J. Merino[1], M. Guasch-Ferre[2], C. Ellervik[3], H. Dashti[1], C.E. Smith[4], T.O. Kilpeläinen[5], D.I. Chasman[6], J.C. Florez[1];
[1]Center for Genomic Medicine, Massachusetts General Hospital, Boston, USA, [2]Department of Nutrition, Harvard T.H. Chan School of Public Health, Boston, USA, [3]Department of Laboratory Medicine, Boston Children's Hospital, Boston, USA, [4]Nutrition and Genomics Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, USA, [5]Novo Nordisk Foundation Center for Basic Metabolic Research, Copenhagen, Denmark, [6]Division of Preventive Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, USA.

Background and aims: Type 2 diabetes (T2D) is a complex disease driven by genetic and lifestyle factors. The extent to which T2D genetic burden modifies the association between dietary fat quality and T2D incidence is unknown.

Materials and methods: We used Cox proportional-hazards models to calculate adjusted hazard ratios (HRs) for T2D among 103,206 participants of European descent from 15 prospective cohort studies. T2D genetic risk profile was characterized by a 68-variant genetic risk score (GRS) weighted by published effect sizes. Diet was recorded using validated cohort-specific dietary assessment tools.

Results: During a median follow-up of 12 years, 20,451 participants developed T2D. The relative risk of T2D per increment of 10 risk alleles in the GRS was 1.68 (95% confidence interval [CI] 1.62–1.74). Increasing polyunsaturated or total ω-3 fat intake in place of refined carbohydrates was associated with a lower risk of T2D (HR per 5% of energy 0.92, 95% CI 0.85–1.00; and HR per increment of 1 g/d 0.95, 95% CI, 0.92–0.99, respectively), while increasing monounsaturated fat intake in place of refined carbohydrates was associated with a higher risk of T2D (HR per 5% of energy 1.08, 95% CI 1.02–1.15). We did not observe evidence of significant interactions between dietary fat subtypes and GRS on the risk of T2D.

Conclusion: In the present long-term prospective study including 103,206 participants, our results support that genetic risk profile and monounsaturated fat intake were each associated with a higher risk of T2D, whereas polyunsaturated fat intake was associated with a lower risk of T2D. Findings from this study suggest that dietary fat recommendations do not need to be tailored to individual T2D genetic risk profile for the primary prevention of T2D, and that dietary fat subtypes associate with the risk of T2D across the spectrum of T2D genetic risk.

Genetic determinants of glucose response patterns during the OGTT: findings from the ADDITION-PRO cohort

A. Hulman[1,2], A. Jonsson[3], K. Færch[4], D. Vistisen[4], T. Hansen[3], N. Grarup[3], M.E. Jørgensen[4], D.R. Witte[1,2];
[1]Aarhus University, Aarhus, [2]Danish Diabetes Academy, Odense, [3]Novo Nordisk Center for Basic Metabolic Research, Copenhagen, [4]Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: We have previously identified heterogeneous glucose response patterns in the RISC cohort based on glucose measurements at five time points during the oral glucose tolerance test (OGTT) and showed that the four identified groups have different metabolic risk profiles. We aim to understand to which degree group membership is determined by unmodifiable (genetic) factors.

Materials and methods: We analysed data from 1222 participants (628 men and 594 women) without diabetes in the ADDITION-PRO cohort who underwent an OGTT with glucose measurements at three time points (0, 30, 120 mins). Individuals were categorised into four groups using a latent class model developed in the RISC cohort based on their class membership probabilities (Figure: *Glucose response patterns derived in the RISC cohort [lines] and plasma glucose measurements at 0, 30 and 120 minutes in the ADDITION-PRO cohort [scatterplot]*). Genetic risk scores for insulin resistance (GRS-IR) and impaired early insulin secretion (GRS-IEIS) were calculated and compared between the four groups with different glucose response patterns using linear and multinomial regression models with adjustment for age, sex and BMI.

Results: More than half of the cohort belonged to class 2 (55%), while 16%, 10% and 18% were members in classes 1, 3 and 4, respectively. Mean GRS-IR values were similar between classes 1, 2 and 3. Only class 4 showed an indication of GRS-IR (class 4 vs. class 2: +0.26 risk allele, 95% CI: −0.06 to 0.58). Mean GRS-IEIS values were lowest in class 1 (class 1 vs. class 2: −0.66 risk allele, 95% CI: −1.12 to −0.20), highest in class 3 (class 3 vs. class 2: +0.64 risk allele, 95% CI: 0.09 to 1.19) and similar in classes 2 and 4. Individuals with a higher GRS-IEIS were more likely to belong to class 3 (OR: 1.08, 95%CI: 1.01 to 1.16 per risk allele) and less likely to be in class 1 (OR: 0.93, 95%CI: 0.88 to 0.98 per risk allele), than to class 2.

Conclusion: The glucose pattern exhibiting the highest peak followed by a rapid fall in the second hour of the OGTT is determined by impaired genetically determined early insulin secretion rather than insulin resistance. Contrarily, higher glucose concentrations at 2 hours seem to be determined to a higher degree by insulin resistance. Our findings show that the four different classes are partially determined by differences in the balance between insulin resistance and secretion, and that these differences play a role throughout life. The interaction between these genetic determinants and environmental exposures needs to be explored further.

OP 41 Novel mechanisms of inflammation in obesity

233

SUCNR1 signalling controls macrophage alternative activation and regulates immune metabolic responses in obesity

S. Fernandez Veledo[1,2], N. Keiran[1,2], E. Calvo[1,2], V. Ceperuelo-Mallafré[1,2], M.I. Hernández-Alvarez[1,2], M. Ejarque[1,2], C. Nuñez-Roa[1,2], D. Horrillo[3], E. Maymó-Masip[1,2], M.M. Rodríquez-Peña[1,2], A. Zorzano[4,2], G. Medina-Gómez[3], C. Serena[1,2], A. Castrillo[5], J. Vendrell[1,2];
[1]Institud d´Investigacio Sanitaria Pere Virgili, Tarragona, [2]CIBERDEM, Madrid, [3]Universidad Rey Juan Carlos, Madrid, [4]IRB Barcelona, Barcelona, [5]IIB Alberto Sols, Madrid, Spain.

Background and aims: Macrophages have a central role in metabolic homeostasis and some metabolites are now known as critical regulators of their functional plasticity. Whereas accumulation of succinate is a hallmark of pro-inflammatory (M1) macrophages, succinate can be released and act through its receptor SUCNR1, which is predominantly expressed in alternative (M2) macrophages. The precise role of this succinate/SUCNR1 axis in macrophages, however, remains unclear.
Materials and methods: Generation and metabolic phenotype of myeloid cell-specific *Sucnr1* knockout mice (LysM-*Sucnr1*$^{-/-}$) fed with a normal chow diet (NCD; 3.1% fat) or challenged to a high fat diet (HFD; 45% fat). Long-term cold exposure and LPS-induced endotoxemia studies. Gene/protein expression and histological analysis. RNAseq and intracellular signalling studies in bone marrow-derived macrophages (BMDMs). Human adipose tissue biopsies obtained from donors undergoing non-acute surgical interventions: lean $n = 15$ (BMI 22.87 ± 1.51); obese $n = 36$ (BMI 31.44 ± 4.55).
Results: Myeloid-specific SUCNR1 deficiency promotes a pro-inflammatory phenotype, disrupting glucose homeostasis in mice under normal chow diet, and exacerbating the metabolic consequences of diet-induced obesity. Intriguingly, succinate signaling via SUCNR1 promotes alternative macrophage phenotype and boosts the IL-4 response through activation of CREB-KLF4 pathway. Accordingly, LysM-*Sucnr1*$^{-/-}$ mice show reduced adipose tissue browning in response to cold-exposure and higher susceptibility to endotoxemia, both M2 immune responses. We also show that succinate/SUCNR1 axis is disturbed in obese humans. SUCNR1 expression in adipose tissue-resident macrophages is significantly lower in obese than in lean individuals, which correlates with a failure of succinate to suppress the inflammatory phenotype of obese adipose tissue.
Conclusion: Our findings establish the succinate/SUCNR1 axis as a novel signal-regulatory mechanism of alternative macrophage activation and assign an unpredicted homeostatic role of succinate in limiting inflammation.

ANKRD26 gene expression depends on the methylation of its promoter and associates with cardio-metabolic risk and altered levels of inflammatory mediators in human obesity

A. Desiderio[1], M. Campitelli[1], G. Cacace[1], A. Leone[1], I. Prevenzano[1], D. Conza[1], F.C. Pignalosa[1], M. Milone[2], C. Miele[1], F. Beguinot[1], G.A. Raciti[1];
[1]URT-GDD, National Council of Research, Department of Translational Medical Sciences, "Federico II" University of Naples, Naples, [2]Department of Public Health, "Federico II" University of Naples, Naples, Italy.

Background and aims: Obesity is now considered to be a major threat to human health and well-being worldwide. This makes the need of achieving a better understanding of its pathogenesis a priority. Furthermore, recent evidence points out that epigenetic modifications have an extraordinary impact on the natural history of this disorder and may explain predisposition for obesity in cases of familial aggregation or as effects of environmental exposure. Thus, understanding how epigenetic changes may contribute to human obesity is of particular importance. We have recognized the *Ankyrin repeat domain 26* (*Ankrd26*) gene as an interesting and proper target. Indeed, we have demonstrated that *Ankrd26* is involved in the development of both obesity and diabetes in mice and is a target sensitive to environment-induced epigenetic modifications in diet-induced obese mice. Here, we aimed at investigating whether impaired *ANKRD26* gene expression and DNA methylation occur in human obesity and may correlate to alteration of metabolic/inflammatory mediators in these subjects.
Materials and methods: Lean ($n = 14$) and obese ($n = 20$) subjects were recruited at the Federico II University of Naples. Gene expression and DNA methylation were evaluated in peripheral blood leucocytes (PBLs) by qRT-PCR and bisulfite sequencing, respectively. Serum mediators were assayed by ELISA. Promoter activity was evaluated by luciferase assay.
Results: *ANKRD26* mRNA levels were reduced by ≈ 25% in PBLs from obese individuals compared with lean subjects ($p < 0.01$). Furthermore, DNA methylation analysis of the *ANKRD26* promoter (−1000/+390 bp from TSS) revealed a 3-fold increased methylation in a restricted region of the *ANKRD26* promoter, containing the CpG dinucleotides, −689 bp, −659 bp and −651 bp, in obese compared with lean individuals ($p < 0.01$). *ANKRD26* gene expression inversely correlates to the percentage of DNA methylation of these 3 CpG sites ($p < 0.05$), as well. Additionally, a luciferase assay performed on the aforementioned region pointed out a cause effect relationship between the DNA methylation of this 3 CpG sites at the *ANKRD26* promoter and its gene expression as shown by a decrease of 30% of the luciferase activity in the methylated compared with the un-methylated *ANKRD26* specific promoter region ($p < 0.01$). Very interestingly, a significant negative correlation was found between *ANKRD26* mRNA levels and both BMI ($p < 0.01$) and TG/HDL-C ratio, a marker of insulin resistance and increased cardio-metabolic risk ($p < 0.001$), as well as with the pro-inflammatory cytokines, IL1β ($p < 0.05$) and TNFα ($p < 0.01$).
Conclusion: The *ANKRD26* gene is sensitive to epigenetic regulation even in humans. Indeed, a site-specific CpG hyper-methylation of its promoter and the down-regulation of its expression represent common abnormalities in obese patients and its gene expression associates to cardio-metabolic risk and altered levels of inflammatory mediators in these subjects.

Loss of fractalkine-CX3CR1 signalling promotes diet-induced adipose tissue inflammation and insulin resistance by controlling the M1/M2 status of macrophage

M. Nagashimada[1], Y. Ni[2], T. Ota[3];
[1]Kanazawa University, Ishikawa, Kanazawa City, Japan, [2]Zhejiang University of Technology, Hangzhou, Zhejiang, China, [3]Asahikawa Medical University, Asahikawa City, Japan.

Background and aims: We previously demonstrated that obesity-induced activates adipose tissue macrophage (ATM) via chemokine of CCR5 system as well as CCR2-MCP-1 system, and is pivotal for the development of insulin resistance. Recently, we found that CX3C chemokine, fractalkine (Cx3cl1) mRNA expression was persistently down-regulated in epididymal white adipose tissue (eWAT) of High fat diet (HFD)-induced obese (DIO) mice, as compared to lean controls. Recent studies reported that fractalkine exerts both negative and positive influences on disease pathogenesis and progression. We observed that *Cx3cr1*$^{-/-}$ (KO) mice exacerbate HFD-induced glucose intolerance, insulin resistance and hepatic steatosis. Here we show that fractalkine-CX3CR1 signaling plays a crucial role in the adipose tissue inflammatory response to HF feeding by regulating M1/M2 status of macrophage. Moreover, we demonstrated that fractalkine attenuated glucose intolerance and insulin signaling in DIO mice.
Materials and methods: The localization of fractalkine and CX3CR1 were examined in the eWAT of DIO mice by immunofluorescence staining. To determine the effect of fractalkine-CX3CR1 signaling on ATM subsets, we performed flow cytometry analysis to quantify M1/M2 ATMs in WT or KO mice fed the NC or HF diet for 16 weeks. In addition, to ascertain whether the therapeutic effect of fractalkine, we performed systemically expression of fractalkine in WT or KO mice fed a HF diet by hydrodynamic tail vein injection and investigated metabolic phenotypes.
Results: Immunofluorescence analysis of eWAT in HF-fed mice revealed that fractalkine and CX3CR1 were F4/80^{+} macrophages, but these are poorly expressed by pelilipin^{+} adipocytes. Interestingly, both CD11c^{+}CD206^{-} (M1-type) and CD11c^{-}CD206^{+} (M2-type) ATM were expressed fractalkine and CX3CR1. To quantify ATM subsets in WT or KO mice on the NC or HF feeding, we performed flow cytometry analysis. KO mice with NC feeding resulted in a 40.3% increase in M1-type macrophages and 17% decrease in M2 type macrophages compared with WT mice. Moreover, KO mice with HF feeding had 39% more M1 type macrophage, 49% fewer M2 type macrophage than WT mice on the same diet, which resulted in predominance of M1 over M2 ATM population. Furthermore, an increased fractalkine concentration in plasma of DIO mice by hydrodynamic tail vein injection, led to attenuate glucose intolerance and enhance insulin sensitivity in both liver and eWAT. While no significant difference was observed in β cell mass between fractalkine administration and control. In addition, an increased fractalkine of KO mice with a HF feeding showed no change in the attenuation of glucose intolerance.
Conclusion: Loss of fractalkine-CX3CR1 signaling exacerbates diet-induced inflammation and insulin resistance by a dynamic M1 shift of ATM. Additionally, a decline in plasma of fractalkine level by obesity is recovery, and, in a consequence, the improvement of insulin resistance. Thus, fractalkine-CX3CR1 signaling plays a critical role in diet-induced insulin resistance by regulating the M1/M2 status of ATM. Fractalkine-CX3CR1 signaling may have a potential clinical utility for type 2 diabetes.

Diverse hepatic microbial DNA fingerprints in healthy lean and obese steatotic humans

J.I. Bagger[1], M.P. Suppli[1], T. Nielsen[2], B. Lelouvier[3], A. Broha[3], M. Demant[1], M.J. Kønig[4], C. Strandberg[4], A. Lund[1], T. Vilsbøll[1], F.K. Knop[1,5];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]Faculty of Health and Medical Sciences, Novo Nordisk Foundation Center for Metabolic Research, Copenhagen, Denmark, [3]Vaiomer, Labege, France, [4]Radiology, Herlev Gentofte Hospital, Gentofte, Denmark, [5]Clinical Medicine, Faculty of Health and Medical Sciences, Copenhagen, Denmark.

Background and aims: Hepatic inflammation associated with non-alcoholic fatty liver disease is generally believed to be a result of steatosis-induced hypoxia, cell death, infiltration of macrophages and expression of chemokines and proinflammatory cytokines. The leaky gut hypothesis links translocating microbial products with hepatic inflammation. We evaluated the 16S rDNA bacterial profiles in liver samples from healthy lean and obese subjects.

Materials and methods: Fifteen lean and 15 obese subjects (body mass index of 18.5–25 and 30–40 kg/m^2, respectively), 25–80 years of age, with normal fasting plasma glucose and HbA1c <40 mmol/mol were recruited for ultrasound-guided transcutaneous liver biopsies. Assessment of steatosis was done by histology. After bacterial DNA extraction from liver biopsies, qPCR targeting the V3-V4 region of the bacterial 16S ribosomal gen was employed to quantify the amount of bacterial DNA. Furthermore, 16SrDNA sequencing of the V3_V4 region was performed using the Illumina Miseq platform. Reads were clustered into operational taxonomic units (OTUs) and taxonomic assignment was performed using the Silva 128 database. Indices of alfa and beta diversity were applied to assess community structure and differentially abundant taxa between the groups were analysed using the LEfSe method.
Results: Histology revealed steatosis in 14 of 15 obese subjects and only 2 of 15 lean subjects ($p > 0.001$). A robust signal from qPCR revealed significantly higher bacterial DNA in liver samples from obese subjects compared to lean (Figure 1). Observed OTUs as well as other indices of alfa diversity were increased in obese subjects compared to lean. No differences between groups were observed in beta diversity. The taxonomic comparison between groups showed increased abundance of *Proteobacteria* in the group of obese subjects.
Conclusion: We provide evidence for the presence of bacterial DNA in the human liver and show significantly higher amounts of bacterial 16S rDNA copies in liver samples from obese compared to samples from lean subjects. Furthermore, we provide a unique window to the hepatic relative proportions of taxa in the two groups. Further studies investigating the clinical implications of our findings are warranted.

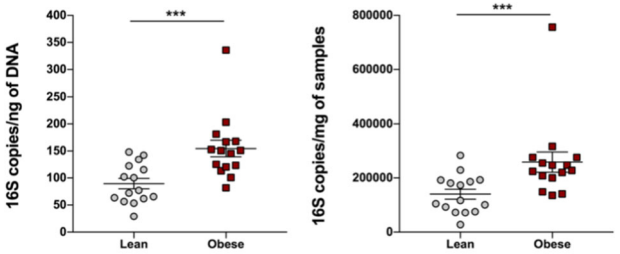

Figure 1. Quantification of 16S copies per ng DNA (left) and 16S copies per mg liver tissue (right) in lean (open symbols) and obese (filled symbols). Asterisks indicate significant difference (Man Whitney test P<0.001)

Bottom-up islet engineering

Q.P. Peterson[1,2], A. Veres[2], D.M. Gonzalez[2], J. Ryu-Kenty[2], B. Tyrberg[3], M. Sörhede-Winzell[3], D.A. Melton[2];
[1]Physiology and Biomedical Engineering, Mayo Clinic, Rochester, USA, [2]Stem Cell and Regenerative Biology, Harvard University, Cambridge, USA, [3]Cardiovascular, Renal and Metabolism, IMED Biotech Unit, AstraZeneca Gothenburg, Mölndal, Sweden.

Background and aims: Diabetes Mellitus results from dysfunction of pancreatic islets leading to elevation of blood glucose levels and an increase in morbidity and mortality. In type 1 diabetics, the precipitating event is the loss of insulin producing pancreatic β cells through autoimmune attack. As such, the *in vitro* production of β cells for use as a cell transplantation therapy has been a major focus of type 1 diabetes research. However, it is unlikely that β cells by themselves will recapitulate the complex biology involved in islet function. Indeed, the three major approaches proposed by the field to regain glycemic control in diabetic patients (bionic pancreas, transplantation of *in vitro* derived β cells, and production of β cells *in vivo* through replication or reprogramming) fail to fully account for the complexity of islet endocrine function and focus almost exclusively on the function of the β cell.
Materials and methods: To this end, we seek to generate human islet organoids from component parts using a bottom-up tissue engineering approach. Here we report the development of separate protocols for generating stem cell-derived α, β and δ cells and subsequently combine these cell types to create islet organoids of defined composition by dispersing and reaggregating in various proportions (β only, 4:1 β to α, 1:1 β to α, and α only). Organoids were cultured for 4 days before assessing glucose stimulated insulin secretion. Organoids were transplanted under the kidney capsule in mice and assessed for survival and human insulin secretion *in vivo*.
Results: Stem cell-derived α, β and δ cells exhibit many of the characteristics of their *bona fide* counterparts including gene expression, hormone secretion, ultrastructure and *in vivo* function. We also find that combination of stem cell-derived α and β cells in islet organoids exhibit improved function *in vitro* and *in vivo* as compared to β cells alone. *In vitro* β cell insulin secretion in response to glucose was increased by 92% in the presence of α cells compared to controls ($p < 0.05$). Upon transplantation, combined α and β cell grafts resulted in a reduced fasting blood glucose (125 ± 7 mg/dl vs. 152 ± 9 mg/dl, $p < 0.05$), increased human insulin secretion after glucose challenge and an improved glucose tolerance (264 ± 23 mg/dl/h AUC vs. 341 ± 32 mg/dl/h AUC, $p < 0.05$) compared to transplantation of β cells alone. Combination of β cells with δ cells resulted in an overall decrease in insulin secretion and a decreased stimulation index *in vitro* (0.8 ± 0.2 for β and δ cells vs. 1.4 ± 0.2 for β cells only, $p < 0.05$).
Conclusion: These studies suggest that stem cell-based products more closely resembling the endogenous architecture and composition of the human islet may be better suited for cell replacement therapy, disease modeling and drug screening efforts.

The DPP4 inhibitor sitagliptin increases intra-islet active GLP-1 levels in human islets and may confer additional protection from cell death

S.A. Campbell, M. Hubert, N. Salamon, K. Ondrusova, A. Barr, W. Long, M. Fatehi, K. Philippaert, P. Light;
Pharmacology, University of Alberta, Edmonton, Canada.

Background and aims: Recent studies in genetic mouse models suggest that intra-islet GLP-1 is required for proper glucose homeostasis,

highlighting the importance of paracrine GLP-1 signalling within the islet. However, information on intra-islet GLP-1 secretion and action within human islets is lacking, despite the fact that 30–40% of islet cells are alpha cells and are capable of secreting GLP-1. Moreover, as DPP4 is found in human islets, treatment with the DPP4 inhibitor sitagliptin should increase levels of active GLP-1 within the islet and have consequences for insulin secretion and cell survival. Therefore, we confirmed that DPP4 is expressed within human islets and then studied the effects of sitagliptin on 1) active and total GLP-1 levels 2) cell survival and 3) glucose-stimulated insulin secretion.

Materials and methods: DPP4 protein was analyzed using Western blot. GLP-1 positive cells were identified with immunofluorescence microscopy on paraffin embedded human islet sections. Human islets were cultured with sitagliptin 200 nmol/L or vehicle control for the GLP-1 secretion assays, dead cell assay, and islet perifusions. Glucose concentrations for the experiments were: dead cell assay (6.1 mmol/L), glucose-stimulated insulin secretion (2.8, 28 mmol/L), glucose-stimulated GLP-1 secretion (2.8, 11 mmol/L), and islet perifusions (2.5, 11 mmol/L). Islet cell death was induced by culture time (48 hour) and detected with Sytox Green. Active and total GLP-1 levels were measured with an immunoassay (Meso Scale Discovery), while insulin levels were measured with an ELISA (Alpco).

Results: Western blot analysis demonstrated that human islets express significant levels of DPP4. In addition, using immunofluorescence microscopy of human islet sections, we identified a sub-population alpha cells that contained cleaved GLP-1. When normalized to islet size, our human islet cultures secrete 50X more active GLP-1 than mouse islets. Furthermore, active GLP-1 levels were significantly increased by ~7-fold ($N = 3$, $P < 0.05$) when islets were cultured with sitagliptin and this negatively correlated with increased cell death ($r = -0.983$, $P < 0.05$). Active GLP-1 levels negatively correlated with the stimulation index for insulin secretion ($r = -0.969$, $P < 0.05$). However, insulin secretion from perifused non-diabetic islets treated with sitagliptin did not differ from controls ($N = 6$). Preliminary results from glucose-stimulated GLP-1 secretion experiments show that active GLP-1 secretion decreases at high glucose with non-diabetic islets, but not with type 2 diabetic islets.

Conclusion: Our results support the concept that intra-islet GLP-1 may play an important physiological role in human islets as alpha cells are more numerous in human islets than mouse islets and also contain a sub-population of GLP-1 positive alpha cells. Moreover, we have determined that human islets secrete much larger amounts of active GLP-1 compared to mouse islets. Our novel results with sitagliptin suggest that DPP4 inhibitors may exert some of their glucose-lowering therapeutic effects via upregulation of intra-islet active GLP-1 levels. Although, the sitagliptin-mediated increase in active GLP-1 is correlated with enhanced islet cell survival, it did not increase insulin secretion in non-diabetic islets. Therefore, experiments are underway in islets from donors with type 2 diabetes.

Acetate stimulates insulin secretion of human pancreatic microislets

E. Lorza Gil[1,2], F. Gerst[1,2], U. Deschl[3], H.-U. Häring[1,2], S. Ullrich[1,2], M. Beilmann[3];
[1]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Zentrum München at the University of Tübingen (IDM), Tübingen, [2]German Center for Diabetes Research, Tübingen, [3]Boehringer Ingelheim Pharma GmbH & Co. KG, Nonclinical Drug Safety, Biberach, Germany.

Background and aims: The effect of short chain fatty acids (SCFA), i.e. acetate, butyrate and propionate on glucose-induced insulin secretion (GIIS) depends on FFAR2 and FFAR3 expression. In isolated rodent islets conflicting results have been published, including stimulatory, inhibitory or no effects of SCFA on GIIS. Due to species-related differences in islet architecture and function, a reliable and reproducible testing in human islet cell preparations is indispensable for the translation to the human situation. However, isolated human islets are poorly glucose-responsive and vary largely in basal secretion, size and architecture. This study aims to establish and validate a standardized in vitro test with islet cells from human donors. To this end microislets were generated by dissociation of isolated human islets into single cell suspension with subsequent reaggregation of defined cell numbers and equal composition of endocrine and non-endocrine cells. The microislets were cultured up to two weeks and functionally characterized.

Materials and methods: Human pancreatic islets were received from ECIT Centers and microislets purschased from InSphero. Islets were cultured overnight, digested with trypsin and reaggregated into microislets. Reaggregation of islet cells was performed using the hanging-drop method. Isolated islets and microislets were tested in parallel for insulin secretion using static incubation and RIA or ELISA for insulin and glucagon measurement.

Results: Basal insulin secretion at 2.8 mM glucose of isolated human islets ($n = 4$) was $3.2 \pm 0.6\%$ of content. At 12 mM glucose the secretion increased to $4.6 \pm 0.8\%$ of content. Forskolin (5 μM) further augmented GIIS to $6.6 \pm 1.2\%$ and palmitate (0.6 mM) to $6.1 \pm 0.8\%$. Basal secretion of microislets was significantly lower (1–2% of content) than of islets, while GIIS was largely improved (13-, 10- and 9-fold in microislets consisting of 1000, 2000 and 4000 cells, respectively). Acetate significantly augmented GIIS. The adrenoceptor agonist adrenaline inhibited GIIS indicating that receptor function is at least partially maintained in the microislets. The secretory capacity did not correlate to insulin content since islets contained significantly more insulin (23.0 ± 1.2 ng/islet) than microislets. The cell aggregates of 1000, 2000 and 4000 cells contained 1.6 ± 0.2, 2.7 ± 0.3, 10.1 ± 1.4 ng insulin/microislet, respectively. Insulin content of microislets and GIIS was maintained after an additional 2 week culture period. Glucagon secretion was not significantly different between 2.8 and 12 mM glucose and was less controllable than insulin secretion. However, glucagon release was lowest at 12 mM glucose and 2-fold higher upon addition of 5 mM arginine to 2.8 mM glucose.

Conclusion: The dissociation and reaggregation of human islet cells into microislets reduced basal insulin secretion and largely improved GIIS. The glucose responsiveness inversely correlated to the microislet size and was maintained over 14 days. FFAR2 and FFAR3 agonists significantly augmented GIIS. Thus, dissociation and reaggregation of human islet cells improves the functional integrity of beta-cells and it can be used as a tool for long term functional test and for standardization of islet cell transplantation.

Using a novel perifusion platform to investigate real-time crosstalk effects of contracting skeletal muscle on pancreatic beta cell function in vitro

J. Barlow, T. Solomon;
University of Birmingham, Birmingham, UK.

Background and aims: It is suggested that mediators liberated by contracting skeletal muscle play a role in mediating the beneficial effects of exercise on β-cell function in patients with type 2 diabetes (T2D). Examining this inter-organ crosstalk in vitro is limited to static co-culture incubation methods which are cumbersome and time limiting. Therefore we have developed a novel in vitro perifusion system to investigate skeletal muscle to β-cell crosstalk in real-time. Using this system, we aimed to examine real-time effects of mediators released by contracting skeletal muscle on insulin release from INS-1E pseudoislets and cells under healthy and T2D-like conditions.

Materials and methods: Krebs Ringer HEPES buffer (pH 7.4) containing 5 mM glucose was perifused from C2C12 myotubes to INS-1E pseudoislets for 270 minutes at a flow rate of 0.5 mL/min. After an initial 30 minute equilibration, C2C12 myotubes were contracted for 60 minutes by electrical pulse stimulation (EPS - 40V, 1.0 Hz, 2 ms) - control myotubes were left unstimulated. To assess for post contraction effects, after EPS, perifusion was maintained for a further 120 minutes, at which stage the glucose concentration of the perifusion buffer was raised to 20 mM for the final 80 minutes of the perifusion. Perifusate was collected every 4 minutes and assayed for insulin by homogenous time-resolved fluorescence. Differences in insulin secretion from INS-1E pseudoislets perifused with perifusate from C2C12 myotubes ± EPS averaged over each 30 minute period were examined by two-way ANOVA. To examine effects of contracted skeletal muscle on β-cell function under T2D-like conditions, perifusate was collected for 2-hours post ± EPS from C2C12 myotubes at 5 or 20 mM glucose and used to assess acute insulin release from INS-1E cell monolayers pre-exposed to 5 or 20 mM glucose ± palmitate (20 nM).
Results: Insulin release from pseudoislets remained similar over each 30 minute period upto 120 minutes of perifusion irrespective of whether pseudoislets were perifused with perifusate from contracting myotubes. Within the 2-hour period post contraction, insulin secretion increased significantly from 0.94 (±0.27) pg/ngDNA to 3.4 (±0.87) pg/ngDNA ($P < 0.0001$) by pseudoislets perifused with EPS-treated myotube perifusate - insulin release from perifused pseudoislets with non-treated myotube perifusate was not significantly different ($P = 0.93$). Specifically, the average amount of insulin secreted between 150–180 minutes ($P < 0.05$) and 180–210 minutes ($P < 0.01$) was significantly more from pseudoislets perifused with myotube perifusate after EPS. Increasing the glucose concentration of the perifusate to 20 mM stimulated insulin secretion further irrespective of EPS. Perifusate from EPS-treated myotubes also potentiated insulin secretion from INS-1E cell monolayers in the presence and absence of palmitate ($P < 0.01$). Pre-treatment of cells to 24-h high glucose ± palmitate dampened this potentiating effect. Moreover, 24-h palmitate plus high glucose lowered acute glucose-stimulated insulin release to a similar extent when induced by perifusate collected from EPS-treated or non-treated myotubes.
Conclusion: Mediators released by contracting C2C12 myotubes potentiate acute insulin release from normal and palmitate treated INS-1E pseudoislets and/or cells at 5 mM but not 20 mM glucose and fail to improve insulin release by INS-1E cells exposed to T2D-like conditions.

Low-calorie sweeteners disrupt the gut microbiome in healthy subjects in association with impaired glycaemic control

R.L. Young[1,2], D. Kreuch[1,2], F.M. Mobegi[3], L. Leong[3], G. Schober[1,2], N.J. Isaacs[1,2], T. Wu[1,4], N. Cvijanovic[1,2], N. Pezos[1,2], M.M. Bound[1,4], M. Horowitz[1,4], D.J. Keating[5,2], C.K. Rayner[1,4], G.B. Rogers[3];
[1]Adelaide Medical School, The University of Adelaide, Adelaide, [2]Nutrition & Metabolism, South Australian Health & Medical Research Institute, Adelaide, [3]Infection & Immunity, South Australian Health & Medical Research Institute, Adelaide, [4]Centre of Research Excellence in Translating Nutritional Science to Good Health, The University of Adelaide, Adelaide, [5]Medicine & Public Health, Flinders University of South Australia, Bedford Park, Australia.

Background and aims: Epidemiological studies indicate that regular high intake of beverages sweetened with low-calorie sweeteners (LCS) increase the risk of developing type 2 diabetes mellitus (T2DM), but the underlying mechanisms are unknown. We recently showed that 2 week dietary supplementation with LCS in healthy non-diabetic subjects led to clinically relevant increases in glycaemic responses to enteral glucose. Augmented glucose absorption (serum 3-O-methyl glucose, 3-OMG) and attenuated release of glucagon-like peptide-1 (GLP-1) contribute to this dysglycaemia, however it is unclear whether gut dysbiosis due to LCS also contributes to dysglycaemia, as occurs in rodents.
Materials and methods: 29 non-diabetic subjects (age 30 ± 2 years, body mass index 24 ± 3 kg/m^2, HbA1c 32 ± 1 mmol/mol (5.2%), 16 male) were randomised, in double-blind fashion, to diet supplementation with a LCS combination (92 mg sucralose +52 mg acesulfame-K, equivalent to ~1.5 L of diet beverage consumption/day, $N = 14$) or placebo ($N = 15$); these were taken in capsules three times daily over 2 weeks. The gut microbiome was assessed by shotgun metagenomic sequencing in stool collected before and after treatment. Differences in taxonomic and functional microbiome characteristics were determined using MetaPhlAn2 and HUMAnN2 abundance, respectively.
Results: LCS-treated subjects exhibited a greater variation in faecal microbiota composition, along with a significant reduction in the health-associated bacterium *Eubacterium cylindroides* (−11 $\log_2$ fold change, FC) and an increased abundance of 11 opportunistic gut pathogens, including *Klebsiella* (17 FC), *Porphyromonas* (15 FC) and *Finegoldia* (12 FC; all $P \leq 0.001$). A decrease in beneficial and fermentative *Bifidobacterium*, *Lactobacillus* and *Bacteroides* populations correlated with augmented glucose absorption (3-OMG), while a decrease in *Butyrivibrio* populations correlated with attenuated GLP-1 release (Spearman correlation: $\rho \geq \pm 0.37$; $P \leq 0.05$). Finally, shifts in the abundance of microbial genes involved in sucrose degradation and pyruvate metabolism correlated with a deterioration in glucose regulation in LCS-treated subjects.
Conclusion: In healthy non-diabetic subjects 2 weeks of LCS supplementation (i) causes gut dysbiosis and (ii) increases the abundance of gut pathogens normally absent in health. Moreover, a decrease in fermentative microbial populations and shifts in bacterial energy harvesting pathways due to LCS predict a deterioration in glucose regulation. Our findings support the concept that LCS disrupt glycaemic responses in healthy humans via dysregulation of glucose uptake and disposal, and secondary to dysbiosis of gut commensal bacteria. This highlights the clinical relevance of dietary LCS patterns to overall glycaemic control.

Gut microbiome induced by intra-intestinal carbohydrates suppresses glucose-dependent insulinotropic polypeptide secretion

E. Lee[1], J. Miyamoto[2], I. Kimura[2], T. Miki[1];
[1]Chiba University, Chiba, [2]Tokyo University of Agriculture and Technology, Fuchu, Japan.

Background and aims: Dietary carbohydrate triggers secretion of the two major incretins: glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP). GLP-1 and GIP are secreted from enteroendocrine L-cells and K-cells in response to carbohydrate ingestion. We previously reported that co-administration of maltose plus the α-glucosidase inhibitor miglitol (maltose/miglitol) potentiates GLP-1 secretion through the activation of SGLT3 expressed in serotonin-secreting enterochromaffin cells. Although the mechanism of carbohydrate sensing and incretin secretion has been considered to be mostly similar between L-cells and K-cells, we found that maltose/miglitol administration evokes the opposite response; stimulatory for GLP-1 but inhibitory for GIP. In the present study, we examined the regulatory mechanism of carbohydrate-induced GIP secretion.
Materials and methods: Maltose (2 g/kg) and miglitol (10 mg/kg) were administered orally to mice. At 30 minutes after oral ingestion, the mice were anesthetized and the blood sample was drawn from the portal vein and was subjected to the measurement of plasma GIP and short chain fatty acid (SCFA) concentrations. Involvement of the gut microbiota and its product SCFAs in GIP secretion was evaluated by oral antibiotics (Abs)-treatment and by using mice lacking the SCFA receptor FFAR2 (also known as GPR43) (*Ffar2*$^{-/-}$) or FFAR3 (also known as GPR41) (*Ffar3*$^{-/-}$). Plasma SCFA levels were determined by gas chromatography-mass spectrometry (GC-MS).
Results: GIP secretion in wild-type mice was significantly decreased by maltose/miglitol administration (GIP concentrations in portal vein; 73.2 ± 4.5 pmol/l in vehicle administration and 45.5 ± 3.0 pmol/l in maltose/miglitol administration, $p < 0.001$). We found that plasma SCFAs in the portal vein was acutely increased after a single administration of maltose/miglitol administration. In addition, oral Abs-treatment for 4 weeks significantly attenuated the maltose/miglitol-induced suppression of GIP secretion, suggesting that the gut microbiome is involved in the GIP suppression by maltose/miglitol. We next examined the suppressive effect of maltose/miglitol administration on GIP secretion in *Ffar2*$^{-/-}$ and *Ffar3*$^{-/-}$ mice. Although GIP secretion was suppressed normally by maltose/miglitol administration in *Ffar2*$^{-/-}$ (GIP concentrations in portal vein; 78.8 ± 6.3 pmol/l in vehicle administration and 57.3 ± 5.2 pmol/l in maltose/miglitol administration, $p < 0.05$), but not in *Ffar3*$^{-/-}$ (GIP concentrations in portal vein; 87.7 ± 6.6 pmol/l in vehicle administration and 76.9 ± 5.9 pmol/l in maltose/miglitol *Ffar3*$^{-/-}$, not significant). Similarly, co-administration of glucose plus the sodium glucose transporter inhibitor phloridzin (glucose/phloridzin) decreased GIP secretion in a microbiome-dependent manner.
Conclusion: Intra-intestinal retention of carbohydrate facilitates its usage by gut flora and release of SCFAs, which inhibits GIP secretion through their binding to FFAR3.

GLP-1 secreting enteroendocrine cells co-release ATP as a fast acting transmitter to modulate vagal afferent neuronal activity

F. Reimann, V.B. Lu, J. Rievaj, C.A. Smith, R. Pais, G. Tolhurst, F.M. Gribble;
University of Cambridge, Cambridge, UK.

Background and aims: Glucagon-like peptide-1 (GLP-1), now widely used in the treatment of diabetes and obesity, is secreted from enteroendocrine L-cells found scattered in the intestinal epithelium. Whilst many of the benefits of GLP-1 rely on its incretin activity on pancreatic beta cells there is also considerable evidence that L-cells directly activate the afferent vagus nerve, thereby triggering signals from the gut to the brainstem. We found previously that GLP-1 itself was a poor stimulus of vagal neurons from the nodose ganglion but strongly sensitised them to other stimuli such as ATP. The aim of this study was to investigate if L-cells co-secrete ATP as a fast transmitter capable of directly activating vagal nerve endings.
Materials and methods: ATP-containing vesicles were visualised by quinacrine (5 μM). ATP concentrations in supernatants of GLUTag-cells, an L-cell model line, were measured by a bioluminescence-assay and ATP release from GLUTag and primary L-cells was also demonstrated by "sniffer patches", detecting ATP through activation of heterologously expressed $P2X_2$ receptors. Quinacrine release was monitored by total internal reflection fluorescence (TIRF) microscopy as a proxy of ATP-containing vesicle fusion. Changes in cytosolic Ca^{2+}-concentration in co-cultured GLUTag cells and nodose ganglion-derived (ND) neurons were monitored after Fura-2 loading.
Results: Quinacrine staining was detected in vesicular structures in GLUTag and primary cultured L-cells. By TIRF microscopy, these vesicles showed transient increases and subsequent dissipation of fluorescence intensity and the frequency of such events approximately doubled in response to a known L-cell stimulus angiotensin-II (1 μM), consistent with enhanced vesicular ATP secretion. This was also demonstrated by "sniffer patch"-currents, which increased in response to AngII, when brought into close proximity of GLUTag or primary L-cells, or by measurement of ATP in cell supernatants. To test for ATP-dependent communication between L-cells and vagal neurons, we co-cultured GLUTag-cells expressing clozapine-N-oxide (CNO)-sensitive designer receptors exclusively activated by designer drugs (Gq-DREADD) and mCherry together with ND neurons labelled with EYFP. Upon stimulation of GLUTag cells with CNO, ~30% of ND neurons showed a Ca^{2+}-elevation that was not seen with CNO in the absence of co-cultured GLUTag cells. This response was sensitive to the broad-spectrum P2Y/P2X inhibitor PPADS (100 μM).
Conclusion: ATP is co-secreted with GLP-1 from intestinal L-cells and can act as a fast local neurotransmitter, triggering activation of vagal neurons and potentially synergising with locally elevated peptide hormones. Co-secretion of small molecular "neurotransmitters" from enteroendocrine cells should be considered more widely in the gut-brain axis.

L cell secretory responses after gastric bypass surgery can be imitated in un-operated individuals by modulating carbohydrate digestion

C. Martinussen[1,2], K.N. Bojsen-Møller[1,2], C. Dirksen[1,2], M.S. Svane[1,2], J.J. Holst[2], S. Madsbad[1,2];
[1]Dept. of Endocrinology, Hvidovre Hospital, [2]NNF center for Basic Metabolic Research and Dept. of Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: Exaggerated postprandial secretion of the L-cell hormones glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) seems important for the metabolic benefits of gastric bypass (GB) surgery and may be explained by the accelerated arrival of carbohydrates to the distal small intestine where L-cell density is high. Therefore, individuals with intact gastrointestinal anatomy could potentially achieve similar enhancements of L-cell secretion if carbohydrates could be delivered to the distal gut. The disaccharides sucrose and isomaltulose are hydrolyzed by alpha glucosidase enzymes to the absorbable monosaccharides glucose (glu) and fructose (fru), but the rate of hydrolysis is much slower for isomaltulose than for sucrose, resulting in prolonged and distal

absorption. Distal absorption may also be obtained for sucrose by inhibiting the action of alpha glucosidases with acarbose. We measured secretion of GLP-1 and PYY, the latter of which is primarily secreted from the distal L-cells, in response to simple saccharides differing in digestibility after GB and in un-operated matched controls (CON).
Materials and methods: 10 GB patients and 10 CON matched on BMI, age and sex. On 4 separate days, participants ingested isomolar oral loads of glu and fru, either given as separate monosaccharides (25 g glu + 25 g fru) or as disaccharides in the form of 47.5 g isomaltulose or 47.5 g sucrose ± acarbose. Blood was sampled frequently for 4 hours and plasma was analyzed for GLP-1, PYY and glucose.
Results: Digestibility of the carbohydrate loads was reflected in the glycemic profiles with glu+fru and sucrose inducing the highest peaks and largest excursions, while more moderate responses were seen for isomaltulose and sucrose + acarbose in both groups. GLP-1 responses (positive iAUC) to rapidly absorbed glu+fru and sucrose were similar within groups, but 3-fold higher in GB than in CON ($p < 0.01$). Intake of the slowly digested isomaltulose led to prolonged and increased GLP-1 secretion especially in CON (+50% in GB, $p = 0.11$, and +160% in CON, $p = 0.01$, vs. sucrose) so that the response to isomaltulose in CON was similar to the glu+fru ($p = 0.91$) and sucrose ($p = 0.79$) induced responses in GB. Acarbose reduced GLP-1 by 50% in GB ($p < 0.01$ vs. sucrose alone), but had no effect on GLP-1 responses in CON. Secretion of PYY after glu+fru and sucrose was 2–4 fold higher in GB than in CON ($p = 0.03$, and $p = 0.06$, respectively), while the response to isomaltulose were similar to glu+fru in GB and comparable between GB and CON. Acarbose increased PYY nearly 3-fold in both GB ($p = 0.08$) and CON ($p = 0.23$), but the response was still lower in CON than in GB.
Conclusion: The exaggerated GLP-1 and PYY secretion after GB in response to rapidly absorbed carbohydrates was mimicked in un-operated matched subjects by ingestion of the slowly digested and distally absorbed disaccharide isomaltulose. Acarbose was effective in increasing the secretion of PYY in both GB and CON but inhibited GLP-1 responses in GB, perhaps due to extensive blockage of sucrose hydrolysis. The results support that the exaggerated L-cell secretion after gastric bypass is due to rapid delivery of nutrients to the distal gut and suggest that modified carbohydrates with slower digestion and distal absorption may be used to produce similar responses in un-operated individuals.

OP 44 Clinical use of insulin: What works and what doesn't

245

Quantitative ultrasound characteristics of insulin-induced lipohypertrophy in subjects with diabetes

M.M. Lazarev, V.V. Klimontov, A.A. Makhotin, D.M. Bulumbaeva, E.A. Koroleva, A.Y. Letyagin;
Research Institute of Clinical and Experimental Lymphology – Branch of the Institute of Cytology and Genetics, Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russian Federation.

Background and aims: Lipohypertrophy at injection sites is one of the most frequent complications of insulin therapy. Recent studies demonstrated the applicability of ultrasound scan for diagnostics of insulin-induced lipohypertrophy in diabetic subjects. Sonoelastography and 3D power Doppler ultrasound could provide new opportunities for quantitative characterization of lipohypertrophy. The aim of our study was to assess the relationships between quantitative ultrasound parameters of lipohypertrophy areas, characteristics of insulin therapy and metrics of glycemic control in insulin-treated diabetic subjects.
Materials and methods: Eighty two adult subjects, 27M/55F, with duration of insulin therapy for more than 3 months, were consecutively recruited. Among them, 26 ones had type 1 diabetes and 56 individuals had type 2 diabetes. The sites of insulin injections were inspected by palpation and ultrasound. The visualization protocol included gray-scale densitometry with Mean Gray Value (MGV) index estimation, strain elastography imaging with Strain Ratio (StR) calculation, and 3D power Doppler ultrasound with Vascularization Index (VI), Flow Index (FI), and Vascularization Flow Index (VFI) assessment. Glucose variability (GV) indices: Standard Deviation, Mean Amplitude of Glucose Excursions, Low Blood Glucose Index, and High Blood Glucose Index were calculated from 6-point glucose profiles on three consequent days. Serum levels of insulin antibodies were determined by ELISA.
Results: Lipohypertrophy was revealed by palpation and ultrasound in 57 and 80 patients (70% and 98%) respectively. The aggregated ultrasound-verified lipohypertrophy square (LS) varied from 50 to 1847 mm^2 (median 370 mm^2). Most of the lipohypertrophy sites demonstrated hyperechogenicity and increased stiffness when compared to surrounding subcutaneous fat (MGV and StR indices: $p < 0.001$). The reduced vascularity in lipohypertrophy areas were confirmed by 3D power Doppler ultrasound vascular indices (all $p < 0.05$). Total LS and MGV showed weak positive correlations with daily insulin dose (both $r = 0.3$, $p = 0.006$), however in patients with type 1 diabetes LS correlated with insulin dose more closely ($r = 0.47$, $p = 0.02$). Patients receiving insulin analogues had smaller aggregated LS than those on human insulin ($p = 0.03$). The LS demonstrated positive correlations with mean postprandial glucose ($r = 0.35$, $p = 0.001$) and triglycerides levels ($r = 0.4$, $p = 0.0002$). The FI index, but not VI and VFI, correlated negatively with mean postprandial glucose ($r = -0.29$, $p = 0.01$). The GV indices, levels of HbA1c and insulin antibodies showed no association with ultrasound parameters.
Conclusion: The gray-scale densitometry, strain elastography and 3D power Doppler ultrasound provide comprehensive quantitative characteristic of the areas of lipohypertrophy in insulin-treated diabetic subjects. Ultrasound indices of insulin-induced lipohypertrophy demonstrate some associations with daily insulin dose and metabolic parameters in these subjects.

Favourable effects of insulin treatment for latent autoimmune diabetes in adults do not outweigh autoimmunity-induced decline in insulin release during 21 months of intervention

I. Hals[1,2], V. Grill[2], H. Fiskvik Fleiner[3], N. Reimers[4], M. Astor[5], Z. Ma[6], K. Filipsson[7], A. Björklund[6];

[1]Dep. of Endocrinology, St Olavs University Hospital, Trondheim, Norway, [2]Dep. of Clinical and Molecular Medicine, Norwegian University of Science and Technology (NTNU), Trondheim, Norway, [3]Dep. of Clinical Pharmacology, St Olavs University Hospital, Trondheim, Norway, [4]Sjøsiden Legesenter, Trondheim, Norway, [5]Dep. of Medicine, Haukeland University Hospital, Bergen, Norway, [6]Dep. of Molecular Medicine and Surgery, Endocrine and Diabetes Unit, Karolinska University Hospital Solna, Karolinska Institutet, Stockholm, Sweden, [7]Dep. of Clinical Sciences, Unit of Molecular Metabolism, Lund University Diabetes Centre, Malmö, Sweden.

Background and aims: The optimal beta cell preserving treatment of LADA patients is unclear - should one treat with insulin from diagnosis as for type 1 diabetes or by peroral drugs, including insulin enhancing ones, as for type 2 diabetes? This uncertainty is due to a lack of randomized clinical trials in LADA. We compared beta cell function during treatment with either insulin or sitagliptin, a DDP4-inhibitor, taking into account a variable degree of autoimmunity in LADA.
Materials and methods: Inclusion criteria included GADA positivity, age 30–75 years, no clinical need for insulin treatment and diabetes diagnosed <3 years before inclusion. Participants were stratified by age, BMI and degree of GADA positivity. Beta cell function was evaluated by C-peptide, insulin and proinsulin recorded during C-peptide glucagon tests performed after 3, 9 and 21 mo. following randomization, always after a 48 h temporary withdrawal of study medication.
Results: In the 61 participants the median age at randomization was 53 years and BMI 27 kg/m^2. These and other parameters (male/female, HbA1c, fasting C-peptide) were similar between the study arms. All participants were treated with metformin before and during the intervention. HbA1c was similar at baseline and after 21 mo. of intervention (in the insulin arm median 6.8% at baseline and 6.6% at 21 mo., in the sitagliptin arm 6.5% and 6.6%). Stimulated C-peptide after 21 mo. of intervention decreased similarly in both arms (median −0.09 nmol/L in the insulin, −0.08 nmol/L in the sitagliptin arm). Stimulated insulin was unaltered at 21 mo. of insulin treatment (median 24.5 μU/ml at randomization, 24.1 μU/ml at 21 mo.), whereas levels decreased following treatment with sitagliptin (from 22.4 μU/ml to 15.2 μU/ml, $p < 0.03$ vs. insulin). The ratio proinsulin/insulin (a marker of beta cell stress) did not change following insulin treatment (median 0.13 at randomization, 0.11 at 21 mo.) but increased following sitagliptin (0.13 at randomization, 0.21 at 21 mo, $p < 0.02$ vs. insulin). We assessed effects of apparent autoimmunity in the whole study population after dichotomizing titers (low/high) of GADA. Stimulated C-peptide did not change in low GADA (median 0.77 at randomization, 0.78 at 21 mo.) but decreased in high GADA participants by 27% (from 0.87 to 0.60 nmol/l, $p < 0.05$ vs. low GADA). Reciprocally the proinsulin/insulin ratio increased from 0.13 to 0.21 in high GADA but was unaffected with low GADA participants (from 0.14 to 0.15, $p < 0.04$ for difference high vs. low GADA). Further analysis did not detect a modulating effect by insulin treatment on these parameters.
Conclusion: Early insulin treatment may be advantageous in LADA but does not protect against an autoimmune assault on beta cells.

Comparison of canagliflozin and liraglutide as a replacement for bolus insulin in type 2 diabetes patients well-controlled by basal-bolus insulin

N. Kumashiro, Y. Ando, F. Shigiyama, H. Igarashi, F. Yoshikawa, H. Uchino, H. Yoshino, M. Miyagi, K. Ikehara, T. Hirose;
Toho University Graduate School of Medicine, Tokyo, Japan.

Background and aims: When we select anti-diabetic drugs, prevention of hypoglycemia, weight gain, and cardiovascular events has been taken into consideration based on the recent results of large clinical trials such as ACCORD, LEADER, and CANVAS. Basal-bolus insulin therapy is available in various situation, but it has risks of hypoglycemia and weight gain that may lead to cardiovascular events. In contrast, canagliflozin, a sodium glucose cotransporter 2 inhibitor (SGLT2i), and liraglutide, a glucagon-like peptide-1 receptor agonist (GLP1RA), are reported to reduce body weight and cardiovascular events. Combination therapy of basal insulin plus GLP1RA is well-known for its effectiveness, but that of basal insulin plus SGLT2i remains to be tested. The aim of this study was to address the efficacy of canagliflozin as a replacement for bolus insulin compared to that of liraglutide in type 2 diabetes patients who were well-controlled by basal-bolus insulin therapy.
Materials and methods: This study was a prospective, randomized, open-label, parallel-group, comparative study. A total of 40 type 2 diabetes patients treated by basal-bolus insulin over 1 year (HbA1c <7.5%) were randomized to either canagliflozin group (Group Cana) or liraglutide group (Group Lira). After consent, bolus insulin was totally switched to canagliflozin or liraglutide. Dose of canagliflozin was fixed at 100 mg/day, but liraglutide was increased from 0.3 to 0.9 mg/day. Basal insulin was continued and its dose was adjusted using algorism. At 24 weeks, changes from baseline in HbA1c, hypoglycemia, glucose fluctuation assessed by continuous glucose monitoring system, body weight, BMI, insulin dose, and diabetes-treatment-related quality of life (DTR-QOL) were compared between the groups. Adverse events were also monitored for 24 weeks.
Results: Subjects were aged 58.1 ± 11.9 years, male/female; 32/8, known duration of diabetes; 9.5 ± 6.9 years, body weight; 74.8 ± 9.9 kg, BMI; 26.6 ± 3.3 kg/m^2, HbA1c; 6.7 ± 0.6%, daily basal insulin dose; 14.4 ± 8.5 U, and daily bolus insulin dose; 18.2 ± 7.1 U at baseline. Finally, 17 patients per each group were analyzed. As results, HbA1c maintained good levels in both groups (from 6.8 ± 0.7 to 6.7 ± 0.7% *vs.* from 6.4 ± 0.6 to 6.2 ± 0.8%, Group Cana *vs.* Lira). No sever hypoglycemia was observed in all patients nor there was no difference in hypoglycemia between the groups, and nocturnal hypoglycemia tended to decrease in both groups. Glucose fluctuation did not change from baseline in both groups. Body weight and BMI tended to decrease in both groups. Basal insulin dose increased significantly in both groups (+44.5% *vs.* +39.2% from baseline in Group Cana *vs.* Lira), but total daily insulin dose decreased significantly in both groups (−34.5% *vs.* −47.6% from baseline in Group Cana *vs.* Lira). Regarding DTR-QOL, total score improved significantly in both groups, but while all domain scores improved in Group Cana, no improvement was observed in domains of anxiety and dissatisfaction with treatment and hypoglycemia in Group Lira.
Conclusion: Replacement from bolus insulin to either canagliflozin or liraglutide was safe and effective on glycemic control, hypoglycemia, body weight, and QOL in type 2 diabetes patients well-controlled by basal-bolus insulin therapy. Supported by basal insulin, canagliflozin as well as liraglutide is a good therapeutic option as a replacement for bolus insulin.

Reasons for discontinuation of insulin therapy: results from the International Diabetes Management Practices Study (IDMPS)

J.-M. Chantelot[1], P. Aschner[2], J.J. Gagliardino[3], H. Ilkova[4], F. Lavalle[5], A. Ramachandran[6], G. Kaddaha[7], J.C. Mbanya[8], M. Shestakova[9], J.C.N. Chan[10];

[1]Sanofi, Paris, France, [2]Javeriana University School of Medicine and San Ignacio University Hospital, Bogotá, Colombia, [3]CENEXA, Center of Experimental and Applied Endocrinology (La Plata National University – La Plata National Scientific and Technical Research Council), La Plata, Argentina, [4]Istanbul University, Cerrahpasa Medical Faculty, Department of Internal Medicine, Division of Endocrinology, Metabolism and Diabetes, Istanbul, Turkey, [5]Facultad de Medicina de la Universidad Autónoma de Nuevo León, Monterrey, Mexico, [6]India Diabetes Research Foundation, Dr. A. Ramachandran's Diabetes Hospitals, Chennai, India, [7]Government of Dubai, Dubai Health Authority, Dubai, United Arab Emirates, [8]Biotechnology Center, Doctoral School of Life Sciences, Health and Environment, and Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon, [9]Endocrinology Research Center, Moscow, Russian Federation, [10]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, The Prince of Wales Hospital, Shatin, Hong Kong SAR, China.

Background and aims: Adherence to insulin therapy is often suboptimal, and understanding patients' perspectives on drug adherence is essential for identification of barriers to therapy. We studied the reasons given for discontinuation of insulin therapy by people with diabetes in the developing world.

Materials and methods: The IDMPS is a global observational survey on the management of people with type 1 (T1D) and type 2 (T2D) diabetes. In 2016–17, participants were enrolled from 24 countries in the Middle East, South Asia, Eurasia and Africa.

Results: In people with T1D ($N = 2000$; mean (SD) age 34.0 (12.3) years; 48.8% male; time since diagnosis 13.1 (9.9) years), 14% (273/1955) discontinued insulin for 1 month (median), without physician indication. The nature of discontinuation, e.g. missed injections either of 1 prandial or 1 basal insulin [basal-bolus regimen] or 1 premixed insulin, is unknown. The main reasons given were impact on social life, cost, fear of hypoglycaemia, and lack of support (**Table**). In people with T2D ($N = 2596$; age 57.2 (11.1) years; 47.8% male; time since diagnosis 13.5 (8.8) years for insulin alone, 12.8 (7.5) years for insulin + oral glucose-lowering drugs [OGLD]), insulin discontinuation for ≥2 months (median), without physician indication, was reported by 13.4% of people treated with insulin alone (86/642) and 13.8% of people who received insulin + OGLD (261/1936). Reasons for discontinuation included impact on social life, fear of hypoglycaemia, lack of support, and cost. The pattern of insulin (e.g., a definitive or temporary stop, or missed injection[s]) was not documented.

Conclusion: These observations are cause for concern, in particular the proportion of people with T1D who discontinue, and indicate the need for a multi-pronged strategy including patient education and access to therapy to improve treatment adherence and optimise outcomes.

Table 1. Reasons for insulin discontinuation

Reasons for discontinuation, %	T1D n=273	T2D	
		Insulin alone n=86	Insulin + OGLD n=261
Lack of efficacy	3.3	5.8	9.2
Fear of hypoglycaemia	26.7	24.4	29.1
Occurrence of side effects	8.4	12.8	10.3
Impact on social life	41.0	29.1	31.0
Lack of experience in insulin dosing	20.9	30.2	24.1
Lack of experience in insulin administration	9.5	16.3	14.2
Cost of medicine and strips	34.4	22.1	25.3
Weight gain	8.8	4.7	10.3
Lack of support	26.4	29.1	24.9

Biliverdin reductase-A mediates the beneficial effects of intranasal insulin administration in Alzheimer disease: a novel molecular mechanism

E. Barone[1], F. Triani[1], A. Tramutola[1], T. Cassano[2], M. Perluigi[1]; [1]Department of Biochemical Sciences, Sapienza University of Rome, Rome, [2]Department of Clinical and Experimental Medicine, University of Foggia, Foggia, Italy.

Background and aims: Biliverdin reductase-A (BVR-A) - known for its role in the degradation of heme - is also a Ser/Thr/Tyr kinase regulating insulin signalling. BVR-A controls IRS1 activation and favours the activation of the protein kinase B (PKB/Akt). Previous studies from our group reported about reduced BVR-A activation in Alzheimer disease (AD) human brain. Furthermore, in a longitudinal study we showed that reduced BVR-A activation precedes the inhibition of IRS1 and the onset of brain insulin resistance in the brain of 3xTg-AD mice, independently from amyloid beta (Aβ) accumulation and TNF- α elevation. Intranasal insulin administration (INI) is under evaluation as therapeutic strategy to mitigate brain insulin resistance in AD, however the molecular mechanisms underlying INI effects are still unknown. Our goal was to clarify whether INI delays the onset of brain insulin resistance by both preventing and rescuing BVR-A impairment in the brain of adult and aged 3xTg-AD mice.

Materials and methods: We evaluated changes of (1) cognitive functions; (2) insulin signalling activation and (3) AD neuropathology in the hippocampus of 3xTg-AD and WT mice that received insulin (2U, 3 times/week) or vehicle for 2 months through the intranasal route. The role of BVR-A was strengthened by evaluating age-associated changes in BVR-A knock-out (KO) mice. Furthermore, cell-based experiments to support *in vivo* data were performed in SH-SY5Y neuronal cells.

Results: INI significantly improved learning and memory functions evaluated through the Morris water maze and the novel object recognition tasks in 3xTg-AD mice both at 6 and 12 months. At 6 months, insulin prevented the reduction of BVR-A activation ($p < 0.01$). Furthermore, INI fostered the activation of the insulin receptor (IR, $p < 0.05$), prevented the IRS1 hyper-activation ($p < 0.01$), improved the activation of Akt ($p < 0.001$) and prevented the downregulation of mTOR ($p < 0.05$). At 12 months, INI recovered BVR-A activation ($p < 0.01$) along with an improvement of the activation state of IR ($p < 0.01$), IRS1 ($p < 0.05$), ERK1/2 ($p < 0.01$) and Akt ($p < 0.05$). The amelioration of the insulin signalling was also associated with reduced Aβ levels and Tau phosphorylation (pTau) both at 6 (Aβ $p < 0.05$; pTau $p < 0.05$) and 12 months (Aβ $p < 0.05$; pTau $p < 0.05$) of age in insulin-treated 3xTg-AD with respect to vehicle-treated mice. BVR-A KO mice showed similar alterations observed in 3xTg-AD mice with age. Indeed, we found an early significant hyper-activation of the IR/IRS1/Akt axis at 2 months, followed by a consistent inhibition of the axis at 6 months, which persists until 12 months. Furthermore, brain insulin resistance was associated with an increased Aβ production in BVR-A KO mice with respect to WT. Finally, we showed that neuronal cells lacking BVR-A (i) rapidly develop insulin resistance [increased IRS1 inhibition ($p < 0.05$), reduced Akt activation ($p < 0.01$)] if treated with insulin (100 nM, 2 h); and (ii) can be rescued from insulin resistance only if insulin is co-administered with the BVR-A mimetic peptide, thus supporting findings about the effects of INI treatment in 3xTg-AD mice.

Conclusion: These findings shed light on the molecular mechanisms underlying the development of brain insulin resistance in AD and suggest BVR-A as potential therapeutic target to develop future treatments.

Activation of LXR-β improves cognitive function of diabetic mice through ABCA1

R. Cai[1], S. Wang[2];
[1]Southeast University Medical School, Nanjing, [2]The Affiliated ZhongDa Hospital of Southeast University, Nanjing, China.

Background and aims: The disorder of cholesterol metabolism is the common pathological basis of type 2 diabetes and alzheimer's disease, and may be associated with the occurrence of cognitive dysfunction in diabetes. Liver X receptor (LXR) is an oxidized steroid-activated nuclear receptor that regulates intracellular cholesterol levels by regulating genes involved in cholesterol transport, such as ATP-binding cassette transporter A1 (ABCA1). LXR agonists can activate LXR-β, regulate cholesterol efflux and decrease β-amyloid protein (Aβ) levels through upregulate ABCA1 gene expression. ABCA1 levels in diabetic patients decrease significantly, looking for effective methods to up-regulate the expression of ABCA1 may be a new target for the prevention and treatment of diabetic cognitive dysfunction. This study aims to observe whether LXR-β agonist improves cognitive function of KKA^y mice by regulating ABCA1 protein and its effect on Aβ metabolism.
Materials and methods: This study used KKA^y mice as the animal model of cognitive dysfunction of T2DM. Different doses of T0901317 were applied to KKA^y mice as prevention or treatment method. The prevention group were given T0901317 at the age of 9 week; the treatment group received daily administration of T0901317 at the age of 15 week. The experiments of dark-avoidance test and the Morris water maze test were used to detect the behavioral changes of mice. The morphological changes in brain tissue of mice were detected by HE and Nissl staining. Immunohistochemistry was used to detect the expression of LXR-β, ABCA1 and $Aβ_{42}$ in hippocampus. RT-PCR and Western Blot were used to determine the mRNA and protein expression levels of LXR-β and ABCA1 in hippocampus of KKA^y mice.
Results: 1. In the dark-avoidance experiment, compared to the control group, mice in the model group showed shorter dark-avoidance latency and increased number of errors than the control group. In the water maze test, the latency period of the model group was prolonged; while the number of crossing the platform and the target quadrant residence time were all reduced. After prevention or treatment of T0901317, the learning and memory functions were significantly improved in KKA^y mice. 2.Compared to the control group, the structure of neurons in hippocampus of T0901317 intervention groups were improved to some extent. Neuron morphology damage in the intervention groups were reduced, and the Nissl bodies were increased. 3. Immunohistochemical staining results showed that the IOD values of LXR-β and ABCAl in model group were significantly decreased compared with those in control group, and the $Aβ_{42}$ staining was statistical deeper. After T0901317 prevention or treatment, the expression of LXR-β and ABCA1 increased, and the amount of $Aβ_{42}$ was significantly reduced. 4. The expression of LXR-β and ABCA1 at mRNA and protein levels were significantly decreased in diabetic model group than those in control group. The prevention and treatment groups all showed higher mRNA and protein levels of LXR-β and ABCA1 than the model group.
Conclusion: ABCA1 is involved in the pathogenesis of cognitive impairment in diabetes, which may have a protective effect on cognitive function. LXR-β agonist may improve diabetes associated cognitive dysfunction by increasing ABCA1 levels and decreasing Aβ deposition.

Dissecting shared pathophysiology of type 2 diabetes and depressive symptoms using multi-phenotype genome-wide association study

Z. Balkhiyarova[1], M.A. Kaakinen[1], H.H.M. Draisma[1], M. Timonen[2], J. Veijola[2], M.-R. Jarvelin[1], A. Nouwen[3], I. Prokopenko[1];
[1]Imperial College, London, UK, [2]University of Oulu, Oulu, Finland, [3]Middlesex University, London, UK.

Background and aims: Type 2 diabetes and depression are among the most prevalent non-communicable diseases, affecting quality of life and well-being. Epidemiological studies suggest shared aetiology between these conditions. Genetic variants, reportedly associated with these conditions, belong to pathways involved in lipid metabolism, cell proliferation, immune and inflammatory response, and oxidative stress, supporting the shared pathophysiology between them. However, the phenotypic variance responsible for type 2 diabetes and depression captured by genome-wide association studies (GWAS) explains only ~5% of susceptibility to these conditions. Our aims were: (1) to elucidate shared pathophysiological mechanisms between depression and type 2 diabetes; and (2) to identify genetic factors contributing to their co-morbidity using multi-variable analytical framework.
Materials and methods: We performed a multi-phenotype GWAS (MP-GWAS) for a combination of two diseases/disease symptoms evaluated at age 46 years: diagnosis of type 2 diabetes and a sum score of depressive symptoms (the Beck Depression Inventory) using GWAS data from the Northern Finland Birth cohort 1966 (NFBC1966, $N = 3597$). Participants were genotyped using the Illumina HumanCNV370DUO platform and imputed to the 1000G reference panel. After quality control of genetic data, >10 M autosomal single nucleotide polymorphisms (SNPs) were available for analysis. We performed the MP-GWAS by fitting a "reverse regression" model between each SNP and the linear combination of residuals for type 2 diabetes and depressive symptoms score, obtained after adjusting for sex and three principal components to control for population structure. We used the SCOPA software for the analysis.
Results: The single locus at *GPR12* (rs9507787) reached genome-wide significance ($P = 3.98 \times 10^{-8}$). It has been suggestively ($P < 10^{-7}$) associated with antipsychotic drug-induced QTc interval change in schizophrenia (PMID:29064910). Three loci at *MICAL2* (rs10765927), *INPP5K* (rs145536147), and near *ATXN8OS-KLHL1* (rs9599553) genes demonstrated suggestive effects and were in regions with previously associated with neuroticism, mean platelet volume, and schizophrenia/major depressive disorder. Replication of these findings in additional datasets is ongoing.
Conclusion: The results of this MP-GWAS provide first evidence for a possible shared aetiology between type 2 diabetes and depressive symptoms.

Pragmatic lifestyle modification programme reduces depression and perceived stress in south Asian adults with pre-diabetes: a randomised controlled trial

S. Drignath[1], K. Winkley[2], M. Wijesuriya[3], L. Vasantharaja[3], D. Thamlini[3], J. Karalliedde[4];
[1]TU Dresden, Dresden, Germany, [2]Florence Nightingale School of Nursing & Midwifery, King's College London, London, UK, [3]Diabetes Association of Sri Lanka, Colombo, Sri Lanka, [4]Faculty of Life Sciences and Medicine, King's College London, London, UK.

Background and aims: Depression and high perceived stress are associated with increased risk for incident type 2 diabetes mellitus diabetes (T2DM). Previous research suggests that pragmatic lifestyle modification programme (trimonthly/P-LSM) versus less-intensive 12-monthly control LSM (C-LSM) is effective in improving cardio-metabolic outcome in a South-Asian prediabetic adult population. This was a secondary analysis of trial data to determine the effectiveness of LSM on depression and stress at 3 years follow-up.
Materials and methods: This was a randomised controlled trial conducted at the National Diabetes Centre, Sri-Lanka, 4672 participants at risk of

T2DM were randomised, (2596 were adults mean age 30.55, range 18–46 years, 52.2% males) to receive trimonthly (P-LSM $n = 1287$) or 12-monthly (C-LSM $n = 1309$) peer educator advice aimed at reducing weight, improving diet, psychological stress and increasing physical activity. Patient Health Questionnaire (PHQ9) was used to determine depressive symptoms and perceived stress scale (PSS) to determine psychological stress.

Results: Regression analysis was conducted with 3 year PHQ9 and PSS scores as the dependent variable. PHQ9 analysis was adjusted for baseline PHQ9 and PSS score, plus age, gender, marital status and BMI. PSS analysis was adjusted for baseline PSS and PHQ9 score, plus age, gender, marital status and BMI. There was significant improvement in depressive symptoms at 3 years ($p < 0.001$) and in perceived stress ($p < 0.001$) in the P-LSM versus the C-LSM group.

Conclusion: In a at-risk South-Asian adult population, a pragmatic LSM programme significantly reduced stress and depressive symptoms. The results presented here are important for the development of future LSM interventions to improve well-being and reduce risk of T2DM for adults with pre-diabetes.

Corneal confocal microscopy detects greater reduction of small fibers in patients with painful neuropathy

A. Kalteniece[1], M. Ferdousi[1], S. Azmi[1], S. Adam[1], A. Marshall[1], A.J.M. Boulton[1], H. Soran[1], R.A. Malik[2];
[1]Institute of Cardiovascular Sciences, University of Manchester, Manchester, UK, [2]Weill Cornell Medicine-Qatar, Research Division, Qatar Foundation, Education City, Doha, Qatar.

Background and aims: About 50% of patients are affected by diabetic peripheral neuropathy (DPN), which is associated with high morbidity, foot ulceration and mortality. Corneal confocal microscopy (CCM) is a rapid non-invasive ophthalmic technique, which has been increasingly utilized to quantify corneal nerve morphology and established as surrogate end point for the assessment of diabetic neuropathy (DN). We aimed to assess corneal nerve morphology, keratocyte and Langerhans cells (LC's) density in patients with and without painful DN.

Materials and methods: A total of 87 patients with DN underwent detailed assessment of neuropathy disability score, quantitative sensory testing (including vibration perception threshold (VPT)), electrophysiology (peroneal motor nerve amplitude (PMNA) and velocity (PMNCV)), quality of life (QoL) using SF-36 questionnaire. Based on visual analogue score (VAS), patients were divided into those with painless (VAS ≤4) ($n = 35$) and painful (VAS >4) ($n = 52$) neuropathy age-matched to each other. CCM was performed in all participants. Corneal nerve fiber density (CNFD), branch density (CNBD), length (CNFL), corneal inferior whorl length (IW), LC's density and keratocyte density were quantified.

Results: CNFD ($p = 0.01$) and IW ($P = 0.01$) were significantly reduced in patients with painful compared to painless neuropathy. However, no significant difference was found for CNBD, keratocytes and LC's density, and nerve conduction studies comparing painful and painless neuropathy. QoL ($P < 0.0001$) was significantly reduced in patients with painful compared to painless neuropathy. There was a significant association between QoL and IW ($r = 0.721$, $P < 0.0001$), CNFD ($r = 0.246$, $P = 0.03$), CNBD($r = 0.312$, $P = 0.007$), CNFL ($r = 0.28$, $P = 0.01$).

Conclusion: This study shows significant reduction of small fibers and quality of life in patients with painful compared to painless DN.

High RAGE expression might be responsible for early corneal nerve fibre damage in diabetic individuals

J. Leckelt[1], F. Thomas[1], A. Kott[1], R. Waterstradt[1], O. Stachs[2], A. Jünemann[2], M. Tiedge[1], S. Baltrusch[1];
[1]Institute of Medical Biochemistry and Molecular Biology, Rostock, Germany, [2]Department of Ophthalmology, Rostock, Germany.

Background and aims: In the assessment of diabetic neuropathy, in vivo corneal confocal microscopy (IVCCM) is currently a matter of

investigation to be established as a non-invasive diagnostic tool. Clinical and experimental animal studies demonstrated a loss of corneal nerve fibres already at the onset of diabetes mellitus. The underlying mechanisms are still unknown. However, neuronal damage could be mediated by increased binding of advanced glycation end products (AGEs) to the AGE receptor (RAGE). In various mouse strains we found that the RAGE expression in the cornea is significantly higher than in other tissues. The aim of this study was to investigate the sub-epithelial corneal nerve plexus in B6J-RAGE knockout mice during diabetes manifestation.

Materials and methods: Diabetes mellitus was induced in 8–10 weeks old male homozygote B6J-RAGE knockout mice by multiple low-dose-injections of streptozotocin (STZ) ($n = 6$). Sodium citrate treated B6J-RAGE knockout mice ($n = 6$) served as controls. Using IVCCM corneal nerve fibre length (CNFL) of the sub-epithelial nerve plexus was determined after 10 and 20 days. The region of the inferior whorl was analysed ex vivo at the endpoint by PGP.9.5 immunostaining and fluorescence microscopy. Expression of the extracellular and membrane RAGE domain was investigated in cornea and liver with quantitative RT-PCR.

Results: Gene expression of the membrane RAGE domain was 30-fold higher in cornea than in liver. Expression of the extracellular RAGE domain was not detectable confirming the knockout. At the endpoint STZ treated B6J-RAGE knockout mice developed significant signs of diabetes compared to controls (blood glucose concentration in mmol/l 6.9 ± 0.3 vs. 21 ± 1.0, $p < 0.0001$; body weight in g 26 ± 0.8 vs. 23 ± 0.6, $p < 0.02$; HbA1c in mmol/mol 21.0 ± 0.7 vs. 48.8 ± 1.7, $p < 0.0001$) and baseline. B6J-RAGE knockout mice showed only a minor reduction in CNFL after diabetes manifestation, which was comparable to the age-dependent nerve fibre loss in controls. The texture of the inferior whorl of the corneal sub-epithelial nerve plexus appeared identical in diabetic and control B6J-RAGE knockout mice.

Conclusion: After diabetes manifestation neither the CNFL nor the appearance of the inferior whorl of the corneal sub-epithelial nerve plexus changed in B6J-RAGE knockout mice. In contrast, in STZ diabetic B6J-thy1 YFP mice we could show a significant loss of corneal nerve fibres. Thus, significant RAGE expression in the cornea could explain the high susceptibility of corneal nerves to the increase in AGEs in diabetes mellitus.

Corneal confocal microscopy shows nerve regeneration after treatment with exenatide/pioglitazone or basal/bolus insulin in patients with poorly controlled type 2 diabetes

R. Malik[1], G. Ponirakis[1], A. Khan[1], H. Al-muhannadi[1], I. Petropoulos[1], O. Migahid[2], A. Jayyousi[2], M. Abdul-Ghani[2];
[1]Weill Cornell Medicine, Doha, [2]Academic Health System, Hamad Medical Corporation, Doha, Qatar.

Background and aims: There are no approved therapies for diabetic peripheral neuropathy (DPN), a major risk factor for diabetic foot ulceration and amputation. The LEADER trial has recently shown a reduction in the incidence of foot ulceration and amputation in T2DM patients treated with Liraglutide. The aim of the study is to compare the effects of combination therapy with Exenatide once weekly/Pioglitazone vs basal plus prandial insulin on structural and functional measures of DPN in patients with poorly controlled T2DM.

Materials and methods: In a sub-group of the Qatar Study ($n = 46$; age = 50 ± 1, female = 47%, BMI = 30.9 ± 1.1, diabetes duration = 11.1 ± 1.0 years), patients with T2DM and poor glycemic control (HbA1c = 10.5 ± 0.3) despite treatment with maximal dose of sulfonylurea and metformin were randomly assigned to receive pioglitazone (30 mg) plus weekly Exenatide (2 mg) (combination) or basal plus prandial insulin (insulin), and underwent corneal confocal microscopy, assessment of painful neuropathy using DN4, vibration perception threshold using a Neurothesiometer and sudomotor function using Sudoscan.

Results: Participants were examined at baseline and at 12 months follow up. HbA1c was markedly reduced in the combination ($10.6 \pm 1.8\%$ to $7.1 \pm 1.4\%$, $P < 0.0001$) and insulin ($10.4 \pm 1.3\%$ to $7.2 \pm 0.9\%$, $P < 0.0001$) therapy groups and combination therapy also reduced triglycerides ($P = 0.01$). Subjects on insulin showed a significant increase in corneal nerve branch density (CNBD) ($P < 0.001$) and fibre length (CNFL) ($P < 0.001$) but not fibre density (CNFD), whereas subjects on combination therapy showed an increase in CNBD ($P = 0.04$) and DN4 ($P = 0.06$). Both therapies showed no improvement in vibration perception ($P = 0.5$–0.7) or sudomotor function ($P = 0.2$–0.8). There was no relationship between the degree of HbA1c reduction and improvement in corneal nerve parameters.

Conclusion: Exenatide/pioglitazone combination therapy and insulin therapy equally effectively reduce HbA1c in poorly controlled T2DM patients and induce corneal nerve fibre regeneration and a reduction in painful neuropathic symptoms, without an improvement in vibration perception or sudomotor function.

Corneal confocal microscopy in screen-detected type 2 diabetes: ADDITION-Denmark

S. Toft Andersen[1], K. Grosen[2], H. Tankisi[3], M. Charles[1], N.T. Andersen[1], H. Andersen[4], I.N. Petropoulos[5], R.A. Malik[5], T.S. Jensen[2], P. Karlsson[2];
[1]Department of Public Health, Aarhus University, Aarhus, Denmark, [2]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark, [3]Aarhus University Hospital, Aarhus, Denmark, [4]Department of Neurology, Aarhus University Hospital, Aarhus, Denmark, [5]Central Manchester University Hospitals Foundation Trust, Manchester, UK.

Background and aims: We aimed to compare corneal confocal microscopy (CCM) measures between participants with type 2 diabetes with and without confirmed diabetic polyneuropathy (DPN) and controls without diabetes.

Materials and methods: CCM, nerve conduction studies, and assessment of symptoms and deficits of DPN were undertaken in 144 participants with type 2 diabetes and 25 controls without diabetes. DPN was defined according to the Toronto criteria for confirmed DPN. We used ANOVAs to compare CCM measures between groups and regression analyses to determine clinical variables associated with CCM measures.

Results: Corneal nerve fiber density (CNFD) was lower in participants with confirmed DPN ($n = 27$) ($P = 0.04$) and without confirmed DPN ($n = 117$) ($P = 0.01$) compared with controls. No difference between participants with and without confirmed DPN was observed ($P = 0.98$). There were no differences in corneal nerve fiber length and corneal nerve branch density between participants with and without confirmed DPN ($P = 0.06$ and $P = 0.29$, respectively). CNFD was associated with age (b −0.150 [95% CI 0.297; 0.003]), height (b 0.154 [95% CI 0.049; 0.260]), total cholesterol (b1.090 [95% CI 0.067; 2.112]), and LDL cholesterol (b 1.358 [95% CI 0.022; 2.694]). The effect of age on CNFD remained stable in multiple linear regressions including DPN status, sex, and diabetes duration.

Conclusion: This study supports CNFD being lower in participants with type 2 diabetes compared with controls. CCM measures were unable to differentiate between participants with type 2 diabetes with and without confirmed DPN.

Determining the contribution of the G319S variant of HNF1a to beta cell dysfunction and type 2 diabetes development

C.A. Doucette[1,2], T. Morriseau[1,2], P. Agarwal[3], M. Fonseca[3,2], C. Nian[4,5], B.A. Wicklow[6,2], E. Sellers[6,2], V.W. Dolinsky[3,2], F.C. Lynn[4,5]; [1]Physiology and Pathophysiology, University of Manitoba, Winnipeg, [2]Children's Hospital Research Institute of Manitoba, Winnipeg, [3]Pharmacology and Therapeutics, University of Manitoba, Winnipeg, [4]Surgery, University of British Columbia, Vancouver, [5]British Columbia Children's Hospital Research Institute, Vancouver, [6]Pediatrics and Child Health, University of Manitoba, Winnipeg, Canada.

Background and aims: In Canada, Manitoba has the highest rate of youth-onset type 2 diabetes (T2D), which is amongst the highest in the world. Disproportionately affected are Indigenous youth with Oji-Cree heritage. Nearly 40% of Oji-Cree youth with T2D in Manitoba carry a single nucleotide polymorphism in the hepatocyte nuclear factor 1α (*HNF1α*) gene, causing replacement of a highly conserved glycine with a serine at codon 319 ("G319S"). Youth with T2D who harbour the G319S variant have higher $HbA1_c$, lower fasting insulin and less insulin resistance at diagnosis compared to youth with T2D who carry the wild type (WT) allele. These observations suggest that T2D in G319S carriers is primarily driven by a β cell defect; however, the mechanistic impact of the G319S variant on the β cell has not yet been explored. Here, we aimed to 1) develop novel animal and cell models to assess the functional impact of the G319S variant on insulin secretion; 2) determine if the G319S variant alone causes diabetes in a rodent model; and 3) elucidate the mechanism(s) whereby the G319S variant triggers β cell dysfunction and diabetes development.
Materials and methods: Using CRISPR-Cas9 to knock-in the g>a.955 mutation into MIN6 clonal β cells and C57BL6 mice, we have generated novel *in vitro* and *in vivo* model systems of the G319S variant. We assessed insulin secretion capacities in response to low and high glucose stimulation and examined how the G319S variant influenced glucose tolerance and metabolic health in mice. Finally, we performed targeted quantitative PCR (qPCR) to elucidate the mechanism(s) by which the G319S variant influences β cell function.
Results: Upon exposure to 16.7mM glucose, WT- and G319S-MIN6 secreted similar amounts of insulin; however, at low glucose, basal insulin secretion was reduced 3.2-fold in G319S-MIN6 compared to WT-MIN6 cells (0.8748 vs 2.764 ng insulin/μgDNA/hr; $p < 0.0001$). A similar phenotype of reduced basal insulin secretion was observed in islets isolated from heterozygous (G/S) male mice compared to G/G mice (0.4794 vs 1.850 ng insulin/μgDNA/hr; $p = 0.0032$). *In vivo* glucose tolerance tests revealed that G/S male mice developed glucose intolerance and fasting hyperglycemia by 3 months old, indicative of diabetes and consistent with reduced/insufficient basal insulin. Targeted qPCR was performed on of a number of genes with key roles in the β cell and found a 2-fold ($p = 0.0012$) upregulation of *Cpt-1a*, which has been shown to play a role in regulating basal insulin secretion capacity.
Conclusion: Our studies suggest that the G319S variant does not impair GSIS, which is typically observed in T2D; but rather, the G319S variant drives T2D via impaired basal insulin secretion, which may involve altered fatty acid metabolism. Future studies will examine if restoration of basal insulin secretion can prevent the diabetes phenotype in S allele-expressing mice as well as to determine how modern dietary influences interact with the G319S variant to influence T2D susceptibility.

Restoration of insulin secretion after bariatric surgery in leptin deficient mice independently of weight loss

C. Amouyal[1], J. Castel[2], C. Guay[3], A. Lacombe[4], J. Denom[2], S. Migrenne[2], J. Sobel[3], C. Rouault[1], F. Marquet[1], S. Luquet[2], R. Scharfmann[5], K. Clement[1], R. Regazzi[3], C. Magnan[2], F. Andreelli[1,6]; [1]Sorbonne Université, INSERM, UMRS1166, NutriOmicsTeam, PARIS, France, [2]Unit of Functional and Adaptive Biology, Paris Diderot University-Paris 7, PARIS, France, [3]Department of Fundamental Neurosciences, University of Lausanne, Lausanne, Switzerland, [4]PreclinICAN, Institute of Cardiometabolism and Nutrition (IHU-ICAN), PARIS, France, [5]INSERM, URMS1016, Institut Cochin, Paris Descartes Université, PARIS, France, [6]APHP, Pitié Salpétrière Hospital, Sorbonne université, ICAN, diabetology departement, Paris, France.

Background and aims: Bariatric surgery has demonstrated metabolic improvement especially in type 2 diabetes. We have previously published in high fat diet mice a bariatric procedure (entero-gastro-anastomosis with pyloric ligature, EGA) that recapitulates the beneficial effects on glucose homeostasis of the Roux-en-Y gastric bypass procedure in humans. Here, we studied the effects of EGA procedure on beta cell functionality in leptin deficient ob/ob mice.
Materials and methods: We performed EGA on ob/ob mice (Ob-EGA) and compared them with ob/ob mice before surgery (Ob-Ob), sham operated ob/ob mice (Ob-sham) and Ob-EGA group intraperitoneally infused by exendin [9-39] amide (Ex9) or saline. Metabolic exploration was performed before and 30 days post surgeries. Immunohistological staining of pancreas, pancreatic insulin content, expression of microRNAs (microarrays profiling and qPCR) and pancreatic islet cell composition by flow cytometry were performed. We used ANOVA or Mann-Whitney tests to compare data (mean ± SD) from different groups.
Results: OGTT dramatically improved after EGA despite persistent obesity and hyperphagia. Indeed, EGA procedure did not induce changes in food intake, body weight, body composition and energy expenditure in these mice. Furthermore, insulin and C peptide secretions were significantly increased after EGA (insulinemia, time 15 min (T15) of OGTT: Ob-Sham: 7.29 ± 3.7 ng/ml Ob-EGA: 28,8 ± 21 ng/ml, $p = 0.03$) whereas whole-body insulin sensibility (insulin tolerance test 0.75 and 2 UI/kg) and systemic inflammation (Il6, TNFa, MCP1, resistine) were unchanged. Infusion of Ex9 during 30 days after EGA resulted in lowering insulin secretion at T15 of OGTT without significant changes in glucose excursion. After EGA, pancreas immunohistology revealed a significantly higher level of insulin positive cell area (Ob-ob: 1,03 ± 0,5%; Ob-Sham: 1,42 ± 1%; Ob-EGA: 1,92 ± 1,16%, $p < 0,001$). and pancreatic insulin content increased. In contrast, ratio alpha/beta cells, alpha and beta cell proliferation rate (Ki67 index) and immune cell infiltration of pancreatic islets were unchanged by EGA. In comparison to Ob-sham mice, EGA procedure modified in pancreatic islets the expression of 5 microRNAs with known functions on apoptosis and/or glucose stimulated insulin secretion (up regulation of miR-184, $p = 0.0269$; down regulation of miR-106b, $p < 0.001$; miR-199a-3p, $p = 0.014$; miR-708, $p < 0.001$; and miR-34a, $p < 0.001$).
Conclusion: Resolution of diabetes after EGA was primarily explained by improvement of beta cell functionality in ob/ob mice and not exclusively by an incretin effect. This was associated with correction of defects in microRNA expression profiles observed in pancreatic islets of Ob-sham diabetic mice. Importantly, our model demonstrated that resolution of diabetes after bariatric surgery can be independent to body weight loss.

A mutation in the NADH-dehydrogenase subunit 2 in the mitochondrial genome protects against diet-induced hepatosteatosis

M. Wietzke, M. Fischer, S. Baltrusch, M. Tiedge;
University of Rostock, Rostock, Germany.

Background and aims: The mitochondrial genome of the diabetes-resistant B6-mtALR (ALR) mouse strain is characterized by a mtDNA encoded ND2 mutation in complex I of the respiratory chain. ALR mice were less prone to liver steatosis despite higher mitochondrial ROS production and showed an effective hepatocellular energy metabolism. In this study, we focused on the susceptibility to hepatosteatosis after feeding a high fat diet. Therefore, we investigated metabolic parameters in serum and tissue, the NAFLD activity score in conplastic B6-mtALR mice compared to B6-mtAKR control strain. Furthermore we analysed expression of metabolic and inflammatory genes in liver.
Materials and methods: Conplastic B6-mt^{AKR} (AKR, control) and B6-mt^{ALR} (ALR, mutant) mice were fed with a high fat diet (HFD, western style diet) or control diet for 3 months. Liver tissue was collected and gene expression was quantified by real-time RT-PCR analysis. Liver histology was assessed using hematoxylin and eosin and Goldner`s trichrome stains. A blinded assessment of NASH was made according to the established NAFLD activity score. Lipid contents of the liver and collagen amounts reflected by hydroxyproline concentrations were quantified by commercial assays.
Results: Fasting blood glucose, serum triglyceride and serum cholesterin levels showed no differences in both strains before and after feeding a HFD for 3 months. However, hepatic triglyceride contents were lower in the ALR mouse strain. In line with these data histological analysis revealed lower hepatic lipid deposition (steatosis score) and ballooned hepatocytes in ALR mice after HFD. Hepatic collagen content was also lower in AKR mice indicating a milder grade of fibrosis. After 3 months of HFD feeding gene expression of glucokinase, Ppara and AcadI were significantly higher in ALR mice. Expression of Atp8, mtND2 and Ndufb4 as key genes for mitochondrial energy metabolism were also significantly increased in ALR mice after HFD. Interestingly, expression of the proinflammatory indicators TNFα and IL1b was increased in the liver from ALR mice. Histological analysis of liver tissue showed no signs of inflammation irrespective of mouse strain and diet.
Conclusion: The mtND2 mutation in complex I of the respiratory chain correlates with a lower risk to develop a hepatosteatosis after feeding a high fat diet. Despite high production of ROS, mitochondrial polymorphism ensuring adequate ATP production to metabolic demands confers protection against NAFLD. Our data suggest that analysis of mitochondrial polymorphisms in combination with functional analysis of energy metabolism in liver will help to stratify the risk for NAFLD in diabetic patients.

The effect of kidney lipotoxicity on renal dysfunction in a model of metabolic syndrome

H. Malinska[1], M. Huttl[1], I. Markova[1], O. Oliyarnyk[1], J. Trnovska[1], P. Kačer[2], L. Kazdova[1];
[1]Institute for Clinical and Experimental Medicine, Prague, [2]Biocev, First faculty of medicine, Charles University, Prague, Czech Republic.

Background and aims: The development of metabolic syndrome-associated renal dysfunction can be exacerbated by dyslipidaemia, ectopic deposition of lipids and their toxic metabolites, impairment of lipid metabolism as well as insulin resistance. Renal dysfunction can also be affected by the production of pro-inflammatory and pro-fibrotic factors secreted from adipose tissue, which can directly impair kidney cells and potentiate insulin resistance. However, the aggravation mechanism of renal function is not fully understood. In our study, we investigated the manifestation of kidney lipotoxicity and its effect on renal dysfunction in a model of metabolic syndrome - hereditary hypertriglyceridaemic rats (HHTg) - by assessing microalbuminuria and target urine proteomics.
Materials and methods: Wistar control rats and a strain of HHTg rats, which served as a model of insulin resistance and metabolic syndrome, were fed a standard diet and observed over the course of ageing at 3, 12 and 20 months of age. Microalbuminuria was determined using the HPLC-method, while assessment of urine proteomics was performed using the mass spectrometry method. Gene expression was measured by quantitative RT-PCR.
Results: Chronically elevated levels of triglycerides in HHTg rats were associated with increased levels of FFA during OGTT as well as over a period of 24 hours (+80%, $p < 0.01$). In the case of the FFA lipid class, animals exhibited qualitative changes in FFA fatty acid composition, which was represented by an increased profile of saturated fatty acid ($p < 0.05$) and a decreased profile of n3-PUFA ($p < 0.01$). Ectopic lipid deposition in the kidneys of HHTg rats - triglycerides (+30%) and cholesterol (+10%) - was associated with markedly elevated microalbuminuria as ageing increased, despite the absence of microalbuminuria at the young age of 3 months in these animals. The presence of neutral lipids in the renal tubule and glomerulus was verified based on histological observation of HHTg rats. According to targeted proteomic analysis, 3-month-old HHTg rats (in comparison to age-matched controls) exhibited increased urinary secretion of pro-inflammatory parameters (MCP-1, IL-6, IL-8, $p < 0.01$) together with decreased urinary secretion of epidermal growth factor (EGF, $p < 0.01$) before manifestation of microalbuminuria. Elevation in the urinary secretion of inflammatory cytokines can be affected by increased weight in perirenal adipose tissue ($p < 0.01$) and increased relative expression of MCP-1 in perirenal adipose tissue ($p < 0.05$) as well as in kidney cortex ($p < 0.05$).
Conclusion: Our results confirm that dyslipidaemia and ectopic lipid accumulation play key roles in the development of metabolic syndrome-associated renal dysfunction. Assessing urinary secretion of pro-inflammatory cytokines and epidermal growth factor can help detect the early development of metabolic syndrome-associated renal dysfunction.

Glucose-induced changes of granules and actin in beta cells as visualised by TIRF-microscopy

D. Bruening, K. Reckers, I. Rustenbeck;
TU Braunschweig, Braunschweig, Germany.

Background and aims: Recently we have noticed that in contrast to potassium depolarization glucose diminishes the granule turnover in the submembrane space. Here, we verified this observation by gradually increasing the glucose concentration. In this context, the role of the actin cytoskeleton for the granule mobility was explored.
Materials and methods: All parameters were measured in perifused single beta-cells from NMRI mice. $[Ca^{2+}]_i$ was measured by the Fura technique, the mobility of granules in the submembrane space and the structure of the actin cytoskeleton were imaged by TIRF microscopy. Actin was visualized by tagRFP-Lifeact and the insulin granules were visualized by the cargo-directed label, Insulin-EGFP. Adenoviral transduction was used for labelling.
Results: Single pancreatic beta cells were continuously perifused during TIRF microscopy. After a 45 min adaption period the glucose concentration was raised stepwise from 5 to 15 mM and then to 30 mM, each step lasted for 10 min. For control purpose measurements of $[Ca^{2+}]_i$ were performed which showed an increase by 15 mM glucose starting after 2 min and reaching 115 nM at 5 min, followed by a slow decrease until 30 mM glucose raised it to about 140 nM at which it remained stable. At 2 and 7 min in the course of each step sequences of 200 TIRF images were acquired at 8 Hz. The number of granules in the first image of each sequence decreased throughout the perifusion as did the total number of granules identified per sequence. The number of granules which arrived at the plasma membrane and the number of granules which stayed for a short time only (≤1 s) increased slightly. However when net values were calculated by subtracting the values obtained during control perifusions (5 mM glucose throughout) from those of the test perifusions, a different picture emerged. The granule number in the first image and the total number was increased at 15 mM glucose and remained at the same level at 30 mM glucose. The net number of arriving granules and short-term granules, in contrast, showed a decrease with high glucose. At basal glucose the actin cytoskeleton in beta cells double transfected with tagRFP-LifeAct and hIns-EGFP showed a heterogeneous pattern. In one third of the cells stress fibers were prominent, in about half of the cells filopodia were visible. Areas with stress fibers were nearly devoid of granules. In cells with a predominant cortical actin web the granules were concentrated in the void spaces between the actin fibers. In the course of glucose stimulation the stress fibers remained virtually unchanged whereas the fiber structure of the cortical actin became blurred and dot-like shapes appeared.
Conclusion: Stimulatory glucose diminished the turnover of granules in the submembrane space. The distribution of the granules in this space appeared to be determined by the cortical actin network, which became loosened during exposure to high glucose. The occurrence of stress fibers and filopodia may be a reaction to the unphysiological condition of single cell existence.

Probing the dynamic fingerprint of insulin secretory granules in living beta cells by spatiotemporal fluctuation spectroscopy

G. Ferri[1,2], M. Bugliani[3], L. Digiacomo[4], Z. Lavagnino[5], M. Occhipinti[3], P. Marchetti[3], G. Caracciolo[4], D.W. Piston[5], F. Cardarelli[1];
[1]NEST - Scuola Normale Superiore, Istituto Nanoscienze - CNR (CNR-NANO), Pisa, Italy, [2]Nanoscopy, Nanophysics, Istituto Italiano di Tecnologia, Genoa, Italy, [3]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, [4]Department of Molecular Medicine, University of Rome "La Sapienza", Rome, Italy, [5]Department of Cell Biology and Physiology, Washington University Scholl of Medicine, St Louis, USA.

Background and aims: Insulin secretory granules (ISGs) exert their complex tasks through tight regulation of key structural and functional properties, such as size, diffusivity, mode of motion, etc. Quantitative description of these parameters in living β-cells is crucial for our understanding of insulin granule function in physiology and pathology. Despite the efforts, however, this goal remains a challenge in the field. We addressed this issue by a fluorescence-based spatiotemporal fluctuation spectroscopy of fluorescently-labelled granules in living cells. The method extracts quantitative information directly from imaging, in the form of a mean square displacement (MSD) versus time-delay plot (named iMSD), with no need for a-priori knowledge on the system, no need for complex labelling, no need to calculate trajectories. Relevant parameters, such as granule average diffusivity, anomalous coefficient, and size are readily accessible by this approach. Their clustering in a multidimensional parametric space defines the "fingerprint" of ISGs at the cell-population level.
Materials and methods: INS-1 E cell culturing. Plasmid transient transfection. Advanced imaging techniques (e.g. time-lapse confocal microscopy, iMSD analysis). Human pancreatic islets; human β-cells.
Results: To start, a reference granule structural and dynamic fingerprint is built by using INS-1 E cells expressing Proinsulin fused to a fluorescent protein (FP) under standard cell-culture conditions and validated under well-known stimuli, such as cholesterol overload, cytoskeleton disruption, glucose stimulation,. Then, the effect of different fluorescent labelling strategies is assessed, by using alternative granule-specific proteins such as Phogrin-FP, Syncollin-FP or IAPP-FP. While the latter two yield a ISG fingerprint very similar to that of the Proinsulin-FP reference, an hitherto-neglected neat alteration of both the structural and dynamic properties of the granule are observed upon the expression of Phogrin-FP, a widely used transmembrane ISG marker. To provide a better characterization of ISGs fingerprint in physiological conditions, we also dissociated human pancreatic islets and transfected the obtained isolated cells with Syncollin-FP. The iMSD-based comparison of INS-1 E and Human β-cells expressing Syncollin-FP highlights differences both in ISGs average size and diffusivity (i.e. ISG in human cells are smaller and slower).
Conclusion: Spatiotemporal fluctuation spectroscopy emerges as a powerful new platform for cell-based rapid and robust screening of the average properties of ISGs, allowing to easily highlight any alteration affecting their structural and/or dynamic characteristics. Reported results suggest caution in the definition of an experimental standard for the study of granule properties, both in terms of labelling strategies and of the cellular model selected.

Control of insulin secretion by basement membrane proteins

P. Thorn, O.H. Do, L. Cottle, E. Kosobrodova, M. Bilek, W.J. Gan;
University of Sydney, Sydney, Australia.

Background and aims: Loss of insulin secretion is a recognised characteristic of diabetes. It is therefore an important goal to determine how insulin secretion is controlled and what goes wrong in disease. Our recent work, in intact islets, shows that beta cells are structurally polarised and that insulin secretion is selectively targeted towards the vasculature. One of the factors that might regulate this targeting of secretion is the extracellular matrix. Here we test the hypothesis that extracellular matrix proteins, secreted by endothelial cells of the vasculature, induce the formation of focal adhesions which provide an important cue for beta cell orientation.

Materials and methods: A PDMS stamp was fabricated and used as a template to stamp basement membrane protein patterns onto coverslips. Isolated mouse pancreatic beta cells were cultured onto the coverslips and the cells imaged using a custom-built 2 photon microscope employed with a 60x objective. SRB was used as an extracellular dye excited at 940 nm with emission light collected >550 nm. A piezo objective stage (PI) rapidly moved the objective in z while collecting images at 3 frames/s.Cells were stimulated with 15 mM glucose and insulin granule exocytosis was detected as the sudden entry of the extracellular SRB into each fusing granule. Image analysis was performed with ImageJ.
Results: Using 3D live-cell two-photon microscopy, we showed that the spatial distribution of glucose-induced fusion of insulin granules was enriched towards the culture coverslips coated with matrix substrates (laminin 511, fibronectin or collagen IV). In contrast, granule fusion occurred all over the cell surface on poly-l-lysine coated control coverslips. Using microcontact printing to further pattern basement membrane proteins on the coverslips surface, we manipulated the area where the granules fused on the coverslips surface. To identify the mechanism of beta cell interaction with the substrate, we bathed the cells in drugs that affect the formation of focal adhesion such as the FAK inhibitor and beta-1 integrin blocking antibody. We showed that the targeting of secretory response is focal adhesion dependent. As the ongoing work, we are investigating the distribution of insulin granule fusion in beta cells following diabetic-induced modification of basement membrane proteins
Conclusion: In summary, our results provide evidence that basement membrane proteins are functionally important for targeting of insulin secretion and the process is focal adhesions dependent.

The positive effect of apolipoprotein A-I on insulin secretion involves priming of insulin granules

O. Nilsson, R. Del Giudice, J.O. Lagerstedt;
Experimental Medical Science, Lund University, Lund, Sweden.

Background and aims: Increasing plasma levels of high density lipoproteins (HDL) and Apolipoprotein A-I (ApoA-I), its main protein component, have been shown to have an anti-atherogenic effect as well as positive action on glucose disposal in type 2 diabetic patients. ApoA-I directly increases insulin synthesis and secretion in insulin resistant mouse model, isolated pancreatic islets and clonal β-cells. The current study investigates ApoA-I's unexplored function to prime β-cells to increase insulin secretion and dissects mechanism behind this phenomenon.
Materials and methods: Rat insulinoma β-cell line INS1-E or isolated murine islets were used as experimental models for insulin secretion. Briefly, INS1-E or islets were pre-incubated for 2 h with low glucose in the presence or absence of ApoA-I, followed by 1 h challenge with glucose or other secretagogues, in the absence of the protein. Insulin was measured using ELISA (Mercodia) and normalized towards total protein content (BCA assay). Confocal and electron microscopy were applied to visualize the distribution of insulin granules in β-cells.
Results: Pre-incubation of β-cells and isolated murine islets with ApoA-I resulted in a significantly higher insulin secretion in response to high glucose (50% $n = 6$ ****$p < 0.0001$ and 30% $n = 12$ *$p < 0.05$ increase in insulin release for INS1-E and islets, respectively, as compared to high glucose control). ApoA-I's priming effect was even more pronounced when cells were challenged with secretagogues that lead to direct cell membrane depolarisation (four-fold higher insulin release in the presence of either Tolbutamide or KCl, as compared to cells incubated with ApoA-I in low glucose $n = 6$, ***$p < 0.001$ ****$p < 0.0001$, respectively). Increased reservoir of insulin granules at the cell membrane, resulting from ApoA-I's action, was confirmed by confocal and negative stain electron microscopy. Electron microscopy allowed for estimation of distances of the granules from the cell membrane, revealing that the incubation with ApoA-I resulted in a higher number of granules in the immediate proximity of the membrane (0–0.4 μm). Proinsulin levels, determined by Western blot, after stimulation with ApoA-I were found not to be changed with respect to controls. At the same time, insulin secretion as well as total insulin levels were significantly higher suggesting a regulatory function of ApoA-I on proinsulin processing as well as on insulin synthesis. Immunoblotting was applied to measure the expression of key regulators of proinsulin processing, protein convertase 1 (PC1/3) and carboxypeptidase E (CPE), showing significantly higher levels of PC1/3 as well as of CPE when ApoA-I was added ($n = 3$ *$p < 0.05$). Finally, inhibitors of endocytosis were used to block cellular uptake of ApoA-I. Incubation with inhibitors partially blocked ApoA-I endocytosis in INS1-E cells, resulting in increased accumulation of the protein at the cell membrane. Preliminary data on functional significance of the partially blocked uptake show an increase in ApoA-I's positive priming effect.
Conclusion: In the presented study, a novel function for ApoA-I has been identified, *i.e.*, its ability to prime β-cells to increase glucose-stimulated insulin secretion. The proposed mechanisms include increased number of insulin granules close to the cell membrane, increased processing of proinsulin and enhanced insulin synthesis. These findings are of interest for future anti-diabetic treatments with added anti-CVD effect.

Health burden in type 2 diabetes and prediabetes: the Maastricht Study

M. Veugen, V. Onete, A. Koster, P. Dagnelie, N. Schaper, C. van der Kallen, M. Schram, R. Henry, C. Stehouwer;
On behalf of The Maastricht Study group; Cardiovascular Research Institute Maastricht (CaRIM); MUMC+, Maastricht, Netherlands.

Background and aims: Premature mortality in type 2 diabetes (T2D) is determined not only by classical complications (e.g., cardiovascular disease), but also by comorbidities (e.g., depression). A similar but less strong pattern is seen in prediabetes. However, prevalent comorbidities in T2D and prediabetes have not been comprehensively and quantitatively examined and compared to normal glucose metabolism (NGM) in a population-based study. Therefore, we investigated health burden in type 2 diabetes and prediabetes as compared to NGM, as defined by the presence of a diverse set of non-classical comorbidities in addition to the presence of classical complications and cardiometabolic risk factors.
Materials and methods: 3,410 participants (mean age: 59.8 ± 8.3 years; 52% men; 975 T2D, 511 prediabetes, and 1,924 NGM) of the population-based Maastricht Study underwent extensive phenotyping to determine presence of 15 comorbidities, 6 classical complications, and 10 cardiometabolic risk factors. These were added up into individual sum scores (for each category) and a combined sum score (with the 80th percentile in NGM as the highest sum score category cut-off). We used (multinomial) regression analyses adjusted for age and sex to study group differences.
Results: Individuals with T2D and prediabetes, as compared to NGM, more often had a comorbidities sum score of ≥3 (frequencies (95% CI): 49.4% (45.3; 53.4) and 28.9% (24.7; 33.2) vs 19.5% (17.8; 21.3), *p*-trend <0.001); a classical complication sum score of ≥2 (26.6% (23.1; 30.1; $p < 0.001$ vs NGM) and 10.1% (7.8; 12.7; $p = 0.065$ vs NGM) vs 8.0% (6.9; 9.3)); a cardiometabolic risk factors sum score ≥6 (39.7% (35.9; 43.4) and 28.5% (24.5; 32.6) vs 14.0% (12.5; 15.6); *p*-trend <0.001); and a combined sum score of ≥8 (60.7% (56.7; 56.7; 64.7) and 38.2% (33.8; 42.7) vs 21.0% (19.2; 22.9), *p*-trend <0.001).
Conclusion: Our results show, independently of age and sex, and in a population-based setting, a considerably greater health burden in both T2D and prediabetes, which to an important extent is related to non-classical co-morbidities. These results emphasize the need for awareness of comorbidities in (pre)diabetes and for further investigation of the potential aetiological role of so-called mild hyperglycaemia.

Circulating cardiac stress, vascular dysfunction and inflammatory biomarkers predict acute kidney injury in French type 2 diabetes patients: the SURDIAGENE cohort

P. Saulnier[1], B. Sautenet[2], E. Gand[1], M. Fraty[1], J. Halimi[2], E. Thorin[3], O. Meilhac[4], E. Burillo[4], G. Velho[5], R. Roussel[5], S. Ragot[1], S. Hadjadj[1], for the SURDIAGENE study group;
[1]INSERM CHU Poitiers, Poitiers, France, [2]CHU Tours, Tours, France, [3]Montreal Heart Institute, Montreal, Canada, [4]INSERM, Saint Denis de la Réunion, France, [5]INSERM, Paris, France.

Background and aims: Acute kidney injury (AKI) is a related to chronic kidney disease and death in patients from the general population, with or without type 2 diabetes. Nevertheless AKI biomarkers are rarely validated in diabetes population. We aimed to explore the individual and combined prognostic value of 8 circulating candidate markers for AKI. This include markers of cardiac and endothelial dysfunction (mid-regional-pro-adrenomedullin [MRproADM], angiopoietinlike-2 [ANGPTL2], N-terminal prohormone brain natriuretic peptide [NTproBNP]) oxidative stress (fluorescent advanced glycation endproducts [AGEs], carbonyls), cardio-renal pathways (copeptin [CTproAVP]), and inflammation (soluble TNF receptor 1 [TNFR1]).
Materials and methods: We prospectively followed-up 1345 (565 women/780 men) type 2 diabetes participants of a French single-centre hospital-based cohort (SURDIAGENE) with baseline GFR ≥30 ml/min/1.73 m^2 and no renal replacement to onset of AKI, death, or December 31, 2015, whichever came first. Intrahospital AKI was diagnosed and staged using the KDIGO criteria (increase in serum creatinine concentration by 0.3 mg/dL or increase in serum creatinine to ≥1.5 times baseline). Cox models were used to estimate the association between time to AKI and baseline value of each biomarker after adjustement for usual risk factors: sex, diabetes duration, HbA1c, systolic blood pressure, GFR, ACR, use of antihypertensive, and history of cardiovascular disease. Hazard ratios were reported per 1 SD increment of the logarithm of the biomarker concentration.
Results: At baseline, mean ± SD age was 64 ± 11 years, diabetes duration 14 ± 10 years, HbA1c 7.8 ± 1.6%, and eGFR 77 ± 21 ml/min/1.73 m^2, and median (IQR) ACR 3 (1–10) mg/mmol. During a median follow-up of 4.7 years, 449 (33%) patients developed an AKI. In univariate analysis, each biomarker was significantly associated with AKI, and 6 remained associated after multivariable adjustment (Table). The addition of a multimarker score summing standardized and weighted values of these 6 markers to the model including usual risk factors significantly improved C-statistics (0.724 to 0.759, $P < 0.0001$), and 5-year risk-predictive performance (relative integrated discrimination improvement index = 0.435, $P < 0.0001$).
Conclusion: A panel of 6 biomarkers representing cardiac, vascular and inflammatory pathways improved the prediction of AKI over usual risk factors in patients with type 2 diabetes.

Glycaemic and cardiovascular risk factor burden post therapy intensification in patients with type 2 diabetes in the USA

S. Paul, O. Montvida;
Melbourne EpiCentre, University of Melbourne, Melbourne, Australia.

Background and aims: The recent drive for holistic management of cardiovascular (CV) and glycaemic risk factors for individualized treatment of patients with type 2 diabetes (T2D) requires a detailed evaluation of population-level risk factor dynamics. Aim is to evaluate the persistent glycaemic and CV risk factor burden over 2 years post therapy intensification (TI).
Materials and methods: From US Centricity Electronic Medical Records, 276,884 patients with T2D aged 18–80 years, who intensified metformin with a second-line anti-diabetic drug (ADD), had longitudinal prescription information for lipid-modifying and blood pressure (BP) control therapies, were selected. Second-line ADDs were sulfonylurea

(SU), DPP-4 inhibitor (DPP-4i), GLP-1 receptor agonist (GLP-1RA), thiazolidinedione (TZD) and insulin. For those with/without history of CV disease (CVD) at TI, systolic BP (SBP) ≥130/140 mmHg and LDL ≥70/100 mg/dL were defined as uncontrolled. Triglycerides (Trig) ≥150 mg/dL and HbA1c ≥7.5% were defined as uncontrolled. Based on 6-monthly longitudinal measures over 24 months post TI, the burden was defined as continuously uncontrolled levels of risk factors.

Results: With 3.7 years mean follow-up, patients were 59 years old, 70% obese, 22% had history of CVD, 60/30/50/48% had uncontrolled HbA1c/SBP/LDL/Trig at TI. 191,883 (69% of cohort) had follow-up ≥2 years. Among patients without a history of CVD, 77% and 63% were receiving therapies for BP and lipid control respectively. Among those with a history of CVD, these proportions were 94% and 84% respectively. The proportion of patients with HbA1c ≥7.5% consistently over 2 years ranged between 31–41% when evaluated by year of TI, with increasing pattern from 2005 to 2014 (Figure). Among those on lipid-modifying drugs, 40–42% continued to have high LDL and around 37% consistently had high Trig over time. Being on BP control therapies, 27–32% continued to have SBP burden over 2 years. Among patients receiving lipid or BP control therapies, 62% failed to achieve control in HbA1c + LDL, 62% failed to achieve control in HbA1c + Trig, and 55% failed to achieve control in HbA1c + SBP over 1 year post TI. These proportions were similar at 2 year follow-up. Compared to patients intensified with SU, those intensified with DPP-4i, GLP-1RA and TZD were 22%, 33% and 35% significantly less likely to fail in HbA1c + LDL control over 2 years respectively (all $p < 0.05$). Patients treated with DPP-4i and GLP-1RA were 32% and 45% less likely to fail in HbA1c + SBP control over 2 years respectively, compared to those with SU (all $p < 0.05$).

Conclusion: More than a third of patients with T2D continued to have clinically unacceptable HbA1c and lipid levels, and about 28% failed to control blood pressure over 2 years post therapy intensification for the multiple risk factor control. The glycaemic risk burden has been increasing over last decade. Treatment with incretins and TZD appears to have residual beneficial association with simultaneous glycaemic and CV risk factor control, compared to SU.

Prevalence of cardiovascular disease and treatment pattern in patients with type 2 diabetes in a real world setting

W. Weng[1], Y. Tian[1], S.X. Kong[2], R. Ganguly[1], M. Hersloev[2], J. Brett[3], T. Hobbs[4];
[1]Health Economics & Outcomes Research, Novo Nordisk, Inc, Plainsboro, [2]Clinical Development & Outcomes Research, Novo Nordisk, Inc, Plainsboro, [3]Medical Affairs, Novo Nordisk, Inc, Plainsboro, [4]CMR, Novo Nordisk, Inc, Plainsboro, USA.

Background and aims: Primarily based on the results of two large cardiovascular outcomes trials, the American Diabetes Association (ADA) issued its 2017 Standards of Medical Care in Diabetes (SOC) which recommends, "for patients with long-standing sub-optimally controlled Type 2 Diabetes (T2D) and established atherosclerotic cardiovascular disease (ASCVD) - empagliflozin or liraglutide should be considered as they have been shown to reduce cardiovascular and all-cause mortality when added to standard care." The current study assessed the prevalence of ASCVD associated with patient characteristics, medication usage, and healthcare utilisation patterns in a real-world T2D population prior to the 2017 ADA standard care guidelines.

Materials and methods: This was a retrospective, cross-sectional analysis of a large US administrative claims database in 2015. Inclusion criteria were: ≥2 diagnoses for T2D or ≥1 T2D diagnosis + ≥1 oral antidiabetic drug (OAD) claim, and no more than 1 T1D diagnosis according to ICD-9/-10 codes, ≥18 years of age, and continuous health plan enrolment in 2014 & 2015. Eligible patients were divided into two groups: T2D patients with ASCVD (with-ASCVD) and those without ASCVD (without-ASCVD). ASCVD was defined based on the ICD-9/-10 codes corresponding to ADA 2017 SOC of atherosclerotic CVD: Acute Coronary Syndrome, Myocardial Infarction, Peripheral Arterial Disease, Stroke, Transient Ischaemic Attack, and Coronary or other arterial particularisation. Sub-group analyses were conducted for 3 age groups (18–44, 45–64, and 65+ years).

Results: A total of 1,202,596 T2D patients were identified and 45.2% had established ASCVD. The with-ASCVD group was older than the without-ASCVD group (mean age 67 vs. 56 years) and had a slightly higher percentage of males (52.9% vs. 49.2%). Less than 10% of all T2D patients had visited an endocrinologist. About 40% of T2D patients with-ASCVD had visited a cardiologist, compared to 11% in the without-ASCVD group. Generally, the use of glucagon-like peptide-1 receptor agonists (GLP-1RA) and sodium-glucose co-transporter 2 inhibitors (SGLT-2i) was very low overall (<11%); and even lower in the with-ASCVD group (<9%). The prevalence rate of ASCVD among 3 age groups (18–44, 45–64, and 65+ years) were 15%, 36%, and 71%, respectively, and use of GLP-1RA and SGLT-2i was 5% or lower among the 65+ subgroup, regardless of ASCVD status.

Conclusion: This analysis of a large, real world claims database showed a high prevalence of ASCVD among T2D patients. It also confirmed as a baseline assessment, the low use of GLP-1RA and SGLT-2i in these at-risk patients prior to the ADA recommendations. It would be of interest to assess changes in the use of GLP-1RA and SGLT-2i among T2D patients with ASCVD based on these new recommendations in the coming years.

High LDL cholesterol levels and risk of peripheral vascular diseases: a Mendelian randomisation study including 116,419 individuals from the general population

F. Emanuelsson[1], B. Nordestgaard[2], A. Tybjaerg-Hansen[1], M. Benn[1];
[1]Department of Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital, Copenhagen, [2]Department of Clinical Biochemistry, Herlev and Gentofte Hospital, Copenhagen University Hospital, Herlev, Denmark.

Background and aims: High LDL cholesterol levels are causally involved in the pathogenesis of atherosclerosis and are causally related to an increased risk of cardiovascular disease. It is unknown whether high LDL cholesterol levels are causally related to an increased risk of microvascular diseases, such as retinopathy and neuropathy, and peripheral vascular diseases also involving larger arteries, such as chronic kidney disease (CKD), and peripheral arterial disease (PAD). We hypothesized that high LDL cholesterol levels are causally related to the risk of retinopathy, neuropathy, CKD and PAD in the general population.

Materials and methods: We included 116,419 individuals from the Copenhagen City Heart Study and the Copenhagen General Population Study and used Mendelian randomization to examine causality between high LDL cholesterol levels and peripheral vascular endpoints. As genetic instrument we selected and genotyped eleven variants in the *LDLR*, *APOB*, *HMGCR*, *NPC1L1* and *PCSK9* genes. To test whether we could replicate the findings in another general population cohort, we performed a 2-sample Mendelian randomization analysis using genetic variants associated with high LDL cholesterol levels in the Global Lipid Genetic Consortium, and peripheral vascular endpoints from the UK Biobank.

Results: Observationally we found no association between high LDL cholesterol levels and risk of retinopathy (P trend = 0.12) or neuropathy (P trend = 0.005). We found a stepwise increase in the hazard rate of CKD and PAD with higher LDL cholesterol levels, with a hazard ratio (HR; 95% confidence interval) of 1.06(0.99–1.14) for CKD and 1.37(1.20–1.57) for PAD in individuals with LDL cholesterol levels above the 95th percentile *versus* below the 50th percentile. In the genetic, causal analyses the risk ratio (95% confidence interval) of disease for a 1 mmol/L higher LDL cholesterol level was 1.06 (0.24–4.58) for retinopathy, 1.05 (0.25–1.72) for neuropathy, 3.10 (1.79–5.39) for CKD and 1.96 (1.26–3.06) for PAD. Summary level data from the UK Biobank using the weighted median of instrumental variable estimates Mendelian randomization gave a risk ratio of 0.65 (0.25–1.70) for retinopathy, 0.86 (0.51–1.46) for neuropathy, 0.88 (0.66–1.18) for CKD and 1.57 (0.91–2.71) for PAD.

Conclusion: Our study suggests that LDL cholesterol has no causal effect on peripheral microvascular diseases such as retinopathy and neuropathy; but may have a causal effect on peripheral arterial diseases involving larger arteries such as PAD and CKD. The findings were replicated in the UK Biobank cohort with similar results for retinopathy, neuropathy and PAD, but with conflicting results for CKD.

More adverse differences in cardiometabolic risk factor levels in women with prediabetes and diabetes compared with men: the Maastricht study

R. de Ritter[1,2], S.J.S. Sep[1,2], M.T. Schram[1,2], E. Derksen[1], C.J.H. van der Kallen[1,2], A. Koster[3,4], N. Schaper[2,4], A.A. Kroon[1,2], R.M.A. Henry[1,2], M.M.J. van Greevenbroek[1,2], S.A.E. Peters[5], P.C. Dagnelie[2,4], C.D.A. Stehouwer[1,2];
[1]Dept. of Internal Medicine, Maastricht University Medical Centre +, Maastricht, Netherlands, [2]Cardiovascular Research Institute Maastricht (CARIM), Maastricht University, Maastricht, Netherlands, [3]Dept. of Social Medicine, Maastricht University, Maastricht, Netherlands, [4]School for Public Health and Primary Care (CAPHRI), Maastricht University, Maastricht, Netherlands, [5]The George Institute for Global Health, University of Oxford, Oxford, UK.

Background and aims: Type 2 diabetes (T2D) attenuates, or may even reverse, the protective effect of female sex on the risk of cardiovascular disease. This may in part be explained by a relatively more adverse cardiometabolic profile in women with versus without T2D compared with men with versus without T2D. However, the mechanisms responsible for these sex differences remain to be elucidated. The metabolic sequences that eventually lead to T2D precede the development of hyperglycemia by years or even decades. Whether women before the onset of T2D already suffer from a relatively more adverse cardiovascular risk profile has only scarcely been investigated. We aimed to evaluate sex differences in metabolic syndrome-related markers of cardiovascular risk both before and after the onset of T2D .

Materials and methods: We analyzed cross-sectionally in a T2D-enriched population-based cohort (age 40–75 y), by means of linear regression analyses adjusting for age, whether the association of prediabetes and T2D with metabolic syndrome-related markers of cardiovascular risk differed between women (n = 1536) and men (1666). Differences in associations between men and women were tested by incorporating interaction terms of glucose metabolism status with sex into the regression models. Sex-stratified analyses were performed with normal glucose metabolism as reference category.

Results: Compared to normal glucose metabolism, women with prediabetes had more adverse age-adjusted mean differences in systolic BP (3.52 (95%-CI 0.73; 6.31) mmHg larger, i.e. mean difference in women exceeds that in men by 3.52), HDL cholesterol (0.10 (0.01; 0.18) mmol/L smaller) and triglycerides (0.14 (0.05; 0.24) mmol/L larger) than men with prediabetes. Mean differences for prediabetes in women equaled those for T2D in men. Compared to normal glucose metabolism, the more adverse mean differences in body mass index and waist circumference as observed for T2D in women versus men (2.27 (1.66; 2.89) kg/m^2, and 5.41 (3.74; 7.08) cm higher, respectively), were less evident for prediabetes (0.53 (−0.16; 1.22) kg/m^2, and 0.99 (−0.89; 2.87) cm, respectively).

Conclusion: The novel finding of this study is that there are already sex differences in cardiometabolic risk factors before the onset of T2D, to women's disadvantage. Besides the relatively more adverse cardiometabolic profile in women with versus without T2D as compared to their male counterparts, sex differences in cardiometabolic risk factors, which were less favourable for the female sex, were also observed in their association with prediabetes. This suggests that the cardiometabolic risk profile of women has deteriorated to a larger extent even before the onset of T2D.

Effect of number of achieved targets for risk factors on coronary artery disease (CAD) in those with and without diabetes

K. Fujihara, M. Harada, M. Yamamoto, Y. Mathubayashi, M. Kaneko, T. Osawa, T. Yamada, K. Kato, S. Kodama, H. Sone;
Niigata University, Niigata, Japan.

Background and aims: Although control of multiple risk factors is essential to prevent CAD in persons with and without DM, longitudinal studies are scarce that directly and quantitatively compared effects of such control in DM and non-DM.

Materials and methods: We investigated effects on subsequent CAD of the number of controlled risk factors among blood pressure, LDL cholesterol and HbA1c using a nationwide claim-based database (median follow-up 4.8 y) in Japan. Targets were based on ADA and Japanese guidelines.

Results: Of 207,029 non-DM persons, 42.8% and 37.9% were at target for 1 and 2 factors, respectively. Of 13,471 persons with DM, 39.5%, 32.1%, and 10.0% were at target for 1, 2, and 3 factors, respectively. Multivariate Cox analysis showed reduced CAD risk with increased numbers of risk factor targets reached in DM compared to non-DM (Table, upper). However, in DM, although fulfillment of the target for only 1 risk factor significantly elevated the hazard ratio (HR) (i.e., 1.98 (1.28–3.07)) to non-significance (i.e., 1.03 (0.68–1.66)), no further significant HR reduction below reference (i.e., non-DM with no target achieved) was found (Table, lower).

Conclusion: These findings show that composite control of modifiable risk factors has a larger effect in DM compared to non-DM, but the effect was not sufficient to bring CAD risk in DM below that for non-DM persons with none of 3 risk factors being at target based on current target levels.

Adjusted HRs (95% CI) for CAD events among persons with and without DM according to individual and composite risk factor targets achieved

events/n	Non-DM (200/207,029)	DM (91/13,471)
	Adjusted HR (95% CI)	Adjusted HR (95% CI)
No. risk factors with target achieved		
None	Ref	Ref
Any one target achieved vs. none	0.79 (0.58-1.07)	0.61 (0.37-0.996)
Any two targets achieved vs. none	0.63 (0.41-0.96)	0.51 (0.30-0.89)
All three targets achieved vs. none	NA	0.28 (0.10-0.80)
None	Ref	1.98 (1.28-3.07)
Any one target achieved	0.77 (0.57-1.05)	1.03 (0.68-1.66)
Any two targets achieved	0.60 (0.39-0.91)	0.81 (0.51-1.30)
All three targets achieved	NA	0.49 (0.18-1.45)

Adjusted for age, sex, BMI, HDLC, current smoking, antihyperglycemic drug therapy, antihypertensive drug therapy and antihyperlipidemic drug therapy.

Target levels were blood pressure <130/80 mmHg, LDL-Cholesterol <3.1 mmol/L, and HbA1c l <7%.

The use of computer simulation modelling to estimate complications in patients with type 2 diabetes: validation of the cornerstone diabetes simulation model

Z.T. Su[1], L. Sauriol[2], J. Bartelt-Hofer[3], S. Brown[1], E. Lew[3], L. Annemans[4], D.T. Grima[1];
[1]Cornerstone Research Group, Burlington, Canada, [2]Sanofi, Laval, Canada, [3]Sanofi, Chilly-Mazarin, France, [4]Ghent University, Ghent, Belgium.

Background and aims: Decision analytic models aim to extend clinical trial (CT) findings to predict long-term outcomes, compare alternative therapies, and test exploratory scenarios. This requires credible models, as such the ability of models to predict long-term complications and mortality should be validated as suggested by the American Diabetes Association (ADA) guidelines for diabetes computer modelling. This study aimed to validate the Cornerstone Diabetes Simulation Model (CDSM), a Microsoft Excel-based, non-product specific, patient level simulation for type 2 diabetes mellitus (T2DM) based on the revised United Kingdom Prospective Diabetes Study Outcomes Model (UKPDS-OM2, aka UKPDS82) risk equations, following the ADA guidelines for diabetes computer modelling.
Materials and methods: Three levels of validation were conducted. Internal validation was assessed through independent review and model stress-testing. External validation was addressed by populating the CDSM with baseline characteristics and treatment effects from 4 major diabetes CTs that were used in the 5th Mount Hood Diabetes Challenge (MH5) for computer simulation models; simulated vs. observed clinical outcomes were compared via coefficient of determination (R^2). Cross-validation of predicted outcomes was tested vs. 8 diabetes models that participated in the MH5. Results are presented for the absolute risk of each clinical outcome and the difference in absolute risk between control and intervention arm in each CT.
Results: There were 45 single and composite endpoints across the 4 CTs. The CDSM could predict 18 of these endpoints, including 15 for macrovascular complications (myocardial infarction, stroke, congestive heart failure, ischemic heart disease, and composite endpoints based on these events) and 3 for all-cause mortality. While the CDSM could predict renal failure, blindness, amputation, and ulcer, it could not predict any CT-specific microvascular complications due to differences in event definitions. Compared to other diabetes models, the CDSM achieved a high level of validity in predicting all endpoints (R^2 0.637), macrovascular complications (R^2 0.822), and all-cause mortality (R^2 0.975). The CDSM ranked in the top 4 of all models in predicting absolute risks for all endpoints, macrovascular complications, and all-cause mortality. The CDSM performed especially well in predicting risk differences for all endpoints and macrovascular complications (Table).
Conclusion: The CDSM for T2DM provides good prediction of diabetes-related complications when compared to actual CT outcomes and alternative models. Future research to assess predictions of costs and cost-effectiveness would complement this validation and provide useful information for decision-makers to optimize health resource allocation.

Table. Summary of external validation and cross-validation results for diabetes clinical trials and simulation models reported in the Fifth Mount Hood Diabetes Challenge.

	All endpoints		Macrovascular complication endpoints		All-cause mortality endpoints		Other endpoints

Prevalence of undiagnosed diabetes and hypertension in high-risk adults across Europe: Feel4Diabetes study

G.E. Dafoulas[1], O. Androutsos[2], C. Mavrogianni[2], C.-P. Lambrinou[2], S. Liatis[1], G. Cardon[3], J. Lindstrom[4], V. Iotova[5], T. Tankova[5], R. Mateo-Gallego[6], L.A. Moreno[7], C. Semanova[8], M. de Sabata[9], K. Makrilakis[1], Y. Manios[2];
[1]National and Kapodistrian University of Athens, Athens, Greece, [2]Department of Nutrition and Dietetics, Harokopio University, Athens, Greece, [3]Department of Movement and Sport Sciences, Ghent University, Ghent, Belgium, [4]National Institute for Health and Welfare, Helsinki, Finland, [5]Department of Pediatrics, Medical University Varna, Varna, Bulgaria, [6]Instituto Investigacion Sanitaria Aragon (IISA), CIBERCV, Zaragoza, Spain, [7]Universidad De Zaragoza, Zaragoza, Spain, [8]University of Debrecen, Department of Family and Occupational Medicine, Debrecen, Hungary, [9]International Diabetes Federation European Region, Brussels, Belgium.

Background and aims: The prevalence of type 2 diabetes (T2D) and hypertension has increased rapidly in recent decades and this trend will continue as the global population ages. Since these chronic diseases have an asymptomatic preclinical phase, the prevalence of undiagnosed cases is also of clinical and public health concern. The present study presents the prevalence of undiagnosed diabetes and hypertension using the baseline data obtained from the Feel4Diabetes study, which is an ongoing school- and community-based intervention aiming to tackle obesity and obesity-related metabolic risk factors among families from vulnerable groups in six European countries (i.e. Belgium, Bulgaria, Finland, Greece, Hungary, Spain).
Materials and methods: In total 24,306 adults (parents of primary school children in selected municipalities) were screened for their diabetes risk using the FINDRISC questionnaire. The adults with increased risk were invited and about 3,000 participated in a medical check-up, including the assessment of fasting blood glucose levels and blood pressure.
Results: The population of the current work was 2,443 adults (mean age 41.2 ± 5.5 years, 64.7% females) with available data for all the variables used in the current analysis. The distribution of subjects in the following FINDRISC score categories <10, 10–14 and ≥15, was 38%, 48% and 14% respectively. The prevalence of self-reported diabetes diagnosis was 3.3%, while among participants without diagnosed diabetes the prevalence of undiagnosed diabetes based on fasting glucose levels ≥126 mg/dl was 1.7%, ranging from 0.8% and 1.4% to 5.5% for participants with FINDRISC score <10, 10–14 and ≥15, respectively. A large percentage (36.4%) of adults with diabetes was undiagnosed. Regarding blood pressure (BP), medication-treated hypertension was reported by 8.2% of adults while among the remaining participants the prevalence of systolic BP ≥140 mmHg and/ or diastolic BP ≥90 mmHg was 15.6%, ranging from 12.1% and 18.2% to 18.6% for participants with FINDRISC score <10, 10–14 and ≥15, respectively. A large percentage (63.7%) of adults with hypertension was undiagnosed.
Conclusion: Considering the young age of this population, the current study revealed a relatively high prevalence of undiagnosed diabetes and hypertension in low-middle income countries and in low socioeconomic status municipalities in high income countries.

A high glucose visit-to-visit variability is associated with a poor metabolic profile in individuals in the Hoorn Diabetes Care System cohort

R.C. Slieker[1,2], A.W.A. van der Heijden[3], P.J.M. Elders[3], G. Nijpels[4], L.M. 't Hart[1,5], J.W.J. Beulens[6,7];
[1]Cell and Chemical Biology, Leiden University Medical Center, Leiden, [2]Department of Epidemiology and Biostatistics, VU University Medical Center, Amsterdam, [3]Department of General Practice and Elderly Care Medicine, VU University Medical Center, Leiden, [4]Department of General Practice and Elderly Care Medicine, VU University Medical Center, Amsterdam, [5]Molecular Epidemiology, Leiden University Medical Center, Leiden, [6]VU University Medical Center, Amsterdam, [7]Julius Center for Health Sciences and Primary Care, Utrecht, Netherlands.

Background and aims: The disease trajectory of individuals with type 2 diabetes is characterized by dynamic glycaemia. Previous studies have identified glycaemic variation as a risk factor for diabetes-related complications. Here we aimed to identify determinants of glycemic visit-to-visit variability within individuals with type 2 diabetes.
Materials and methods: Individuals with type 2 diabetes ($n = 6770$) from the Hoorn Diabetes Care System cohort were included in this study when they had at least five years follow-up data and an age of onset over 35 years. Measurements within the first six months after diagnosis were excluded to reduce the first treatment effect. The coefficient of variation (CV, σ/μ) was used for the visit-to-visit variability of fasting glucose (FG). CVs were calculated over 5-year sliding interval (I), that is over 1–5 years, 2–6, $n–n + 5$ years until the end of the follow-up. Intervals were aligned based on the diabetes duration and within the interval divided in glucose-CV quintiles (Q). The 5-year average triglycerides, HDL, BMI and the age of disease onset and any insulin use were tested against the quintiles using an ANOVA with adjustment for (the interval average) of glucose, sex, smoking, systolic blood pressure, BMI and use of antihypertensive agents.
Results: Individuals with low or high FG-CV largely remained in the same quintile across their follow-up, i.e. 74.4% had at least 50% of their intervals (I) in one quintile and 72.0% had at least 75% of their intervals in two adjacent quintiles. No difference was observed between sexes, in FG-CV at any time point ($P_{bonf} > 0.05$). Individuals with a high FG-CV were those with an early age of diabetes onset ($I_{1\text{-}12,14}$, average difference between Q5 and Q1 ($D_{Q5\text{-}Q1}$) -3.9 years, $P_{bonf} \leq 0.01$). A high FG-CV was associated with a higher BMI ($I_{1\text{-}11,15\text{-}20}$, $D_{Q5\text{-}Q1} = +2.7$ kg/m^2, $P_{bonf} \leq 0.05$). Higher FG-CV was associated with an unfavourable lipid profile, i.e. lower levels of HDL in individuals with high FG-CV ($I_{1\text{-}20}$, −0.2 mmol/L, $P_{bonf} \leq 0.05$) and higher triglycerides levels ($I_{1\text{-}14,16,17,19,20}$, $D_{Q5\text{-}Q1} = +0.3$ mmol/L, $P_{bonf} \leq 0.05$). For total cholesterol, blood pressure and eGFR, no consistent associations were observed across quintiles. Also, individuals in Q5 versus Q1 showed a higher risk of insulin initiation (HR = 4.07, CI: 3.07–5.40, $P < 0.0001$). In line with that, individuals with high variation were often on insulin with ORs ranging from 19.4 (95%CI = 12.9–30.6, $P = 2.1 \cdot 10^{-39}$) in the first interval to 17.5 (95%CI = 6.0–58.4, $P = 5.9 \cdot 10^{-05}$) in the 20th interval.
Conclusion: Individuals with higher a glucose visit-to-visit variability tend to have a less favorable metabolic profile and are at increased risk of insulin initiation. Whether glucose visit-to-visit variability adds to prediction of vascular complications needs to be further investigated.

Diabetes prevalence, mortality and healthcare expenditure in 2017 and 2045 in Europe: data from the IDF Diabetes Atlas

S. Karuranga[1], Y. Huang[1], A. F Moura[1], W. Rathmann[2], B. Malanda[1];
[1]International Diabetes Federation, Brussels, Belgium, [2]German Diabetes Center, Düsseldorf, Germany.

Background and aims: Diabetes is among the leading causes of death in the IDF Europe Region (EUR), imposing high human, social and economic costs. Therefore, robust estimates of its prevalence are required for effective allocation of resources. The International Diabetes Federation

(IDF) Diabetes Atlas illustrates the continuing burden of diabetes estimates and projections in this region. Aim: To estimate diabetes prevalence, mortality and health care expenditure in the IDF Europe Region (EUR) for the years 2017 and 2045.

Materials and methods: A total of 63 population-based, high-quality data sources from 35 countries were used to generate age- and sex-specific adult diabetes prevalence for the 57 countries in the IDF Europe Region (EUR). Countries without good quality data sources were extrapolated based on data from countries with similar geography, economics and ethnicity. The UN population projections in 2045 were used to project the diabetes prevalence in 2045 for each country.

Results: Approximately 66 million people, 9% of the population aged 18–99, were living with diabetes in the IDF Europe region in 2017. This represents 1 in 11 adults living with diabetes. The age-adjusted prevalence was 6.7% (5.4–9.7%). About 38% of those people living with diabetes were estimated to be undiagnosed. If the trend continues, the number of people with diabetes is projected to reach 81 million in 2045 in the IDF Europe region. The 5 countries with the highest diabetes prevalence were Russian Federation, Germany, Turkey, Spain and Italy. In addition, a further 41 million people, 5.6% of the adult population, were estimated to be living with impaired glucose tolerance (IGT). The number of deaths attributed to diabetes from age 18 to 99 years was about 693,000 in 2017. The total healthcare expenditure related to diabetes was USD 208 billion, representing 25% of the expenditure worldwide.

Conclusion: Our findings demonstrate that diabetes exerts a heavy burden in European Region. Effective management programs should focus on diabetes prevention, in order to avoid harmful and costly consequences in the coming decades.

BMI z-score trajectories in youth with type 1 diabetes: an international analysis from Australia, Germany/Austria and USA

A. Schwandt[1,2], N. Foster[3], H. Phelan[4], C. Steigleder-Schweiger[5], M. Wu[3], J.J. Couper[6], P. Kroschwald[7], S.M. Willi[8], T.W. Jones[9], N. Prinz[1,2], D. Maahs[10], M.E. Craig[11];

[1]Institute of Epidemiology and Medical Biometry, ZIBMT, University of Ulm, Ulm, Germany, [2]German Center for Diabetes Research (DZD), Munich-Neuherberg, Germany, [3]Jaeb Center for Health Research, Tampa, USA, [4]John Hunter Children's Hospital, Newcastle, Australia, [5]Department of Pediatrics, Paracelsus Medical University, Salzburg, Austria, [6]Department of Diabetes and Endocrinology, Women's and Children's Hospital, and University of Adelaide, Adelaide, Australia, [7]Ruppiner Clinics, Department for Pediatrics and Adolescent Medicine, Neuruppin, Germany, [8]Children's Hospital of Philadelphia and Perelman School of Medicine at the University of Pennsylvania, Philadelphia, USA, [9]Department of Diabetes and Endocrinology, Princess Margaret Hospital, and Telethon Kids Institute, Western Australia, Australia, [10]Stanford University, Stanford, USA, [11]Institute of Endocrinology, Childrens Hospital Westmead, and University of Sydney, Sydney, Australia.

Background and aims: Data on individual change in BMI during puberty are limited in T1D cohorts. We aimed to analyze international differences in individual BMI z-score (BMIz,WHO) patterns over time among youth with T1D.

Materials and methods: Longitudinal data from 11,513 youth from the Australasian Diabetes Data Network (N_{ADDN} = 1073, female: 46%), German/Austrian Diabetes Prospective Follow-up (N_{DPV} = 8722, 46%), and US T1D Exchange registry (N_{T1DX} = 1718, 45%) were examined. Subjects with follow-up from age 8–17 years, T1D duration >1 year and >5 aggregated BMI values were included. Children with celiac or thyroid disease were excluded. Latent class growth modeling (PROC TRAJ) was applied to identify distinct BMIz trajectories.

Results: International BMIz trajectories are presented in the figure. The most dramatic BMIz change during puberty were observed in DPV. Obese subjects (BMIz ≥2) from ADDN had a BMI decrease over time, while obese individuals in T1DX exhibited decreasing BMIz from age 8 to 12 years, followed by increasing BMIz during puberty. Comparing the reference group (BMIz ~0) with the other groups, higher BMIz was associated with older age at T1D onset, racial/ethnic minority, elevated HbA1c and lower insulin pump use ($p < 0.05$). In DPV boys were more likely to follow a low BMIz or had a decreasing BMIz from childhood to young adulthood, whereas girls more often experienced pubertal BMIz increase. In ADDN, a preponderance of boys was found in lower and near-normal patterns, while elevated BMI trajectories were more likely in girls. However, in the T1DX data sex ratio did not differ.

Conclusion: In three registries, the majority of T1D youth have a BMI pattern above the age- and gender-specific norms. The large international and individual differences in BMIz trajectories among youth with T1D likely result from diverse genetic and therapeutic factors, and suggest the need for personalized treatment regimens that consider healthy weight in addition to glucose control.

Comparison of the incidence of diabetes in U.S. and Indian youth: an international harmonisation of youth diabetes registries

E.T. Jensen[1], D. Dabelea[2], P.A. Praveen[3], A. Anandakumar[4], C.W. Hockett[2], S. Isom[5], T.C. Ong[6], V. Mohan[4], R. D'Agostino, Jr.[5], M.G. Kahn[6], R.F. Hamman[2], E. Mayer-Davis[7], N. Tandon[3];

[1]Epidemiology and Prevention, Wake Forest School of Medicine, Winston-Salem, USA, [2]Epidemiology, University of Colorado, Denver, USA, [3]All India Institute of Medical Sciences, New Delhi, India, [4]Madras Diabetes Research Foundation, Chennai, India, [5]Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, USA, [6]Pediatrics, University of Colorado, Denver, CO, USA, [7]Nutrition, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA.

Background and aims: Diabetes in youth has increased in both India and the United States (U.S.). To date, few data exist for comparing population-based estimates of the burden of diabetes in contemporary youth cohorts in the U.S. and India. Such comparisons not only offer context for understanding the relative burden of disease, but may also provide insight into the pathogenesis of diabetes.

Materials and methods: We harmonized data elements from the SEARCH for Diabetes in Youth registry (SEARCH) from five sites in the U.S. and the Registry of People with Diabetes with Youth Age at Onset (YDR - Chennai and New Delhi regions) in India to the structure and terminology in the Observational Medical Outcomes Partnership (OMOP) Common Data Model (v5). Data analyzed were from youth with incident type 1 (T1D) and type 2 (T2D) diabetes cases age <20 diagnosed between 2006 and 2012. Denominators were obtained from Census data for the demographic regions corresponding to the registry case ascertainment areas. We compared diabetes incidence across registries by type and within age and sex categories using a 2-sided, skew-corrected inverted score test.

Results: Overall, the incidence of both T1D and T2D was significantly higher in SEARCH as compared to YDR (Table). Age at peak incidence of T1D was similar across registries, whereas T2D incidence was higher at an earlier age in SEARCH. Comparing the incidence of T1D in Asian

and Pacific Islanders (API) in SEARCH to the overall incidence of T1D in YDR, the difference in rates was reduced (7.8 [95% CI: 5.2, 11.8] in SEARCH vs 4.0 [95% CI: 3.6, 4.5] in YDR). Sex and age differences existed, with a higher rate of T2D among females in SEARCH (7.5/100,000, females vs 4.4/100,000. males) as compared to YDR, where the distribution of T2D by sex was similar in YDR (0.5/100,000, females vs 0.4/100,000, males) (Table).

Conclusion: Comparison of India-based and U.S.-based youth-onset diabetes registries indicated that the incidence of T1D and T2D in youth was significantly different. The proportion of females with T2D was higher in SEARCH and the age distribution at diagnosis for T2D was older in YDR. Examination of the distribution of risk factors for T2D is needed to elucidate whether the differences observed represent a diagnostic delay or differences in distribution of risk factors.

Table. Average annual incidence rates (per 100,000 per year) by type and, within type, by sex, age at diagnosis

Prevalence of pre-diabetes, undiagnosed and diagnosed diabetes among adults aged 18 to 70 years in France: the CONSTANCES cohort

S. Fuentes[1], S. Fosse-Edorh[1], N. Regnault[1], M. Goldberg[2,3], E. Cosson[4,5];
[1]Santé Publique France, Paris, France, [2]INSERM UMS 11, Population-based Epidemiological Cohorts Unit, Villejuif, France, [3]Paris Descartes University, Paris, France, [4]Direction de maladies non transmisibles, Department of Endocrinology-Diabetology-Nutrition, AP-HP, Jean Verdier Hospital, Paris 13 University, Sorbonne Paris Cité, CRNH-IdF, CINFO, Bondy, France, [5]Sorbonne Paris Cité, UMR U1153 Inserm/U1125 Inra/Cnam/Université Paris 13, Bobigny, France.

Background and aims: There is a lack of knowledge on rates of pre-diabetes and undiagnosed diabetes. This study aimed to update the prevalence of different dysglycemic states in France among adults aged 18 to 70 years according to gender, age, body mass index (BMI - kg/m^2-) categories and socioeconomic status.

Materials and methods: The CONSTANCES cohort is a randomly selected representative sample of French adults. In 2013, 16,340 participants were recruited. Based on data from self-administered questionnaires , medical examination (including fasting plasma glucose (FPG) measurement) and data from the French National Health Insurance Information System(antidiabetic drugs consumption and hospitalization), three states were defined: pre-diabetes (WHO definition), diagnosed and undiagnosed (FPG ≥126 mg/dL) diabetes. Weighted prevalence of each dysglycemic state was estimated for all population and by gender, age, BMI categories and educational level. Confidence intervals were calculated using logit transformation.

Results: In 2013, the prevalence of pre-diabetes, undiagnosed diabetes and diagnosed diabetes was 7.4%, 1.9% and 3.9%, respectively. All these rates were higher in males, increased steadily with age and BMI category, while decreasing with education (Figure).

Conclusion: Our results show that the prevalence of prediabetes and unknown diabetes are still very high in developed countries, like France. They highlight the need to increase primary prevention, and to reinforce secondary prevention of diabetes, especially through promotion of screening in population at risk.

DIAGESTCAT. Trends in prevalence of diabetes in pregnancy and perinatal outcomes: a large, population-based study in Catalonia, Spain, 2006–2015

L. Gortazar[1], A. Goday[1,2], D. Benaiges[1,2], E. Sarsanedas[1], L. Mañé[1], G. Llauradó[1,2], J.J. Chillarón[1,2], M. Prados[1], A. Paya[3], J.A. Flores[1,2];
[1]Department of Endocrinology and Nutrition, Hospital del Mar, Barcelona, Spain, [2]Department of Medicine, Universitat Autònoma de Barcelona, Campus del Mar, Barcelona, Spain, [3]Department of Gynecology and Obstetrics, Hospital del Mar, Barcelona, Spain.

Background and aims: There are no recent epidemiological studies of Diabetes Mellitus (DM) in Pregnancy in Catalonia. Our aims were to explore trends in the prevalence of diabetes in pregnancy and examine whether the risk of adverse perinatal outcomes has changed during the period of 2006–2015 in Catalonia.

Materials and methods: Retrospective epidemiological study about prevalence of DM and pregnancy in Catalonia. All hospital admissions for singleton births during the study period were collected from The Minimum Basic Data Set for Hospital Discharge. Cases of Gestational Diabetes (GDM), type 1 DM (T1DM) and type 2 DM (T2DM) were identified in every hospital delivery discharge report using ICD-9-MC codes. Data regarding maternal characteristics and obstetric complications (pre-eclampsia, prematurity, macrosomia, Large for gestational age (LGA), small for gestational age (SGA) and caesarean deliveries) were analysed. Crude and age-adjusted annual prevalences were calculated for every DM type. Poisson regression model was used to assess trends in prevalence and in obstetric outcomes during the study period, adjusting for age.

Results: Data from 743,762 hospital deliveries were collected. From 2006 to 2015, there was an increase in crude and age-adjusted prevalence of GDM, T2DM and T1DM. A rising in crude and age-adjusted rates of pre-eclampsia was observed in non diabetic, T2DM and T1DM during the study period. Prematurity only showed and increasing rate in women

without DM. An increment in cesarean deliveries was detected in non-diabetic and GDM but none of them was statistically significant when adjusted for age. We observed a decrease in crude and age-adjusted rates of macrosomia during the study period in non-diabetic and in all diabetes categories but a reduction of LGA was only observed in non-diabetic women and T2DM. The rates of SGA decreased in non-diabetic women, no significant changes were detected for any type of DM.

Conclusion: Prevalences of T1DM, T2DM and GDM have progressively increased during the study period in Catalonia. There has been a decrease in some of the adverse maternal-fetal outcomes.

Regional burden of obesity and diabetes in adults: projections from 2017–2045

S. Nielsen[1], D. Napier[2], B.B. Jensen[3], A. Moses[4], N. Lund[1];
[1]Health Advocacy, Novo Nordisk A/S, Bagsværd, Denmark, [2]University College London, London, UK, [3]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [4]Novo Nordisk Inc, Plainsboro, NJ, USA.

Background and aims: Obesity and type 2 diabetes (T2D) are rising at alarming rates. T2D is a complex disease influenced by multiple diverse factors and long delays between causes and effects. The most significant modifiable driver of T2D is excess bodyweight. Currently, around 650 million people worldwide have obesity and more than 400 million have diabetes. To support the WHO target 7 "Halt the rise in diabetes and obesity" we have previously demonstrated that targeting a global diabetes prevalence stabilised at 10% by 2045 requires 25% reduction of obesity prevalence. The study is part of Cities Changing Diabetes established to improve the understanding of diabetes in urban settings. It is a partnership between Novo Nordisk, Steno Diabetes Center Copenhagen, University College London and local partners. The study shows how regional prevalence of T2D is affected from 2017 to 2045 in a *past trend* scenario assuming that future increase in obesity prevalence is extrapolated linearly and in a *target* scenario assuming that obesity prevalence is reduced by 25% in 2045.

Materials and methods: BMI data for all countries in the world 2000–2014 were obtained from the Non-communicable Disease Risk Factor Collaboration. For each country the adult population was divided into age and BMI groups and share of people in each BMI class was projected depending on scenario. Risks of T2D for age and BMI obtained from the literature were applied allowing estimates of prevalence of T2D for each country each year.

Results: North America and Caribbean (NAC) shows the highest current obesity and T2D prevalence (35.7% and 13.2%) and continues to do so in 2045 in both *past trend* (51.5% and 16.8%) and *target* scenario (26.8% and 13.1%). The *target* scenario results in 15.3 million fewer people with T2D in 2045 compared to *past trend* scenario. Despite moderate current obesity prevalence (9.0%) Africa (AFR) shows the lowest current T2D prevalence (3.3%) and this pattern persists in 2045 for *past trend* (16.4% and 4.2%) and *target* scenario (6.4% and 3.5%). In this region, 7.2 million fewer people have T2D in 2045 if the current obesity prevalence is reduced by 25%.In contrast, the lowest current obesity prevalence is found in South-East Asia (SEA) (4.0%) despite relatively high current T2D prevalence (8.7%). This tendency proceeds in 2045 for *past trend* (7.9% and 12.0%) and *target* scenario (3.1% and 10.7%) resulting in 17.1 million fewer people with T2D in 2045 in *target* compared to *past trend* scenario. AFR is the most dynamic with growth of people with T2D in 2045 between 150 and 180% while Europe (EUR) which has a high prevalence of obesity and T2D (26.3 and 9.2%) is the most stable with growth between 23 and 3% depending on scenario. Share of people with T2D also suffering from obesity differs substantially among regions. In NAC 60% of people with T2D also have obesity while it is only 10% in SEA.

Conclusion: NAC and EUR where obesity has been on the rise for decades have the highest T2D prevalence but also the slowest future increases. In regions with lower T2D prevalence like AFR, the number of people with T2D will increase up to three fold in the coming three decades unless obesity prevalence is reduced. To realise the *target* scenario, health should be integrated into all policies in order to contribute to reduce the obesity and T2D burden. Not doing so represents a lost opportunity to improve peoples' health, well-being and economic productivity.

PS 003 Type 2 diabetes prediction

281

Are the normal glucose tolerance individuals totally outside of the diabetes spectrum?

A.F. Pina[1,2], R.S. Patarrão[1,3], R.T. Ribeiro[4,5], C. Penha-Gonçalves[3], J.F. Raposo[1,5], R.M. de Oliveira[1], L. Gardete-Correia[5], R. Duarte[5,6], J.M. Boavida[5], R. Andrade[5], I. Correia[5,6], J.L. Medina[6], R. Henriques[7], M. Macedo[1,5];
[1]CEDOC-NOVA Medical School, Lisbon, Portugal, [2]Departamento de Ciências Médicas, Universidade de Aveiro, Aveiro, Portugal, [3]IGC - Instituto Gulbenkian e Ciência, Lisbon, Portugal, [4]Departamento de Ciências Médicas, Universidade de Aveiro, Lisbon, Portugal, [5]APDP - Associação Protectora dos Diabéticos de Portugal, Lisbon, Portugal, [6]SPD - Sociedade Portuguesa de Diabetologia, Lisbon, Portugal, [7]NovaIMS - Nova Information Managment School, Lisbon, Portugal.

Background and aims: Type 2 diabetes (T2D) and prediabetes (PD) glycemia cut-off values are established by convention, and for the latter there is no agreement about fasting glycemia cut-off values. Some normal glucose tolerant individuals (NGT's) presents a higher risk of developing diabetes and its micro and macrovascular complications. In the PD group there are cases that don't progress to T2D. Glycemia, *per si*, is insufficient to an accurate diabetes risk assessment and diagnosis. Also, association of multiple factors, involved in T2D pathophysiology, can lead to diverse phenotypes. Cluster analysis, as Self Organizing Maps (SOM), is used to identify populations patterns. Analyzing complex data, identifies clusters, highlighting relevant data structures to the understanding of the aggregation. We hypothesize that by analyzing glycemia levels, not considering the predefined cut-offs, together with parameters classically associated with T2D, will reveal novel clusters, reflective of different pathological phenotypes.
Materials and methods: We applied cluster analysis to 1010 individuals, from PREVADIAB2 cohort (Portuguese Diabetes Prevalence Study: 73% NGT, 22% PD and 5% diabetic). We first reduced data to 27 units, applying superSOM algorithm, using variables distributed over 8 grids (g1 - Glycemia OGTT profile, g2 - Insulin OGTT profile, g3 - C-peptide OGTT profile, g4 - Insulin clearance OGTT profile, g5- free fatty acids OGTT profile, g6- Fasting cholesterol LDL, HDL, triglycerides, g7-HOMA IR, HOMA B, g8 - BMI, waist circumference). The units were analysed and clustered (hierarchical clustering algorithm, in R).
Results: We found 10 clusters with different C peptide, insulin levels and insulin *clearance* along the OGTT (0′, 30′ and 120′). Most of the clusters group together NGT, PD and diabetic individuals. However, there are clusters where the majority are NGT, while others group a greater proportion of hyperglycemic people. The proportions differ with the profile patterns. We found diabetic patients in 5 clusters, which differ in parameters classically associated with T2D.
Conclusion: We found cluster with different insulin, C-peptide and insulin clearance profiles, not based solely on glycemia. Surprisingly, most clusters group together NGT, PD and diabetic individuals. We know that there are individuals with prediabetes that already show T2D-assocaited microvascular complications, while others never progress in the disease spectrum. In the same line of thought, and in view of our results, are the NGT, who we found to group together with a greater proportion of hyperglycemic individuals, totally outside of the diabetes spectrum? Cluster analysis reveals new risk factors for the NGT individuals. These clusters can represent different phenotypes and contribute to clarify the pathophysiological mechanisms responsible for glycemia changes that will imprint a precision medicine approach.

A simple clinical risk score in detecting diabetes in the Chinese populations: insights from two population-based Chinese cohorts

Y.C. Woo[1], B. Gao[2], C.H. Lee[1], C.H.Y. Fong[1], J. Ming[2], S. Lin[1], T.H. Lam[3], E. Janus[4], Q. Ji[2], K.S.L. Lam[1];
[1]Department of Medicine, The University of Hong Kong, Hong Kong, Hong Kong, [2]Department of Endocrinology, Fourth Military Medical University, Xi'an, China, [3]Department of Public Health, The University of Hong Kong, Hong Kong, Hong Kong, [4]Department of General Medicine, University of Melbourne, Melbourne, Australia.

Background and aims: Diabetes is a major health problem in China. Early diagnosis and intervention should be beneficial for prevention of diabetes-related complications. We aim to develop and validate a simple clinical parameter-based diabetes risk score by two independent Chinese cohorts.
Materials and methods: 3132 subjects (age 18–84) without known diabetes who had oral glucose tolerance tests (OGTT) performed during the China National Diabetes and Metabolic Disorders Study in Shaanxi Province (Shaanxi cohort) were investigated for risk factors independently associated with diabetes by multiple logistic regression analysis. The risk factors identified were used to develop a categorisation point scoring system, the Chinese Diabetes Score (CDS). The application of CDS for diabetes screening was validated in 2694 subjects without known diabetes (age: 25–74) assessed at the baseline visit of the Hong Kong Cardiovascular Risk Factors Prevalence Study (Hong Kong cohort). The area under the receiver operating characteristic curve (AUROC) of CDS was calculated to assess the accuracy of the model. The optimal cut-off of CDS was determined by Youden's index. Diabetes was defined as fasting glucose ≥7 mmol/L or 2 hours post OGTT glucose ≥11.1 mmol/L.
Results: Among the Shaanxi cohort, 229 (7.31%) subjects were screened to have diabetes. Age (O.R. 1.05, $P < 0.05$), family history of diabetes (O.R. 1.62, $P < 0.05$), hypertension (O.R. 1.42, $P < 0.05$) and body mass index (O.R. 1.14, $P < 0.05$) were independently associated with diabetes and were included in the CDS. The CDS showed good accuracy in detecting diabetes with an AUROC at 0.752. Subjects with ≥17 points out of 47 were considered at risk of having diabetes. Validation of CDS in the Hong Kong cohort also showed good accuracy (AUROC 0.804). The CDS showed good negative predictive value when applied to both cohorts (Shaanxi 97.5%, Hong Kong 98.1%). The sensitivity (82.1 vs. 86.5) and specificity (55.5 vs. 54.5) of the model was comparable when used in Shaanxi and Hong Kong. Applying the CDS, 8 subjects were needed to screen to detect one case of diabetes in both regions.
Conclusion: The CDS is an effective screening tool for Chinese residing in northwest (Shaanxi) and southern (Hong Kong) China. The difference in geographic location and composition of rural and urban subjects appear to have minimal impact on the performance of the CDS. It involves only four clinical parameters and can be adopted as a public health strategy for identifying Chinese individuals with undiagnosed diabetes for early intervention.

The predictive role of endothelial progenitor cells and asymmetric dimethylarginine in the onset of type 2 diabetes: a 10-year prospective study

A. Angelidi[1], A. Papazafiropoulou[1], A. Gritzapis[2], T. Sergentanis[3], E.-M. Tzouganatou[1], S. Papantoniou[1], E. Efstratiadi[1], S. Matsagos[4], P. Spyropoulou[4], J. Protopsaltis[1], E. Boutati[5], G. Dimitriadis[5], A. Melidonis[1];
[1]First Department of Internal Medicine and Diabetes Center, Tzanio General Hospital, Piraeus, Greece, [2]Department of Pathology, Locus-Medicus SA, Athens, Greece, [3]Department of Hygiene, Epidemiology and Medical Statistics, School of Medicine, National University of Athens, Athens, Greece, [4]Blood Bank Service, & Molecular Biology

Department, Tzanio General Hospital, Piraeus, Greece, [5]Second Department of Internal Medicine & Research Institute and Diabetes Center, "Attikon" University Hospital, Athens University Medical School, Athens, Greece.

Background and aims: Endothelial Progenitor Cells (EPCs) take part in postnatal neovascularization and promote vascular homeostasis. Asymmetric dimethylarginine (ADMA) is a major endogenous inhibitor of nitric oxide synthase. EPCs and ADMA have been associated with endothelial dysfunction, cardiovascular disease (CVD) and diabetic vascular complications. According to a hypothetical scenario, EPC alterations may precede and determine the development of both CVD and type 2 diabetes (T2DM). The aim of the present study is to investigate possible associations of EPCs, ADMA and other cardiometabolic risk factors with the development of T2DM.
Materials and methods: A total of 57 volunteers, without a previous history of a cardiovascular, renal or metabolic disease, undergone a 75 gr OGTT (42 subjects with prediabetes and 15 controls) and they were followed up for a 10-year period. All participants were retested after performing a new 75 gr OGTT. Several anthropometric and cardiometabolic risk factors (including HOMA-IR insensitivity index, high sensitivity-CRP) and the initial levels of EPCs and ADMA were determined in each participant both at baseline and at 10-year follow up of the study. Flow cytometry identified and quantified the EPCs (CD34+ CD133+ KDR+ cells), while ADMA levels were determined by immunoenzymatic method (ELISA). Statistical analysis was performed using SPSS 20.0 software.
Results: T2DM was developed in 30 participants from the prediabetes group and two subjects from the control group. The median age of the participants was 58.47 ± 11.28 years. Univariate analyses performed separately for all estimated parameters examining their association with the onset of T2DM. Parameters statistically associated with T2DM onset were included in the stepwise multivariate analysis. From the multivariate analysis statistically significant association was observed between the development of T2DM and age (OR: 1.052, 95% CI: 1.002–1.1104, $p < 0.001$), Body Mass Index (OR: 1.186, 95% CI: 1.065–1.322, $p = 0.003$), Impaired Glucose Tolerance (OR: 12.00, 95% CI: 2.944–48.907, $p = 0.001$), HbA1c (OR: 3.213, 95% CI: 1.575–6.555, $p = 0.006$), hypertension (OR: 10.267, 95% CI: 2.953–35.693, $p < 0.001$), ADMA (OR: 6.616, 95% CI: 2.676–16.356, $p < 0.001$) and EPCs (OR: 0.990, 95% CI: 0.984–0.995, $p = 0.001$).
Conclusion: According to the results of this 10-year prospective study, it appeared that in addition to the presence of some traditional risk factors, the incidence of T2DM was independently associated with ADMA and low EPC levels. These two parameters may reflect a disrupted pathophysiological microenvironment, which may precede and potentially associated with the more unfavorable cardiovascular profile of these individuals and the development of T2DM.

Mathematical modelling of glucose tolerance tests describing glucose, insulin and C-peptide levels in different cohorts: an IMI DIRECT study

C. Dings[1], N. Scherer[1], V. Nock[2], A.M. Hennige[2], E.R. Pearson[3], P.W. Franks[4], T. Lehr[1], for the IMI DIRECT consortium;
[1]Clinical Pharmacy, Saarland University, Saarbrücken, Germany, [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany, [3]Medical Research Institute, Ninewells Hospital and Medical School, University of Dundee, Dundee, Scotland, UK, [4]Department of Clinical Sciences, Genetic and Molecular Epidemiology Unit, Lund University, Sweden.

Background and aims: The oral glucose tolerance test (OGTT) and mixed meal tolerance test (MMTT) are well-established tests for the diagnosis and study of diabetes. However, comparing the resulting data, such as post challenge levels and AUCs of glucose and insulin, is impossible, as the amount of glucose intake differs between the two types of tests. To address this problem, we aimed to develop a mathematical model that simultaneously describes glucose, insulin and c-peptide levels during OGTT and MMTT and to estimate individual model parameters which allow comparison independently of the type of the tolerance test.
Materials and methods: The model was developed on data from the Diabetes Research on Patient Stratification (DIRECT) study using nonlinear mixed effects methods implemented in the software NONMEM (version 7.3.0). 2247 pre-diabetic as well as 821 recently diagnosed type 2 diabetic participants with frequently sampled OGTT and MMTT measurements, respectively, were included.
Results: The developed model simultaneously describes glucose, insulin and c-peptide using a one compartment turn-over model for each entity. The data was best described when oral glucose uptake was implemented as a transit model with a first-order absorption rate constant and one and two transit compartments for the OGTT and MMTT, respectively. Glucose utilization followed a second-order process. Endogenous glucose release was decreased exponentially by change in insulin levels. A hill function described the release of c-peptide and was multiplied by a bioavailability factor to describe the release of insulin, accounting for its pre-systemic hepatic clearance. The effect of incretin hormones influenced the hill function. C-peptide elimination followed a first-order, and insulin degradation a saturable process. The precision of all parameter estimates was excellent (relative standard error <17%). The population estimate for fasting glucose (FG) was 5.61 mmol/l and 7.07 mmol/l for the pre-diabetic and the diabetic participants, respectively. Fasting c-peptide was lower in the pre-diabetic population (808 vs 1010 pmol/l in diabetics). However, their maximum c-peptide release rate was higher (5630 vs 4110 pmol/l/h in diabetics). The insulin sensitivity was higher in the pre-diabetic population (54.2 vs 30.4 nmol/h in diabetics). FG measurements were used as a surrogate parameter for disease status. Especially the model parameters for insulin sensitivity and maximum c-peptide release depict the same trend when correlated against FG ($p < 0.0001$), indicating that they are meaningful and comparable descriptors of disease status.
Conclusion: A mathematical model describing OGTT and MMTT in prediabetic and diabetic participants was developed successfully. The derived model parameters of both populations show physiologically plausible differences, while their correlation to FG is similar. We will further test the parameters for their comparability, hopefully providing a powerful tool to identify disease status independently of the used tolerance test.

Performance of existing risk assessment models for prevalent or undiagnosed type 2 diabetes in a multi-ethnic population

M. Obura[1], I.G.M. van Valkengoed[2], L. 't Hart[1,3], S.P. Rauh[1], R.J. Peters[4], F. Rutters[1], M.B. Snijder[2], J.W.J. Beulens[1];
[1]Epidemiology and Biostatistics, VU Medical Center, Amsterdam, Netherlands, [2]Department of Public Health, Academic Medical Center, Amsterdam, Netherlands, [3]Molecular Cell Biology and Dept. of Molecular Epidemiology, Leiden University Medical Center, Leiden, Netherlands, [4]Department of Cardiology, Academic Medical Center, Amsterdam, Netherlands.

Background and aims: Different ethnicities have varying risks for type II diabetes mellitus (T2DM). Little is known about the performance of risk assessment models for prevalent (undiagnosed) T2DM in ethnicities other than the development population. We therefore aimed to identify existing models for the risk of prevalent or undiagnosed T2DM and externally validate them in a large multiethnic population.
Materials and methods: A systematic literature search in PubMed was performed until December 2017 to identify risk assessment models for

prevalent or undiagnosed T2DM. We cross-sectionally validated these scores in 4,547 Dutch, 3,035 South-Asian Surinamese, 4,119 African Surinamese, 2,326 Ghanaians, 3,598 Turkish, and 3,894 Moroccans from the HELIUS (Healthy LIfe in an Urban Setting) study carried out in Amsterdam. T2DM was defined as having fasting glucose level ≥7.0 mmol/l, and/or using glucose-lowering medication, and/or if the participant self-reported to have been diagnosed with diabetes by a health care professional. Model performance was assessed in terms of discrimination (C-statistic) and calibration (Hosmer-Lemeshow test).

Results: We identified 27 studies containing 30 risk assessment models for prevalent or undiagnosed T2DM. The prevalence of T2DM among the participants was 3.9% ($n = 179$), 22.2% ($n = 675$), 14.4% ($n = 593$), 14.4% ($n = 334$), 11.4% ($n = 410$) and 12.4% ($n = 482$) for Dutch, South-Asian Surinamese, African Surinamese, Ghanaians, Turkish, and Moroccans, respectively. The C-statistic varied between 0.77–0.92 among the Dutch, 0.66–0.83 in the South-Asian Surinamese, 0.70–0.82 in African Surinamese, 0.61–0.81 in Ghanaians, 0.69–0.86 in the Turkish and 0.69–0.87 in the Moroccan populations. The C-statistics were consistently lower among the Ghanaians, compared to other ethnicities. One model with Hba1c as a predictor had C-statistics varying between 0.92–0.98 across ethnicities. Calibration was poor (Hosmer-Lemeshow $p < 0.05$) for all models except one.

Conclusion: In general, existing risk assessment models show moderate to good discriminatory ability in different ethnic populations, but poor calibration. Furthermore, these models show heterogeneous discrimination per ethnicity.

Triglycerides, triglyceride-rich lipoprotein subfractions and genetic predisposition for type 2 diabetes in the Women Genome's Health Study (WGHS)

S. Ahmad, S. Mora, P.M. Ridker, F.B. Hu, D.I. Chasman;
Harvard University Boston, USA, Boston, MA, USA.

Background and aims: Higher triglyceride (TG) is an independent risk factor for the development of type 2 diabetes mellitus (T2DM). Previously genetic-susceptibility for TG has shown to be paradoxically protective for the development of T2DM and further a genetic risk score has shown interaction with baseline TG for incident T2DM. Whether such an interaction is present in our prospectively ascertained sample and the interaction pattern is selective with respect to TG-rich lipoprotein particle (TRLP) subfractions remains to be explored.

Materials and methods: The prospective sample of WGHS cohort consists of 15,813 participants with fasting status including 1453 incident T2DM cases. A weighted genetic risk score (TG-wGRS) was calculated based upon the 40-TG associated published genetic variants.

Results: The TG-wGRS was inversely associated with incident T2DM (HR 0.66, 95%CI (0.58, 0.75), P value ≤ 0.0001 per 10-TG associated risk alleles) when the Cox model was adjusted for baseline BMI, HDL-C and TG. TG was associated with higher risk of incident-T2DM in individuals within the low TG-wGRS tertile (HR [95%CI] = 1.98 [1.83, 2.14]) per mmol/L compared to the high TG-wGRS tertile (HR [95%CI] = 1.68 [1.58, 1.80] per mmol/L, $P_{interaction} = 0.0007$). Similarly, in TG-adjusted analysis, large and medium but not the small-TRLPs associated with higher T2DM-incidence in the low TG-wGRS tertile compared to the middle and higher TG-wGRS tertiles, $P_{interaction}$ = 0.014, 0.012 and 0.6203, respectively.

Conclusion: Our results confirm the original findings and further suggest that increased TG-risk for the incident-T2DM among low genetic risk individuals compared to higher TG-associated genetic risk individuals, and these interaction effects are mostly observed through larger TRLP subfractions.

A prospective study on fasting glucagon prior to OGTT and mixed meal and 7-year change of fasting glucose: the Hoorn Meal Study

A.D.M. Koopman[1], F. Rutters[1], M. Alssema[1,2], A. van der Heijden[3], P. Elders[3], J. Beulens[1,4], J. Dekker[1];
[1]Department of Epidemiology and Biostatistics, Amsterdam Public Health Institute, Amsterdam, Netherlands, [2]Unilever Research and Development, Vlaardingen, Netherlands, [3]Department of General Practice and Elderly Care, Amsterdam Public Health Institute, Amsterdam, Netherlands, [4]Julius Centre for Health Sciences and Primary Care, University Medical Centre Utrecht, Utrecht, Netherlands.

Background and aims: Several cross-sectional studies observed that abnormal glucagon responses already exist in individuals with impaired glucose tolerance. However, prospective data on elevated fasting glucagon levels possibly preceding glucose deterioration is limited.Therefore, the aim of this study was to examine the association of fasting glucagon preceding an oral glucose tolerance test (OGTT) and a mixed meal test (MTT) at baseline with changes in fasting glucose levels 7 years later, in individuals who were non-diabetic at baseline.

Materials and methods: We used data from the Hoorn Meal Study; a cohort study among 121 persons without diabetes (age 61.0 ± 6.7, 50% men), who were subjected to a 5-point 75 g-OGTT and 7-point MMT, in random order, at baseline. After 7 years, fasting glucose levels were determined. The association of fasting glucagon at baseline with fasting glucose levels after 7y, corrected for baseline glucose levels, age, sex, follow-up duration, BMI and fasting incretin levels, was determined using linear regression analysis.

Results: Median (IQR) fasting glucagon level prior to OGTT was 9.55 (3.4) pmol/l and prior to MTT, 8.81 (3.4) pmol/l. As this was systematically different, fasting glucagon was examined as the average of OGTT and MMT and separately for OGTT and MMT. Whether this is a chance finding or reflects anticipatory mechanisms needs to be evaluated. For OGTT, compared to the lowest tertile of fasting glucagon levels, those in the middle and highest tertiles had a higher change in fasting glucose levels at follow-up, respectively 0.17 (95%CI, −0.1; 0.4) and 0.14 (95%CI, −0.1; 0.4) mmol/l. For MMT, compared to the lowest tertile, those in the middle and highest tertiles had a change in fasting glucose levels of −0.11 (95%CI, −0.4; 0.1) and 0.06 (95%CI, −0.2; 0.3) mmol/l at follow-up. For fasting glucagon averaged for OGTT and MMT, for those in the middle and highest tertiles, compared to the lowest tertile, the change in fasting glucose levels at follow-up was 0.001 (95%CI, −0.2; 0.3) and 0.02 (95%CI, −0.3; 0.3) mmol/l.

Conclusion: Within our non-diabetic cohort, fasting glucagon levels at baseline were not associated with changes in fasting glucose levels after 7-year follow-up, suggesting that high fasting glucagon levels are not associated with glucose deterioration over time.

Plasma acylcarnitines and risk of type 2 diabetes in a Mediterranean population at high cardiovascular risk

M. Guasch-Ferré[1], M. Ruiz-Canela[2], J. Li[3], M. Bullo[1], D. Wang[3], E. Toledo[2], C. Clish[4], D. Corella[5], R. Estruch[6], E. Ros[6], M. Fitó[7], L. Liang[3], M.A. Martinez-Gonzalez[2], F.B. Hu[3], J. Salas-Salvado[1];

[1]Rovira i Virgili University, Reus, Spain, [2]Department of Preventive Medicine and Public Health, Pamplona, Spain, [3]Harvard TH Chan School of Public Health, Boston, MA, USA, [4]The Broad Institute, Cambridge, MA, USA, [5]University of Valencia, Valencia, Spain, [6]Hospital Clinic, Barcelona, Spain, [7]Hospital del Mar Research Institute (IMIM), Barcelona, Spain.

Background and aims: Elevated concentrations of acylcarnitine metabolites may be indicative of impaired β-oxidation and mitochondrial dysfunction and have been associated with insulin resistance and type 2 diabetes (T2D). We aimed to evaluate the associations between baseline and 1-year changes in acylcarnitines and their diabetes predictive ability beyond traditional risk factors in individuals at high cardiovascular risk.
Materials and methods: We designed a case-cohort study within the PREDIMED Study including all incident cases of T2D ($n = 251$) after a median of 3.8-years of follow-up, and a random subsample of participants free of diabetes at baseline with available metabolomics data (641 non-cases). Plasma acylcarnitines were measured using a targeted approach by LC-MS/MS. We tested the associations between baseline and 1-year changes in individual acylcarnitines and diabetes risk using weighted proportional hazards Cox regression models. We used elastic net regressions to select acylcarnitines for T2D prediction and compute a weighted score using a cross-validation approach. We evaluated the prediction capability of acylcarnitines beyond conventional risk factors.
Results: An acylcarnitine profile, especially including short-chain and long-chain, was significantly associated with a higher risk of T2D independent of traditional risk factors. The relative risk of T2D per SD increase of the predictive model score were 4.03 (95%CI, 3.36–4.83; $P < 0.001$) for the conventional model, and 4.85 (95%, 3.97–5.94; $P < 0.001$) for the model including acylcarnitines, with a HR of 1.33 (95%CI, 1.13–1.56; $P < 0.001$) attributed to the acylcarnitines. Although the area under the receiver operator characteristic curve improved only slightly after including acylcarnitines (0.86 to 0.88, $P = 0.53$), the net reclassification index (0.19 [95% CI, 0.03–0.34; $P = 0.02$]) and integrated discriminatory improvement (0.04 [95%CI 0.02–0.05]) were significantly improved. One-year increase in C4OH-carnitine was associated with higher risk of T2D after adjustment for potential confounders [per SD increase: 1.44 (1.03–2.01)].
Conclusion: An acylcarnitines profile, mainly including short- and long-chain acylcarnitines, was significantly associated with higher T2D risk in a Mediterranean population at high cardiovascular risk.

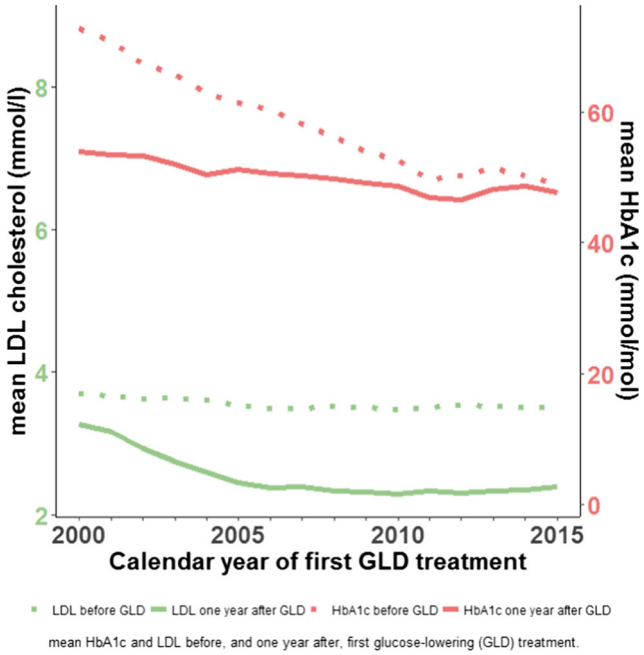
PS 004 Diabetes: therapeutic approaches

289

Improvements in HbA_{1c} and LDL-cholesterol in type 2 diabetes in Denmark, 2000–2015: a population based study

J.S. Knudsen[1], A. Hulman[2,3], D.R. Witte[2,3], R.W. Thomsen[1];
[1]Department of Clinical Epidemiology, Aarhus University Hospital, Aarhus University Hospital, Aarhus, Denmark, [2]Department of Public Health, Aarhus University, Aarhus, Denmark, [3]Danish Diabetes Academy, Odense, Denmark.

Background and aims: Guidelines for monitoring and treating LDL cholesterol and HbA_{1c} in adults with type 2 diabetes have changed in recent decades. The implementation of these guidelines in a clinical setting has not been properly documented. We examined 16-year time trends of blood lipid and HbA_{1c} testing, test results, and the use of lipid lowering drugs in people with type 2 diabetes in Denmark.
Materials and methods: Sequential population-based cross-sectional analysis. We used routine clinical care databases to identify all people living in Northern Denmark from 2000–2015 who initiated first (ever) glucose-lowering treatment (GLD) for type 2 diabetes ($n = 94{,}162$). Within one year following GLD start we assessed whether each patient: (1) had one or more HbA_{1c} tests; (2) had one or more blood lipid tests; (3) received any lipid lowering drug. For each calendar year 2000–2015, we examined pre-treatment HbA_{1c} and LDL cholesterol values, and post-treatment values achieved at 12 months after GLD start. We assessed the proportion of patients achieving post-treatment HbA_{1c} targets below 6.5% and 7%, and LDL values below 1.8 mmol/l and 2.0 mmol/l.
Results: The proportion of patients with at least one HbA_{1c} test within 12 months after GLD start increased from 53% in 2000 to 92% in 2015. The chance of having at least one blood lipid test increased from 82% to 98% and lipid lowering drug therapy within 12 months increased from 12% to 60%. The mean pre-treatment HbA_{1c} declined two percentage points (95% CI: −2.2; −2.0) from 8.8% to 6.6% between 2000 and 2015 (Figure 1). For the mean post-treatment HbA_{1c}, a much smaller decline was seen (−0.6 percentage point (95% CI: −0.7; −0.6), from 7.1% to 6.5%). Contrastingly, pre-treatment LDL cholesterol remained stable, but the mean post-treatment value declined by 1.0 mmol/l (95% CI: −1.0; −0.9) from 3.3 mmol/l to 2.4 mmol/l (Figure 1). From 2000 to 2015, the proportion of patients who achieved a post-treatment HbA_{1c} target <6.5% increased from 37% to 59% and for <7% increased from 54% to 83%. The proportion of patients achieving LDL cholesterol <1.8 mmol/L increased from 5% to 26% and for <2.0 mmol/l increased from 7% to 35%.
Conclusion: Monitoring and treatment of HbA_{1c} and LDL cholesterol in type 2 diabetes have improved substantially in the past 15 years. HbA_{1c} levels before first GLD therapy have decreased substantially and likely drive improvements in meeting HbA1c targets. In contrast, decreasing lipid levels over time are likely related to more intensive lipid lowering therapy.



Disclosure: **J.S. Knudsen:** None.

Socioeconomic factors, gender and adherence to lipid-lowering therapy in type 1 diabetes

C. Hero[1], S. Axia Karlsson[1], S. Franzén[2], A.-M. Svensson[2], M. Miftaraj[2], K. Andersson Sundell[1,3], S. Gudbjörnsdottir[1], B. Eliasson[1], K. Eeg-Olofsson[1];
[1]University of Gothenburg, Gothenborg, Sweden, [2]National Diabetes Register, Centre of Registers Västra Götaland, Gothenborg, Sweden, [3]AstraZeneca AB, Medical Evidence and Observational Research, Gothenburg, Sweden.

Background and aims: High adherence and persistence to lipid-lowering therapy (LLT) are important to reduce risk of cardiovascular disease (CVD) in patients with and without diabetes. The aim of this study was to assess the impact of socioeconomic factors and gender on the level of refill adherence and persistence to LLT in persons with type 1 diabetes (T1D).
Materials and methods: We included 6192 T1D persons, 18 years or older, registered in the Swedish National Diabetes Register who initiated novel use of LLT between 1 July 2006 and 31 December 2010. Information on socioeconomic factors were collected from Statistics Sweden and comorbidity from the National patient register. Age and income were divided into quartiles. Marital status was defined as married, single, divorced or widowed and education into compulsory school or lower, upper secondary and post-secondary school. Country of origin was born in Sweden or not. We followed the patients for 36 months estimating adherence to LLT after 18 months and 36 months, by calculating the medication possession ratio (MPR), i e. the proportion of days with medicines on hand, divided into two categories, MPR above 80% and MPR below or equal to 80%. Non-persistence, referred to as discontinuation, was defined as being without medication on hand for more than 180 days. A logistic regression was performed, the models were adjusted for gender, age, socioeconomic factors and previous CVD.
Results: Mean age was 45 ± 12 years and diabetes duration 30 ± 13.5 years. 57% were male. 9% had previous CVD. 93% were born in Sweden. 45% were married. 83% had an education above elementary school. After 18 and 36 months the mean MPR was 72.5 ± 28% and 69.3 ± 28% respectively. 52% had an MPR above 80% at 18 months and 48% after 36 months. 27% discontinued their LLT within 18 months and 42% within 36 months. After 18 months women were more likely to be adherent (MPR above 80%) then men (odds ratio (OR) = 1.18, $p = 0.002$) and less prone to discontinue LLT (OR = 0.81, $p = 0.0006$). At 36 months there was no difference between genders. Adherence increased by age OR = 2.62, $p < 0.0001$ at 18 months, among persons above 53 years compared to those under 36 years, slightly attenuated at 36 months (OR = 3.00, $p < 0.0001$). Discontinuation of therapy decreased by age with OR = 0.43, $p < 0.0001$ at 18 months. Divorced persons were less adherent compared to married with OR = 0.73, $p = 0.001$ at 18 months and OR = 0.71, $p < 0.0001$ at 36 months and discontinued their medication more often OR = 1.39, $p = 0.0002$ after 18 months and OR = 1.52, $p < 0.0001$ after 36 months. Persons who were not born in Sweden discontinued their medication more often (OR = 1.36, $p = 0.0042$) at 18 months. Neither educational level nor income was associated with adherence at 18 or 36 months but persons with high income were less prone to discontinuation.
Conclusion: This nationwide register-based cohort study with data from routine care showed that refill adherence to novel use of LLT in T1D was associated with gender, age, marital status and whether born in Sweden or not. Lower adherence was associated with male gender, younger age and if not born in Sweden. Level of Income and education did not affect adherence. These factors should be taken into consideration when evaluating adherence to medication in clinical practice.
Disclosure: **C. Hero:** None.

Investigation of an association of the anti-inflammatory drug sulfasalazine on HbA_{1c} in a large cohort of individuals with type 2 diabetes

S.M.S. N'Dow, L.A. Donnelly, E.R. Pearson, G. Rena;
University of Dundee, Dundee, UK.

Background and aims: Earlier studies including a recent case series have suggested that the anti-inflammatory drug sulfasalazine falsely lowers HbA_{1c}, attributed to hemolytic effects of the drug. In the current study we have investigated possible mechanisms of this effect by comparing sulfasalazine with other structurally related aminosalicylate (5-ASA) drugs (mesalazine, olsalazine and balsalazide) for associations with changes in HbA_{1c} and other hematological parameters.
Materials and methods: An observational cohort study was performed using comprehensive electronic medical records from individuals in the Scottish Care Information Diabetes Collaboration (SCI-Diabetes) in Tayside and Fife, Scotland. Individuals with type 2 diabetes and an incident prescription for a 5-ASA drug between 1st January 2006 and 30th April 2017 were eligible for the study. To allow assessment of HbA1c change, individuals were required to have a baseline HbA_{1c} (defined as closest measure between 6 months prior and 7 days after drug start date) and a treatment HbA_{1c} (defined as the measure closest to 6 months after drug start but within a 3 to 9 months window). To investigate the hemolytic association, change in the constituents of the full blood count were also assessed between baseline and 6 months, where measures were available. As sulfasalazine is used to treat rheumatoid arthritis and mesalazine, olsalazine and balsalazide are used to treat inflammatory bowel disease, we compared patient characteristics at baseline between the drug groups. Variables of interest included gender, age, duration of diabetes, HbA_{1c}, diabetes therapy and constituents of the full blood count. Comparison of baseline characteristics by drug group was by t-test for continuous variables and Chi-square test for categorical variables. Paired t-tests were used to compare the difference in baseline and treatment measures.
Results: A total of 216 individuals were eligible for the study. This was split by 113 individuals on sulfasalazine, 103 on mesalazine with no eligible individuals on olsalazine or balsalazide. There were no significant differences in patient characteristics between the sulfasalazine and mesalazine groups at baseline. We observed a mean(SD) HbA_{1c} reduction of −0.85(1.4)% ($p < 0.0001$) in the sulfasalazine group. There was no significant association in the mesalazine group (0.17(1.4)% ($p = 0.23$)). Sulfasalazine was associated with a mean(SD) increase in mean cell corpuscular volume of 3.7(5.9)fL ($p < 0.0001$) and a decrease in red blood cells of $-0.23(0.4) \times 10^{-12}$/L ($p < 0.0001$).
Conclusion: In this large, observational, population-based study we show that sulfasalazine was associated with a significant decrease in HbA_{1c} of 0.85%

within a 6 month period. In contrast, mesalazine use was associated with a non-significant increase in HbA_{1c}. Our results are consistent with hemolytic effects of sulfasalazine contributing to HbA_{1c}-lowering. These may be contributed by the sulfapyridine pharmacophore in sulfasalazine, which is absent in mesalazine. We do not exclude, owing to the observational nature of our study, that the difference in effect of these two drugs on HbA_{1c} may also be related to differences in absorption or prescribing patterns. This study provides numerous future research opportunities that could guide future clinical practice in diabetes.

Long-term relapse of type 2 diabetes after bariatric surgery: prediction and clinical relevance

J. Debédat[1], N. Sokolovska[1,2], M. Coupaye[3], L. Genser[4], G. de Turenne[1], J.-L. Bouillot[5], C. Poitou[1,6], J.-M. Oppert[6], S. Ledoux[3], J.-D. Zucker[1,2], K. Clément[1,6], J. Aron-Wisnewsky[1,6];
[1]NutriOmics team, Sorbonne Universités, INSERM, Paris, France, [2]Integromics team, Institute of Cardiometabolism and Nutrition, ICAN, Paris, France, [3]Explorations Fonctionnelles Department, Assistance Publique Hôpitaux de Paris, Louis Mourrier Hospital, Colombes, France, [4]Visceral Surgery Department, Assistance Publique Hôpitaux de Paris, Pitié-Salpêtrière Hospital, Paris, France, [5]Visceral Surgery Department, Assistance Publique Hôpitaux de Paris, Ambroise Paré Hospital, Paris, France, [6]Nutrition Departement, Assistance Publique Hôpitaux de Paris, Pitié-Salpêtrière Hospital, Paris, France.

Background and aims: Roux-en-Y gastric bypass (RYGB) induces 1-year type 2 diabetes remission (DR) in 60–80% of patients, yet relapse occurs in roughly half of them on the longer-term. One-year DR-predictive scores such as the DiaRem or the Ad-DiaRem, including solely baseline parameters, lack to accurately predict 5-years DR (5y-DR). We aimed to develop a new score better at predicting 5y-DR.
Materials and methods: Among our bariatric surgery cohort, we retrospectively included all patients with type-2 diabetes (T2D) who underwent RYGB before May 2013 ($n = 175$; 48 ± 10 years, 29% male, BMI 47 ± 7 kg/m², follow-up 5 ± 0.7 years). An extensive bioclinical phenotyping was performed (i.e. medical history and comorbidities, body composition, bioclinical data, treatments) before RYGB and 3, 6, 12 and 60 months after. We used the 2009 ADA's definition of DR. Using machine-learning algorithms, we developed the "5y-Ad-DiaRem" by integrating variables strongly associated 5-year diabetic outcomes (remission, relapse or non-remission). The variable selection was based on odd-ratios values and statistical significance between our three groups (i.e. 5y-DR, 5-years non-remission (5y-NDR) or 5-years relapse (5y-Relapse)). We examined this score in an independent French RYGB cohort ($n = 54$) in a confirmation purpose.
Results: 61% ($n = 106$) of our patients were in DR 1-year post-RYGB (concordant with the literature), and 25% ($n = 27$) relapsed between the 1st and 5th year. Compared to 5y-DR patients, 5y-Relapse patients exhibited a more severe T2D condition at baseline, as seen with higher HbA1C values and increased anti-diabetic treatments and insulin usage. Besides, they lost significantly less weight during the 1st year post-RYGB (−22% vs −30%, $p < 0.0001$) and regained more afterwards (+8% vs +2.5%, $p < 0.01$). In the 5y-Ad-DiaRem, we included baseline (T2D duration, number of anti-diabetic treatments and HbA1C) and 1-year parameters (fasting glycaemia, number of anti-diabetic treatments, 1-year remission status and weight lost during the first-year). The 5y-Ad-DiaRem was more accurate (AUROC 0.90, accuracy 85%) at predicting long-term T2D outcomes (5y-DR vs 5y-NDR) than both the DiaRem and Ad-DiaRem (AUROC 0.81 and 0.84, accuracy 79% and 78%, respectively). Below a score of 12, patients were predicted to enter in 5y-DR at 5-year (accuracy >0.90). Overall, this improved predictive power translated in the correction of one third (13/39) of the misclassifications of the DiaRem.
Conclusion: The 5y-Ad-DiaRem performed significantly better at predicting 5-year DR status than the published scores and appears relevant to identify patients at risk of relapse (score >11). Using this score could help intensify patient care following the first-year post-surgery, to maximize weight-loss or limit weight regain to prevent DR relapse.

Effect of vitamin D_3 therapy on immunological parameters at stages of development of type 1 diabetes in children and adolescents

N.M. Muz, V.V. Popova, V.L. Orlenko, K.Y. Ivaskiva, Y.A. Sayenko, K.M. Tron'ko, O.V. Furmanova, O.V. Bolshova, K.P. Zak, M.D. Tron'ko; State Institution «V.P. Komisarenko Institute of Endocrinology and Metabolism of Natl. Acad. Med. Sci. of Ukraine», Kyiv, Ukraine.

Background and aims: Dysregulation of the immune processes is the basis of autoimmune development of type 1 diabetes (T1D). Active participation of vitamin D3 in modulating the functions of the immune system in T1D development was established by numerous clinical studies to date. However, the mechanism of this effect is not fully understood. Therefore, the aim of this study was to analyze the prospective immunological data in children positive for the presence of diabetes-associated autoantibodies (DAAb) at the preclinical stage and debut of disease with oral administration of vitamin D3 in comparison with similar children without taking vitamin D3.
Materials and methods: We prospectively studied 37 children positive for DAAb aged 13.43 ± 2.16 years at the preclinical stage with prognostic duration of the preclinical stage of T1D development for 3 years, established on the basis of determining DAAb titers - decarboxylase glutamic acid (GADA) and autoantibodies against the protein tyrosine phosphatase (IA-2A) and 21 children positive for DAAb with predicted debut of T1D. The control group consisted of 17 healthy children of the same age. Oral administration of vitamin D3 at a daily dose of 2000 IU/day for 6 months in children at the preclinical stage and in T1D debut with detected vitamin D deficiency. The titre of DAAb - IA-2A and GADA - was determined by the radioimmunoassay method, the immunophenotype of lymphocytes - by FACS analysis, and the level of cytokines (IL-1β, TNFa, IL-10) - by ELISA.
Results: The maximum significant decrease in elevated titers of DAAb in 6 months after oral administration of vitamin D3 was determined in DAAb positive children at the preclinical stage of the disease development after taking vitamin D3: IA-2A (21.76 ± 3.36 vs 4.03 ± 1.03 U/ml, $p < 0.001$) and GADA (18.31 ± 2.43 vs 5.98 ± 1.57 U/ml, $p < 0.05$) regarding DAAb-positive children at latent stage of T1D formation without taking vitamin D3 and similar DAAb-positive children with T1D debut. At the same time, a predominant decrease in the levels of proinflammatory cytokines IL-1β (5.22 ± 0.21 vs 1.04 ± 0.13 pg/ml, $p < 0.001$), TNFa (2.14 ± 0.32 vs 0.30 ± 0.12 pg/ml, $p < 0.001$), and an increase in the level of the protective cytokine IL-10 (5.53 ± 0.19 vs 7.07 ± 0.27 pg/ml, $p < 0.001$), as well as an increase in the absolute number of CD3 + (0.79 ± 0.05 vs 1.27 ± 0.06 10^9/l, $p < 0.001$), CD4 + (0.52 ± 0.03 vs 0.84 ± 0.04 10^9/l, $p < 0.05$), CD56 + (0.18 ± 0.02 vs 0.84 ± 0.04 10^9/l, $p < 0.05$) were observed in DAAb-positive children at the preclinical stage of T1D after 6-months of cholecalciferol therapy comparing to DAAb-positive children without cholecalciferol use, and similar groups of DAAb-positive children with T1D debut and healthy children.
Conclusion: The use of vitamin D3 at the stages of T1D developmen can serve as pathogenetic-protective therapeutic factor with respect to the subsequent formation of disease.

Change over 12 months in HbA_{1c}, fasting plasma glucose and weight among patients with type 2 diabetes in 37 countries: DISCOVER

P. Fenici[1], F. Bonnet[2], H. Chen[3], J. Cid-Ruzafa[4], M.B. Gomes[5], N. Hammar[6], L. Ji[7], K.F. Kennedy[8], K. Khunti[9], M. Kosiborod[8], S. Pocock[10], W. Rathmann[11], M.V. Shestakova[12], I. Shimomura[13], B. Charbonnel[14];
[1]AstraZeneca, Cambridge, UK, [2]University of Rennes, Rennes, France, [3]AstraZeneca, Gaithersburg, MD, USA, [4]Evidera, Barcelona, Spain, [5]Rio de Janeiro State University, Rio de Janeiro, Brazil, [6]AstraZeneca Gothenburg, Mölndal, Sweden, [7]Peking University People's Hospital, Beijing, China, [8]Saint Luke's Mid America Heart Institute, Kansas City, MO, USA, [9]University of Leicester, Leicester, UK, [10]London School of Hygiene and Tropical Medicine, London, UK, [11]German Diabetes Center, Duesseldorf, Germany, [12]Endocrinology Research Center, Diabetes Institute, Moscow, Russian Federation, [13]Osaka University, Osaka, Japan, [14]University of Nantes, Nantes, France.

Background and aims: DISCOVER is a 3-year, observational study of patients with type 2 diabetes initiating second-line glucose-lowering therapy in 37 countries. We report change from baseline in HbA_{1c}, fasting plasma glucose (FPG) and weight over 12 months.
Materials and methods: HbA_{1c} and weight were assessed in patients who had values recorded for these variables at baseline and 12 months (HbA_{1c}, $N = 7225$; weight, $N = 10\ 332$). FPG was assessed in patients who had FPG values at baseline and 12 months, but who had HbA_{1c} unreported at either time point ($N = 1788$). Patients were categorized by second-line therapy, and changes over 12 months were adjusted for baseline values using least-squares means.
Results: Overall mean (SD) changes over 12 months were: HbA_{1c}, −1.1% (1.6%); FPG, −34.2 mg/dL (59.4 mg/dL); and weight, −0.5 kg (5.5 kg). At 12 months, the overall mean (SD) HbA_{1c} value was 7.3% (1.2%), ranging from 7.0–7.3% in all treatment categories except insulin (8.0%; Table). After initial baseline adjustment, changes in HbA_{1c} were comparable across treatment categories. Weight increased in patients receiving a sulphonylurea or insulin, and decreased in patients receiving a dipeptidyl peptidase 4 inhibitor.
Conclusion: HbA_{1c} and FPG were reduced substantially after 12 months in all treatment categories, with overall mean values only slightly above guideline-recommended targets. Mean weight increases in patients receiving insulin or a sulphonylurea were moderate.

Can a visit at the dentist's help prevent type 2 diabetes?

L. Czupryniak[1], M. Czerniuk[1], E. Szymańska-Garbacz[2], P. Bijoś[3];
[1]Medical University of Warsaw, Warsaw, Poland, [2]Military Medical Academy Memorial Teaching Hospital - Central Veterans' Hospital, Lodz, Poland, [3]Teva Pharmaceuticals Polska Sp. z o.o., Warsaw, Poland.

Background and aims: Type 2 diabetes should be diagnosed and optimally treated as early as possible, because it is the best evidence-based way to prevent long term vascular complications. Despite universally increasing knowledge of risk factors for diabetes development as well as better understanding of its pathogenesis, with growing public awareness of diabetes and its deadly consequences, still at least a third of cases remain undiagnosed globally. Importantly, the rate of diagnosed individuals with prediabetes is even lower, which decreases global chances for diabetes prevention. Therefore, identifying any means which would facilitate early diagnosis of glucose intolerance conditions is of utmost importance for current public health strategies worldwide. As diabetes is a well known risk factor for periodontal and dental disease, we assumed that a visit at the dentist's might be a valuable opportunity to assess one's glucose tolerance. The aim of the study was to evaluate whether visiting a dentist by a person at risk of developing diabetes may help diagnose glucose metabolism disturbances.
Materials and methods: Between March and June 2017 we conducted a nationwide cross-sectional study with thirty individual dental surgeries involved. Each dentist, having received basic training in diabetes pathophysiology and diagnosis delivered by the authors of the study, was given 20 laboratory referral notes for free fasting plasma glucose (FPG) measurement to be handed over to 20 consecutive eligible individuals who gave their consent to take part in the study. The referred patients were asked to perform FPG test during the following 4 weeks. The study inclusion criteria were: age ≥ 18 yrs, any degree of any dental or periodontal disease, presence of at least one diabetes risk factor (i.e. BMI ≥25 kg/m^2, family history of diabetes, sedentary lifestyle, past gestational diabetes, hypertension, dyslipidemia, cardiovascular disease, policystic ovary syndrome) and negative history of any persistent glucose metabolism disturbances.
Results: Out of 600 referred patients, 469 (78.2%, 330 [70.4%] women, mean [±SD] age 53.7 ± 15.4 yrs) had FPG assessed. Mean FPG in all subjects was 5.4 ± 1.16 mmol/l [97.2 ± 20.9 mg/dl] (range 3.5–20.9 mmol/l [63–377 mg/dl]). In 140 subjects (29.9% of those tested and 23.3% of those referred) impaired fasting glucose (IFG; i.e. FPG ≥5.55 mmol/l [100 mg/dl] and <7.0 mmol/l [126 mg/dl]) was diagnosed. 19 subjects had FPG ≥7.0 mmol [126 mg/dl]. IFG subjects were significantly older than those with normal FPG: 60.1 ± 12.6 vs 50.9 ± 15.7 yrs ($p < 0.001$), and were more often men (40% vs 27%; $p < 0.01$). Odds ratio for IFG in subjects aged ≥60 vs those <60 yrs was 3.413 (95% CI 2.215–5.264). All individuals with any degree of glucose intolerance were referred to diabetes care outpatient centres for further assessment and treatment.
Conclusion: Approximately every fourth patient at the dentist's with at least one diabetes risk factor presents with IFG. Dentists should be particularly aware of prediabetes risk in their male patients aged ≥60 yrs. This population may consitute an important group to whom diabetes prevention programmes should be addressed. In general, increasing awareness of glucose metabolism disturbances among the dentists may help diagnose prediabetes and thus lead to more effective diabetes prevention.

Burden of illness associated with generalised lipodystrophy (GL) in leptin replacement therapy-naive patients: a longitudinal medical chart review study

B. Akinci[1], E. Oral[2], A. Neidert[3], D. Rus[3], W. Cheng[4], P. Thompson-Leduc[5], T. Salinardi[6], E. Cochran[7], R. Brown[7];
[1]Department of Endocrinology, Dokuz Eylul University Hospital, Izmir, Turkey, [2]Department of Internal Medicine, University of Michigan

Medical School and Health Systems, Ann Arbor, MI, USA, [3]University of Michigan, Ann Arbor, MI, USA, [4]Analysis Group, Boston, MA, USA, [5]Analysis Group, Montreal, QC, Canada, [6]Employee at the time of study, Aegerion Pharmaceuticals, A Novelion Therapeutics Company, Cambridge, MA, USA, [7]National Institutes of Health, Bethesda, MD, USA.

Background and aims: GL is an ultra-rare disorder characterized by lack of adipose tissue, hyperphagia, altered physical appearance, and is associated with increased risk of organ abnormalities and potentially accelerated death. While severe GL patients may receive leptin therapy in research studies, little is known about GL patients that do not receive this treatment. This study assessed the burden of illness associated with GL among leptin-naïve patients using longitudinal, multi-center medical chart review data.

Materials and methods: Medical records of patients (pts) with confirmed non-HIV-related GL, never treated with leptin replacement therapy, from the National Institutes of Health, the University of Michigan, and Dokuz Eylul University, Turkey, were reviewed. Pts were observed from birth to loss to follow-up, death, or end of chart abstraction. Date of first symptoms was defined as the onset of GL-related evidence (1st of symptoms/diagnosis). Physical characteristics were assessed at last visit. Lifetime prevalence of organ abnormalities of the liver, pancreas (including diabetes), kidney, and heart was determined. Kaplan-Meier curves were used to describe 1) time to first organ abnormality from the date of first symptoms, 2) time to progression: from first to second organ abnormality and 3) time to death from birth. A time-varying Cox model was used to describe the association between number of organs with abnormalities and death. HR and 95% CI are reported.

Results: Among 56 pts included in the study 41.1% were male, which is a larger proportion than that found among treated patients. Pts experienced first symptoms at mean age 11.5 y; diagnosis of GL occurred 3.9 years later, at age 15.4 y (SD = 14.4). Most pts (87.5%) had congenital GL, 8.9% had acquired GL and 3.6% had generalized progeroid lipodystrophy. The five most common physical characteristics were muscular appearance, hepatomegaly, lack of facial fat, prominent veins and acanthosis nigricans. Lifetime prevalence of organ abnormalities was 89.3% for liver, 67.9% for pancreas (53.6% diabetes, 12.5% pancreatitis), 50.0% for kidney, and 39.3% for heart. 92.9% of pts had ≥1 organ with abnormalities after appearance of first symptoms, with a median (IQR) time to first organ abnormality of 5.0 (0.8–12.7) y. 53.8% had a second organ abnormality a median (IQR) of 5.7 (2.0–10.4) y later. Among the 14.3% of pts who died, median (IQR) age at death was 31.7 (28.2–52.4) y. A positive association existed between number of organs with abnormalities and death (HR = 3.8, 95%CI = 2.2–6.6, $p < 0.0001$).

Conclusion: This study documents the high burden of GL among leptin-naïve patients, and is the first to quantify the high risk of organ abnormalities, survival/mortality patterns, and the association between organ abnormalities and death. Since more severe patients may have sought leptin therapy under ongoing research studies, evaluation of leptin-naïve patients may underestimate the impact of GL on all patients..

CVB5 proteases 2A reduces insulin granule maturation only indirect

K.-P. Knoch[1], A. Petzold[1], C. Wegbrod[1], A. Sönmez[1], C. Münster[1], A. Friedrich[1], Z. Zuzana Marinicova[1], J.-P. Merl-Pham[2], S. Hauck[2], M. Solimena[1];
[1]Molecular Diabetology, Paul Langerhans Institute Dresden of the Helmholtz Center Munich at Univ. Hospital and Faculty of Medicine, TUD, Dresden, Germany, [2]Molecular Diabetology, Research Unit Protein Science Helmholtz Center Munich, München, Germany.

Background and aims: Regulation of insulin translation is a key process in pancreatic islet beta cells. We previously showed that Coxsackieviruses B (CVBs), which are among the potential environmental factors for triggering/accelerating the autoimmune destruction of beta cells in type 1 diabetes (T1D), exploit for translation of their genome the same cap-independent translation machinery used by beta cells for expression of secretory granule (SG) cargoes, including insulin. CVB Infection on MIN6 cells, however, strongly reduces the stores and release of insulin SGs. Therefore, in these studies we aimed at gaining insight into how CVBs affect the turnover of insulin SGs.

Materials and methods: MIN6 cells were transfected with either CVB5 protease 2A or 3C or infected with CVB5. Levels of insulin and other granule cargoes in control and CVB expressing cells were assessed by western blotting, ELISA, immunostaining and quantitative proteomics.

Results: The levels of insulin and other SG markers were unaffected in MIN6 cells expressing CVB5 3C, while they were reduced in cells infected with CVB5 or expressing CVB5 2A. SG cargo depletion in CVB5 and CVB 2A-expressing cells correlated neither with increased ER stress nor apoptosis. Proteomic analysis of CVB 2A-expressing MIN6 cells revealed the depletion of several factors involved in post-Golgi vesicular transport, including Arf1, GGA2, Rab3b and Sytl4. Knockdown of Rab3b and GGA2, but not of Arf1 or Sytl4, reduced the levels of SG cargoes similarly to the expression of CVB5 2A. No cleavage products attributable to GGA2 or Rab3b were detected in CVB5 2A-expressing cells. On the other hand, time-course studies in MIN6 cells treated with the translation inhibitor cyclohexamide indicated that the half-life of GGA2 and Rab3b is approximately only 12-hours. Hence, reduced cap-dependent translation of GGA2 and Rab3b rather than cleavage could account for their depletion upon CVB 2A expression.

Conclusion: We propose that CVB 2A protease leads to depletion of SG stores by altering their biogenesis/traffic from the Golgi complex, possibly by inducing their premature targeting to lysosomes, hence reducing insulin secretion. Massive intracellular degradation of SG cargoes may in turn affect their antigen presentation.

Relationship of C-peptide persistence and HbA_{1c} in type 1 diabetes

M. Colombo[1], T.J. McDonald[2,3], P.M. McKeigue[1], H.M. Colhoun[4,5], on behalf of the SDRNT1BIO Investigators;
[1]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, UK, [2]University of Exeter Medical School, Exeter, UK, [3]Blood Sciences, Royal Devon and Exeter Hospital, Exeter, UK, [4]Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK, [5]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: To show if C-peptide persistence is associated with average longitudinal glycated haemoglobin A_{1c} (HbA_{1c}) in type 1 diabetes mellitus (T1DM) patients.

Materials and methods: The study comprised 5608 adult patients with T1DM recruited from diabetes clinics and primary care into the Scottish Diabetes Research Network Type 1 Bioresource (SDRNT1BIO). Retrospective and prospective clinical record measures of risk factors, eGFR and $HbA_{1c}$and direct measures of eGFR, C-peptide and glucose on day of recruitment were available. We investigated associations of random serum C-peptide with recruitment day HbA_{1c} and average of all retrospective and prospective HbA_{1c} readings through linear regression in models incrementally adjusted for age, sex, diabetes duration and in-sample glucose. Models were also stratified for diabetes duration.
Results: At recruitment median (interquartile range) age was 44.1 (32.6, 53.9) years, duration 21 (11.6, 31.6) years, HbA_{1c} 69 (61, 80) mmol/mol. C-peptide was below 5 pmol/l in 3459 patients (61.6%), while the rest had a median of 91 (21, 321) pmol/l. C-peptide was inversely associated with both recruitment day HbA_{1c} and average longitudinal Hba_{1c}: having a C-peptide of at least 5 pmol/l was associated with an average longitudinal HbA_{1c} that was 2.0 mmol/mol lower (95% CI: −2.8, −1.2; $p = 3.8 \times 10^{-7}$) in models adjusted for age, sex and duration. There was evidence of a linear effect ($p = 4.9 \times 10^{-6}$), with those having C-peptide above 100 pmol/l having an average longitudinal Hba_{1c} that was 3.6 mmol/mol lower (95% CI: −4.5, −2.6; $p = 4.7 \times 10^{-13}$). Models stratified by diabetes duration revealed strongly significant effects in the group of 1901 patients with fewer than 15 years of diabetes, in which having a C-peptide of at least 5 pmol/l was associated with an average longitudinal HbA_{1c} that was 4.2 mmol/mol lower (95% CI: −5.7, −2.8; $p = 2.1 \times 10^{-8}$), while the association was weaker for those with longer duration (−1.1 mmol/mol, 95% CI: −2.0, −0.2; $p = 1.6 \times 10^{-2}$), in models adjusted for age, sex, duration and in-sample glucose.
Conclusion: The effect of persistent C-peptide secretion on average glycaemia is small but independent of confounders and easily detected in this large sample. Possible clinical impact of C-peptide persistence on risk of severe hypoglycaemia is a subject for future study.

Population screening of type 1 diabetes and coeliac disease: Autoimmunity Screening for Kids (ASK)

M. Rewers, C. Geno-Rasmussen, J. Baxter, K. Waugh, L. Yu, B. Frohnert, A.K. Steck, E. Liu;
Univ of Colorado School of Medicine, Aurora, CO, CO, USA.

Background and aims: Early detection can prevent morbidity associated with type 1 diabetes (T1D) and celiac disease (CD). ASK is a 4-year program designed to screen 50 000 children for islet autoantibodies (IA) and transglutaminase autoantibodies (TGA), increase public awareness of T1D and CD, and provide evidence for universal screening. We are reporting first-ever prevalence data for IA and TGA in the U.S. general population children aged 2–17 y.
Materials and methods: ASK has approached ~24,000 children for consent, screened 7295, with results available for 7021. Study participants' age, sex, and race/ethnicity closely reflected Denver's general population; 4% had a first-degree relative (FDR) with T1D. Standard radiobinding assays (RBA) and more specific electrochemiluminescence (ECL) assays for autoantibodies to insulin, GAD, IA-2, ZnT8 and TGA were used for screening and confirmation 2–6 weeks later. Children with confirmed persistent IA received follow-up with education to prevent DKA, metabolic monitoring, psychological support, and referrals to prevention trials or clinical services.
Results: Multiple IA, predicting a 44% 5-y risk of T1D, were found in 37 (0.5%; 95% CI 0.4–0.7%) children. A single positive IA, confirmed as high-affinity by ECL and predicting a 29% 5-y risk of T1D, was found in an additional 36 (0.5%; 0.4–0.7%) children. Nearly 90% (64/73) of the screening-detected high-risk children did not have an FDR with T1D. Of the 73 high-risk children, all remained persistently IA positive, 12 have developed dysglycemia and four have already progressed to clinical T1D. The prevalence of TGA varied from 2.7% (2.4–3.1%) using the most sensitive ECL assay (detects IgA, IgG and IgM antibodies) to 2.1% (1.8–2.5%) using standard RBA assay and 0.6% (0.5–0.8%) using a cutoff 10 times the upper limit of normal range. Only 30% of TGA-positive children reported symptoms usually associated with CD.
Conclusion: This novel population-based screening program for the two most common autoimmune diseases of childhood reports high prevalence of pre-symptomatic T1D and CD in Denver children. Prospective follow-up of screening-detected cases for clinical outcomes and cost-effectiveness analysis will inform potential future universal screening.

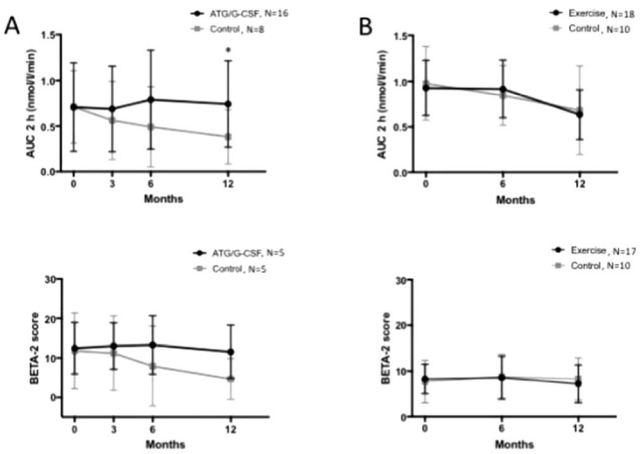
The BETA-2 score: a novel measure of beta cell function in type 1 diabetes intervention trials

A. Lam[1], R. Oram[2], R. Andrews[2], P. Narendran[3], M. Haller[4], P. Senior[1]; [1]University of Alberta, Edmonton, AB, Canada, [2]University of Exeter, Exeter, UK, [3]University of Birmingham, Birmingham, UK, [4]University of Florida, Gainesville, FL, USA.

Background and aims: Stimulated C-peptide following mixed meal tolerance test (MMTT) is the gold standard endpoint in type 1 diabetes (T1D) intervention trials. Unfortunately, MMTTs are costly, time consuming and fail to capture the clinical benefit expected with beta cell preservation. The BETA-2 score is a validated index of beta cell function in clinical islet transplantation. The score is conveniently calculated from a single fasting blood sample based on C-peptide, HbA_{1c}, blood glucose and insulin dose. It may therefore be useful as a practical and clinically relevant endpoint in T1D trials. This was a proof of concept study comparing BETA-2 score with AUC C-peptide as measures of beta cell function in T1D trials.
Materials and methods: Data from 2 RCTs were analyzed separately post-hoc. The primary or secondary endpoint of each trial was change in AUC C-peptide following 2 h MMTT at 12 months. The anti-thymocyte globulin (ATG)/pegylated granulocyte CSF (GCSF) trial included T1D subjects (age 12–45 years, duration 4–24 months) randomized to ATG/GCSF ($n = 17$) or placebo ($n = 8$). The EXTOD trial included T1D subjects (age 16–60 years, duration <12 weeks) randomized to exercise ($n = 27$) or usual care ($n = 17$). The BETA-2 score were calculated before, during and end of study where data were available. Data are expressed as mean ± SD (control vs. treated).
Results: In both trials, the BETA-2 score significantly correlated with AUC C-peptide at 0, 6 and 12 months (ATG/G-CSF trial $r = 0.685$–0.853, $P < 0.01$; EXTOD trial $r = 0.391$–0.657, $P = 0.00$–0.01).

Intriguingly, BETA-2 measured at both 3 and 6 months correlated significantly with AUC C-peptide at 12 months in the ATG/G-CSF trial (3 months: $r = 0.60$, $P = 0.02$; 6 months: $r = 0.80$, $P = 0.00$). Compared with control, ATG/GCSF treatment was associated with superior beta cell function at 12 months measured by AUC C-peptide (0.43 ± 0.32 vs. 0.74 ± 0.47 nmol/l/min, $P = 0.05$) or BETA-2 although this difference was not statistically significant (5.2 ± 5.4 vs. 9.7 ± 5.4, $P = 0.11$). In the EXTOD trial, there were no differences between control or intervention using either AUC C-peptide (0.69 ± 0.44 vs. 0.61 ± 0.30 nmol/l/min, $P = 0.51$) or BETA-2 score (7.8 ± 4.8 vs. 7.1 ± 4.1, $P = 0.69$) at 12 months.

Conclusion: The BETA-2 score allows for more convenient and frequent assessment of both beta cell function and metabolic outcome. It may therefore be useful as a surrogate endpoint in T1D intervention trials allowing for smaller and shorter duration trials. We show here that the BETA-2 score correlates well with AUC C-peptide and that early BETA-2 score appears to be predictive of AUC C-peptide at 1 year. Furthermore, we found that the BETA-2 score showed a trend in response to treatment that was similar to AUC C-peptide. Our study was limited in terms of missing data limiting statistical power and thus, further prospective studies evaluating the reliability and responsiveness of the BETA-2 score in T1D trials are warranted.



AUC C-peptide and BETA-2 score in subjects from the ATG/G-CSF trial (A) and the EXTOD trial (B). AUC C-peptide are shown as total AUC divided by 120 minutes. *P=0.05.

Type 1 diabetes leading to severe insulin deficiency occurs after 30 years of age and is commonly treated as type 2 diabetes in clinical practice

N. Thomas, A. Grubb, T. McDonald, A. Hill, M. Weedon, R. Oram, A. Hattersley, A. Jones;
Exeter University, Exeter, UK.

Background and aims: Severe loss of endogenous insulin secretion defines type 1 diabetes treatment requirements. We aimed to determine the prevalence and characteristics of type 1 diabetes leading to severe endogenous insulin deficiency after age 30 in patients with insulin treated diabetes.

Materials and methods: We assessed the characteristics of type 1 diabetes defined by rapid insulin requirement (within 3 years) and severe endogenous insulin deficiency (non-fasting C-peptide <200 pmol/l) in a population cohort of 583 participants with insulin treated diabetes diagnosed after age 30. We compared characteristics with participants with retained endogenous insulin secretion (>600 pmol/L) and 220 participants with severe insulin deficiency diagnosed under age 30.

Results: 21% (18–25) of insulin treated diabetes diagnosed after 30 had severe insulin deficiency. 39% of these participants did not receive insulin at diagnosis, of whom 46% self-reported type 2 diabetes. Rapid insulin requirement was highly predictive of late onset type 1 diabetes, with 84% requiring insulin within 1 year. 44% of participants progressing to insulin within 3 years develop severe endogenous insulin deficiency. Clinical, biochemical and genetic characteristics were comparable to participants diagnosed before age 30. In contrast patients with retained endogenous insulin secretion had substantially lower type 1 diabetes genetic risk scores (0.268 vs 0.229, $p < 0.001$), antibody positivity (82% vs 6%, $p < 0.001$) and higher BMI (26.0 vs 31.6, $p < 0.001$). 39% of participants with late onset type 1 diabetes and severe insulin deficiency did not receive insulin at diagnosis as shown in table 1, these participants were a median of 12 months from diagnosis before insulin treatment was started. Those where insulin commencement was delayed (compared to immediate insulin) were older at diagnosis, 48 vs 41 years $p < 0.049$ but had similar BMI (25.6 vs 26.9) $p = 0.69$, T1DGRS (0.267 vs 0.268) $p = 0.88$ and islet autoantibodies positivity (78% vs 85%, positive for any antibody) $p = 0.37$. Of those with delayed commencement of insulin only 50% self-reported as having type 1 diabetes vs 96% in those immediately starting insulin ($p < 0.001$), these participants were also more likely to receive oral hypoglycaemic agents: 29% vs 7% $p = 0.001$.

Conclusion: Type 1 diabetes leading to severe insulin deficiency has similar clinical and biological characteristics to that occurring at younger ages, but is frequently not identified. Clinicians should be alert to the possibility of type 1 diabetes in patients requiring insulin within three years of diagnosis.

Impact of routine C-peptide screening in individuals with a clinician diagnosis of type 1 diabetes

E. Foteinopoulou, C. Clarke, R. Pattenden, J. McKnight, M.W.J. Strachan;
Western General Hospital, Edinburgh, UK.

Background and aims: Type 1 diabetes (T1D) is typically diagnosed on clinical grounds using criteria such as younger age at presentation, low body mass index, rapid onset of symptoms and the presence of ketosis. It is well recognised that these criteria are not perfect and that some

individuals with other causes of diabetes, such as Type 2 diabetes (T2D) and monogenic diabetes, may be incorrectly diagnosed as having T1D. Such individuals may be commenced unnecessarily on insulin. C-peptide provides a measure of endogenous insulin secretion and can be used to distinguish individuals with severe insulin deficiency (T1D) from those with substantial insulin secretion (T2D and monogenic diabetes).

Materials and methods: In July 2017, C-peptide screening was introduced in our centre as part of routine clinical care for patients with a clinician diagnosis of T1D (1,205 registered patients). Patients with a duration of T1D of ≥3 years were considered for C-peptide screening. Plasma C-peptide was measured on a random sample using the ARCHITECT immunoassay (Abbott). Blood glucose was measured contemporaneously. Severe insulin deficiency was defined as C-peptide <200 pmol/L, when blood glucose was >4 mmol/L. C-peptide ≥200 pmol/L prompted evaluation for other aetiologies of diabetes (measurement of anti-GAD and IA-2 autoantibodies and where appropriate monogenic diabetes screening).

Results: Data for the first 390 patients screened are reported. 335 (85.9%) patients had C-peptide <200 pmol/L, and so were considered to be appropriately managed with insulin, with a probable diagnosis of T1D. 55 patients (14.1%) had C-peptide ≥200 pmol/L and their initial diagnosis of T1D was re-evaluated. 8 of these patients (14.5%) had C-peptide >900 pmol/L, consistent with significant insulin resistance. All had negative autoantibodies and their diagnosis was revised to T2D. Two of these patients were Caucasian and had presented with ketoacidosis at diagnosis. So far 4 patients have switched from insulin to alternative anti-diabetic therapy (median [range] duration of insulin therapy was 10 [4–28] years) and 3 other patients are in the process of insulin withdrawal. 11 patients (20.0%) had C-peptide ranging from 600–900 pmol/L. Of these, 3 patients had at least one autoantibody positive in high titre. 1 patient had an isolated anti-GAD antibody titre of 12.5 U/ml and a high T1D genetic risk score (93rd centile); this patient has successfully stopped insulin after 6 years. These 4 patients were all considered to have T1D; their median (range) duration of diabetes was 6 (6–11) years. 7 had negative autoantibodies, of whom 3 were considered to have T2D. 3 patients are undergoing further investigation; 1 patient has confirmed HNF1α monogenic diabetes and has now discontinued insulin after 10 years. 36 patients (65.5%) had C-peptide 200–600 pmol/L. 11 of these patients had positive autoantibodies, 10 had negative autoantibodies (and are undergoing further investigation) and 15 are awaiting confirmation of antibody status.

Conclusion: The introduction of C-peptide testing has permitted cessation of long duration insulin therapy in some patients. We have identified that ketoacidosis can occur in Caucasians with T2D, while substantial endogenous insulin secretion can persist for many years in some patients with T1D. The current clinical criteria used to diagnose T1DM are insufficient. C-peptide testing should be performed in all individuals with a diagnosis of T1D of at least 3 years duration from secondary care service.

Serum 25-hydroxyvitamin D concentration at birth in children screened for HLA-DQB1 conferred genetic risk for type 1 diabetes

M. Mäkinen[1], E. Löyttyniemi[2], M. Koskinen[1], M. Vähä-Mäkilä[1], H. Siljander[3], M. Nurmio[1], J. Mykkänen[2], S.M. Virtanen[4,5], O. Simell[2], H. Hyöty[5,6], J. Ilonen[1], M. Knip[3,5], R. Veijola[7], J. Toppari[1];
[1]University of Turku and Turku University Hospital, Turku, Finland, [2]University of Turku, Turku, Finland, [3]University of Helsinki and Helsinki University Hospital, Helsinki, Finland, [4]National Institute of Health and Welfare, Helsinki, Finland, [5]Tampere University and University Hospital and Science Centre, Tampere, Finland, [6]Pirkanmaa Hospital District, Tampere, Finland, [7]University of Oulu and Oulu University Hospital, Oulu, Finland.

Background and aims: Vitamin D has several effects on the immune system that might be of relevance for the pathogenesis of type 1 diabetes. The aim of this study was to evaluate whether cord serum concentration of 25-hydroxy-vitamin D (25[OH]D) differ in children developing either islet autoimmunity or type 1 diabetes during childhood and adolescence.

Materials and methods: Umbilical cord serum samples from 764 children born 1994–2004 with HLA-DQB1 conferred risk for type 1 diabetes participating in the Type 1 Diabetes Prediction and Prevention (DIPP) study were analyzed for 25(OH)D using enzyme immunoassay. The participants comprised 250 case children who developed type 1 diabetes at a median age of 6.7 years (Interquartile range [IQR] 4.0–10.1 years) and 132 additional case children who developed islet autoimmunity, i.e. turned positive for multiple islet autoantibodies. Cases were matched for date of birth, gender and area of birth with 382 control children, who remained autoantibody negative. The median duration of follow-up was 9.8 years (IQR 5.7–13.1 years)

Results: The median 25(OH)D concentration in cord serum were low (31.1 nmol/L [IQR 24.0–41.8]; 88% <50 nmol/L), and not statistically different between children who developed type 1 diabetes or islet autoimmunity and their control groups ($P = 0.70$). The levels were associated mainly with geographical location, year and month of birth, age of the mother and maternal intake of vitamin D during pregnancy.

Conclusion: The 25(OH)D concentration at birth is not associated with the development of type 1 diabetes during childhood.

Gene expression profile of peripheral blood mononuclear cells of recent-onset type 1 diabetes

A.S. Santos[1], C. Chevillard[2], N.V. Gonfinetti[3], J. Kalil[4], E. Cunha-Neto[4], M.R. Silva[1];
[1]Endocrinologia, Laboratório de Carboidratos e Radioimunoensios- LIM 18 -Hospital das Clinicas HCFMUSP, Faculdade de Medicina, Universidade de Sao Paulo, Sao Paulo, SP, BR, Sao Paulo, Brazil, [2]Aix-Marseille Université/ INSERM/AMU UMR_1090 – France, Marselha, France, [3]Endocrinologia, Instituto Castro de Medicina, Sao Paulo, Brazil, [4]Imunologia, Disciplina de Imunologia e Alergia- LIM 60 e Laboratório de Imunologia - Instituto do Coração- FMUSP-Universidade de São Paulo, Sao Paulo, Brazil.

Background and aims: Type 1 diabetes mellitus (T1D) is characterized by the autoimmune destruction of insulin-secreting β-cells, mediated by T auto reactive infiltrating cells, inflammatory cytokines and immunological mechanisms. However, little is known about the expression of genes and pathways dysregulated in peripheral blood mononuclear cells (PBMC) of patients with T1D. Aims: to investigate the gene expression profiles of circulating PBMC in recent-onset T1D patients (up to 6 months of diagnosis) in comparison with controls in the context of putative disease-related pathobiological processes and pathways

Materials and methods: expression of mRNA from PBMC of 12 T1D patients, 16.4 ± 8.9 years and age-matched 12 healthy controls, 15.0 ± 8.1 years, ($p > 0.05$) was evaluated with the Whole Human Genome Microarray Kit Agilent (58341 probes) and analyzed by GeneSpring software with a fold change cutoff of 1.5 and adjusted P value <0.05; pathways analysis was performed with the software Ingenuity Pathway Analysis (IPA).

Results: 223 genes (259 probes) were differentially expressed between T1D patients and controls, of which 129 (58%) were upregulated, while 94 (42%) genes were downregulated in T1D. The interactions between the differentially expressed genes evidenced expression patterns of 30 networks. The 10 most significantly enriched (most discriminating) canonical pathways between groups were those related to tumor necrosis factor (TNF) pathway and cell cycle regulation (cellular growth, mitosis, survival, apoptosis, DNA repair and genomic stability). Pathways

analysis indicated there was a trend for activation of inflammatory pathways like TNF receptors (TNFR1 and TNFR2) associated with increased expression of genes TNFAIP3 (TNP alpha induced protein 3), TNFRSF12A (OX40 receptor,TNF receptor superfamily member 12A), CDC42 (cell division cycle 42) and reduction of IKBKB (inhibitor of nuclear factor kappa B kinase subunit beta) , favoring also NFkB signaling.

Conclusion: our data suggest a proinflammatory activation profile dependent on TNF receptor pathway and inflammatory NFkB signaling in peripheral blood mononuclear cells, which could play a role in T1D pathogenesis.

305

Impact of visit-to-visit fasting plasma glucose variability on the development of type 2 diabetes: a nationwide population based cohort study

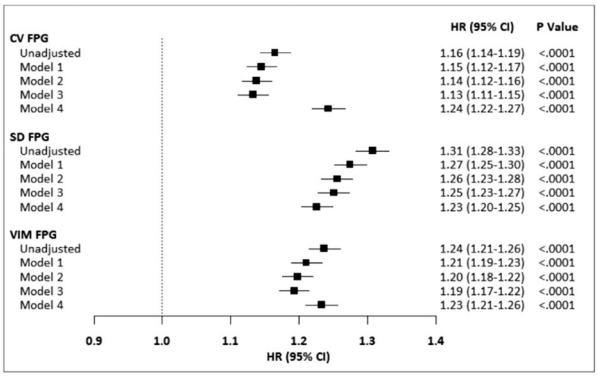
J. Kim, Y. Lee, E. Roh, S. Hong, N. Kim, H. Yoo, J. Seo, S. Kim, N. Kim, S. Baik, K. Choi;
College of Medicine, Korea University, Seoul, Republic of Korea.

Background and aims: Glucose variability is the deviation from steady state of glucose concentration. Glycemic variability have recently draw attention as an another aspect of glycemic control and may contribute to additional risk for diabetic complications independent of HbA1c. Previous studies demonstrated that fluctuations in blood glucose levels had a greater impact on oxidative stress, inflammatory cytokines, and endothelial function than sustained hyperglycemia. On the other hand, oxidative stress-activated signaling pathway leads to both insulin resistance and impaired insulin secretion, which are main pathogenic mechanism of diabetes. Although these evidences suggest the relationship between long-term glycemic variability and development of type 2 diabetes, there has been no previous study. Therefore, we examined the impact of visit-to-visit FPG variability on the development of type 2 diabetes using a large population-based cohort data from the National Health Insurance Service-National Health Screening Cohort.

Materials and methods: The current study analyzed 131,744 Korean men and women without diabetes using the Korean National Health Insurance System cohort with periodic health examination program. FPG variability was calculated using the coefficient of variance (FPG-CV), standard deviation (FPG-SD), and variability independent of the mean (FPG-VIM). The number of FPG measurements per subject ranged from 3 to 6: 3 measurements (n = 68,027, 52%), 4 measurements (n = 14,078, 11%), 5 measurements (n = 18,663, 14%), and 6 measurements (n = 30,976, 24%). Kaplan-Meier and Cox proportional hazard analyses were used to evaluate the association between FPG variability and type 2 diabetes.

Results: During the median follow-up of 8.3 years, Kaplan-Meier curves demonstrated lower disease-free probability in higher FPG variability group compared to lower FPG variability group. Multivariable Cox proportional hazard analysis exhibited that the hazard ratio (HR) for incident T2DM was 1.67 (95% confidence interval [CI] = 1.58–1.77; P < 0.001) in the highest quartile of FPG-CV compared to the lowest quartile of FPG-CV after adjusting for confounding variables. The association between FPG variability and the risk of T2DM was consistent when modelling using FPG-SD and FPG-VIM in both normal and impaired fasting glucose (IFG) group. An increase of 1 SD in the FGP-CV was associated with a 24% increased risk of T2DM in the fully adjusted model.

Conclusion: Increased variability of FPG is associated with the development of type 2 diabetes independent of diverse risk factors. These results suggest that long-term FPG variability may be useful for risk stratification of type 2 diabetes in the general population.



Hazard ratios and 95% confidence intervals for every one SD increase of fasting plasma glucose variability

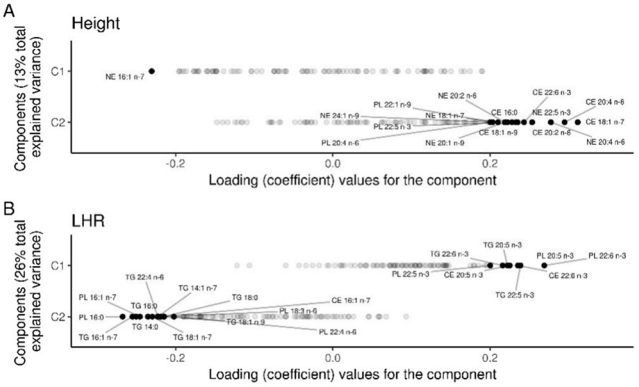
Leg length, a marker of early childhood conditions, associates with specific clusters of serum fatty acids

L.W. Johnston[1], Z. Liu[2], R. Retnakaran[2], S.B. Harris[2], R.P. Bazinet[2], A.J. Hanley[2];
[1]Aarhus University, Aarhus, Denmark, [2]University of Toronto, Toronto, ON, Canada.

Background and aims: Adverse early childhood conditions have been associated with greater risk for adult chronic diseases such as type 2 diabetes (T2DM) and cardiovascular disease. However, the specific mechanism of action is not well elucidated. Adult leg length is an established biomarker of early childhood conditions. We aimed to explore distinct clusters of a broad spectrum of serum fatty acids (FA) by height and leg length.
Materials and methods: Canadian adults ($n = 453$) at risk for T2DM from the Prospective Metabolism and Islet Cell Evaluation (PROMISE) cohort had detailed personal and metabolic data collected, including the measurement of FA and stature. The concentrations of 22 FA in the cholesteryl ester (CE), phospholipid (PL), triacylglycerol (TG), and non-esterified (NE) fractions were quantified. Height and sitting height were measured, which were used to compute leg to height ratio (LHR). To identify clusters in the FA profile, we used the supervised dimensionality reduction method partial least squares (PLS) with the stature components as the constraining variables and the FA as the predictor variables. Separate models were analyzed for height and LHR.
Results: The participants were mostly female (72%) and of European-ancestry (71.6%). Mean (SD) age was 50.4 (10.0) years, height was 166.1 (9.1) cm, and LHR was 0.47 (0.02). The four FA with the largest proportion in serum were CE 18:2 n-6 (20.6%), PL 16:0 (11.5%), PL 18:2 n-6 (8.2%), TG 18:1 n-9 (7.8%). For each PLS model, we extracted the first two components (C1 and C2; Figure). Higher LHR tended to load with a higher C1 cluster (i.e. more 20:5n-3 and 22:6n-3 in multiple lipid fractions) and loaded with a lower C2 cluster (i.e. less 14:1n-7, 14:0, 16:0, 16:1n-7, 18:0 in primarily the TG and PL fractions). There were no well defined specific cluster of FA in C1 for height, which may reflect that higher height correlates positively with total FA concentration. Height tended to load with a higher C2 cluster (e.g. 20 or more carbon long FA in multiple fractions).
Conclusion: We found that shorter adult leg length had a distinct lipid profile compared to shorter height, reflecting more omega-3 long chain FA and less of the 14 and 16 chain FA. Previous research has shown that these 14–16 chain FA associate with greater de novo lipogenesis and exert lipotoxic effects. Our results suggest that early childhood conditions, as reflected in adult leg length, may lead to changes in lipid production and usage.



PLS loadings of C1 and C2 by height (A) and LHR (B). Higher loading values indicate a stronger contribution of the FA to the component. Interpretation is that a higher loading score correlates with a higher height or LHR, and that higher FA corresponds to its loading value. For example, in Figure B, one unit increase in PL 22:6 n-3 contributes to the C1 score by 0.269.

Individuals fulfilling criteria for type 2 diabetes display transient evidence of autoimmunity preceding diagnosis with possible clinical implication: the HUNT study

E.P. Sørgjerd[1], B.O. Åsvold[2,1], P.M. Thorsby[3], V. Grill[4];
[1]Department of Public Health and Nursing, Faculty of Medicine and Health Sciences, NTNU, Norwegian University of Science and Technology, Levanger, Norway, [2]Department of Endocrinology, St. Olavs Hospital, Trondheim University Hospital, Trondheim, Norway, [3]Hormone Laboratory, Department of Medical Biochemistry, Oslo University Hospital, Oslo, Norway, [4]Department of Clinical and Molecular Medicine, Faculty of Medicine and Health Sciences, NTNU, Norwegian University of Science and Technology, Trondheim, Norway.

Background and aims: Type 2 diabetes is heterogeneous, and phenotype, prognosis and efficacy of treatment can vary greatly between individuals. In this context, we examined if some individuals may have transient evidence of autoimmunity preceding the diagnosis of type 2 diabetes, and if so, if clinical characteristics differed from those of other individuals with type 2 diabetes.
Materials and methods: We used data and serum samples from the second (HUNT2, 1995–1997) and third (HUNT3, 2006–2008) surveys of the Nord-Trøndelag Health Study (HUNT). We included 794 individuals diagnosed with type 2 diabetes between HUNT2 and HUNT3. Classification criteria of type 2 diabetes were autoantibody-negativity (GADA and IA-2A) and no insulin treatment within one year after diagnosis. From these individuals, serum samples from HUNT2 (prior to diabetes diagnosis) were assayed for GADA, IA-2A, ZnT8A and IAA.
Results: Among 794 individuals, 26 (3.3%) were positive for at least one autoantibody before type 2 diabetes diagnosis. Autoantibody-positive individuals were younger at the time of diagnosis (53 vs. 61 years of age, $p < 0.001$) than autoantibody-negative individuals. There was a tendency of more symptomatic onset of diabetes and also lower insulin production (fasting C-peptide 861 vs. 1006 pmol/L), lower beta-cell function (HOMA2-%B 60.6 vs 78.1) and higher HbA1c (7.1 vs 6.7%) after diagnosis (HUNT3) in previously autoantibody positive participants.
Conclusion: To our knowledge, we are the first to demonstrate transient evidence of autoimmune activity prior to diagnosis in a subgroup of type

2 diabetes. These individuals were diagnosed at a younger age and might have reduced beta-cell function and poorer glycemic control than other diagnosed with type 2 diabetes.

Longitudinal analyses of serum metabolite phenotypes in the EarlyBird cohort identify metabolic readouts associated with childhood insulin resistance

J. Hosking[1], M. Lauria[2], O. Cominetti[3], A. Jeffery[1], J. Hager[3], J. Pinkney[1], F.-P. Martin[3];
[1]University of Plymouth, Plymouth, UK, [2]University of Trento, Trento, Italy, [3]Nestle Institute of Health Sciences, Lausanne, Switzerland.

Background and aims: Metabolite signatures have emerged as biomarkers associated with insulin resistance (IR) and type 2 diabetes (T2D). These biomarkers have potential to elucidate the mechanisms linking obesity to IR, and identify individuals at risk of T2D, but there are few longitudinal data in children through adolescence, when IR undergoes profound changes. Longitudinal studies in healthy children are essential to resolve whether altered metabolite signatures precede the development of IR. We conducted longitudinal modelling of metabonomic and clinical data from the Earlybird cohort to determine whether metabolite signatures are associated with IR.

Materials and methods: EarlyBird is a non-intervention prospective cohort study (347 healthy UK children followed throughout childhood and puberty). Annual fasting serum samples from a sub-group of 150 children underwent metabonomic profiling by proton nuclear magnetic resonance spectroscopy. Subjects were chosen to represent the range of blood glucose observed in the cohort from 5y to 16y. We applied a combination of methods: consensus based clustering (CClust), and mixed effects modelling (MEM). CClust was used to group children according to their temporal profile of IR (HOMA-IR). Non-parametric testing was performed at each time point, and results aggregated according to the Fisher method to identify influential variables. MEM was used to assess the association between HOMA-IR and individual metabolites, taking into account age, BMI, physical activity and pubertal timing.

Results: MEM identified several metabolites that were significantly and inversely associated ($p < 0.05$) with IR across childhood independently of BMI sds, physical activity and age at peak height velocity. Amongst the most influential metabolites were ketone bodies, branched amino acids, histidine, glutamine, lysine, and creatine. CClust analyses of HOMA-IR trajectories were performed at pre-puberty and adolescence, for both genders (f, females, m, males). This enabled the identification of metabolic patterns of high IR status at specific biological ages. At puberty IR was associated with reduced concentrations of amino acids histidine (f adj. $p = 0.09$, m adj. $p = 0.02$), glutamine (f adj. $p = 0.09$, m adj. $p = 0.03$), lysine (f adj. $p = 0.09$, m adj. $p = 0.007$) and valine (f adj. $p = 0.09$, m adj. $p = 0.02$). Additional patterns in central energy metabolism at puberty were increased 3D-hydroxybutyrate (f adj. $p = 0.09$, m adj. $p = 0.003$) and reduced creatine (f adj. $p = 0.08$, m adj. $p = 0.007$).

Conclusion: The integrative approach developed here enabled us to explore the interactions between metabolite signatures and IR over time, during pubertal development. Several metabolites were associated with IR in children independently of pubertal development, adiposity and physical activity. This longitudinal analysis in healthy children confirms that IR is associated with complex but changing metabolite signatures. Amino acid signatures observed in more obese populations may be consequences rather than antecedents of IR. Ketogenesis was inversely associated with IR throughout childhood, but became positively associated with IR in puberty. Longer term observational studies may show whether these metabolite signatures predict adult health risks such as T2D, or could be used as a basis for intervention.

Quantification of individual disease progression in type 2 diabetes patients using a semi-mechanistic model: an IMI DIRECT study

N. Scherer[1], C. Dings[1], V. Nock[2], A.M. Hennige[2], E.R. Pearson[3], P.W. Franks[4], T. Lehr[1], for the IMI DIRECT consortium;
[1]Clinical Pharmacy, Saarland University, Saarbruecken, Germany, [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany, [3]Medical Research Institute, Ninewells Hospital and Medical School, University of Dundee, Dundee, Scotland, UK, [4]Department of Clinical Sciences, Genetic and Molecular Epidemiology Unit, Lund University, Sweden.

Background and aims: Fasting plasma glucose (FPG) and HbA1c are biomarkers to diagnose type 2 diabetes mellitus (T2DM) and to observe disease progression. Intensive glycemic management by body weight (BW) loss or medication intake results on average in decreased HbA1c levels leading to reduced morbidity and mortality. Likewise, the underlying mechanisms of T2DM progression are still not completely understood, and predictive biomarkers associated with fast and slow rates of glycemic deterioration are currently not available.

Here, we firstly aim to develop a mathematical model to describe the interaction between FPG and HbA1c over time, quantifying the effects of BW changes and pharmacological intervention. Secondly, the model is used to identify the intrinsic disease progression independent of medication intake or BW changes.

Materials and methods: Data from 795 recently diagnosed T2DM patients fulfilling the inclusion criteria of the Diabetes Research on Patient Stratification (DIRECT) study were used for the model development. FPG and HbA1c concentrations and information on BW and pharmacological interventions were reported every nine months during an observation period of 36 months. For model development, nonlinear mixed-effects methods implemented in the software NONMEM (version 7.3.0) were used.

Results: The dataset includes 2745 FPG, 2767 HbA1c concentrations and 2760 BW measurements from 795 patients. FPG is described by a turn-over model with zero-order production and first-order elimination. The formation of HbA1c from hemoglobin (Hb0) is described by a second-order process dependent on FPG and Hb0. The degradation of Hb0 and HbA1c is described by a first-order process assuming an erythrocyte half-life of 120 days. Pharmacotherapy and changes in BW significantly influence the production rate of FPG ($p < 0.001$) and lead to a decreased production rate under medication intake or BW loss. Despite therapeutic intervention, T2DM is known to progress over time at different rates across individuals. Therefore, we estimate an individual progression factor that is multiplied by the production rate of FPG to evaluate the progression of the disease. We observed that during the observation period, 45% of our participants show an increase of their HbA1c levels despite therapy. Assuming no medication and BW changes, our model predicts that 60% are participants progressing in their disease status. The mean observed difference in HbA1c was 1.46 mmol/l (range from −26.0 to 52.0), while the expected difference without any intervention was 1.73 mmol/l (range from −9.54 to 28.2).

Conclusion: We developed a model that successfully describes progression of T2DM considering two key clinical biomarkers (FPG and HbA1c) simultaneously. In addition, it allows to determine intrinsic disease progression not affected by the influence of body weight and other clinical interventions. Our approach presents a new strategy to determine new parameters that can be used in predicting disease progression.

Breastfeeding effect on insulin and adipokines secretion in women during postpartum period

L. Tchapmi Wandji, S. Leumi, M. Guewo-Fokeng, E. Djahmeni, M. Dehayem, M. Etoa, J. Mbanya, E. Sobngwi;
Molecular medicine and metabolism, University of Yaounde 1, Yaoundé, Cameroon.

Background and aims: Health benefits of breastfeeding have so far focused mainly on infants. However, lactating women could be concerned including weight loss and improved lipid and glycemic metabolism. Because of the energy expenditure associated with breastfeeding and the possible stimulation of insulin secretion by prolactin, we aim to determine the effects of breastfeeding on insulin and adipokines secretion in lactating women.
Materials and methods: We conducted a prospective observational study in a cohort of 38 women over the first six weeks postpartum. They were classified into two groups including exclusive breastfeeding, and mixed or bottle feeding, according to the self-reported predominant infant feeding practice over the observation period. In all participants, we calculated the BMI, measured serum lipids, and performed a 75-g oral glucose tolerance test (OGTT) at two days postpartum, and at the six weeks postpartum vaccination visit. At the second visit, serum levels of C-peptide, adiponectin and TNF-alpha (tumor necrosis factor alpha) were measured. Eating habits and physical activity were recorded using an interviewer-administered standardized questionnaire.
Results: The median age of the participants was 27 [22–29] years old. No participants had a glycemic abnormality at both visits, however, the "exclusive breastfeeding" group had a lower fasting blood glucose at the second visit (4.31 ± 0.55 mmol/L vs. 4.59 ± 0 25 mmol/L, $p = 0.03$). There was no significant difference in the anthropometric and lipid profile between the two groups at the first visit and after six weeks of observation. At the second visit, compared to the mixed or artificial breastfeeding group, the exclusive breastfeeding group had lower levels of C-Peptide (14.50 ± 1.04 pmol/L vs. 14.56 ± 0.73 pmol/L) a higher HOMA-B (54.28 [52.93; 56.86] vs 53.44 [52.96; 54.19]) and a lower HOMA-IR (1.522 ± 0.003 vs. 1.524 ± 0.002). In addition, this group had lower TNF-alpha levels (5.53 ± 3.82 pg/mL vs. 7.48 ± 7.28 pg/mL) and higher adiponectin levels (66.99 ± 4.45 ng/mL vs 65.28 ± 6.13 ng/mL) compared with mixed and artificial breastfeeding group. These associations were significant after adjustment for age, diet and physical activity.
Conclusion: Exclusive breastfeeding is associated with better insulin sensitivity, better insulin secretion, higher levels of adiponectin and lower levels of TNF-alpha compared to mixed or artificial breastfeeding during the first six weeks postpartum. Thus, exclusive breastfeeding has metabolic benefits in postpartum women and may be useful in the prevention of diabetes and related diseases.

Effects of preoperative hepatitis B virus infection, hepatitis C virus infection, and co-infection on the development of new-onset diabetes after kidney transplantation

M. Yu, J. Liang, C. Lv, M. Xu, J. Gao, R. Rong, T. Zhu;
Zhongshan hospital, Fudan university, Shanghai, China.

Background and aims: The effects of preoperative hepatitis B virus (HBV) infection, hepatitis C virus (HCV) infection, and co-infection with both viruses on the development of new-onset diabetes after transplantation (NODAT) remains unexplored and controversial in kidney transplant recipients (KTRs). We aimed to examine the associations between different preoperative viral statuses, including HBV infection, HCV infection, as well as co-infection and incident NODAT in a large population of Chinese KTRs. Important confounders were adjusted.
Materials and methods: We conducted a retrospective cohort study of 915 KTRs from Zhongshan Hospital (1993–2014). Exclusion criteria included pre-transplant diabetes, incomplete information, graft loss or death within the first post-transplant year, multiple organ transplantation and renal retransplantation, and the remaining 557 KTRs were enrolled in present study. Pre- and postoperative data were extracted and analyzed. NODAT was diagnosed following the American Diabetes Association guidelines (2014). Viral status was defined by the serological results for hepatitis B surface antigen and anti-HCV antibody. The cumulative incidence of NODAT was compared across 4 groups of KTRs with different viral statuses. Multivariate COX regression models were used to estimate the effects of HBV infection, HCV infection, and co-infection on incident NODAT; potential confounders including sex, age, family history of diabetes, body mass index, donor type, type of dialysis, primary polycystic kidney disease, preoperative levels of biochemical indicators, preoperative viral status, occurrence of acute rejection, medication for immunity induction and immunosuppression were adjusted.
Results: HCV seropositive KTRs, including those with HCV monoinfection and co-infection, presented with a significantly higher cumulative incidence of NODAT than the uninfected KTRs (both $P < 0.05$). Multivariate regression analysis showed that only HCV infection was a notable risk factor for NODAT, increasing the NODAT risk by 3.03 times (95% CI 1.77–5.18, $P < 0.001$). HBV infection and co-infection were not independently correlated with incident NODAT in KTRs.
Conclusion: Preoperative HCV infection remarkably increased the risk of NODAT in Chinese KTRs, while HBV infection and co-infection were not correlated with NODAT development.

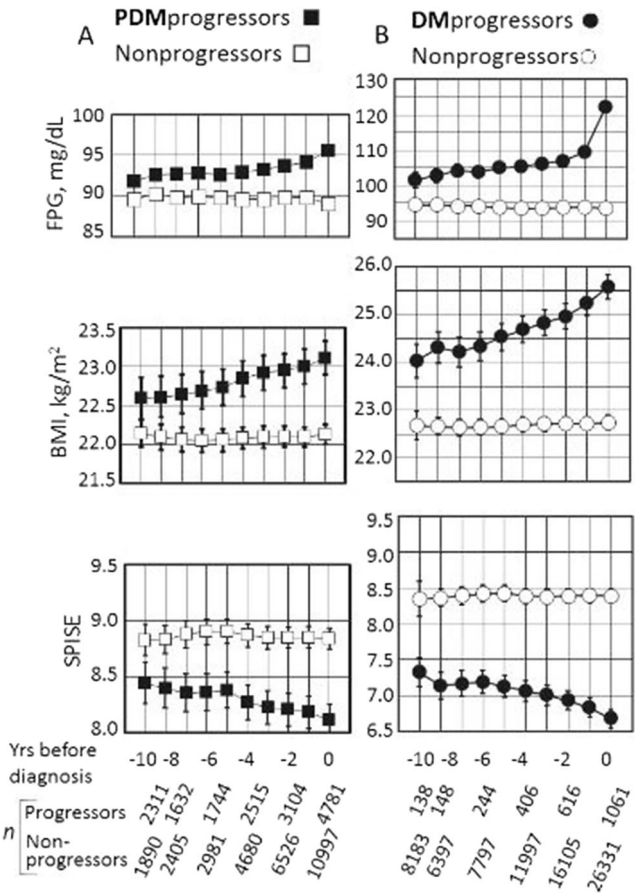
Type 2 diabetes: When does it start?

H. Sagesaka[1], Y. Sato[1], K. Yamashita[1], K. Hirabayashi[1], H. Koike[1], Y. Someya[2], Y. Tamura[2], H. Watada[2], M. Komatsu[3], T. Aizawa[1];
[1]Aizawa Hospital, Matsumoto, Japan, [2]Juntendo University, Tokyo, Japan, [3]Shinshu University, Matsumoto, Japan.

Background and aims: Timeline of type 2 diabetes (DM) has not fully been understood. Above all, it remains unclear when it begins. To disclose the onset of dysglycaemia leading to DM, we assessed trajectories of fasting plasma glucose (FPG) in individuals developed DM, and those developed prediabetes (PDM), separately.
Materials and methods: Data from 27,392 non-diabetic health examinees (male/female ratio, 15,897/11,495; mean age 49 years and body mass index (BMI) 22.6 kg/m^2) containing 15,778 with normal glucose regulation (NGR) and 11,614 with PDM, was retrospectively analyzed with a 5.3 year (mean)-observation. DM was diagnosed with fasting plasma glucose (FPG) ≥126 mg/dL and/or HbA1c ≥6.5%, PDM with FPG 110–125 mg/dL and/or HbA1c 5.7–6.4%, and NGR with FPG <110 mg/dL and HbA1c <5.7%. Trajectories of FPG, BMI, the single point insulin sensitivity estimator (SPISE) and HbA1c, prior to diagnosis of PDM or DM were assessed separately by mixed effects model. SPISE, $[(600 \times \text{HDL-c}^{0.185})/(\text{TG}^{0.2} \times \text{BMI}^{1.338})]$, is an index of insulin sensitivity (Si), where HDL-c is high-density lipoprotein cholesterol and TG triglycerides, both in mg/dL. Validity of SPISE in the Japanese subjects was confirmed in an independent non-diabetic cohort at Juntendo University: correlation between the rate of disappearance of glucose upon hyperinsulinaemic, euglycaemic clamp and SPISE was robust (Spearman rho 0.688, $P < 0.01$, $n = 111$).
Results: Out of 27,392 non-diabetic individuals, 1,061 developed diabetes in whom FPG and BMI were higher and SPISE lower than in those who did not, already at −10 years (all $P < 0.01$): the differences were progressively greater to year 0 (the time of DM diagnosis) (Figure, the right panels). In those developed diabetes, 986 were with PDM and 75 with NGR at baseline, and FPG at −10 years were significantly higher than in newly diagnosed subjects with PDM. Out of 15,778 with NGR,

4781 developed prediabetes, in whom FPG, BMI and SPISE were slightly but significantly different from those who did not at −10 years (all $P < 0.01$). Again, the differences were progressively greater to year 0 (the time of PDM diagnosis).

Conclusion: Glucose dysregulation, increased BMI and lowered Si were detectable at −10 years of diagnosis of DM, and the same abnormalities, albeit mild in degree, existed at least 10 years before diagnosis of PDM. Vast majority of patients with DM gone through the stage of PDM, so that diabetes may have commenced >20 years before its diagnosis. *Figure Legend.* Trajectories of FPG, BMI and SPISE. The right panels, subjects developed and not developed diabetes; the left panels, those developed and not developed prediabetes. Differences between the two groups at each year were all statistically significant ($P < 0.01$). Data are estimated marginal means and 95%CI obtained by mixed effects model. Variation in the graphs for FPG was so small that it is not visible. Years and the number of subjects (every two years for the sake of visibility) shown at the bottom.



Disclosure: **H. Sagesaka:** None.

Vitamin D, prediabetes and diabetes: bi-directional Mendelian randomisation analysis

N. Wang, L. Zhao, F. Xia, Y. Chen, C. Chen, B. Han, Q. Li, B. Hu, Y. Lu; Shanghai Ninth People's Hospital, Shanghai JiaoTong University School of Medicine, Shanghai, China.

Background and aims: Vitamin D deficiency is associated with prediabetes and diabetes in many observational studies. However, the causality between them has not been well established. We used bi-directional mendelian randomization (MR) analysis to explore the causal relationship between 25-hydroxyvitamin D [25(OH)D] and glycemic status and indices.

Materials and methods: Participants were included from a survey in East China from 2014–2016 (10,338 and 10,655 participants having diabetes and vitamin D related genotyping information). We calculated weighted genetic risk scores (VD_GRS and DM_GRS) as the instrumental variables for 25(OH)D concentration and diabetes based on related single nucleotide polymorphisms (four SNPs for 25(OH)D and eighteen for diabetes and prediabetes). Fasting plasma glucose and HbA1c were measured. Diagnosis of diabetes and prediabetes was based on American Diabetes Association criteria.

Results: Mendelian randomization analysis showed no significant associations of 25(OH)D with FPG, HbA_{1c} and risk of type 2 diabetes and prediabetes. The causal OR of genetically determined 25(OH)D for risk of diabetes and prediabetes was 0.985 (95%CI 0.940, 1.032) and 0.982 (95%CI 0.948, 1.016) respectively. Using $VD\_GRS_{metabolism}$ and $VD\_GRS_{synthesis}$, the results were not significantly changed. Moreover, the causal regression coefficient of genetically determined diabetes and prediabetes for 25(OH)D was 0.448 (–0.395, 1.291) and 1.303 (–1.210, 3.816). Thus, both directions showed no significant association.

Conclusion: Our results support the conclusion that there is no causal association between vitamin D and diabetes and prediabetes using a bi-directional MR approach.

FGF21 regulates insulin sensitivity following long-term chronic stress

M. Dille[1,2], T. Jelenik[1,2], S. Müller-Lühlhoff[1,2], D.G. Kabra[1,2], Z. Zhou[1,2], C. Binsch[1,2], A. Chadt[1,2], M. Roden[1,2], T.R. Castañeda[1,2], H. Al-Hasani[1,2];
[1]German Diabetes-Center, Düsseldorf, Germany, [2]German Center for Diabetes Research (DZD), München, Germany.

Background and aims: Chronic variable stress (CVS) may cause post-traumatic stress disorder (PTSD) and has been linked to increased risk for type 2 diabetes. However, the impact of stress on tissue-specific insulin sensitivity and metabolic long-term adaptations to stress are unknown. We investigated the influence of early life exposure to CVS on long-term insulin sensitivity and glucose metabolism.
Materials and methods: Twelve weeks old male, body weight matched C57BL/6J mice on standard chow were exposed to a 15 day intervention of CVS (swimming, cold exposure, shaking, restraint and isolation). The unstressed control (Ctrl) mice were housed separately. One group of Ctrl and CVS mice were analyzed directly after the CVS intervention. Another group of mice was kept three months without any further stress application (Ctrl3m, CVS3m). Whole-body insulin sensitivity was determined by hyperinsulinemic-euglycemic clamps. Additionally, insulin-stimulated glucose uptake and fatty acid oxidation was measured in intact isolated skeletal muscle. Insulin-stimulated glucose uptake was also determined in isolated primary white adipose cells. Tissues and plasma were collected for molecular and biochemical analyses. Organ-specific insulin signaling was analyzed following i.p. injection of insulin (1 unit/ kg body weight) or saline as a control.
Results: Acutely after stress intervention CVS mice showed markedly increased plasma corticosterone levels (Ctrl: 36.57 ± 8.27 ng/ml, CVS: 186.19 ± 47.49 ng/ml, mean ± SEM, One-Way ANOVA with Bonferroni post-test) and hepatic insulin resistance compared to the Ctrl (Ctrl: 117.1 ± 6.7% of basal, CVS: 91.7 ± 6.5% of basal, mean ± SEM, unpaired student's T-test). However, three months after the stress intervention (CVS3m) mice exhibited improved whole-body insulin sensitivity (Ctrl3m: 275.8 ± 16.7% of basal, CVS3m: 363.3 ± 28.7% of basal, mean ± SEM, unpaired student's T-test), increased insulin stimulated glucose uptake in adipose cells (Ctrl3m: 268.6 ± 35.16 CPM/mg lipid, CVS3m: 432.2 ± 63.1 CPM/mg lipid, mean ± SEM, One-Way ANOVA with Bonferroni post-test) and enhanced mitochondrial function. Plasma levels of fibroblast growths factor 21 (FGF21) were substantially elevated (Ctrl3m: 119.9 ± 26.26 pg/ml, CVS3m: 283 ± 73.55 pg/ml, mean ± SEM, One-Way ANOVA with Bonferroni post-test). Moreover, adipose tissue from CVS3m mice showed increased expression of genes involved in fatty acid oxidation (*Pgc1a*, *Cpt1a*) and formation of brown-like adipocytes (*Ucp1*, *Prdm16*, *Bmp7*).
Conclusion: Early life exposure to CVS leads to long-term improvements in insulin sensitivity, oxidative metabolism and adipose tissue remodeling. These improvements are related to the increase in FGF21 plasma levels and linked to a physiological memory mechanism for maintenance of metabolic homeostasis after early life CVS intervention.

Did decreasing prevalence of obesity and intensifying regular exercise reduce the number of people at high risk of developing diabetes? Results from nationwide survey

S. Katoh[1], H. Toshima[1,2], Y. Sakamoto[1], K. Utsunomiya[1];
[1]Jikei University, Tokyo, Japan, [2]Chiba Prefectural University of Health Sciences, Chiba, Japan.

Background and aims: The annual National Health and Nutrition Survey (NHNS) is a nationwide population-based survey composed of a questionnaire, physical examination and blood test, conducted by the Japanese Ministry of Health, Labour and Welfare (MHLW). Geographic areas covered by the survey are randomly selected every year. According to the NHNS, the number of people treated with antidiabetic medication or with glycated hemoglobin (HbA1c) ≥6.5% has increased since 1997, while the number of people with 6.5 > HbA1c ≥ 6.0%, who are at high risk of developing diabetes, has decreased since 2007. The MHLW in 2008 began an annual specific medical examination (SME) program for all Japanese workers, followed by lifestyle interventions among those who are at high risk of developing obesity and diabetes. We examined the effectiveness of the SME program by using NHNS data to investigate relationships among trends in the prevalence of obesity, regular exercise, and the number of people who are at risk of developing diabetes.
Materials and methods: As individual data are unavailable, we conducted retrospective analyses using publically available NHNS age group data from 2016 (n = 26,354) and 2015 (n = 6,655) to investigate the longitudinal trend in the prevalence of obesity (body mass index ≥25.0) in Japan. Participants were divided into groups according to sex and age group (20–29, 30–39, 40–49, 50–59, and 60–69 years; and 70 years or older). For example, the population aged 50–59 years in the 2016 survey was aged 40–49 years in 2006 and aged 30–39 years in 1996. In this way, we extrapolated population data and compared 10-year age groups by 10-year survey intervals as if they were longitudinal quasi-cohorts (i.e., we compared NHNS group data from 2016 with data from 2006 and 1996, as well as NHNS group data from 2015 with that from 2005 and 1995; in total, 12 male and 12 female groups). Ratio of persons engaged in regular exercise (RPERE) was calculated, with regular exercise defined as ≥30-min sessions at least 2 times a week, continued for 1 year or more. The same method was applied to the Korean National Health and Nutrition Examination Survey (KNHANES) and the US National Health and Nutrition Examination Survey (NHANES) for reference.
Results: Prevalence of obesity significantly increased from NHNS 1996/1997 to 2006/2007 (25.6 ± 3.2 to 29.3 ± 3.2, $p < 0.0001$) but significantly decreased from 2006/2007 to 2016/2017 (29.3 ± 3.2 to 26.0 ± 3.7, $p = 0.0041$). The delta of prevalence of obesity from NHNS 1996/1997 to 2006/2007 was +6.49 ± 4.6, and that from 2006/2007 to 2016/2017 was +0.13 ± 4.5. These delta values were significantly different ($p = 0.0001$) and were significantly correlated with the corresponding delta of RPERE ($r = 0.447$, $p = 0.0097$ for a total of 32 group data sets). A similar decreasing trend in the prevalence of obesity was observed in KNHANES among only Korean men aged 40–59 years from 1998 to 2013/2014, while an increasing trend was observed among Korean women in KNHANES and among American men and women in NHAMES from the 1960s to 1999/2000.
Conclusion: Prevalence of obesity in the Japanese population decreased (or at least, leveled off), and this was associated with intensified regular exercise. A nationwide lifestyle intervention program may successfully contribute to this change, followed by a decrease in the number of people at high risk of developing diabetes (6.5 > HbA1c ≥ 6.0%).

Insomnia and incident risk of diabetes related complications in Hong Kong Chinese patients with type 2 diabetes

C. Ding[1], J. Zhang[2], E. Lau[1], A. Luk[1,3], E. Chow[1], R. Ma[1,3], J. Chan[1,3], Y. Wing[2], A. Kong[1,3];
[1]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Shatin, Hong Kong, [2]Department of Psychiatry, The Chinese University of Hong Kong, Shatin, Hong Kong, [3]Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Shatin, Hong Kong.

Background and aims: Insomnia is associated with worse glycaemic control in patients with type 2 diabetes (T2D). However, whether insomnia has impact on the development of diabetes related complications is under-explored. We hypothesized that insomnia might be associated with increased risk of incident clinical endpoints. Here, we tested the

hypothesis by examining the associations between insomnia and incident clinical endpoints in patients with T2D.

Materials and methods: Participants of Hong Kong Diabetes Register were assessed for sleep habits and insomnia by questionnaires between July 2010 and June 2015 and were prospectively followed up for outcomes. Insomnia was defined as the Insomnia Severity Index score >14. Clinical outcomes including incident cardiovascular disease (CVD), chronic kidney disease (CKD), end-stage renal disease (ESRD), cancer and all-cause death were censored on 30th June 2017.

Results: Among 3407 patients with T2D [mean (standard deviation) age was 54.4 (8.5) years, 57.5% were men], 9.5% had insomnia. Compared to T2D without insomnia, T2D with insomnia had more women (52.2 vs 41.5%), anxiety/depressive symptoms (51.6 vs 15.4%), habitual snoring (44.5 vs 34.9%), worse glycaemic control [glycated haemoglobin, HbA_{1c} 7.72 (1.74) vs 7.50 (1.46) %; fasting plasma glucose 7.91 (3.21) vs 7.54 (2.37) mmol/l] despite the fact that there were higher percentage of T2D with insomnia were put on insulin treatment (31.1 vs 24.6%) than those without insomnia (all $p < 0.05$). At baseline, T2D with insomnia had a higher percentage of sensory neuropathy (7.5 vs 3.2%, $p < 0.001$) and macroalbuminuria (13.1 vs 9.2%, $p = 0.024$) We excluded snorers ($n = 1360$) who might have obstructive sleep apnoea. Among 2047 non-snorers, after a mean follow-up of 4.74 (1.22) years, T2D with insomnia had a higher incidence of ESRD (1.51% versus 0.50%, $p = 0.001$) than T2D without insomnia. After adjusted for potential confounders including age, sex, disease duration of diabetes, HbA_{1c}, low density lipoprotein cholesterol, triglyceride, body mass index, blood pressure, mean sleep duration, anxiety and depression, smoker and drinking habits and medications (anti-diabetic drugs, insulin, anti-hypertensives and lipid-lowering agents), insomnia remained to be significantly associated with increased risk of incident ESRD in patients with T2D (Hazard ratio, HR 2.36, 95% confidence interval, CI 1.02–5.45, $p = 0.044$). However, the effect became attenuated after further adjustment for macroalbuminuria and sensory neuropathy (HR 1.99, 95% CI 0.83–4.75, $p = 0.121$).

Conclusion: T2D patients with co-morbid insomnia may have increased risk of ESRD when compared to their counterparts without insomnia. Our findings suggest a possible link between mental and physical health and call for a holistic approach to improving diabetes care. Long-term prospective studies including T2D with insomnia but without complications at baseline would be required to examine the impact of insomnia on the development of diabetic complications.

Effects of dietary and physical activity interventions on type 2 diabetes risk in South Asians: individual participant data meta-analysis of randomised controlled trials

A.K. Jenum[1], I. Brekke[2], I. Mdala[1], M. Muilwijk[3], A. Ramachandran[4], M. Kjøllesdal[5], K.R. Richardsen[2], G. Cezard[6], A. Sheikh[6], C.A. Celis-Morales[7], J.M.R. Gill[7], N. Sattar[7], K. Stronks[3], E.J.A. Beune[3], I.G.M. van Valkengoed[3];

[1]1. General Practice Research Unit, Dept. of General Practice, University of Oslo, Oslo, Norway, [2]Oslo Metropolitan University, Oslo, Norway, [3] Dept. of Public Health, Academic Medical Center, Amsterdam, Netherlands, [4]Dr.A.Ramachandran's Diabetes Hospital, Chennai, India, [5]Dept. of Community Medicine and Global Health, University of Oslo, Oslo, Norway, [6]University of Edinburgh, Edinburgh, UK, [7]University of Glasgow, Glasgow, UK.

Background and aims: People of South Asian origin are at higher risk of type 2 diabetes. Effectiveness of lifestyle modification (LSM) interventions incorporating diet and/or physical activity to prevent diabetes in South Asians is unclear, given the small number of studies, the relatively low numbers of cases, and variation in outcome reporting across studies. Therefore, we performed an individual participant data (IPD) meta-analysis of randomised controlled trials (RCTs) in these high-risk populations.

Materials and methods: We searched PUBMED, Embase, Cochrane Library and Web of Science (to September 30th 2017), and obtained IPD on 1816 participants from all six eligible RCTs on LSM in high-risk South Asian adults, both from Europe and India. The quality according to the Quality Assessment Tool for Quantitative Studies was strong for five studies, and moderate for one. Applying a 2-step approach, we generated hazard ratio (HR) estimates for incident diabetes and mean differences for fasting glucose, 2-hour glucose, weight and waist circumference, using fixed-effects meta-analysis overall, and by pre-specified subgroups. We applied the GRADE system to rate the quality of evidence. (PROSPERO registration CRD4217078003).

Results: Incident diabetes was observed in 118 of 932 (12.6%) participants in the intervention group and in 176 of 876 (20.0%) participants in the control group. The adjusted HR was 0.65 (95% CI 0.51 to 0.82; $I^2 = 0\%$) in the intervention compared with control groups; the absolute difference was 7.4% (95% CI 1 to 16), with no subgroup differences for sex, age, BMI, study duration or region. The GRADE quality of evidence was rated as moderate. Mean difference for intervention versus control groups for 2-hour glucose was −0.35 mmol/l (95% CI −0.63 to −0.06; $I^2 = 51\%$); for weight −0.76 kg (95% CI −1.36 to −0.15; $I^2 = 72\%$) and for waist −1.16 cm (95% CI −2.15 to −0.17; $I^2 = 74\%$). Findings were also similar across subgroups for these measures, except for weight by region. No effect was found for fasting glucose.

Conclusion: In high-risk South Asian populations, LSM interventions resulted in a 35% relative reduction in diabetes incidence, which was consistently present across pre-specified subgroups. This suggests that LSM interventions should be more widely used in these populations across different contexts.

Investigation of vitamin D metabolites, vitamin D genes, and risk of type 1 diabetes: the Diabetes Autoimmunity Study in the Young (DAISY)

J.M. Norris[1], N.L. Zwick[1], B.C. DeFelice[2], R.K. Johnson[1], F. Dong[3], L. Vanderlinden[1], P. Carry[1], J. Seifert[1], B.I. Frohnert[3], K. Kechris[1], T. Fingerlin[4], O. Fiehn[2], M. Rewers[3];

[1]Colorado School of Public Health, Aurora, CO, USA, [2]University of California Davis, Davis, CA, USA, [3]The Barbara Davis Center, Aurora, CO, USA, [4]National Jewish Health, Denver, CO, USA.

Background and aims: Vitamin D has been inconsistently identified as a protective factor for type 1 diabetes (T1D). Lack of evidence regarding the timing of the effect of vitamin D, i.e., before or after islet autoantibody seroconversion, and the influence of genetic variation on the effect of vitamin D may explain these inconsistencies. This study investigated the associations between several metabolites in the vitamin D pathway and T1D, and examined whether the effect of these metabolites was modified by alleles in vitamin D pathway genes.

Materials and methods: Children at increased genetic risk of T1D have been followed from birth by the Diabetes Autoimmunity Study in the Young (DAISY). We conducted a nested case-control study in 74 T1D cases and 72 controls, frequency matched on age at autoantibody seroconversion (in the case) and ethnicity. Plasma vitamin D metabolites (vitamin D_3, $25(OH)D_3$, $25(OH)D_2$, 3-epi $25(OH)D_3$, $24,25(OH)_2D_3$, and $1,25(OH)_2D_3$) were quantified by LC-MS/MS analysis in samples collected prior to the development of T1D at time points both before and after autoantibody seroconversion for the T1D case and age-similar time points for the control. Variants in vitamin D pathway genes (*GC*, *CYP27B1*, *CYP24A1* and *VDR*) were genotyped using the Taqman OpenArray platform. Multivariable logistic regression analyses were conducted examining vitamin D metabolite levels from pre- and post-

autoantibody seroconversion time points on the odds of T1D, adjusting for HLA-DR3/4. Gene variant x metabolite interaction terms were used to test for effect modification.

Results: Significant interactions between the rs4588 variant in *GC* and post-seroconversion levels of vitamin D_3 ($p = 0.016$), $25(OH)D_3$ ($p = 0.017$) and $24,25(OH)_2D_3$ ($p = 0.033$) on the odds of T1D were detected. Higher vitamin D_3 (OR: 0.80; CI: 0.66–0.96), $25(OH)D_3$ (OR: 0.84; 95%CI: 0.73–0.97) and $24,25(OH)_2D_3$ (OR: 0.87; CI: 0.79–0.97) levels were inversely associated with T1D in children carrying at least one minor allele at rs4588 but not in children with no minor alleles. No consistent associations or interactions were observed for levels of vitamin D metabolites measured prior to autoantibody seroconversion.

Conclusion: The *GC* gene encodes the vitamin D binding protein, which is responsible for transporting all vitamin D pathway metabolites and therefore plays an important role in the action of vitamin D. Moreover, the rs4588 variant of *GC* has been associated with differences in protein glycosylation and levels of binding protein. These results suggest that *GC* may modify the effect of multiple vitamin D pathway metabolites on T1D development in children at increased genetic risk of the disease, particularly later in the disease process.

Adherence to the Dutch dietary guidelines 2015 and the risk of prediabetes and type 2 diabetes in Dutch adults: the New Hoorn study

N.R. den Braver[1], A.L.J. van der Spek[1], M. Looman[2], M.M.E. Geelen[2], J. Lakerveld[1], F. Rutters[1], J. Brug[1,3], S.S. Soedama-Muthu[2,4], J.W.J. Beulens[1,5];

[1]Epidemiology & Biostatistics, VU Medical Center, Amsterdam, Netherlands, [2]Division of Human Nutrition, Wageningen University and Research, Wageningen, Netherlands, [3]Faculty of Social and Behavioural Science, University of Amsterdam, Amsterdam, Netherlands, [4]Department of Medical and Clinical Psychology, Tilburg University, Tilburg, Netherlands, [5]Julius Center for Health Sciences and Primary Care, Univesity Medical Center Utrecht, Utrecht, Netherlands.

Background and aims: In order to prevent ten major chronic diseases including type 2 diabetes (T2D), new Dutch dietary guidelines were developed with a focus on food groups rather than nutrients. In this study, we investigated whether adherence to these Dutch dietary guidelines was associated with prediabetes and T2D.

Materials and methods: In this prospective cohort 1624 participants, with an average age of 53.5 ± 6.5 years, 46.7% male and without T2D at baseline, were included in the analyses. Information on baseline dietary intake was assessed using a validated 104-item Food Frequency Questionnaire and classified in tertiles of adherence to the Dutch Healthy Diet 2015 (DHD15) index (range: 0–140). Prediabetes and T2D were classified according to the WHO criteria 2011. Multivariable multinomial regression analyses were performed to estimate odds ratios for prediabetes and T2D, adjusted for follow-up duration, energy intake, baseline prediabetes, sociodemographic- and lifestyle factors. In addition, fasting plasma glucose (FPG) levels (mmol/L) were analysed using linear regression analyses, additionally adjusted for baseline value and medication use.

Results: During a mean follow-up of 7.2 ± 0.7 years, 419 participants developed prediabetes and 143 participants developed T2D. Highest adherence to the DHD15 was associated with prediabetes, compared to lowest adherence ($OR_{T3\text{-}T1} = 0.72$ (0.53; 0.99), $p_{trend} = 0.05$), while there was no association with T2D incidence ($OR_{T3\text{-}T1} = 1.01$ (0.60; 1.72), $p_{trend} = 0.98$). Each 15 point increase in DHD index was not associated FPG levels (0.014 mmol/L (−0.035; 0.007)).

Conclusion: In this Dutch population-based study, adhering to the Dutch dietary guidelines 2015 was associated with lower prediabetes, but not association with T2D, during seven years of follow-up. These results indicate that prevention strategies should focus on early stage disease development.

Plasma ceramides and dairy consumption in the D.E.S.I.R. study

F. Fumeron[1,2], A. Nicolas[1,3], L. Wigger[4,5], M. Ibberson[4], C. Cruciani-Guglielmacci[2,6], H. Le Stunff[6], G. Velho[1], C. Magnan[2,6], M. Marre[2,7], B. Balkau[8,9], R. Roussel[2,7];

[1]INSERM UMRS 1138, Paris, France, [2]Université Paris Diderot, Sorbonne Paris Cité, Paris, France, [3]UPMC Univ Paris 6, Sorbonne Universités, Paris, France, [4]Vital-IT Group, SIB Swiss Institute of Bioinformatics, Lausanne, Switzerland, [5]Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland, [6]Unité de Biologie Fonctionnelle et Adaptative (BFA), CNRS UMR 8251, Paris, France, [7]Diabetology, Endocrinology, Nutrition, APHP - Bichat Hospital, Paris, France, [8]Centre for research in Epidemiology and Population Health (CESP), INSERM, U1018, Villejuif, France, [9]Umr-s 1018, University Paris-Sud, University Versailles Saint-Quentin, Villejuif, France.

Background and aims: In the D.E.S.I.R. cohort, a higher consumption of dairy products is associated with lower 9-year incidence of the metabolic syndrome and of impaired fasting glycemia/type 2 diabetes. In the same population, plasma dihydroceramide concentrations are higher in people who progress to diabetes, up to 9 years before disease onset. Our aim is to study relationships between dairy consumption and concentrations of dihydroceramides and ceramides.

Materials and methods: In total, 5212 volunteers from western-central France were included in the D.E.S.I.R. cohort. At baseline they reported the frequency and level of consumption of different foods; two items concerned dairy products (cheese, other dairy products). For these two items, we divided participants into two groups (high, low) according to the consumptions. At baseline, then at years 3, 6 and 9, dihydroceramides and ceramides were determined by mass spectrometry in a subset of the cohort ($n = 295$); we analyzed the 105 people who did not progress to diabetes, because disease *per se* might be a confounding factor. The associations between plasma lipids (log values) over follow-up with baseline dairy intake, sex and their interaction, were tested by analysis of covariance (ANCOVA) for repeated measures, adjusted for age, BMI, alcohol intake, total energy intake, physical activity, plasma cholesterol, triglycerides and fasting plasma glucose.

Results: A higher consumption of dairy products (other than cheese) was associated with total plasma dihydroceramides during follow-up, in interaction with sex ($P = 0.01$): dihydroceramide levels were lower in women with high consumption as compared to the low consumers ($P = 0.03$), with a significant increase in dihydroceramides during the follow-up ($P = 0.01$) in low consumers only. In men, no significant association was found. There was also a trend for lower plasma ceramides in women with a high intake of dairy (other than cheese) ($P = 0.08$). Cheese intake was associated with plasma dihydroceramides and ceramides during follow-up ($P = 0.04$ for both), with trends for lower levels in high consumers, and for higher levels in low consumers (non-significant).

Conclusion: These results show, in women, an inverse association between fresh dairy product consumption and plasma predictive markers of type 2, dihydroceramides.

Plasma total plasma dihydroceramide concentration (µmol/l, median [25-75%]) in 51 women without diabetes at follow-up, according to intake of dairy (except cheese)

	Baseline	3 years	6 years	9 years
Low intake	0.135 [0.114-0.158]	0.137 [0.118-0.167]	0.155 [0.124-0.218]	0.164 [0.131-0.236]
High intake	0.125 [0.101-0.175]	0.122 [0.090-0.167]	0.125 [0.103-0.189]	0.135 [0.088-0.170]

P (intake)=0.03; in low intake group, P (time)=0.01; in high intake group, P (time)=0.95 by ANCOVA for repeated measures, adjusted for age, BMI, alcohol intake, total energy intake, physical activity, plasma cholesterol, triglycerides, fasting plasma glucose

Factors predicting participation in the Diabetes Prevention Program (DPP) among people with prediabetes

W.H. Herman, K.L. Joiner, M.B. Stites, L.N. McEwen;
University of Michigan, Ann Arbor, MI, USA.

Background and aims: Since September 2015, the University of Michigan has paid for interventions for diabetes prevention for its employees, dependents, and retirees with prediabetes. We studied individuals with prediabetes who chose to participate or not participate in the DPP to identify strategies to better target interventions to improve uptake.
Materials and methods: As a first implementation strategy, nondiabetic individuals ≥18 years of age with BMI ≥25 kg/m² (23 if Asian) and a claims diagnosis of prediabetes or an HbA1c 5.7–6.4% (39–46 mmol/mol) were identified using insurance claims data. They were then mailed one letter of invitation and one reminder letter. After human subjects approval, surveys were mailed to individuals who enrolled in the DPP and a random sample of those who did not. T-tests and chi-square tests were used to compare the demographic characteristics and domains of the Health Belief Model between DPP enrollees and non-enrollees and a multivariable model was subsequently constructed.
Results: By January 2018, 7,389 individuals with prediabetes were invited to participate and 565 (8%) enrolled. 356 of 510 DPP enrollees and 472 of a random sample of 1,200 non-enrollees completed surveys (response rates 74% and 39% respectively). Women (73% vs. 61%) and individuals with higher education (68% vs. 59% ≥ college) were significantly more likely to enroll. Enrollment did not differ by age (55 ± 11 yrs) or race (79% white). Enrollees reported higher perceived susceptibility based on family history of diabetes (60% vs. 50%), greater knowledge of diabetes risk factors, higher body mass index (32 vs. 30 kg/m²), higher perceived risk of developing diabetes, more worry about diabetes, and less optimistic bias. Both enrollees and non-enrollees perceived diabetes to be a serious disease. Enrollees and non-enrollees did not differ with respect to perceived benefit of engaging in lifestyle interventions or perceived barriers to action. Self-efficacy as assessed by sense of personal control was greater in enrollees but confidence in ability to eat a healthy diet and engage in regular physical activity did not differ between groups. Cues to action and social support were the major factors distinguishing enrollees and non-enrollees. 74% of enrollees but only 24% of non-enrollees were aware that they had prediabetes. 62% of enrollees vs. 15% of non-enrollees recalled receiving a letter encouraging them to enroll. 30% of enrollees indicated that their doctor and 17% indicated that a family member, friend, or coworker had encouraged them to enroll. Among non-enrollees, these rates were only 10% and 4%. In multivariate analysis, enrollees were significantly more likely to be women, have more knowledge of diabetes risk factors, have higher BMI, report more personal control over their health, be aware of their prediabetes status, recall receiving a letter encouraging them to enroll, and receiving support from a physician, family member, friend, or coworker to enroll in the DPP.
Conclusion: Making the DPP available at no cost to people with prediabetes has been effective in increasing enrollment above previously reported rates. Efforts to increase enrollment should target men and focus on increasing individual awareness of prediabetes and support for participation from physicians, family, friends, and coworkers.

Phthalates exposure as determinant of albuminuria in type 2 diabetes subjects: a cross-sectional study

A. Mengozzi[1], F. Carli[2], V. Della Latta[2], E. Buzzigoli[2], M. Seghieri[1], E. Biancalana[1], A. Solini[1], A. Gastaldelli[2];
[1]University of Pisa, Pisa, Italy, [2]National Research Council, Pisa, Italy.

Background and aims: Albuminuria is considered an independent risk factor for cardiovascular (CV) disease. Recent epidemiological studies have reported an association between exposure to phthalates, a group of environmental and dietary contaminants, and states of higher CV risk like insulin resistance, obesity and type 2 diabetes (T2D). No studies have so far addressed the presence of these compounds in urines of T2D individuals with different degrees of renal function.

Materials and methods: We enrolled 209 T2D patients (75.5% normoalbuminuric, 19.7% microalbuminuric, 4.8% macroalbuminuric) consecutively referring to Pisa hospital outpatient diabetes clinic. Routine blood laboratory tests were centrally performed. Total concentrations of three different phthalate urinary metabolites of di-2-ethylhexylphthalate (DEHP), *i.e.* mono 2-ethylhexyl phthalate (MEHP), mono-2-ethyl-5-oxohexyl phthalate (MEOHP) and mono 2-ethyl-5-hydroxyhexyl phthalate (MEHHP), were quantified in a spot morning urine sample by ultra-HPLC coupled with electrospray ionization/quadrupole time-of-flight MS. Data were normalized for creatinine urinary excretion and related to clinical and biochemical parameters, adjusting for potential confounders by univariable and multivariable regression models.

Results: Mean age of the participants was 67.8 ± 12.4 years; 59% males. Median T2D duration was 10.5 ± 9.7 years, HbA_1c was 7.18 ± 1.31%; 29% of them were insulin-treated. The three metabolites were detected in 92% (MEHP), 96% (MEOHP), 94% (MEHHP) of the subjects. Creatinine-adjusted urinary concentrations medians of MEHP, MEOHP, MEHHP were 7.53 [4.84–12.60] μg/g, 3.04 [1.03–5.14] μg/g and 10.70 [7.02–17.40] μg/g. Data from DEMOCOPHES, a recent European human biomonitoring study, showed similar ranges of exposure. Using the median values as cut-off, no difference emerged according to age, sex, BMI, T2D duration, smoking, BP, HBA_1c; GFR (estimated with CDK-EPI equation) did not influence urinary levels of these metabolites, even in subjects below 45 ml/min/1.73 m^2 (n = 22). This was also true after adjusting for confounders. Exposure to MEHP and MEOHP was significantly higher in micro/macroalbuminuric than in normoalbuminuric individuals ($p < 0.02$ for MEHP; $p < 0.04$ for MEOHP). When stratified for quartiles of each urinary metabolite, after adjustment for clinical variables (age, sex, BMI, T2D duration, smoking, BP, HBA_1c and GFR), 4th vs 1st quartile of MEHP and MEOHP showed a significant higher risk of albuminuria (OR 4.83 [CI 1.45–16.06], $p < 0.03$ for trend for MEHP; OR 3.29 [CI 1.08–10.04], $p < 0.04$ for trend for MEOHP). Comparing their levels in subjects with and without previous CV events, MEOHP was significantly higher in the former ($p = 0.034$), with a positive trend ($p = 0.061$) for MEHP too.

Conclusion: These findings point out for the first time an association between exposure to specific metabolites of DEHP and degree of AER in T2D subjects; the lack of relation with GFR suggests their urinary levels to be independent of renal function, rather representing a potential early hallmark of widespread vascular damage. Though with the limitations of a cross-sectional study, a long-term exposure to these contaminants might mark a higher CV risk, thus implying the need for prospective studies addressing the pathophysiologic mechanisms underlying such association.

Selected osteoprotegerin gene variants as diabetic foot risk factors

P. Nehring[1], B. Mrozikiewicz-Rakowska[2], K. Szymański[3], A. Sobczyk-Kopcioł[4], N.A. Acharya[5], R. Płoski[3], W. Drygas[6], J. Krzymień[2], L. Czupryniak[2];

[1]Department of Gastroenterology and Internal Medicine, Medical University of Warsaw, Warszawa, Poland, [2]Department of Diabetology and Internal Medicine, Medical University of Warsaw, Warszawa, Poland, [3]Department of Medical Genetics, Medical University of Warsaw, Warszawa, Poland, [4]Department of General Biology and Parasitology, Medical University of Warsaw, Warszawa, Poland, [5]Medical University of Warsaw, Warszawa, Poland, [6]Department of Epidemiology, Cardiovascular Disease Prevention and Health Promotion, Institute of Cardiology, Warszawa, Poland.

Background and aims: Diabetic Foot (DF) ulceration and Charcot Neuroarthropathy (CN) are end point complications in type 1 and type 2 diabetes mellitus affecting up to 6% of population. Osteoprotegerin (OPG) is a key protein in bone metabolism. An emerging contribution of signaling pathway RANKL/RANK/OPG in the pathogenesis of DF and CN has been proposed. Here, we aimed to elucidate the role of selected OPG gene variants and their role in the risk of DF occurrence in diabetic patients.

Materials and methods: We enrolled 1268 individuals; 300 cases with diabetes mellitus and DF and 968 healthy controls. Of these, there were 252 subjects with type 2 diabetes, 43 with type 1 diabetes, 166 with DF of neuropathic origin, 102 with DF of neuroischemic origin and 77 with CN. Anthropometric analyses were obtained on all subjects and segregated for vascular and neuropathic complications due to diabetes. Genotyping for 15 OPG variants was performed using real time polymerase chain reaction.

Results: Compared to controls, rs1872426 and rs1485286 showed correlation with DF in diabetic subjects (OR = 1.4; $P = 0.05$ and OR = 0.46; $P = 0.003$, respectively). Significant association between rs2073618, rs1872426, rs7464496 and rs1485286 in men were reported (OR = 1.57; $P = 0.02$, OR = 1.92; $P = 0.005$, OR = 1.46; $P = 0.05$ and OR = 0.40; $P = 0.008$; respectively). The aforementioned correlations were also present in type 2 diabetes patients' subgroup. Between type 2 and type 1 diabetes patients, there was a difference in distribution of rs7464496 and rs2073618 alleles. Variant rs1485286 was associated to DF of neuropathic origin (OR = 0.36; $P = 0.007$). Sex-specificity for females was present for rs6993813 in patients with DF of neuropathic origin and type 1 diabetes (OR = 2.89; $P = 0.05$). In males with DF of neuropathic origin and type 2 diabetes were correlated with rs2073617 (OR = 1.76; $P = 0.04$), and males with DF of neuroischemic origin and type 2 diabetes with rs1872426 (OR = 3.05; $P = 0.02$). Variants rs1872426, rs2073617and rs1485286 were correlated with CN. There was a sex-specificity for woman of rs6993813 in patients with CN and type 1 diabetes. Anthropometric analyses proved that except height, the patients' age, body weight, body mass index, waist circumference, hip circumference and waist-hip ratio were among the basic risk factors of DF, except for diabetes itself.

Conclusion: Our findings suggest that the variants *TNFRSF11B* (rs2073618, rs2073617, rs1872426, rs1032128, rs7464496 and rs1485286), *COLEC10* (rs6993813) and *TNFSF11* (rs9533156) influence diabetic foot occurrence. This correlation is specific for sex, diabetes type and DF etiology. Altogether, it contributes towards the use of these OPG variants in genetic panels assessing in assessing risk of DF in the diabetic population alongside adequate correlation with clinical data, such as diabetes type, gender, age and other features.

Ramachandran's Diabetes Hospitals, Chennai, India, [6]Government of Dubai, Dubai Health Authority, Dubai, United Arab Emirates, [7]Biotechnology Center, Doctoral School of Life Sciences, Health and Environment, and Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde,

Cameroon, [8]Endocrinology Research Center, Moscow, Russian Federation, [9]Sanofi, Paris, France, [10]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, The Prince of Wales Hospital, Shatin, Hong Kong SAR, China.

Background and aims: New therapies and technologies mean that diabetes treatment has evolved over the last decade. We investigated whether this evolution has had any impact on the degree of glycaemic control and the frequency of diabetes-related complications in people with T2D in the developing world over this period.

Materials and methods: From 2005 to 2017, the IDMPS, a global observational survey on the management and patterns of care of people with type 1 (T1D) and T2D diabetes in the developing world, has collected data in 7 individual waves. Each wave enrolled different participants who were recruited from 48 countries across Africa, the Middle East, South Asia, Latin America, Asia and Eurasia.

Results: Mean disease duration ranged from 6.8 to 7.5 years across waves. From wave 1 to wave 7, no improvement in the proportion of people achieving HbA_{1c} <7% was seen. This was the case for all groups, i.e. those receiving oral glucose-lowering drugs (OGLDs) plus injectable treatments, and those receiving insulin (**Table**). The proportions of participants with micro- and macrovascular complications remained relatively unchanged. Throughout all waves, the proportion of participants receiving insulin remained constant (≈20%). For those treated with OGLDs plus basal insulin, the median daily dose of insulin was 0.21 U/kg in 2005 and 0.32 U/kg in 2017; over this period, the median BMI at diagnosis increased from 27 kg/m^2 to 29 kg/m^2.

Conclusion: Despite the introduction of new drugs/technologies, there has only been a small improvement in degree of metabolic control or experience of chronic complications for people with T2D in the developing world. For optimum outcomes, provision of new therapeutic tools should be accompanied by education of people with diabetes and their medical teams on proper use.

The impact of blood pressure on retinal vascular traits in patients with type 2 diabetes: a Mendelian Randomisation study

Y. Huang[1], T. Li[1], S. Hogg[2], G. McKay[3], E. Trucco[2], C. Palmer[1], A. Doney[1];

[1]Ninewells Hospital and Medical School, School of Medicine, University of Dundee, Dundee, UK, [2]Computing, School of Science and Engineering, University of Dundee, Dundee, Dundee, UK, [3]Centre for Public Health, Queen's University Belfast, Belfast, UK.

Background and aims: In patients with Type 2 Diabetes (T2D), Retinal Vascular Traits (RVTs) have potential for use as biomarkers for T2D complications. However, their clinical use in this context depends on their relationship to modifyable risk factors. In previous observational studies, BP has been associated with several RVTs. However, in patients with T2D this association may be confounded by other clinical factors such as dyslipidaemia or dysglycaemia etc. Therefore we used a Mendelian Randomization (MR) approach employing a genomic Instrumental Variable (IV) comprising a weighted Genetic Risk Score (wGRS) for systolic BP (SBP) to determine whether there is a true association between SBP and RVTs in patients with T2D.

Materials and methods: 3950 patients with T2D from Genetics of Diabetes Audit and Research in Tayside Scotland (GoDARTS) were selected for this study. RVTs were measured by VAMPIRE software from standard Diabetes Retinal Screening photographs. We considered central retinal artery/vein equivalent (CRAE, CRVE), their ratio (AVR), arterial/ venular fractal dimensions (d0a, d0v), tortuosity of the largest arterioles/venules (TORTA, TORTV). For each individual, the median SBP of all available measures before retinal image date was determined as the overall estimation of SBP exposure. A 262 SNP wGRS for SBP was constructed based on previous GWAS for BP by summing the number of risk alleles multiplied by their corresponding effect size. Linear regression was used to model the association of SBP with each RVT adjusting for sex and age (Observational Study). Two-stage least square regression was used for the MR study - wGRS for SBP as IV, adjusted for sex and age. The Wu-Hausman statistic was used to illustrate the difference between the observational and MR models. The 'ivreg' package in R was used for MR study.

Results: The median age at date of image was 70.9 years, 45.8% were female and median SBP was 140 mmHg. Overall, the wGRS could explain 1.36% of the variance of SBP after adjusting for sex and age. In the observational analysis SBP was found to be associated with CRAE, AVR, d0v and VTORT. However, in the MR model, SBP was only found to be associated with AVR and ATORT. Comparing observational model with the MR model, the Wu-Hausman statistic was significant when using AVR and ATORT as outcome variable. Meanwhile, in observational study, the effect size of SBP for AVR and ATOR are smaller than MR studies, which suggest the existence of confounding factors in observational study (Table 1).

Conclusion: According to this MR study, SBP is causally linked with ATORT and AVR. Thus these RVTs may be of particular relevance in therapeutic stratification of T2D risk of complications with respect to SBP management.

Table1. Results from observational study model and MR model

Diabetic kidney disease occurrence in a large cohort of patients with incident diabetes in the UK

D. Vizcaya[1], A. Gonzalez-Perez[2], M.E. Saez[2], L.A. Garcia Rodriguez[2]; [1]Epidemiology, Bayer Hispania SL, Barcelona, Spain, [2]Spanish Centre for Pharmacoepidemiologic Research (CEIFE), Madrid, Spain.

Background and aims: Chronic kidney disease (CKD) is a common and life-threatening complication of diabetes. We aimed to evaluate the incidence and time to CKD onset by stage in a large cohort of newly diagnosed type 1 and type 2 diabetes mellitus (T1D and T2D, respectively) patients.
Materials and methods: We identified a cohort of incident T1D and T2D patients aged 2 to 90 years old between 2002 and 2014 registered in the Health Improvement Network (THIN) database (UK). We followed this cohort from first diabetes mellitus (DM) diagnosis until the first of the following endpoints: occurrence of CKD, last data collection, 31 December 2015, or death. We defined CKD based on Read codes, eGFR and albuminuria values, using a modified version of a previously published algorithm. We assessed CKD stage based on eGFR values. We used two alternative definitions of CKD: CKD stages 3–5, and CKD/proteinuria (that includes CKD stages 3–5 and/or presence of proteinuria). Proteinuria was ascertained using Read codes, UACR >30 mg/g, and/or Albumin in urine >20 mg/L. We calculated age- and sex-adjusted incidence rates of CKD by using direct standardization.
Results: We identified 5,116 T1D and 161,852 T2D patients. As expected, the latter were noticeably older at time of first diagnosis, and consequently had greater number of comorbidities. Among the subcohort of DM patients free of CKD/proteinuria at baseline (n = 115,437), a total of 29,833 (25.8%) developed overall CKD/proteinuria during follow-up. Of these, 468 (1.57%) reached stage 5 and 71 (0.24%) reached end-stage renal disease (ESRD). Crude incidence rates of CKD/proteinuria per 100 person-years were 1.6 in T1D and 5.7 in T2D, with a mean follow-up of 5.6 (interquartile range: 2.6–8.1) and 4.7 (interquartile range: 2.0–6.8) years, respectively. The corresponding age- and sex-adjusted incidence rates were 6.1 and 5.5. In this cohort, average time from DM onset to CKD/proteinuria was 4.3 years among T1D and 3.6 years among T2D. On the other hand, crude incidence rates of CKD stages 3–5 were 0.4 and 2.8 per 100 person-years respectively in T1D and T2D. The corresponding age- and sex-adjusted incidence rates were 3.3 and 2.6 per 100 person-years.
Conclusion: According to our results, crude incidence rates of CKD are markedly higher among T2D patients as compared to T1D. In contrast after adjustment, in particular for age, results showed similar estimates between the two types of DM. In any case, caution is warranted when directly comparing DM types given inherent differences in disease etiology and patients' characteristics.

Larger and faster decline in eGFR among patients with vs without type 2 diabetes

G.A. Nichols[1], A. Deruaz-Luyet[2], S.J. Hauske[2], K.G. Brodovicz[3]; [1]Kaiser Permanente, Portland, OR, OR, USA, [2]Boehringer Ingelheim GmbH, Ingelheim am Rhein, Germany, [3]Boehringer Ingelheim Pharmaceuticals, Ridgefield, CT, USA.

Background and aims: Type 2 diabetes (T2D) is a well-known risk factor for chronic kidney disease (CKD) and for progression to end-stage renal disease (ESRD). Baseline kidney function is associated with rate of decline, which in turn increases ESRD risk. To our knowledge, no large study has evaluated baseline kidney function and rate of eGFR decline by T2D status. We aimed to compare the annual rate of eGFR decline for up to 11 years among patients with and without T2D.
Materials and methods: We used the electronic medical records of an integrated delivery system in the USA to identify 31,727 patients with and 33,157 patients without diagnosed T2D for whom we could calculate eGFR (CKD-EPI formula) from the first available serum creatinine value from 2006–2012 (baseline), confirmed by a second eGFR at least three months later if the first was <60 mL/min/1.73 m^2. We defined kidney function by KDIGO stages of eGFR (G1: ≥90 mL/min/m^2; G2: 60–89; G3a: 45–59; G3b: 30–44; G4: 15–29) and followed patients until their last available eGFR through December 2016. We calculated the annual decline in eGFR by subtracting the last eGFR from the baseline value, dividing by months between the two measures and multiplying by 12. Percentage change was calculated by dividing the change in value by the baseline value. We compared the mean percentage changes by baseline eGFR category between patients with and without T2D in total, by age strata (<65/≥65 years), and by sex.
Results: Mean percentage decline in eGFR (±SE) was greater among patients with T2D across all eGFR categories (Figure). Among those with T2D, the percentage change was substantially greater as baseline kidney function declined but was relatively constant across eGFR categories among those without T2D. As a result, the relative difference in eGFR decline between patients with vs. without T2D increased by category. For the category G1/G2, T2D was associated with a 1.56 times greater percent decline in eGFR (2.07% vs. 1.32%, $p < 0.001$). For G3a, G3b, and G4, the differences were 2.23 (3.55% vs. 1.59%, $p < 0.001$), 2.69 (4.14% vs. 1.54%, $p < 0.001$), and 3.61 (7.80% vs. 2.16%, $p = 0.217$) times greater, respectively. Mean percentage changes were somewhat greater among patients who were <65 or male with but not without T2D, resulting in larger relative differences in these strata (not shown).
Conclusion: Poorer baseline kidney function is associated with largerdeclines in eGFR among patients with T2D while declines by kidney function were much more modest among those without T2D. Thus, T2D is a major risk factor for eGFR decline and the rate of decline accelerates as kidney function worsens, especially among younger and male patients. Analyses did not account for proteinuria/albuminuria, which may play an important role in eGFR decline. This warrants further study.

MicroRNAs associated with insulin secretion in type 1 diabetes

A.S. Januszewski[1,2], M. Joglekar[1], Y. Cho[3], E. Scott[1], R. Farr[1], Y. Loh[1], D.N. O'Neal[2], P. Benitez-Aguirre[3], M. Craig[3], K. Donaghue[3], A. Hardikar[1], A.J. Jenkins[1,2];
[1]NHMRC Clinical Trials Centre, University of Sydney, Camperdown, NSW, Australia, [2]Department of Medicine, University of Melbourne, Fitzroy VIC, Australia, [3]Children's Hospital at Westmead, University of Sydney, Westmead NSW, Australia.

Background and aims: Low level insulin secretion can persist even in long-term Type 1 diabetes (T1D) and may reduce risks of hypoglycaemia and chronic complications.
Materials and methods: Plasma C-peptide and microRNAs were quantified in a cross-sectional study of 211 healthy controls (CON, F/M 113/98) age (mean ± SD) 35 ± 16 yo and 304 T1D patients (F/M 170/134), age 30 ± 16 yo; T1D duration 15 ± 12 y; 99 with vascular complications (CX+). HbA1c 8.4 ± 1.6% and 5.1 ± 0.4% in T1D and CON respectively ($p = 0.00001$). C-peptide was by ultra-sensitive ELISA (Mercodia, Sweden). Cycle threshold (CT) values of 50 miRs were used. T1D subjects were divided by age of diagnosis (DX, <18 and ≥18 yo) and duration (DUR: ≤10, 10–≤20 and >20 y).
Results: C-peptide was detectable in all CON and in 55% T1D. Median (LQ, UQ) C-peptide levels were 535 (401, 762) and 5.0 (2.6, 31.2) pmol/L in T1D with detectable levels respectively. Young age of T1D DX (<18 yo) and short T1D DUR (≤10 y) vs adult DX and short DUR was associated with lower rates of detectable C-peptide (39% vs 88%; $p = 0.008$). There was a positive relationship in young DX for percentage with detectable C-peptide by T1D duration (Cochrane-Armitage $p = 0.009$). miRs: Upregulated (lower CT values) in T1D included (Mann-Whitney p value): miR-24 ($p < 0.0001$), miR-146A ($p < 0.0001$), miR-155 ($p = 0.007$), miR-199a-3p, miR-30c, miR-223 ($p < 0.0001$), miR-22*, miR-125a-5p, miR-125b ($p < 0.0001$) and miR-126 ($p < 0.0001$) (all $p < 0.05$ unless otherwise stated). In T1D with undetectable (vs. detectable) C-peptide miRs with lower CT values (Mann-Whitney p value) included: *miR-24* (<0.0001), *miR-146a* (0.003), *miR-155* (<0.0001), *miR-199a* (0.03), *miR-223* (0.0002), *miR-126* (0.0006), *miR-22* (<0.001), *miR-125b* (0.02), *miR-152* (0.006), miR-181a (0.01). Higher CT value: miR-326 (0.03). *C-peptide and miR value correlations included*: Positive: (Spearman (R; p -value)) *miR-24* (0.25; <0.0001), *miR-155* (0.28; <0.0001) and *miR-223* (0.21; 0.0003). Penalized logistic regression: CT values positively associated with detectable C-peptide included: *miR-24, miR-155, miR-199a, miR-223*; Negatively associated: *miR-22*, miR-152, miR-181a*. Exhaustive search: miRs associated with detectable C-peptide level values included: *miR-30c and miR-125a-5p*. Adjusted R of best model 0.37.
Conclusion: Residual C-peptide is more common in LONGER T1D diagnosed in youth vs. later, even if of similar T1D DUR. Data support more beta cell loss in young onset T1D, and potential beta cell regeneration. Many MiR differences exist by C-peptide status and T1D DX age and DUR. Most differences are between T1D DX young and of short DUR vs. those DX as adults, irrespective of T1D DUR. There were no miR difference between T1D DX young and long DUR vs. those DX late and of short DUR. Longitudinal studies are merited.

Figure: miRs significantly different (Mann-Whitney) between T1D subgroups. For clarity only 4-groups shown: ① - DX <18 yo and DUR ≤10 y, ② - DX ≥18 yo and DUR >20 y, ③ - DX ≥18 yo and DUR ≤10 y. and ④ - DX ≥18 yo and DUR >20 y.

Impact of family history on the phenotype and genotype of type 1 diabetes at diagnosis

M. Turtinen[1], T. Härkönen[2], A. Parkkola[1], J. Ilonen[3], M. Knip[1];
[1]Children's hospital, University of Helsinki and Helsinki University Hospital, Helsinki, Finland, [2]Research Programs Unit, Diabetes and Obesity, University of Helsinki, Helsinki, Finland, [3]Immunogenetics laboratory, Institute of Biomedicine, University of Turku, Turku, Finland.

Background and aims: In previous studies, the risk of developing familial type 1 diabetes (T1D) has been about two times higher when the father is affected by T1D compared to the affected mother. We tested the hypothesis of more severe clinical features and a more aggressive humoral autoantibody profile at diagnosis in index cases with an affected father compared to the other familial subgroups.
Materials and methods: A cross-sectional, observational study was performed based on the Finnish Pediatric Diabetes Register. Clinical and metabolic characteristics, β-cell autoantibodies and HLA class II genetics were analyzed from the index cases diagnosed under the age of 15 years, between January 2003 and December 2016 in Finland. The information on the presence of T1D in first-degree relatives (FDR) was collected at diagnosis by a structured questionnaire.
Results: Out of 4,993 newly diagnosed index cases, 523 (10.5%) had familial T1D. More than 5% ($n = 254$, 5.1%) had an affected father, 2.9% ($n = 143$) an affected mother, 1.9% ($n = 95$) an affected sibling and 0.6% ($n = 31$) two or more affected family members. All the clinical and metabolic parameters were markedly poorer in the sporadic cases compared to the familial cases. The index cases with an affected father or mother were younger than those with an affected sibling ($p < 0.001$). After age- and sex-adjusted analyses, index cases with an affected father presented more often with ketoacidosis ($p = 0.03$) and had greater weight loss before diagnosis ($p = 0.001$) than those with an affected mother. There was a trend, that those with more than one affected family members had a lower number of positive autoantibodies at diagnosis, and this group tended to test negative for all autoantibodies more frequently than the sporadic cases. The absence of both major HLA risk haplotypes (DR3-DQ2 and

DR4-DQ8) was more common in the group of sporadic cases than in the familial group ($p = 0.015$). In contrast, the DR4-DQ8 haplotype was more frequent in the familial vs. the sporadic group ($p = 0.002$) and especially among those with an affected father when compared to sporadic cases ($p = 0.029$).

Conclusion: The more severe metabolic derangement at diagnosis in sporadic cases compared to those with familial T1D was confirmed. The higher frequency of diabetic ketoacidosis and increased weight loss at diagnosis in index cases with an affected father support the hypothesis that paternal T1D is associated with a more severe disease in the offspring than maternal diabetes.

Circulating miRNAs as predictive biomarkers for type 2 diabetes development in individuals at risk: outcomes of a 5-year prospective observational cohort study

M. Niemira[1], K. Maliszewska[2], M. Paczkowska-Abdulsalam[1], A. Bielska[1], A. Szalkowska[1], E. Adamska[1], A. Citko[1], L. Szczerbinski[2], E. Siewiec[1], M. Gorska[2], M. Ciborowski[1], A. Kretowski[2];
[1]Clinical Research Centre, Medical University of Bialystok, Bialystok, Poland, [2]Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Bialystok, Bialystok, Poland.

Background and aims: Due to a global increase in prevalence to type 2 diabetes (T2DM), there is an urgent need to take preventive actions among populations with risk factors like prediabetic state, obesity, family history of diabetes or significant lack of physical activity. Identification of early biomarkers, which would help to predict an increased risk of progression to T2DM a few years before disease fully develops, can improve the chance for effective prevention. Epigenetic modifications, along with genetic predisposition, play significant role in T2DM development. Here, we postulate that circulating serum-derived microRNAs may serve as biomarkers for early T2DM diagnosis and help to identify individuals with predisposition to develop diabetes.

Materials and methods: For the present case-control study 33 subjects were selected from the large 1000PLUS cohort study (Bialystok, Poland), including 18 patients (mean age: 48.7 ± 8.2 yrs, mean BMI: 33.6 ± 6.7 kg/m²) who developed type 2 diabetes during the 5-year prospective observation (the study group) and 15 healthy individuals with matching age, sex and BMI for control group, without carbohydrate tolerance disturbances detected during the follow up period. The presence of diabetes based on WHO criteria was excluded at the beginning of study (baseline) and was examined after 60 months or during the follow if clinical symptoms were observed. The microRNA profiling was performed using Nanostring nCounter Technology in serum collected at baseline from both T2DM patients and healthy controls.

Results: A total of 21 miRNAs were differentially expressed between the healthy and diabetic individuals (fold change >1.5 or <−1.5; $P < 0.05$). The serum expression levels of miR-1307, miR-1287, miR-548n, miR-548z, miR-548ah, miR-3144, miR-221, miR-509, let-7b, let-7g, miR-1269a, miR-1245b, miR-125a, miR-4707, miR-519e were higher in patients with T2DM, compared with healthy subjects, however, the levels of miR-1200, miR-216b, miR-508, miR-3614, miR-615, miR-372 were lower. The predicted target genes were identified using Ingenuity Pathway Analysis (Qiagen). The results indicated 482 putative target genes for the upregulated and downregulated miRNAs. Based on the above we constructed four interactive signalling networks. Top functions of target genes were related to muscle atrophy and insulin resistance (CASP3, PTGR2, SMARCD3), insulin signalling and translocation of GLUT4 (TBCC, PRKCZ, CD42EP3), beta-mass cell (CCND1), insulin resistance (PPARG, FOXO1) and several cancer-associated pathways.

Conclusion: The results of the present study indicate that circulating miRNAs may be used as potential biomarkers for early diagnosis of T2DM.

Epigenetic regulation of Slc2a4 gene in skeletal muscle of type 2 diabetic mice: participation of post-translational modifications of histone H3

C.Y. Yonamine[1], A.B. Alves-Wagner[1], J.V.D. Esteves[1], M.M. Okamoto[1], M.L. Corrêa-Giannella[2], D. Giannella-Neto[3], U.F. Machado[1];
[1]Physiology and Biophysics, University of Sao Paulo, Sao Paulo, Brazil, [2]University of Sao Paulo, Sao Paulo, Brazil, [3]University Nove de Julho, Sao Paulo, Brazil.

Background and aims: The main characteristic of diabetes mellitus is the loss of glycemic homeostasis. In this process, skeletal muscle plays a key role and maintenance of the GLUT4 glucose transporter (encoded by the *Slc2a4* gene) expression is fundamental. Epigenetic regulations of *Slc2a4*have never been investigated in diabetes; and resveratrol, suggested as an insulin sensitizer, might be a modulator of these regulations, as it is an activator of the deacetylase sirtuin 1 (SIRT1). The present study aimed to evaluate in type 2 diabetic mice (T2D) the effect of resveratrol treatment on glycemic homeostasis, *Slc2a4*/GLUT4 expression in skeletal muscle, epigenetic regulations of *Slc2a4* such as lysine acetylation (ac) or tri-methylation (me3) of histone 3 (H3Kac and H3K9me3), and the possible participation of SIRT1.

Materials and methods: T2D was induced by neonatal subcutaneous injection of monosodium glutamate (MSG) from day 1 to day 5 (2 mg/kg body weight) and day 7 (4 mg/kg body weight). Control mice received only the vehicle (0.9% NaCl). At the age of 19 weeks, T2D mice were treated or not with resveratrol (30 mg/kg body weight) for 60 days. Resveratrol was offered in the drinking water. On the 53rd day of treatment, insulin tolerance test (ITT) was performed. On the 60th day of treatment the animals were anesthetized with sodium thiopental (7 mg/kg body weight), blood was collected from the left ventricle and the gastrocnemius muscle was removed for analysis of: *Slc2a4* mRNA (RT-qPCR), total GLUT4 and nuclear SIRT1 (Western blotting), acetylation of H3K9,14,18,23 and 27 and tri-methylation of H3K9 (ChIP assay).

Results: T2D mice developed obesity, increased concentrations of plasma glucose (by 1.8 folds, $P < 0.001$), fructosamine (by 1.5 folds, $P < 0.05$) and insulin (by 6.8 folds, $P < 0.001$), and decreased rate of glucose decay in the ITT; resveratrol treatment reversed all these alterations, except the obesity. The *Slc2a4*/GLUT4 expression was reduced in muscle of T2D (by 30%, $P < 0.01$ and 50%, $P < 0.05$, respectively), and that was partially reversed by resveratrol. ChIP assay evinced that diabetes increased the content of both H3Kac (1.5 folds, $P < 0.01$) and H3K9me3 in the *Slc2a4* promoter (by 1.4 folds, $P < 0.001$); and the later was reversed by resveratrol. Additionally, although the nuclear SIRT1 content did not alter in T2D, the resveratrol treatment increased it (by 1.7 folds, $P < 0.05$).

Conclusion: T2D induced epigenetic regulations in skeletal muscle *Slc2a4* gene, such as increased H3Kac and H3K9me3, the later potentially participating on the *Slc2a4* gene repression. Resveratrol treatment improved the metabolic control of T2D mice and partially reversed the *Slc2a4*/GLUT4 expression. These regulations could not be explained by deacetylase activity of SIRT1 upon *Slc2a4* gene, but may be related to modulations of H3K9me3. These results point out the histone H3 post-translational modifications as potential targets to control GLUT4 expression and, consequently, to improve glycemic homeostasis in T2D.

Epigenetic response to bariatric surgery in human skeletal muscle

M. Ouni[1,2], S. Gancheva[3,4], C. Koliaki[4,5], J. Szendroedi[4,3], T. Jelenik[4,2], D. Markgraf[2,4], M. Jähnert[1,2], M. Schlensak[6,2], A. Schürmann[1,2], M. Roden[4,2];
[1]Department of Experimental Diabetology, German Institute of Human Nutrition, Potsdam-Rehbruecke, Germany, [2]German Center for Diabetes Research (DZD), München-Neuherberg, Germany, [3]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Düsseldorf, Germany, [4]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany, [5]Laikon University Hospital, Athens, Greece, [6]General Surgery, General Surery, Schön Clinic, Düsseldorf, Germany.

Background and aims: Epigenetic states are highly metastable and reversible in response to different environmental signals such as drugs, aging and diet. Rapid weight loss after bariatric surgery can be considered as an environmental stimulus and provides an interesting system to investigate DNA methylation flexibility. Although, skeletal muscle insulin sensitivity (IS) is known to increase after bariatric surgery, the underlying molecular mechanisms remain unclear. We hypothesized that DNA methylation contributes to improvement of insulin sensitivity and therefore tested whether epigenetic changes participate in the modulation of skeletal muscle metabolism in response to bariatric surgery.
Materials and methods: Genome-wide gene expression and DNA methylation were analyzed in skeletal muscle biopsies of 16 obese humans OBE (OBE; 38 ± 10 yrs, BMI 44 ± 10 kg/m^2), who also underwent detailed metabolic phenotyping, at baseline, 2 and 52 weeks after bariatric surgery.
Results: At 2 w, excessive adipose tissue lipolysis with subsequent accumulation of specific muscle diacylglycerols prevented from rapid improvement of IS despite slightly increased muscle oxidative capacity. At the same time, alteration of 1,287 genes of the skeletal muscle was found when compared to baseline levels. Gene ontology analysis showed a significant enrichment in cAMP biosynthesis and lipid metabolism. None of differentially expressed genes exhibited differences in DNA methylation. After 52 w, IS had markedly improved along with normalization of myocellular mitochondrial function and lipid species levels in OBE when compared to lean humans. The improvement of the muscle metabolism was associated with DNA methylation changes in 1,467 CpGs of 430 differentially expressed genes. These genes were related to metabolic processes such as cAMP biosynthesis and oxidative stress. Interestingly, among those genes with the highest changes in DNA methylation, only a few were described previously to be epigenetically regulated in obese subjects such as *KCNQ1* (potassium voltage-gated channel subfamily KQT member 1), *ATP10A* (ATPase phospholipid transporting 10A) and *MYO7A* (myosin VIIA).
Conclusion: While initial metabolic alterations after bariatric surgery do not associate with epigenetic changes, the long-term beneficial changes in muscle insulin sensitivity are related to distinct changes in muscle DNA methylation.

Increased serum expression of miR-518d-3p and miR-618 in individuals with type 1 diabetes with microvascular chronic complications

D.P. Santos-Bezerra[1], A.S. Santos[1], G.C. Guimarães[1], S.N. Admoni[1], R.V. Perez[1], T.S. Pelaes[1], C.G. Machado[2], M. Passarelli[3], U.F. Machado[4], M.S. Queiroz[5], M.E.R. Silva[1], M.L.C. Corrêa-Giannella[1,6];
[1]Laboratório de Carboidrato e Radioimunoensaio, LIM-18, Hospital das Clinicas HCFMUSP, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil, [2]Divisão de Oftalmologia do Hospital das Clinicas HCFMUSP, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil, [3]Laboratório de Lípides, LIM-10, Hospital das Clinicas HCFMUSP, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil, [4]Departamento de Fisiologia e Biofisica, Instituto de Ciências Biomédicas, Universidade de São Paulo, São Paulo, Brazil, [5]Divisão de Endocrinologia do Hospital das Clínicas, Faculdade de Medicina da Universidade de São Paulo, SAO PAULO, Brazil, [6]Programa de Pós-Graduação em Medicina, Universidade Nove de Julho (UNINOVE), Sao Paulo, Brazil, São Paulo, Brazil.

Background and aims: Epigenetic changes have been recognized in the pathogenesis of chronic diabetic complications; several studies have shown that periods of hyperglycemia result in permanent abnormalities in the target tissues of complications, a phenomenon known as "metabolic memory". One of the epigenetic mechanisms is the control of gene expression by microRNAs (miRNAs), which are small non-coding RNAs which repress the translation of messenger RNAs (mRNAs). The hypothesis of the present study is that the serum profile of miRNAs is different between individuals with type 1 diabetes (T1D) with and without chronic complications.
Materials and methods: In order to characterize and compare serum miRNAs profile, blood from 10 pre-selected patients from the Diabetes Outpatient Clinic was collected; Group 1 ($n = 5$) patients without microvascular complications (without diabetic kidney disease [DKD], without distal sensory-motor polyneuropathy [PN], without cardiovascular autonomic neuropathy [CAN] and without diabetic retinopathy [DR]) and Group 2 ($n = 5$) patients with microvascular complications (DKD, PN, CAN and severe DR), matched for sex, diabetes duration and degree of glycemic control. The profile of miRNAs was characterized with the use of the commercial kit *Taqman® Human MicroRNA Array A* that use hydrolysis probes for the analysis of 381 miRNA expression. Five out of 25 miRNAs differentially expressed between the two groups (the ones with the highest statistical difference: 518-3p, 34a-5p, 126-5p, 425-5p and 618) were validated in the serum of 47 individuals with T1D, 20 without microvascular complications and 27 with all microvascular complications.
Results: A total of 193 out of 381 evaluated miRNAs was expressed in the serum of patients with T1D; 21 miRNAs were found overexpressed in the group with microvascular complications (ANOVA test with a fold change >1.50 and $P < 0.05$ considered as significant). Of the 5 validated miRNAs, two were confirmed as differentially expressed between the two groups of patients studied, 518d-3p and 618 ($P = 0.02$ for both).
Conclusion: miR-518d-3p targets the peroxisome alpha proliferator (*PPARA*) mRNA, which plays a critical role in lipid homeostasis and inflammation, and whose low expression has been demonstrated in the retina of animals with diabetes. One of the targets mRNA of miR-618 is *TXNIP*, which interferes with the antioxidant activity of thioredoxin and whose low expression has already been observed in peripheral blood mononuclear cells from individuals with T1D and chronic complications.

Hyperglycaemia changes the miRNA expression pattern during differentiation and maturation of human visceral adipocytes

J. Strycharz, E. Swiderska, A. Wroblewski, M. Podolska, J. Drzewoski, J. Szemraj, A. Sliwinska;
Medical University of Lodz, Lodz, Poland.

Background and aims: MiRNAs are short endogenous non-coding RNAs and negative epigenetic regulators. Adipogenesis is a process of differentiation of mesenchymal stem cells to adipocytes. Obesity, especially visceral one, increases the risk of developing type 2 diabetes. The latter is preceded by hyperglycemia, which exerts deleterious effects on various tissues, including visceral adipose tissue. Thus, the aim of our study was to examine the effect of exposure to high glucose during

differentiation and maturation of human visceral adipocytes on the expression profile of selected miRNAs.
Materials and methods: miRNA expression pattern was determined during adipogenesis of HPA-v cells performed under normoglycemia and hyperglycemia. The differentiation and maturation of adipocytes involved three culture stages: (1st) preadipocytes stage, (2nd) differentiated and (3rd) mature adipocytes stages. To obtain hyperglycemia, D-(+) glucose was added to medium to provide 30 mM concentration. Expression of 78 miRNAs was determined by Real-time PCR after completion of each culture stage using ΔCt method. Statistical significance was evaluated using ANOVA with Tukey post hoc test with $p \leq 0.05$ considered as significant. We performed hierarchical clustering/Pearson's correlation for studied comparisons of variants (Gitools2.3.1) and pathway enrichment analysis for significant miRNAs (DIANA mirpath v3).
Results: miRNAs expression changes detected during adipogenesis are presented in Table 1. The completion of 2nd stage in normoglycemia (NN vs N) revealed the majority of miRNAs to be downregulated and the reverse was observed for the transition from 2nd to 3rd stage (NNN vs NN). There was no strongly dominant direction of miRNAs expression changes for NNN vs N, yet the expression level of above one third of studied miRNAs was reduced. In hyperglycemia, 2nd stage (HH vs H) completion evoked the increase of a small majority of miRNAs, while a similar number of miRNAs was decreased in HHH to H. A large majority of miRNAs was declined in HHH in relation to HH. Several comparisons of variants were strongly and positively correlated ($r = 0.8$), being confirmed by hierarchical clustering. We revealed 22 miRNAs differentially expressed during adipogenesis in both conditions, which were enriched in pathways connected with fatty acids, ECM, cell cycle and Hippo, p53, PI3K/AKT and TGF-β signaling. miR-140-5p, miR-31-3p, miR-376c-3p were changed during normo- and hyperglycemic adipogenesis.
Conclusion: The numbers of miRNAs being upregulated, downregulated and unchanged in adipogenesis revealed that the miRNAs expression pattern is pronouncedly disparate in hyperglycemia comparing to normoglycemia. Differentially expressed miRNAs may be important for visceral adipogenesis independently of glycemia, possibly via regulating genes indispensable for adipocytes functionality.

Table 1. The miRNA expression pattern reported during adipogenesis of HPA-v carried out in normoglycemia and hyperglycemia

Culture variant	upregulation	downregulation	No changes
NN vs N	14	50	14
NNN vs N	23	32	23
NNN vs NN	47	2	29
HH vs H	36	22	20
HHH vs H	17	39	22
HHH vs HH	15	50	13

Familial diabetes status and the risk of incident type 2 diabetes in Denmark

O. Silverman-Retana[1,2], A. Hulman[1,2], J. Nielsen[3,4], C.T. Ekstrøm[5], B. Carstensen[6], R.K. Simmons[7], D.R. Witte[1,2];
[1]Department of Public Health, Aarhus University, Aarhus, Denmark, [2]Danish Diabetes Academy, Odense, Denmark, [3]Global Health Section, Department of Public Health, University of Copenhagen, Copenhagen, Denmark, [4]Hubert Department of Global Health, Rollins School of Public Health, Emory University, Atlanta, GA, USA, [5]Section of Biostatistics, Department of Public Health, University of Copenhagen, Copenhagen, Denmark, [6]Clinical Epidemiology Department, Steno Diabetes Center Copenhagen, Gentofte, Denmark, [7]The Healthcare Improvement Studies Institute, University of Cambridge School of Clinical Medicine, Cambridge, UK.

Background and aims: Individuals with a family history of diabetes have an increased risk of developing the same disease. Despite known effects of the shared environment and genetic determinants, familial aggregation of diabetes at the population level is not fully understood. This study aims to quantify the association between parental and sibling diabetes status and individual's risk of developing the disease at the level of the entire Danish population.
Materials and methods: We performed a register-based analysis of all individuals in Denmark who were 30 years or older and did not have diabetes on January 1st 1995, following them until the end of 2012. We restricted the analysis to those individuals who had available information on their parents. Parental and sibling diabetes status (exposure) and date of diabetes onset in the index individual (outcome) were defined from the Danish National Diabetes Register. We used Poisson models to calculate the age and sex-adjusted incidence rate of diabetes among individuals whose parents and siblings did not have diabetes (reference) and incidence rate ratios (IRR) for those with maternal, paternal diabetes and/or siblings with diabetes. We tested interaction terms to determine whether the risk for those with diabetes in both parents and siblings exceeded the contribution from each family member.
Results: We included 877,807 individuals (53.7% male, median age at baseline: 36 years [IQR: 33–40]) who contributed 14,226,923 person-years of follow up (median duration: 17 years). Paternal diabetes was present in 132,468 (15.0%) individuals; maternal diabetes was found in 142,414 (16.2%) and 35,004 (3.9%) individuals had one or more siblings with diabetes. In 26,746 (3.0%) individuals, both parents had diabetes. The number of incident diabetes cases was 60,256; the age and sex-adjusted (for a 50-year-old male) incidence rate of diabetes for those without familial diabetes was 4.1/1000 person-years (95%CI: 4.0; 4.2). The IRR for individuals with maternal diabetes was 1.89 (95%CI: 1.83; 1.96), for individuals with paternal diabetes was 1.79 (95%CI: 1.73; 1.87) and for those individuals with a sibling with diabetes was 2.02 (95% CI: 1.93; 2.11) compared to individuals without familial diabetes. Among individuals whose both parents had diabetes, the IRR was 2.95 (95% CI: 2.79; 3.13). We found no indication of a deviation from the multiplicative effect when both parents and siblings had diabetes.
Conclusion: Family history of diabetes confers a marked risk elevation at the population level. The ability to extract valid familial diabetes data from population-wide registers offers the opportunity to hone and improve population-based strategies for prevention and early detection of diabetes.

PS 010 Monogenic diabetes

336

Patients with Down syndrome who present with neonatal diabetes are unlikely to have a monogenic aetiology

M.B. Johnson, K.A. Patel, E. De Franco, S. Ellard, S.E. Flanagan, A.T. Hattersley;
Institute of Biomedical and Clinical Science, University of Exeter Medical School, Exeter, UK.

Background and aims: Autoimmune diabetes is 4–6 times more prevalent in individuals with Down syndrome compared to the general population. Diabetes typically presents early in patients with Down syndrome with 1 in 5 presenting before the age of 2 years. Neonatal diabetes, diagnosed in the first 6 months of life, is usually monogenic with >82% of patients having a mutation in a known gene. We aimed to discover the aetiology of diabetes in patients with Down syndrome and diabetes diagnosed in the first 6 months of life.
Materials and methods: We studied 12 individuals with Down syndrome (reported by the referring clinician) diagnosed with diabetes in the first 6 months of life (median age of diagnosis 2 weeks (range 1 day–26 weeks). All patients required insulin therapy from diagnosis. We screened all known monogenic diabetes genes by targeted next generation sequencing. We genotyped all patients for the top 9 risk alleles for type 1 diabetes to generate a type 1 diabetes genetic risk score. This was compared to gold-standard type 1 diabetes ($n = 1963$) and non-diabetic ($n = 2938$) controls from the Wellcome Trust Case Control Consortium. Islet autoantibody testing (GAD, IA2 and ZnT8) was performed by commercially available ELISA assays where serum was available ($n = 8$).
Results: We did not identify a pathogenic mutation in the known monogenic diabetes genes in any of the 12 individuals. This finding is unlikely to have occurred by chance ($p < 0.0005$) considering the prior probability of identifying a monogenic aetiology in neonatal diabetes is >82%. This suggests that the diabetes in these individuals is unlikely to be monogenic. 5/8 (63%) patients were positive for 1 anti-islet antibody (4 anti-GAD and 1 anti-IA2) supporting an autoimmune aetiology in these individuals. We found evidence that the aetiology of the diabetes in individuals with Down syndrome is distinct to that of type 1 diabetes. The type 1 diabetes genetic risk score was lower in the diabetic patients with Down syndrome than in type 1 diabetes controls (median 0.53 v 0. 0.67, $p = 0.002$) and similar to population controls without diabetes (median 0.53 v 0.50, $p = 0.32$).
Conclusion: Individuals with Down syndrome and neonatal diabetes do not have a mutation in a known monogenic diabetes gene. Our data suggest that the aetiology of the diabetes in these patients is autoimmune but is not due to polygenic susceptibility for type 1 diabetes. These individuals are likely to represent the extreme phenotype of autoimmunity in Down syndrome. Further studies to determine the underlying aetiology of diabetes in these individuals is warranted.

Excess insulin secretion with a high protein meal in sulphonylurea treated KCNJ11 neonatal diabetes patients shows the limitations of amplifying insulin secretion pathways

P. Bowman[1,2], M.H. Shepherd[1,2], T.J. McDonald[1,2], R.C. Andrews[1,2], S.R. Spaull[1,2], S. Statton[1,2], S. Hammersley[1,2], M. Leveridge[3], B.M. Shields[1,2], S.E. Flanagan[1], B.A. Knight[1,2], K.A. Patel[1,2], A.T. Hattersley[1,2];
[1]University of Exeter Medical School, Exeter, UK, [2]Exeter NIHR Clinical Research Facility, Exeter, UK, [3]Royal Devon and Exeter NHS Foundation Trust, Exeter, UK.

Background and aims: *KCNJ11* mutations cause permanent neonatal diabetes (PNDM) by preventing ATP binding and closing the pancreatic ATP-dependent potassium (K_{ATP}) channel. This hyperpolarises the beta-cell and stops all insulin secretion. High dose oral sulphonylureas (SUs) repolarise the beta-cell allowing insulin secretion in response to the amplifying pathways including incretins, but the classical pathway of insulin secretion where glucose acts through ATP plays a minimal role. Despite this patients with SU-treated *KCNJ11* PNDM have excellent glycaemic control with no severe hypoglycaemia. These patients represent a unique opportunity to assess the physiological response to different food types mediated by the amplifying pathways of insulin secretion with minimal response to glucose via the classical ATP pathway. We aimed to assess for the first time the insulin, glucose and glucagon response to both a protein and a carbohydrate-rich meal in patients with SU-treated *KCNJ11* PNDM.
Materials and methods: 6 adults with SU-treated *KCNJ11* PNDM and 6 non-diabetic controls matched for age, gender and BMI, were given a high protein breakfast and an isocaloric high carbohydrate breakfast on 2 separate days. Individuals with *KCNJ11* PNDM took SU as normal with each meal. Blood insulin, glucagon, and glucose were measured 12 times in 4 hours and compared between the different meals in each group and between cases and controls. Non-parametric statistical methods were used.
Results: *KCNJ11* patients had similar insulin secretion with protein vs. carbohydrate (median 0–4 hour insulin incremental area under the curve ($iAUC_{0\text{-}4h}$) 230 vs 228 pmol/L, $p = 0.75$). Controls without diabetes had lower insulin secretion with protein vs. carbohydrate (median insulin $iAUC_{0\text{-}4h}$ 121 vs 577 pmol/L, $p = 0.03$). These different patterns of insulin secretion were associated with different glycaemic responses: *KCNJ11* patients had much lower glucose values after a protein rich meal compared to controls (glucose $iAUC_{0\text{-}4h}$ −9.3 vs −1.1 mmol/L, $p = 0.004$) and much higher glucose values after a carbohydrate meal (glucose $iAUC_{0\text{-}4h}$ 16.2 vs. 1.4 mmol/L, $p = 0.02$). Counter-regulatory glucagon secretion was higher after protein than carbohydrate in both *KCNJ11* patients and controls (median glucagon $iAUC_{0\text{-}4h}$ with protein 7.7 vs 13.3 pmol/L, $p = 0.63$ and with carbohydrate 0.5 vs 0.2 pmol/L, $p = 0.42$).
Conclusion: In patients with SU-treated *KCNJ11* PNDM insulin secretion is stimulated to a similar extent by a protein rich meal and carbohydrate rich meal leading to relatively lower blood glucose after a protein rich meal and a potential risk of moderate postprandial hypoglycaemia. The high protein meal is likely to result in excessive postprandial insulin secretion as a result of the marked stimulation of insulin secretion by amplifying pathways such as incretins which, unlike normal subjects, is not moderated by the glucose responsive classical ATP pathway. This has implications for the dietary advice offered to patients with *KCNJ11* PNDM and also shows that nutrient detection by the amplifying pathways of insulin secretion is imperfect in the absence of glucose regulation by the classical pathway.

The diagnostic utility of urinary C-peptide/creatinine ratio (UCPCR): insights from a review of the local use of UCPCR in the diabetes clinic

A. Poddar[1], J.S. Clark[1], V. Nayyar[1], S. Zachariah[1], N. Maghsoodi[1], B.C.T. Field[1,2];
[1]Diabetes and Endocrine, East Surrey Hospital, Redhill, UK, [2]Department of Clinical and Experimental Medicine, School of Health and Medical Sciences, University of Surrey, Guildford, UK.

Background and aims: UCPCR is a less burdensome measure of endogenous insulin secretion compared to traditional serum C-peptide, and 24-hour urinary C-peptide. It can be used to diagnose maturity onset

diabetes of the young (MODY), and helps identify absolute insulin deficiency.

Materials and methods: All UCPCR results at our NHS Trust from September 2015 to September 2017 were identified. Electronic notes were reviewed to collect the following information: clinical justification, age, time to initiating insulin, antibody serology, family history and HbA_{1c}. Changes in diagnosis and management following UCPCR quantification were recorded.

Results: Eighty UCPCR requests were identified. The diagnosis for 40 patients was changed after consideration of UCPCR and other clinical data. Ten people with a clinical diagnosis of type 1 diabetes were reclassified as type 2, and one as HNF1A MODY. Eight people with apparent type 2 diabetes were reclassified as type 1. There was a change in management in 32 cases. Ten individuals have restarted oral medication of which five patients are off insulin and five now on basal only; four such patients had been on insulin for over 15 years, of whom two were on insulin pump therapy. Three patients with LADA are under surveillance using serial UCPCR as well as HbA_{1c} and glucose measurements to inform decision-making on the need for exogenous insulin therapy.

Conclusion: UCPCR is a convenient tool for classifying diabetes and guiding management in the absence of serum or 24-hour urinary C-peptide.

Functional characterisation of HNF1A variants identified in Norwegian diabetes registries can be important for precision medicine in diabetes clinics

I. Aukrust[1,2], A. Kaci[1,2], J. Molnes[1,2], H.U. Irgens[1,3], B.B. Johansson[1], L. Bjørkhaug[4], P.R. Njølstad[1,3];
[1]KG Jebsen Center for Diabetes Research, Department of Clinical Science, University of Bergen, Bergen, Norway, [2]Department of Medical Genetics, Haukeland University Hospital, Bergen, Norway, [3]Department of Pediatrics and Adolescents, Haukeland University Hospital, Bergen, Norway, [4]Department of Biomedical Laboratory Sciences and Chemical Engineering, Western Norway University of Applied Sciences, Bergen, Norway.

Background and aims: Genetic variants in *HNF1A* encoding the transcription factor hepatocyte nuclear factor-1 alpha (HNF-1A) can cause Maturity-Onset Diabetes of the Young type 3 (MODY3; HNF1A-MODY). The aim of this study was to investigate possible pathogenic effects of 16 *HNF1A*variants of unknown clinical significance identified in the Norwegian MODY Registry and the Norwegian Childhood Diabetes Registry, using functional protein analyses, and to correlate findings with family history and clinical characteristics of *HNF1A* variant carriers.

Materials and methods: All *HNF1A* variants were classified using a five-tier score system commonly used in clinical diagnostic laboratories. To investigate the effect of *HNF1A* variants on normal HNF-1A transcriptional activity, we used a Dual-Luciferase assay system in transfected HeLa cells.

Results: 15 of the *HNF1A* variants investigated were classified as variants of unknown clinical significance, while one variant was classified as likely pathogenic, i.e. *HNF1A* (NM_000545.5) c.1640_1641del p.(T547Rfs*5). This variant was found in a patient diagnosed with diabetes from 11 years of age, initially thought to have type 1 diabetes. He was later established to be GAD- and IA-2 autoantibody negative. Interestingly, his non-diabetic mother (age 38) also carries the variant. The transcriptional activity of this variant was significantly reduced to ~37% ± 6.3 ($p < 0.0001$) compared to wild-type (WT) HNF-1A (100%), but not as severely as for classical MODY3 variants (20–25%). Another variant, c.346G>A p.(A116T), also demonstrated significantly reduced transcriptional activity (~36% ± 4.9 ($p < 0.0001$)). This variant was found in two sisters diagnosed with diabetes at 16 and 20 years of age. One of the sisters had a slightly elevated BMI, and their father (not genetically tested), of normal weight, was diagnosed with type 2 diabetes at age 30–35. Further, three variants caused severe reduction in transcriptional activity (<25%), thus functionally resembling a MODY3 variant. These were c.797A>G p.(N266S), c.666_668del p.(K222del) and c.428A>C p.(H143P). Interestingly, p.(K222del) was found in a family including four affected family members in two generations (mother and three children), all with diabetes onset from 11–25 years of age, supporting this variant to be causative for MODY3. The two other variants, p.(N266S) and p.(H143P), were both found in patients with early onset diabetes (13 and 15 years, respectively) and who are currently treated with insulin. The patient carrying p.(N266S) has normal BMI, is negative for GAD autoantibody, and has no known family relatives with diabetes. The patient carrying p.(H143P) is negative for both autoantibodies GAD and IA-2.

Conclusion: Functional investigation of *HNF1A* variant effects should support precision medicine in diabetes clinics and could help to distinguish neutral variants from variants causing type 2 or MODY3 diabetes, in combination with family history and clinical characteristics.

Double monogenic diabetes of the young: implications for treatment in pregnancy

H. Khan[1], A.T. Hattersley[2], D.L. Browne[1];
[1]Endocrine and Diabetes, Royal Cornwall Hospitals NHS Trust, Truro, Cornwall, UK, [2]Molecular Medicine, University of Exeter Medical School, Exeter, UK.

Background and aims: Co -inheritance of HNF 1alpha and Glucokinase (GCK) -maturity-onset diabetes of the young (MODY) mutation is extremely rare. The effects of two simultaneous heterozygous pathogenic mutations on pregnancy and optimal management strategy are not known.

Materials and methods: A 29 year old female in her first pregnancy presented with persistent glycosuria. She had a strong family history of diabetes in her paternal grandfather, father and two siblings. One of her brothers and his son had been diagnosed with HNF1A recently. Her pre-pregnancy body mass index was 22.3.Her oral glucose tolerance test (OGTT) at 8 weeks of gestation demonstrated fasting blood glucose (FBG) of 8.8mmol/L and two hour glucose of 16.5mmol/L. HbA1c at that time was 58mmol/mol. Gene Sequencing for MODY confirmed two heterozygous disease causing mutations; GCK missense variant, c.676G>A, p.Val226Met and HNF1A splicing variant, c.526+1G>A. She was initiated on basal bolus insulin regimen (Isophane and Insulin Aspart). To date, 29 weeks in pregnancy she is requiring 17–20 units total daily Insulin with mean FBG/pre-prandial and 1 hour post prandial capillary blood glucose (CBG) of 4.89 ± 0.7 mmol/L and 6.5 ± 0.98 mmol/L respectively. (Target range: FBG 4.0–5.3 mmol/L, 1 hour Post prandial CBG 4.0–7.8 mmol/L). The foetal growth is normal.

Results: The effects of MODY on pregnancy and foetus largely depend on maternal glycaemic control and whether or not the foetus has inherited the mutation. Treatment during pregnancy usually depends on the type of mutation. In isolated HNF1A MODY outside pregnancy, sulphonylureas are effective but currently transfer to insulin is recommended in pregnancy. In isolated GCK mutation treatment is not required unless there is evidence of foetal macrosomia in the third trimester where insulin is indicated but has little impact on glycaemia. Co-existence of GCK mutation with HNF1A could make it difficult to control FBG due to higher set point of glucose homeostasis and increased gluconeogenesis.

Conclusion: It is the first patient in 2,531 probands with MODY mutations who is known to have a definite pathogenic mutation in both HNFA1 and GCK genes. This case suggests that insulin may be required earlier in pregnancy. Whilst conventional experience shows GCK mutation would make it difficult to achieve optimal control, our patient has progressed well in pregnancy with excellent control on a modest dose of insulin.

"De Novo" Maternally Inherited Diabetes and Deafness (MIDD)? Variable genetic transmission in MIDD

A. Lam[1], Y. Zhao[2], L. Ong[2], W. Sim[2], L. Zhu[1], S. Rama Chandran[1], D.-L. Gardner[1];
[1]Department of Endocrinology, Singapore General Hospital, Singapore, Singapore, [2]Department of Clinical Translational Research, Singapore General Hospital, Singapore, Singapore.

Background and aims: The m.3243A>G mutation is the most prevalent pathogenic mitochondrial (mt) mutation resulting in Maternally Inherited Diabetes and Deafness (MIDD). Maternal inheritance of diabetes (DM) should trigger consideration of the presence of mtDNA mutations, but its absence should not negate it. We aimed to describe the variable transmission of MIDD in a proband and four immediate relatives.

Materials and methods: We describe a 40 year old Chinese woman (III-3) with MIDD and mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS) from m.3243A>G mutation. The mother-child and inter-sibling genotype-phenotype relationship is examined, using blood leucocyte and urine epithelial cell (UEC) DNA. Real-time PCR (Taqman assay) was used to quantify heteroplasmy levels, through absolute and relative quantification, and digital PCR.

Results: III-3 had gestational DM during her pregnancy (28y). At 33y, she was diagnosed with DM despite a lean BMI of 15 kg/m^2 and absent features of insulin resistance. Beta cell autoantibodies were negative. Bilateral sensorineural hearing loss was present since childhood. On metformin alone, she maintained HbA1c levels 6.2–7.7% (44–61 mmol/mol) until age 40y when she developed seizures and high lactate levels. C-peptide was 2.62 μg/L (plasma glucose 11.2 mmol/L), suggesting adequate beta cell function. MRI brain showed inflammation in multiple cerebral territories. She had no cardiac, renal or ophthalmologic manifestations. III-3's maternal grandmother (I-2), now 96y, had late onset DM and bilateral hearing loss in her 50s. III-3's mother (II-4) had late onset DM (66y), was overweight (BMI 25 kg/m^2) and was diet-controlled. 4 of 8 maternal siblings have DM (II-2, II-6, II-7, II-8). III-3's eldest sister (III-1) was obese (BMI 40.6kg/m^2) at DM diagnosis (40y) and is on oral glucose lowering agents (OGLA). III-2 had DM at age 28y (BMI 25.6 kg/m^2), and is on OGLA. The youngest sister (III-4, 37y, BMI 23.2 kg/m^2) does not have DM. III-3's daughter (now 12y) has no manifestations. Only I-2 and the proband (III-3) have hearing loss. Genotyping of blood leucocytes from III-3, her mother and 3 sisters revealed the presence of the m.3243A>G mutation in III-3 (19% heteroplasmy), but not in her mother or sisters. UEC from all 5 were analyzed using real-time and digital PCR. The m.3243A>G mutation was detected at lower heteroplasmy levels in the mother (II-4) (3.9%) but remained negative in the 3 sisters, indicating that III-1 and III-2 likely have type 2 DM.

Conclusion: The transmission of m.3243A>G mutation from mother to child is variable, and female carriers do not necessarily transmit the mutation to all offspring. This highlights the challenges of genetic counselling in MIDD. Genotyping of UEC DNA should be performed in those who are negative for mutations in blood leucocytes before dismissing the diagnosis of MIDD.

The utility of MODY probability calculator among HNF1A- and GCK-MODY Polish patients: a retrospective analysis

M. Szopa, D. Ucieklak, S. Mrozinska, I. Solecka, B. Zapala, J. Hohendorff, B. Matejko, M. Sani, M.T. Malecki;
JUMC, Krakow, Poland.

Background and aims: The most common form of monogenic diabetes is MODY (Maturity Onset Diabetes of the Young). The optimal approach to identify MODY families is still a challenge as there is no ideal non genetic biomarker. An easy-to-use MODY prediction model for identifying genetic-test indicated patient cases was developed in 2012 by the Hattersley's group from Exeter, UK (www.diabetesgenes.org/content/mody-probability-calculator). The aim of this study was to validate the utility of this tool with MODY patients in the Polish population.

Materials and methods: Our MODY patient database was established 18 years ago at the Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland. Patient selection into the database has been based on the following criteria: a) autosomal dominant inheritance pattern of diabetes mellitus; b) presence of the disease in at least three subsequent generations; c) at least two diabetic family members diagnosed at or before the age of 30 who have received at least two years of treatment with diet, oral drugs, or insulin in a dose lower than 0.5 U/kg. Patients in the database who provided all answers to the MODY probability calculator questionnaire were included in the current study. This patient sub-population currently includes 85 GCK-MODY and 74 HNF1A-MODY patients. The control group was established with 100 randomly selected T1DM (Type 1 Diabetes Mellitus) individuals from our outpatient clinic. The control group does not include any T2DM patients due to insufficient number of T2DM cases diagnosed at or before the age of 35 from our outpatient clinic - as required in the calculator model.

Results: The mean predictive value using the calculator was 61.42% for GCK-MODY and 40.38% for HNF1A-MODY patients. This is in contrast with the mean calculator predictive value of 4.48% for T1DM patients. Only one T1DM patient out of 100 obtained a calculator predictive value higher than 20% – the minimum suggested criteria for genetic testing referral. Only 8 GCK-MODY patients and 23 HNF1A-MODY patients received a sub-20% score. More than 60% of GCK-MODY and almost 30% HNF1A-MODY patients obtained a positive predictive value greater than 75.5%.

Conclusion: The model based on the Hattersley's group calculator reliably indicated genetic testing for GCK-MODY patients among our sub-population of Polish patients. The obtained results for HNF1A-MODY patients were also satisfactory. The results are surprising as the probability calculator was initially focused on transcription-factor mutation MODY

rather than GCK ones. The model also efficiently helped to rule out unnecessary genetic testing for patients with T1DM. The usage of this tool will be expanded among our database MODY patients in the near future, at least partly to assess for potential fine-tuning of its predictive power among Polish MODY patients.

Paradoxical worsening of glucose tolerance after metformin in a patient with insulin resistance due to the SHORT syndrome

K.C. Lewandowski[1,2], K. Dabrowska[2], M. Brzozowska[1], J. Kawalec[2], A. Lewinski[1,2];
[1]Department of Endocrinology & Metabolic Diseases, The Medical University of Lodz, Lodz, Poland, [2]Department of Endocrinology & Metabolic Diseases, "Polish Mother's" Memorial Hospital Research Institute, Lodz, Poland.

Background and aims: Metformin is regarded as the first line treatment for type 2 diabetes and insulin resistant states. Hereby, we present a case of an unexpected response to metformin in a 21 year patient (BMI 17.5 kg/m²) with a history of SHORT syndrome *(**S**hort stature, **H**yperextensibility, **O**cular depression, **R**ieger anomaly, **T**eething delay),* an autosomal dominant disorder, that was also diagnosed in her father and younger brother. SHORT syndrome is also characterised by partial lipoatrophy and severe insulin resistance (IR) due to post-receptor defect in insulin signaling (Phosphoinositide-3-Kinase Regulatory Subunit 1 - PIK3R1).

Materials and methods: She had normal thyroid function, prolactin, luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol and dehydroepiandrosterone sulfate (DHEAS), Free Androgen Index 4.52 ($N < 8$), while pelvic ultrasound showed polycystic ovaries. Vitamin D concentration was low (11.0 ng/ml, frank deficiency<20 ng/ml). Lipid concentrations were normal (total cholesterol 156 mg/dl, triglycerides 99 mg/dl). Extended OGTT was performed and showed severe IR. She was then started on Metformin 850 mg bd, and had repeated OGTT (Table 1).

Results: Glucose and insulin concentrations during an extended 75 gram OGTT, before and on Metformin treatment, are presented in Table 1. After three days of Metformin treatment there was a dramatic worsening of glucose tolerance, with insulin concentrations above the upper assay detection limit, at 120, 150 and 180 minutes post glucose load. Metformin was discontinued and she was discharged home on Dydrogesterone and vitamin D supplementation.

Conclusion: The precise cause of such profound and paradoxical worsening of glucose tolerance post metformin remains unknown. As metformin is, however, known to partially inhibit PIK3, then we speculate that further inhibition of this already mutated enzyme might have prevented any beneficial effects of metformin, as these generally affect further steps of insulin signaling. In contrast, further inhibition of PIK3R1 could have worsened insulin resistance.

Table 1: 75 gram OGTT before and after metformin treatment

		0 min.	60 min.	120 min.	150 min.	180 min.	240 min
Initial OGTT	Glucose [mg/dl]	82	146	96	68	57	64
	Insulin [µIU/ml]	37.74	688.8	488.6	246.8	100.6	30.1
OGTT post Metformin 850 mg.	Glucose [mg/dl]	72	169	187	204	176	42
	Insulin [µIU/ml]	29.27	902.7	>1000	>1000	>1000	341.8

Quality of life in patients with type 2 diabetes initiating a second-line glucose-lowering therapy: the global DISCOVER study

A. Nicolucci[1], M.B. Gomes[2], K. Khunti[3], M. Kosiborod[4], S. Pocock[5], W. Rathmann[6], M.V. Shestakova[7], I. Shimomura[8], H. Watada[9], H. Chen[10], J. Cid-Ruzafa[11], P. Fenici[12], N. Hammar[13], F. Tang[4], L. Ji[14];
[1]Center for Outcomes Research and Clinical Epidemiology, Pescara, Italy, [2]Rio de Janeiro State University, Rio de Janeiro, Brazil, [3]University of Leicester, Leicester, UK, [4]Saint Luke's Mid America Heart Institute, Kansas City, MO, USA, [5]London School of Hygiene and Tropical Medicine, London, UK, [6]German Diabetes Center, Duesseldorf, Germany, [7]Endocrinology Research Center, Diabetes Institute, Moscow, Russian Federation, [8]Osaka University, Oaska, Japan, [9]Juntendo University, Tokyo, Japan, [10]AstraZeneca, Gaithersburg, MD, USA, [11]Evidera, Barcelona, Spain, [12]AstraZeneca, Cambridge, UK, [13]AstraZeneca Gothenburg, Mölndal, Sweden, [14]Peking University People's Hospital, Beijing, China.

Background and aims: DISCOVER is a 3-year, global, observational study of patients with type 2 diabetes (T2D) initiating a second-line glucose-lowering therapy in 37 countries. Here, we report health-related quality of life (HRQoL) at baseline.

Materials and methods: HRQoL was assessed using the 36-item Short-Form Health Survey version 2 (SF-36v2) and the Hypoglycaemia Fear Survey II (HFS-II) in 32 countries ($N = 13\,320$) and 24 countries ($N = 10\,264$), respectively. The SF-36v2 is divided into Physical Component Summary (PCS) and Mental Component Summary (MCS) scores, which were normalized to 50 (SD: 10) using the 2009 US population (lower scores indicate decreased HRQoL). The HFS-II is divided into two subscales (higher scores indicate increased fear of hypoglycaemia): behaviour (HFS-B; maximum score 60) and worry (HFS-W; maximum score 72). Factors associated with decreased SF-36v2 scores and increased HFS-II scores were assessed using multivariable regression models.

Results: For the 9449 patients (70.9%) with SF-36v2 data, mean scores for PCS and MCS were 48.3 (SD: 7.8; across-country range [ACR]: 43.6–53.0) and 46.0 (SD: 10.4; ACR: 41.1–53.5), respectively. Lower scores for both PCS and MCS were associated with being female, having a history of macrovascular disease, abstaining from alcohol, using a sulphonylurea (vs metformin) as first-line therapy, and higher HFS-B and HFS-W scores. Lower PCS (but not MCS) scores were significantly associated with older age, lower education level, higher BMI and a history of chronic kidney disease (Table). For the 7090 patients (69.1%) with HFS-II data, mean HFS-W and HFS-B scores were 6.9 (SD: 11.4; ACR: 2.2–26.1) and 7.8 (SD: 9.7; ACR: 5.8–55.9), respectively. Higher scores for both HFS-B and HFS-W were significantly associated with being female, receiving diabetes education and a history of vascular complications. Higher HFS-B (but not HFS-W) scores were significantly associated with older age and higher BMI.

Conclusion: Factors associated with lower HRQoL in patients with T2D are related to both disease (e.g. history of complications) and treatment (e.g. use of sulphonylureas). Fear of hypoglycaemia varied greatly across countries and was associated with lower HRQoL.

	SF-36v2 PCS (difference in score [95% CI])	SF-36v2 MCS (difference in score [95% CI])
Male (vs female)	1.84 (1.52 to 2.16)	2.09 (1.64 to 2.54)
Age (per 10-year increment)	−0.80 (−0.95 to −0.66)	0.29 (0.09 to 0.49)
Time since T2D diagnosis (per 1-year increment)	0.00 (−0.03 to 0.03)	0.02 (−0.02 to 0.06)
HbA_{1c} at baseline (per 1% increment)	−0.01 (−0.10 to 0.09)	−0.20 (−0.32 to −0.07)
BMI (per 5-kg/m² increment)	−0.84 (−0.99 to −0.69)	−0.08 (−0.28 to 0.12)
Education level (vs 0–6 years of education)		
Secondary education (7–13 years)	0.51 (0.09 to 0.94)	0.56 (−0.01 to 1.13)
Higher education (> 13 years)	1.52 (1.05 to 1.98)	0.59 (−0.05 to 1.24)
T2D education in the past year (yes vs no)	1.38 (1.01 to 1.75)	0.86 (0.35 to 1.37)
Health insurance (yes vs no)	−0.35 (−0.80 to 0.09)	0.89 (0.29 to 1.49)
Current smoker (yes vs no)	−0.38 (−0.86 to 0.11)	−0.61 (−1.28 to 0.06)
Alcohol drinking (vs lifetime abstainer)		
Former drinker	0.03 (−0.54 to 0.61)	−0.15 (−0.92 to 0.61)
Current drinker	0.76 (0.31 to 1.22)	1.32 (0.69 to 1.95)
Medical history		
Macrovascular complications	−1.88 (−2.34 to −1.42)	−0.93 (−1.55 to −0.30)
Microvascular complications	−0.02 (−0.36 to 0.31)	1.02 (0.57 to 1.48)
Chronic kidney disease	−1.46 (−2.30 to −0.63)	1.30 (0.17 to 2.44)
First-line treatment (vs metformin)		
Sulphonylurea	−0.42 (−0.78 to −0.06)	−0.71 (−1.19 to −0.22)
DPP-4 inhibitor	0.03 (−0.65 to 0.72)	−0.32 (−1.25 to 0.62)
Sulphonylurea + DPP-4 inhibitor	−0.51 (−1.56 to 0.54)	−3.59 (−5.01 to −2.17)
Other	−0.52 (−1.24 to 0.20)	−1.75 (−2.73 to −0.77)
HFS-II subscale scores (per 5-unit increment)		
Behaviour	−0.91 (−1.01 to −0.80)	−0.93 (−1.09 to −0.77)
Worry	−0.23 (−0.33 to −0.14)	−0.66 (−0.78 to −0.53)

Table. Factors associated with changes in quality of life in patients initiating a second-line glucose-lowering therapy, as measured by the SF-36v2 PCS and MCS scores adjusted for regions according to the World Health Organization classification (data not shown; no significant associations) and all variables in the table, using multivariable regression models. BMI, body mass index; CI; confidence interval; DPP-4, dipeptidyl peptidase-4; HbA1c, glycated haemoglobin; HFS-II, Hypoglycaemia Fear Survey II; PCS, Physical Component Summary; MCS, Mental Component Summary; SF-36v2, 36-item Short-Form Health Survey version 2; T2D, type 2 diabetes.

Second line glucose lowering treatment therapies as chosen by cardiologists vs non-cardiologists: an analysis of the Diabetes Collaborative Registry (DCR)

D. Koehn[1], E. Repetto[2], I. Brookes-Smith[2], J. Eudicone[2], K. Olsson[2], T. Schutt[3], S. Arnold[4];
[1]Internal Medicine, Virginia Commonwealth University Health System, Richmond, VA, USA, [2]AstraZeneca, Gaithersburg, MD, USA, [3]American College of Cardiology, Washington, DC, USA, [4]Cardiology, University of Missouri-Kansas City School of Medicine, Kansas City, MO, USA.

Background and aims: While metformin is the recommended first agent for diabetes, guidelines suggest a patient-centered approach to choosing second line agents according to side effect profile, weight, comorbidities, and patient preference. Given the results of recent cardiovascular outcomes trials, we sought to better understand the real-world prescribing patterns for second line therapy in type 2 diabetes (T2D) and how this may differ between cardiologists and non-cardiologists.
Materials and methods: We used data from the Diabetes Collaborative Registry (DCR), a US-based outpatient registry of patients across the spectrum of diabetes care and currently includes 11,847 providers across 47 states. Our analytic cohort included adults with T2D on metformin and 1 other glucose-lowering medication. We compared the demographics, comorbidities, and prescribed medications between patients seen by cardiology vs. non-cardiology providers.
Results: Among 95,960 adults with T2D already on metformin in DCR (76% cardiology patients), we found a predominance of sulfonylureas used as 2nd line therapies (Figure). Glucose-lowering medications with CV positive outcomes (SGLT-2i or GLP-1RA) were used less often in patients with established CVD (MI/Stroke/HF) vs in patients without CVD (5.7% vs 7.6%; $p < 0.001$). SGLT-2i were used more commonly in patients with better renal function compared to other second line combinations (GFR in SGLT2i vs other: 86.4 vs 71.8 mL/min/1.73 m^2; $p < 0.001$). GLP-1RA were used more frequently in obese patients (GLP-1RA vs other: 78% vs. 60%; $p < 0.001$). Insulin was used more often in patients with worse glycemic control (A1c in insulin vs other: 8.4 vs 7.5%; $p < 0.001$). There were no clinically relevant differences in practice patterns between cardiologists and non-cardiologists.
Conclusion: Despite greater number of patients with DM and CVD being seen by cardiologists, practice patterns for second-line therapies for patients with T2D appear to be driven more by renal function, obesity, and glycemic control as opposed to CV risk. As these patients may benefit from more targeted treatment for CV risk reduction, greater dissemination of guideline statements and educational efforts to cardiologists and non-cardiologists might optimize these decisions.

The characterisation of people with type 2 diabetes and polypharmacy in the Netherlands: the Diabetes Pearl cohort

F. Rutters[1], S. van Oort[1], P. Elders[1], K. Kramers[2], on behalf of the Diabetes Pearl from the Parelsnoer Initiative;
[1]VU University Medical Center, Amsterdam, Netherlands, [2]Radboud University Medical Center, Nijmegen, Netherlands.

Background and aims: Polypharmacy in people with type 2 diabetes mellitus (T2DM) is highly prevalent and a risk factor for suboptimal glycemic control. The aim of this study was to describe the prevalence of polypharmacy, as well as the subject characteristics and drug types associated with polypharmacy in the general Dutch T2DM population.
Materials and methods: The study population consisted of people with T2DM, treated in different geographical areas and all types of care, from

the Dutch Diabetes Pearl cohort. Data on drug use, as well as sociodemographic, metabolic and complication characteristics were gathered. Logistic regression analyses were performed, stratified by mild polypharmacy (5–9 drug types) and hyperpolypharmacy (≥10 drug types).

Results: We included 6447 participants (60% men, aged 62 ± 10 years). The prevalence of mild polypharmacy and hyperpolypharmacy was 48% and 19%, respectively. Compared to those with mild polypharmacy or no polypharmacy, people with hyperpolypharmacy were characterized by a higher age, female sex, lower educational level, longer diabetes duration, treatment in tertiary care, obesity, suboptimal glycemic control (HbA1c >53 mmol/mol) and more diabetes complications. The use of cardiovascular and diabetes drugs was similar in the three groups, while people with hyperpolypharmacy more often used other drugs than those with mild or no polypharmacy.

Conclusion: Hyperpolypharmacy and mild polypharmacy were highly prevalent in the general Dutch T2DM population and were associated with poorer metabolic control. As the other drugs rather than cardiovascular or diabetes drugs were causing hyperpolypharmacy, this could provide focus for development of future deprescribing guidelines in the T2DM population

Disclosure: **F. Rutters:** None.

Individualised HbA_{1c} targets in people with type 2 diabetes initiating second-line therapy: the global DISCOVER study

K. Khunti[1], H. Chen[2], J. Cid-Ruzafa[3], P. Fenici[4], M.B. Gomes[5], N. Hammar[6], K.F. Kennedy[7], S. Pocock[8], M.V. Shestakova[9], I. Shimomura[10], F. Surmont[11], L. Ji[12];
[1]University of Leicester, Leicester, UK, [2]AstraZeneca, Gaithersburg, MD, USA, [3]Evidera, Barcelona, Spain, [4]AstraZeneca, Cambridge, UK, [5]Rio de Janeiro State University, Rio de Janeiro, Brazil, [6]AstraZeneca Gothenburg, Mölndal, Sweden, [7]Saint Luke's Mid America Heart Institute, Kansas City, MO, USA, [8]London School of Hygiene and Tropical Medicine, London, UK, [9]Endocrinology Research Center, Diabetes Institute, Moscow, Russian Federation, [10]Osaka University, Osaka, Japan, [11]AstraZeneca, Luton, UK, [12]Peking University People's Hospital, Beijing, China.

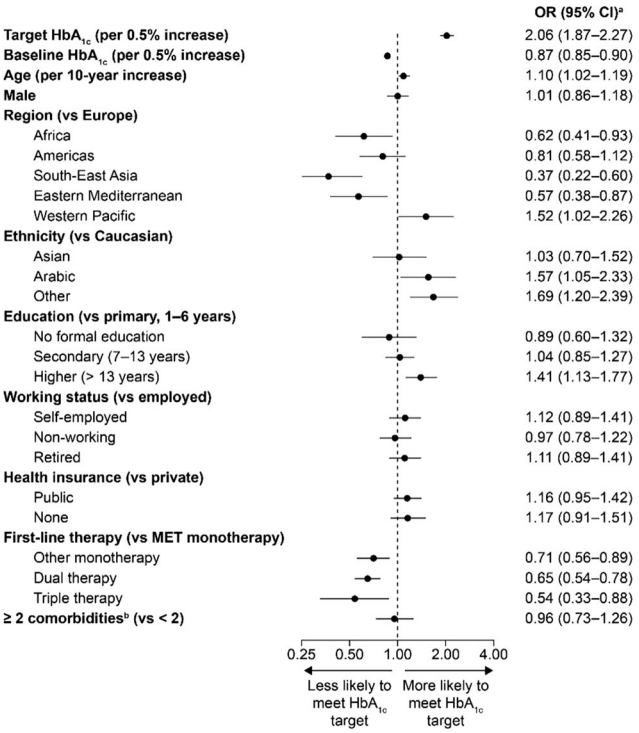
Background and aims: International guidelines recommend setting individualized HbA_{1c} targets for people with type 2 diabetes (T2D). DISCOVER is an observational study of patients with T2D initiating second-line glucose-lowering therapy in 37 countries. We report the proportion of patients set individualized targets, the proportion meeting these targets after 1 year, and factors associated with meeting these targets.

Materials and methods: Patients included had HbA_{1c} data at baseline and at 1 year. Factors associated with meeting targets were assessed using multivariable logistic regression.

Results: Of the 7225 patients with complete HbA_{1c} data who remained in the study after 1 year, 5070 (70.2%) had been set an individualized glycaemic control target. Targets were 7.0% for 2513 patients (49.6%), <7.0% for 2073 patients, (40.9%) and >7.0% for 484 patients (9.6%). Overall, 1744 of these patients (34.4%) met their target after 12 months of follow-up (range across regions: 21.4–42.7%). Factors associated with meeting HbA_{1c} targets are shown in the Figure.

Conclusion: Twelve months after initiating second-line therapy, only one third of patients with set individualized HbA_{1c} targets had met their targets, with considerable variation between regions. Older age, higher education level, lower baseline HbA_{1c} level and higher target were factors associated with meeting targets.

Figure. Factors associated with meeting individualized HbA_{1c} targets.



CI, confidence interval; MET, metformin; OR, odds ratio.
[a]OR adjusted for all variables shown in the figure.
[b]Cormorbidities: heart failure, angina, myocardial infarction, stroke, transient ischemic attack, peripheral artery disease, atrial fibrillation, ventricular arrhythmia, severe valve disease, respiratory disease, depression, dementia, sleep apnea, thyroid disease.

Treatment thresholds for patients with newly diagnosed diabetes: an application of dynamic marginal structural models in the Clinical Practice Research Datalink

R.E. Farmer[1], D. Ford[2], L. Smeeth[1], N. Chaturvedi[3], K. Bhaskaran[1];
[1]Non Communicable Diseases Epidemiology, London School of Hygiene and Tropical Medicine, London, UK, [2]Medical Research Council Clinical Trials Unit at University College London, London, UK, [3]Institute of Cardiovascular Science, University College London, London, UK.

Background and aims: Current guidelines for newly diagnosed type 2 diabetes (T2DM) advocate treatment initation once HbA_{1c} exceeds 6.5%. However, whether this threshold is optimal for minimising adverse clinical endpoints is unclear. There is a lack of trial data examining differing treatment thresholds, but using large-scale routinely collected observational data sources, people initiating at different thresholds can be compared. A naïve comparison would likely be confounded by time-varying factors that cannot be handled by standard statistical models, but dynamic marginal structural models (dMSMs) use weighting to appropriately

remove such confounding. We used this methodology to compare the effects of different HbA_{1c} thresholds for treatment initiation, on time to subsequent target HbA_{1c}, myocardial infarction (MI), stroke and all-cause mortality.

Materials and methods: A cohort of adults with newly diagnosed T2DM were identified from the Clinical Practice Research Datalink. dMSMs were fitted to compare strategies of initiating treatment at HbA_{1c} thresholds between 6.5% and 10%: each patient's follow up was duplicated for each of the strategies of interest, censoring once the patient became non-compliant with the given strategy. Specifically, follow-up was censored if they initiated treatment below the given threshold, or if they did not initiate within one month of exceeding the given threshold. Patients were considered at risk until the earliest of 10 years; the event of interest; death; administrative censoring; or initiation of any other therapy than metformin or sulfonylureas. Inverse probability of censoring weights were then used to adjust for informative censoring. The association between treatment strategy and outcome was evaluated within the weighted population using pooled logistic regression to approximate a Cox model.

Results: 47,950 patients with incident T2DM were included (median follow up 4.7 years). Initiation at higher thresholds of HbA_{1c} was associated with lower rates of reaching target HbA_{1c} of 6.5%. The estimated proportion of patients reaching target by 1 year were 0.36 (0.35, 0.38), 0.32 (0.31–0.32), 0.30 (0.30–0.31) and 0.30 (0.30–0.31) for thresholds of 7, 8, 9 and 10% respectively. Higher thresholds of initiation showed a trend for increased risk of MI, though observed incidence of MI was low and CI's overlapped (4 year cumulative incidence (%) of 1.13 (0.85–1.44), 1.16 (0.96–1.41), 1.41 (1.17–1.68), 1.52 (1.25–1.79) and 1.53 (1.31–1.85) for thresholds of 6.5, 7 , 8 , 9 and 10% respectively). Longer term differences in MI incidence between strategies had the same pattern but lacked precision. There was no evidence of differences in cumulative incidence of stroke or all-cause mortality at 4 years. Cumulative incidence curves to 10 years also showed no long term differences between strategies.

Conclusion: This analysis suggests a benefit of early intervention in terms of subsequent glucose control and risk of MI. A limitation of the study was limited follow up and low overall observed cardiovascular events. dMSMs are a useful tool for examining clinically important treatment strategy questions using routinely collected medical records.

Impact of treatment intensification in patients with type 2 diabetes suboptimally controlled on basal insulin in The Health Improvement Network UK primary care database

E. Lew[1], M. Myland[2], M. Nixon[2], N. Gooch[3], C. O'Leary[2], A. Shaunik[4], E.B. Jude[5];
[1]Sanofi, Chilly-Mazarin Cedex, France, [2]IQVIA, London, UK, [3]Sanofi, Guildford, UK, [4]Sanofi, Bridgewater, NJ, USA, [5]Diabetes Center, Tameside General Hospital, Ashton-under-Lyne, UK.

Background and aims: Despite an abundance of antidiabetes therapies and guidelines, treatment intensification is often delayed in patients with suboptimal glycaemic control. The aim of this study was to assess the effect of treatment intensification on change from baseline HbA_{1c} in patients with type 2 diabetes (T2D) suboptimally controlled on basal insulin (BI).

Materials and methods: Patients with T2D and uncontrolled HbA_{1c} (>8.0% high-risk, >7.5% otherwise) prescribed BI between 1 January 2005 and 16 May 2017 were identified in The Health Improvement Network (THIN) database. Treatment intensification (Intensifiers) was defined as the addition of a glucagon-like peptide-1 receptor agonist (GLP-1 RA) or rapid-acting insulin (RAI) within 12 months of uncontrolled HbA_{1c} (Index). Intensifiers were matched 1:1 on key demographics to patients who did not intensify treatment within 12 months of Index (Non-intensifiers). The difference between baseline and earliest recorded HbA_{1c}, greatest change, and proportion of patients achieving target HbA_{1c} in the 12 months post intensification were calculated. Descriptive statistics and mixed models repeated measures were used to compare HbA_{1c} changes between Intensifiers and Non-intensifiers. Adjusted logistic regression was used to compare proportions of patients achieving target HbA_{1c}.

Results: The study included 1,342 BI users (646 Intensifiers; 696 Non-intensifiers). In the Intensifier group, 8.5% added a GLP-1 RA and 91.5% a RAI to BI therapy. Baseline characteristics and outcomes in the 12 months post intensification are shown in **Table 1**. In the 12 months post intensification, the magnitude of reduction for the earliest change in HbA_{1c} for Intensifiers was twice that for Non-intensifiers; this difference was statistically significant (mean −0.54% versus −0.26%, respectively; adjusted $P = 0.0004$). Greatest HbA_{1c} change in the 12 months post intensification was also more substantial for Intensifiers compared with Non-intensifiers (mean −0.81% versus −0.49%, respectively; adjusted $P = 0.0077$). In addition, a greater (and statistically significantly) proportion of Intensifiers achieved 12-month target HbA_{1c} compared with Non-intensifiers (33% Intensifiers vs. 28% Non-intensifiers; $P < 0.0001$).

Conclusion: Our study shows that timely intensification of BI therapy in patients with T2D and uncontrolled HbA_{1c} provided clinically meaningful glycaemic reductions within 12 months post intensification. In addition, more patients achieved target HbA_{1c} after intensifying antidiabetes therapy; however, the proportions were small, which may be a reflection of high HbA_{1c}. Our results emphasise the need for improved therapeutic options to more effectively manage glycaemic control.

Patient characteristics	Intensifiers (n = 646)	Non-intensifiers (n = 696)
Age at baseline, years, mean (SD)	58.3 (12.9)	59.0 (13.3)
Male, n (%)	343 (53.1)	375 (53.9)
BMI, kg/m², mean (SD) [n]	31.8 (7.3) [436]	32.1 (7.4) [463]
Diabetes diagnosis duration, n (%)		
< 5 years	51 (7.9)	56 (8.0)
5-9 years	200 (31.0)	233 (33.5)
≥ 10 years	373 (57.7)	407 (58.5)
Comorbidities, n (%)		
Hypertension	63 (9.8)	74 (10.6)
Dyslipidaemia	8 (1.2)	15 (2.2)
Obesity[a]	238 (36.8)	262 (37.6)
Baseline HbA_{1c} , %, mean (SD) [n]	9.38 (1.45)	9.40 (1.57)
Earliest change in HbA_{1c}, 12 months post intensification		
Mean (SD)	−0.54 (1.47)	−0.26 (1.55)
Estimated treatment difference (95% CI)[b]	−0.38 (−0.59, −0.17)*	
Greatest change in HbA_{1c}, 12 months post intensification		
Mean (SD)	−0.81 (1.99)	−0.49 (2.13)
Estimated treatment difference (95% CI)[b]	−0.32 (−0.55, −0.08)	

* $P = 0.0004$. [a] Including baseline BMI > 30 kg/m². [b] Adjusted treatment difference in HbA_{1c} change using mixed models repeated measures. Bonferroni adjustments were made ensuring $P < 0.001$ indicates a statistically significant finding.

Proportion of patients reaching HbA_{1c} targets related to second-line treatment initiation: a Nordic observational study comparing type 2 diabetes management in primary care

F. Persson[1], J. Bodegard[2], S.T. Knudsen[3], H.L. Gulseth[4], K. Furuseth[5], M. Thuresson[6], A. Lindh[7], M. Alvarsson[8], M.E. Jørgensen[1], J. Søndergaard[9], K.I. Birkeland[4], P.M. Nilsson[10];
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]AstraZeneca Nordic-Baltic, Oslo, Norway, [3]Aarhus University, Aarhus, Denmark, [4]Oslo University Hospital, Oslo, Norway, [5]Solli Klinikk, Jessheim, Norway, [6]Statisticon AB, Uppsala, Sweden, [7]., Åkersberga, Sweden, [8]Karolinska University Hospital, Stockholm, Sweden, [9]University of Southern Denmark, Odense, Denmark, [10]Lunds University, Lund, Sweden.

Background and aims: Second line treatment with glucose lowering drugs (GLD) is an important part of type 2 diabetes (T2D) management. Previous research has shown that the Nordic countries differ with respect to proactivity when initiating second-line treatment, despite that guidelines argue for early intervention of uncontrolled HbA_{1c}. The aim of this study was to describe proportion of patients successfully below HbA_{1c} target levels below 47.5 mmol/mol (DCCT 6.5%), 53 (7.0) and 58.5 (7.5) at initiation of second-line and up to 5 years after using data from Denmark (DK), Norway (NO) and Sweden (SE).
Materials and methods: Electronic medical records (EMR) data on T2D patients was extracted from 60 primary care clinics in DK, NO and SE, and linked with national Prescribed Drug-, National Patient- and Cause of Death Registry data in respective country. Second line treatment (index date) was defined as dispense of new GLD class after ≥6 months metformin monotherapy.
Results: Between 2010–2015, 2861 patients were identified in DK, NO and SE; 646, 635 and 1580 patients, respectively. Mean age 60, 62 and 64 years; females 42, 42 and 39%; established CVD 19, 21 and 26%; and chronic kidney disease 1, 4 and 3%, respectively. Use of sulphonylurea and insulin as second line treatment was 2-fold greater in SE compared with NO and DK. In 2015, the greatest initiation of either DPP-4i, SGLT-2i or GLP-1a was observed in DK (70%) and NO (75%) compared to SE (48%). At index date, DK had the lowest HbA_{1c} (61.7 mmol/mol, 95%CI [59.6–62.8]) compared to NO (67.2 [65.0–68.3]) and SE (66.1 [63.9–67.2]). In DK, initiation of second-line treatment showed the greatest proportion with HbA_{1c} below all targets compared to NO and SE (Figure). During follow-up, the proportion of patients below targets was also greatest in DK compared to the other countries. Norway and Sweden demonstrated similar target patterns.
Conclusion: Despite similar demographics and health care systems in three Nordic countries, we have shown marked differences in drug treatment patterns and HbA1c target strategies related to second-line treatment. In Denmark, second-line treatment was initiated earlier, i.e. in patients with lower mean HbA_{1c}, which also resulted in an observed better glycaemic control over the next two years compared to Norway. These observations may indicate a more proactive disease management in the included general practices in Denmark in a primary care setting compared to the other countries.

Initiation of combination therapy in type 2 diabetes patients with high HbA_{1c} at diagnosis

R.M. Klok[1], A. Kumar[2], S. Rajpathak[1], A.Z. Fu[2,3], K. Khunti[4];
[1]Merck & Co., Inc., Kenilworth, NJ, USA, [2]Complete HEOR Solutions (CHEORS), North Wales, PA, USA, [3]Georgetown University Medical Center, Washington, DC, USA, [4]Diabetes Research Centre, University of Leicester, Leicester, UK.

Background and aims: Clinical guidelines for type 2 Diabetes (T2DM) recommend that patients with high HbA_{1c} (≥HbA_{1c} of 9.0%) at the time of diagnosis, should be initiated with a combination therapy. In this study we evaluated the proportion of patients that start with a combination therapy in this patient population.
Materials and methods: A retrospective study of adult T2DM patients using the UK Clinical Practice Research Datalink (CPRD). The study population was T2DM patients aged 18 years and older, with a first prescription of an antidiabetic agent (index date) from January 2010-December 2015. Patients with continuous enrolment in the database one year prior to the index date, having an HbA_{1c} lab value between 3 months before to 2 weeks after index date were included. Patients were excluded if they had type 1 diabetes mellitus, other forms of secondary diabetes, gestational diabetes mellitus, or had taken any of the antidiabetic drugs in the baseline period. Patients were classified as initiated on combination therapy if they received a prescription for 2 or more different antidiabetic agents in the first month post index date, and both drug classes had at least 1 follow-up prescription after the initial prescription.
Results: There were totally 19,409 eligible patients initiated on monotherapy or combination therapy, among which 42.5% were female. Their median age was 61 years and a median baseline HbA_{1c} 8.2%. Of these new users, 38.7% had an initial HbA_{1c} ≥9.0%, of whom 14.5% were initiated on a combination therapy, while 85.5% were initiated on mono-therapy.
Conclusion: Despite clinical guidelines only 14.5% of newly diagnosed patients with T2DM and an HbA_{1c} of ≥9.0% are initiated on a combination therapy.

PS 012 Diabetes mortality

352

Microvascular disease and all-cause mortality in a single-center cohort of individuals with type 1 diabetes: a 10-year follow-up study

M. Garofolo, R. Giannarelli, M. Aragona, D. Lucchesi, L. Giusti, V. Sancho Bornez, G. Daniele, R. Miccoli, G. Penno, S. Del Prato;
Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy.

Background and aims: The incidence rate of type 1 diabetes (T1DM) is increasing worldwide. Despite improvements, T1DM continues to be associated with a sustantially increased risk of cardiovascular (CV) events and premature death. The effect of microvascular disease (MD) burden on all-cause mortality in T1DM is still poorly explored.
Materials and methods: The relationship between the cumulative burden of retinopathy, nephropathy and peripheral neuropathy (diabetic microvascular triopathy) and all-cause mortality was evaluated in 774 T1DM recruited in an observational, single-center study (age 40.2 ± 11.7 years; BMI 24.8 ± 3.6 kg/m^2; diabetes duration (DD) 19.4 ± 12.2 years; HbA1c 7.8 ± 1.2%) over a mean follow-up of 10.7 ± 2.5 years. Hazard ratios for the risk of all-cause mortality associated with MD was calculated by unadjusted and adjusted Cox regression. EURODIAB PCS risk score was calculated for all patients.
Results: Out of 774 T1DM 425 (54.9%) had no MD, 250 had 1 MD (32.3%); 75 had 2 MD (9.7%) and: 24 had 3 MD (3.1%). Distribution was unchanged after esclusion of 41 T1DM (5.3%) with prior CV events (57.0%, 32.2%, 8.5% and 2.3%, respectively). Compared to no-MD, 1–3 MD had an adverse CV risk profile with steeply increase in age, DD, BMI, WHR, sBP, dBP, HbA1c, uric acid, and EURODIAB PCS risk score for major vascular outcomes ($p < 0.0001$); differences were observed for total- and LDL-cholesterol, and triglycerides as well ($p < 0.05$). Genders and smoking habits (in particular current smokers) were equally distributed between groups. As expected, eGFR (CKD-EPI) decreased and albuminuria progressively increased ($p < 0.0001$). Rates of CV events and EURODIAB PCS risk score ≥20 increased with MD: 1.6%, 5.6%, 17.3%, and 29.2%; 4.0%, 14.4%, 41.3% and 79.2%, respectively ($p < 0.0001$). As expected, number of subjects on BP-lowering agents, RAS-blockers, statins and anti-platelet drugs increased wirh MD number ($p < 0.0001$). A total of 52 deaths occurred over a 8,184 person-years follow-up (6.7%; 6.36 ×1000 person-years). Death rate increased with number of MD: no-MD 1.9%; 1 MD, 6.8% (HR: 3.75, 95%CI 1.62–8.69); 2 MD, 14.7% (HR: 7.10, 2.85–17.67); 3 MD 66.7% (HR: 45.64, 19.50–106.79; $p < 0.0001$). Death rate did not change after exclusion of the 41 subjects with prior CV events (1.9%, 6.4%, 12.9%, and 64.7%; $p < 0.0001$). After adjustment for age and sex, HRs were: 1 MD: 2.61, 1.11–6.14; 2 MD: 3.42, 1.29–9.06; 3 MD: 16.21, 6.20–42.35 ($p < 0.0001$). In fully adjusted model, HRs were: 1 MD: 2.51, 95%CI 1.01–6.23; 2 MD: 2.97, 1.07–8.25; 3 MD 9.68, 3.19–29.36; ($p = 0.001$), with independent effects for age (HR 1.06; 95%CI 1.04–1.09), uric acid (1.37; 1.15–1.64), and smoking (2.45; 1.28–4.70). In a different fully adjusted model including the EURODIAB risk score, the MD burden as well the EURODIAB score were strong and independent predictors of all-cause mortality.
Conclusion: The development of microvascular disease increases in a dose-dependent manner the risk of all-cause mortality in type 1 diabetes individuals. This effect is independent of conventional cardiovascular risk factors and risk score for major vascular outcomes. In conclusion, presence and number of microvascular complications should be considered in stratifying cardiovascular risk in type 1 diabetes.
Disclosure: **M. Garofolo:** None.

Diabetes increases the mortality in myocardial infarction, heart failure and stroke: results from a longitudinal study over 40 years

E. Lampa[1], J. Ärnlöv[2], J. Sundström[3], U. Risérus[4], L. Lind[3];
[1]Uppsala Clinical Research Center, Uppsala University, Uppsala, Sweden, [2]Dept of Neurobiology, Care Sciences and Society, Karolinska Institutet, Huddinge, Sweden, [3]Department of Medical Sciences, Uppsala University, Uppsala, Sweden, [4]Department of Public Health and Caring Sciences, Uppsala University, Uppsala, Sweden.

Background and aims: It is well known that diabetes increase the risk of the main cardiovascular diseases, myocardial infarction (MI), ischemic stroke or congestive heart failure (HF), as well as mortality. Since it is less known how diabetes influences mortality risk once a diabetic individual has obtained a main cardiovascular diagnosis, we investigated this using data from a 40-year longitudinal study.
Materials and methods: In the Uppsala Longitudinal Study of Adult Men (ULSAM) cohort, participants were physically examined at 50 ($n = 2322$), 60 ($n = 1860$), 70 ($n = 1221$), 77 ($n = 839$) and 82 ($n = 530$) years of age. Hospital diagnoses on diabetes, acute myocardial infarction (MI), ischemic stroke or congestive heart failure (HF) and death were obtained during 40 years of follow-up. A multi-state model was used to model transition rates between the different cardiovascular states and mortality as a function of the covariates. The model was adjusted for blood pressure, LDL and HDL cholesterol, triglycerides, smoking, diabetes duration and use of antihypertensive and lipid lowering medication.
Results: During a median of 31 years follow-up (interquartile range 22–38 years, max 43 years) 458 MI events, 331 stroke events and 177 HF events were observed as the first event. 1916 deaths occurred of which 1109 occurred without prior CV event. Diabetes ($n = 360$) was associated with an increased risk for a first CV event at 60 years of age (Rate Ratio (RR) = 1.76 (95% CI: 1.05–2.94) for MI, 1.61 (0.74–3.51) for stroke and 2.94 (1.10–7.83) for HF). The association with HF was attenuated, but still relevant, as age increased (RR = 1.95 (1.25–3.06) at age 82. The associations for MI and stroke were almost unchanged at age 82; RR = 1.93 (1.20–3.10) for MI and 1.86 (1.21–2.87) for stroke. Diabetes was also associated with death at higher age; RR = 1.87 (1.51–2.32) at age 82. In individuals experiencing a CV event, diabetes was associated with increased mortality; RR = 4.48 (2.17–9.24) at age 60 to 1.30 (0.87–1.94) at age 82 following an MI and RR = 2.81 (1.11–7.14) at age 60 to 1.60 (1.13–2.26) following a HF. The association between diabetes and death following a stroke was less conclusive; RR = 1.58 (0.62–4.05) at age 60 to RR = 1.79 (1.20–2.69) at age 82.
Conclusion: Diabetes was associated with a first main cardiovascular event and mortality both in middle-age and in the elderly. Diabetes was also associated with an increased mortality risk following a cardiovascular event, especially in heart failure, middle-aged individuals with a myocardial infarction and elderly with stroke.
Disclosure: **E. Lampa:** None.

Decreasing trend in years of life lost due to diabetes: a nationwide cohort study

L. Niskanen[1], T. Partonen[2], A. Auvinen[3], J. Haukka[4], CARING Project;
[1]Endocrinology and Diabetology, Helsinki University Hospital, Helsinki, Finland, [2]Public Health Solutions, National Institute for Health and Welfare, Helsinki, Finland, [3]Epidemiology and Health Sciences, University of Tampere, Tampere, Finland, [4]Public Health, University of Helsinki, Helsinki, Finland.

Background and aims: We analyzed all-cause mortality and mortality from main causes of death in a large national cohort.
Materials and methods: Nationwide cohort of patients with diabetes (DM): individuals who received reimbursement for ≥1 prescription between 1.1.1997–31.12.2010 and sex, age and area-matched reference (Ref) group. All the insulin users were included and 50% random sample of the OAD (oral antidiabetic drug) users. DM-groups were divided as OAD only, OAD + insulin or insulin only. The prescription, cancer and mortality data was obtained by register linkages from national registries.

Follow-up started on the date of the first purchase of diabetes medication prescription, till 31.12.2012 or the date of death. End-points were death from any cause, CHD, cerebrovascular diseases (CVD), and cancer. The cohort data were analyzed using Poisson regression models separately for each end-point and reported as mortality rate ratios (MRR). Competing risks of four causes of death were analyzed by competing risks regression. Years of life lost (YLL) were calculated as the difference of the areas under the survival curves.

Results: The study population consisted of 434,629 individuals (226,372 men). The mean follow-up time was 6.9 years. We observed total 85,180 deaths (23,236 from IHD, 7671 from CVD, and 19,765 from cancer). The mortality rates were elevated among the patients with diabetes. Mortality was highest on those with OAD+insulin, followed by insulin only, and lowest in subjects with OAD only. CVD mortality was significantly higher in women than in men. Unadjusted survival was clearly lower in all diabetes groups compared to the reference population. In the OAD group, survival was substantially higher than in the OAD+insulin and to the only-insulin groups. When comparing the OAD+insulin and the insulin only groups, survival was higher in the former for about five years after start of the follow-up, but reversed after that. Proportions of different causes of death remained similar. We detected a significant interaction between start of the follow-up year and diabetes group in Poisson regression models for all-cause mortality, as well as cause-specific mortalities. All-cause mortality in the OAD group approached that of the reference population by 2009. A similar trend was observed for CHD mortality, but not for cancer mortality or CVD mortality. Estimated YLL diminished considerably in the OAD group, with smaller decreases in the other medication groups.

Conclusion: Difference in mortality between the OAD group and the reference population in Finland has decreased in the 14-year period from 1997 to 2010.

Association between postprandial hyperglycaemia at clinic visits and cancer mortality in patents with type 2 diabetes

T. Takao[1], K. Takahashi[1], K. Kimura[1], M. Suka[2], H. Yanagisawa[2], Y. Iwamoto[1];
[1]The Institute for Adult Diseases Asahi Life Foundation, Tokyo, Japan, [2]The Jikei University School of Medicine, Tokyo, Japan.

Background and aims: There is evidence that patients with diabetes have an increased risk of several site-specific cancers and a high rate of cancer mortality. Acute glucose excursions rather than sustained hyperglycemia trigger oxidative stress. Oxidative stress generates DNA damage, increased inflammation, and vascular endothelial damage, which may contribute to cancer progression and atherosclerosis. However, few studies have examined the relationship between postprandial hyperglycemia and cancer mortality in patients with type 2 diabetes. Thus, we aimed to evaluate the impact of postprandial hyperglycemia at clinic visits on all-cause and cancer mortality in patients with type 2 diabetes independent of the HbA_{1c} level in a real-world setting.

Materials and methods: Blood glucose (BG) and HbA_{1c} levels were measured at each clinic visit. Postprandial time intervals were calculated and classified, according to 15-min units, by a medical technologist. BG levels at 2 h ± 30 min after breakfast were defined as 2-h post-breakfast BG (2h-PBBG). The intrapersonal mean values of 2h-PBBG, HbA_{1c}, and other clinical data during the 3 years after the first visit were used as baseline data. This retrospective observational cohort study included 1089 patients with type 2 diabetes who first visited our clinic between 1995 and 1998, had been followed up for at least 3 years, and had undergone 2h-PBBG measurements during the initial 3 years. They were followed up through 2017, and then questionnaires were mailed. The association between the intrapersonal mean 2h-PBBG during the initial 3 years and death from all causes and cancer were determined by multivariate Cox regression analysis. SAS software (version 9.4) was used.

Results: During follow-up, 167 patients died. The cause was cancer in 57 and cardiovascular disease in 47 patients. The overall follow-up rate was 73.3% (798/1089). During the 3 years in which baseline values were established, the median (interquartile range) number of 2h-PBBG measurements was 3 (2–7) and the median follow-up period was 16.7 (10.8–18.2) years. At baseline, the mean patient age was 58.4 years; 81% were male, and 42% were smokers. Cox regression analysis showed the mean 2h-PBBG significantly predicted all-cause and cancer mortality, after adjusting for mean HbA_{1c}, number of 2h-PBBG measurements (ln-transformed), age, sex, and smoking status. In the model in which the duration of diabetes, mean BMI, mean systolic BP, and mean total cholesterol/HDL cholesterol were added, similar results were obtained (Table). Using a stepwise method adjusted for mean HbA_{1c} and the number of 2h-PBBG measurements, the results were the same.

Conclusion: Postprandial hyperglycemia at clinic visits is associated with all-cause and cancer mortality in type 2 diabetes patients, independent of the HbA_{1c} level. Further studies are warranted to confirm our findings.

Table Multivariate Cox proportional hazard models for mortality from all-causes and cancer.

	All-cause mortality (Event/Patients 167/1089)				Cancer mortality (Event/Patients 57/1089)			
	HR (95% CI)	*p* value	HR (95% CI)	*p* value	HR (95% CI)	*p* value	HR (95% CI)	*p* value

Socioeconomic status and mortality risk among patients with hypertension and diabetes: a cohort study from the Swedish Primary Care Cardiovascular Database (SPCCD)

T. Andersson[1,2], M. Pikkemaat[3], L. Schiöler[2], P. Hjerpe[4], A.C. Carlsson[5], P. Wändell[5], K. Manhem[6], T. Kahan[7], J. Hasselström[5], K. Bengtsson Boström[4];
[1]Närhälsan Norrmalm Health Centre, Skövde, Sweden, [2]Department of Public Health and Community Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, [3]Department of Clinical Sciences, Lund University, Malmö, Sweden, [4]Närhälsan R&D Centre Skaraborg Primary Care, Skövde, Sweden, [5]Department of Neurobiology, Care Sciences and Society, Karolinska Institutet, Huddinge, Sweden, [6]Department of Molecular and Clinical Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, [7]Department of Clinical Sciences, Danderyd Hospital, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Hypertension and diabetes are important risk factors for cardiovascular complications and premature death, often coexist, and are mostly managed in primary care. No studies with a primary care setting seem to have estimated the mortality risk among hypertensive patients who develop diabetes, and how this risk is associated with socioeconomic status. Thus, the aim of the study was to estimate mortality risk among hypertensive patients with diabetes (DM+) versus without diabetes (DM-), and how the risk associated with level of income, education, and country of birth.

Materials and methods: The SPCCD is an observational database of patients diagnosed with hypertension in primary care 2001–2008. The

medical records have been linked with five national population-based registers. The current study cohort consisted of 66 659 patients, of whom 10 577 were subsequently diagnosed with predominantly type 2 diabetes. Patients were included at the date of the first registration of hypertension, and were followed until end of study (31 December, 2012) or date of death, retrieved from the Cause of Death Register. Mortality hazard ratios (HR) were calculated by Cox regression models with diabetes as a time-updated variable, and were adjusted for quintiles of income, level of education, country of birth, sex, attained age, cardiovascular comorbidity, cancer, smoking, BMI, BP, lipids, and creatinine. Missing data was handled by multiple imputation.

Results: During 455 443 person-years 12 014 deaths (26.4/1000 person-years, 95% CI 25.9–26.9) occurred among DM- and 2 927 deaths occurred during 68 675 person-years (42.6/1000 person-years, 41.1–44.2) among DM+. The overall adjusted HR for mortality was 1.56, 1.49–1.63, for DM+, as compared to DM-. Low versus high income was associated with increased adjusted mortality risk (reference DM- highest income quintile: HR 1.00; DM+ highest income quintile: HR 1.96, 1.64–2.34; DM- lowest income quintile: HR 2.59, 2.33–2.87; DM+ lowest income quintile: HR 3.84, 3.41–4.32). Level of education was not associated with adjusted mortality risk among either DM+ or DM-. Compared to Sweden as country of birth, the adjusted mortality risk was increased for Finland among DM- (HR 1.25, 1.14–1.36) but not among DM+ (HR 1.09, 0.92–1.29) and decreased for country of birth outside Europe (DM-: HR 0.66, 0.57–0.77; DM+: HR 0.60, 0.48–0.75).

Conclusion: Adding diabetes to hypertension was associated with 56% excess mortality risk in primary care patients. The mortality risk was 3.8 and 2.6-fold increased among hypertensive patients in the lowest income quintile with and without diabetes, as compared to patients with hypertension in the highest quintile. Risk of mortality varied with country of birth.

Thirty-day mortality following admission with lactic acidosis in diabetes patients using metformin: a Danish nationwide study

A. Aharaz[1], R.W. Thomsen[2], K. Berencsi[2], T. Frøslev[2], H. Beck-Nielsen[1,3];
[1]Dpt. of Endocrinology, Odense University Hospital, Odense, Denmark, [2]Dpt. of Clinical Epidemiology, Aarhus University Hospital, Aarhus, Denmark, [3]The Danish Centre for Strategic Research in Type 2 Diabetes (DD2), Department of Endocrinology,, Odense University Hospital, Odense, Denmark.

Background and aims: Few population-based data are available on the prognosis of lactic acidosis associated with diabetes treatment. We examined seven-day and 30-day mortality following hospital admission with lactic acidosis associated with metformin and other glucose-lowering drug (GLD) use in 2004–2012.

Materials and methods: We linked three different Danish population-based registers to obtain data for this study: The Civil Registration System, The National Patient Register and The National Prescription Register. We identified 233 lactic acidosis admissions in GLD users, of which 191 events were in metformin-treated individuals and 42 in users of other GLDs. We compared mortality following lactic acidosis in metformin and other GLD users using Kaplan-Meier survival estimates, and using Cox regression analysis to adjust for differences in age, sex, renal disease and other comorbidity.

Results: We identified 233 lactic acidosis admissions in GLD users, of which 191 events were in metformin-treated individuals and 42 in users of other GLDs.Among metformin-treated patients with lactic acidosis, 77 of 191 (40.3%) died within the first 30 days of admission, whereas in patients using other GLDs admitted with lactic acidosis, 27 out of 42 (64.3%) died. After controlling for potential confounders, seven-day and 30-day mortality for metformin-associated lactic acidosis was lower than for lactic acidosis associated with other GLDs: adjusted seven-day hazard ratio (HR) = 0.50 (95% confidence interval (CI) 0.28–0.87) and adjusted 30-day HR = 0.51 (95% CI 0.31–0.81). A lower lactic acidosis mortality associated with metformin than other GLD use was consistently found in all subgroups regardless of age, sex, presence or absence of comorbidity or renal disease.

Conclusion: Mortality 30 days after admission with lactic acidosis is high among metformin users in a population-based setting, yet prognosis is even worse in users of other GLDs.

Haemoglobin glycation index and all-cause mortality in individuals with type 2 diabetes: the Pisa Mortality Study

G. Penno[1], M. Garofolo[1], D. Lucchesi[1], L. Giusti[1], V. Sancho Bornez[1], R. Miccoli[1], C. Bianchi[1], G. Sesti[2], S. Del Prato[1];
[1]Department of Clinical and Experimental Medicine, University of Pisa, PISA, Italy, [2]Department of Medical and Surgical Sciences, "Magna Graecia" University of Catanzaro, Catanzaro, Italy.

Background and aims: Data from RCTs have proposed hemoglobin glycation index (HGI), the difference between measured HbA1c and HbA1c predicted from fasting plasma glucose (FPG), as an independent marker of higher risk for diabetic micro- and macrovascular complications. HGI accounts for interindividual variation in the association between HbA1c and plasma glucose concentrations. We have tested the association between HGI (as a continuous or a categorized variable) and all-cause mortality in a large group of outpatient with type 2 diabetes mellitus (T2DM).

Materials and methods: The linear relationship between FPG and HbA1c [predicted HbA1c = 0.015*FPG (mg/dl) + 5.169; $r = 0.547$, $r^2 = 0.299$] was determined in a large sample of 9,696 consecutively recruited T2DM subjects after exclusion of 335 "outliers" (FPG and/or HbA1c values below 1st or above 99th percentile). HbA1c was measured with HPLC using a National Glycohemoglobin Standardization Program (NGSP) and FPG determined by enzymatic method. We have then identified 1019 T2DM individuals recruited in an observational, cross-sectional, single-center study with baseline cardio-metabolic risk stratification and prospective assessment of all-cause death.

Results: HGI (0.036 ± 1.011; mean ± SD) was normally distributed, ranging from −2.66 to 3.82. Study population was stratified as HGI tertiles (low ≤−0.474, intermediate −0.475 to 0.331, high ≥0.332). At baseline, intermediate and high HGI individuals had similar age, BMI, FPG, blood pressure, LDL-cholesterol, HDL-cholesterol, eGFR (CKD-

EPI), albumin-to-creatinine ratio, gender, and active smoking, but longer diabetes duration (DD), higher HbA1c and triglycerides than low HGI. Rates of retinopathy (23.0%, 26.1%, 38.3%; $p < 0.0001$), peripheral neuropathy (19.5%, 21.8%, 27.1%, $p = 0.017$) and peripheral artery disease (3.5%, 6.5%, 8.3%; $p = 0.035$) were the highest in high HGI. Finally, in high HGI more subjects were on glucose-lowering agents including insulin. A total of 234 deaths occurred over 13,131 person-years and 12.9 ± 2.7 year mean follow-up (23.0%; 17.8 ×1000 person-years) with no difference in mortality rate among HGI tertiles: 24.2%, 21.7%, and 23.1% (K-M; Log Rank, $p = 0.777$). In Cox regression model gender (HR 1.53, 95%CI 1.16–2.01; $p = 0.003$), age (1.08, 95%CI 1.06–1.11; $p < 0.0001$), DD (1.02, 95%CI 1.00–1.03; $p = 0.014$) and HbA1c (1.28; 95%CI 1.06–1.56, $p = 0.011$) were associated with increased risk of all-cause mortality while this risk decreased per unit HGI increase (HR 0.76; 95%CI 0.60–0.95; $p = 0.017$). The opposite effects of HbA1c and HGI were lost after adjustment for confounders. In a second Cox model including both HbA1c and HGI tertiles the opposite effects of HbA1c and HGI on all-cause death were confirmed but, once again, the associations were lost after adjustment for confounders.

Conclusion: In conclusion, in a large population of individuals with type 2 diabetes the predictive effect on all-cause mortality of both HbA1c and HGI is less powerful than gender, age, and duration of diabetes. The present findings do not support the hypothesis that HGI may identify a subset of individuals with type 2 diabetes at high risk for long-term all-cause mortality.

Aryl-hydrocarbon receptor binding and the incidence of type 2 diabetes: the Brazilian Longitudinal Study of Adult Health (ELSA-Brasil)

B.B. Duncan[1], C.D. Castilhos[1], P.A. Bracco[1], M.I. Schmidt[1], H.K. Lee[2], A. Vigo[1], Y.K. Pak[3];
[1]UFRGS, Porto Alegre, Brazil, [2]Eulji University, Seoul, Republic of Korea, [3]Kyung Hee University, Seoul, Republic of Korea.

Background and aims: Persistent organic pollutants (POPs) are a suspected cause of diabetes, but investigation of their risk has been hampered by the large number of different molecules, and the difficulty and cost of analyses. Much of their toxicity may result from their binding to the aryl hydrocarbon receptor (AhR), a transcriptional enhancer which affects various regulatory proteins. Ensuing mitochondrial dysfunction is postulated as a mediator of their action. Our aim is to investigate the association of POPs exposure with incident and prevalent diabetes indirectly by bioassaying the degree of AhR binding and mitochondrial inhibiting potential by *in vitro* incubation of cellular bioassays with plasma samples.

Materials and methods: We conducted incident and prevalent case-cohort analyses of participants from the Rio Grande do Sul center of the Brazilian Longitudinal Study of Adult Health (ELSA-Brasil), an ongoing cohort study. Of 2061 subjects enrolled between 2008 and 2010, 1598 were free of diabetes at baseline, returned for a follow-up visit 4 years later, and had complete information to classify diabetes. AhR binding was determined by a cell-based AhR-dependent luciferase activity bioassay and mitochondrial function with a serum mitochondria inhibiting activity bioassay. Diabetes was ascertained by self-report, medication use, OGTT or HBA_{1c}.

Results: 366 (17.8%) participants had diabetes at baseline and 106 (6.6%) developed diabetes during follow-up. In logistic regression analyses adjusting for sex, age, ethnicity, educational attainment, parental history of diabetes, hypertension, BMI, and waist-hip ratio, those with above-median values for AhR binding and for mitochondrial inhibiting potential had 72% and 187% greater odds developing diabetes (OR = 1.72; 95%CI 1.04–2.86 and 2.87; 1.66–4.96), respectively. Restricted spline analyses, when similarly adjusted, demonstrated tapering of associations at highest levels of AhR binding. Associations with prevalent diabetes, however, were less consistent. Although statistically significant cross-sectional associations for AhR binding were seen in restricted spline analyses (e.g. OR = 1.53; 1.12–2.08 for an AhR binding level of 3.0 vs. a reference level of 1.5), no association was found for mitochondrial inhibiting potential.

Conclusion: The increased incidence of diabetes associated with higher AhR binding and with greater mitochondrial inhibiting potential in this cohort suggest that ambient exposure to POPs could be an important contributing cause to the current diabetes epidemic.

Local traditions and conventions impact vulnerability to type 2 diabetes

A.-M. Volkmann[1], L. Hesseldal[2], M. Bagger[2], D. Napier[1];
[1]University College London, London, UK, [2]Health Advocacy, Novo Nordisk A/S, Bagsværd, Denmark.

Background and aims: More than half of the world's population live in cities, and two thirds of the more than 400 million people with diabetes live in urban areas. That makes cities an important focal point for

researching diabetes and for improving its prevention, care and management. To reduce the global diabetes burden, a variety of interventions have been implemented all over the world. However, the success of any intervention is significantly influenced by inter-related geographical, economic, environmental, social, and cultural factors, which up until now have been under-explored. Cultural factors, i.e. shared traditions and conventions, influence, among others, health beliefs and food practices, gender attitudes, and local practices to care seeking and health management, and therefore impact vulnerability to type 2 diabetes. For example, where foods and beverages that are high in calories and low in nutrition play an important role in local traditions sustaining social bonds, vulnerability may emerge as preventive lifestyle change is harder to implement and management more difficult to sustain.

Materials and methods: In order to obtain data about relevant environmental, social and cultural factors that make certain people vulnerable to type 2 diabetes, Vulnerability Assessments were carried out in five highly diverse cities around the world, namely Copenhagen, Houston, Mexico City, Shanghai, and Tianjin. In total, 740 individual semi-structured interviews were conducted across the five cities as part of the assessments, which also included demographic and ethnographic data collection. The research was part of the Cities Changing Diabetes programme established by Novo Nordisk together with Steno Diabetes Center Copenhagen, University College London and local partners. The aim of the programme is to understand the complexity of urban diabetes and to provide concrete guidance for policy change, urban planning, and public health interventions through collaborative research.

Results: The research identified a set of social factors and cultural determinants relevant to type 2 diabetes vulnerability that were evident across all cities with considerable local variations. 'Traditions and Conventions' was one such factor and was exemplified as follows: Copenhagen: standard medical referral practices acted as barriers to preventive care and services. Houston: food traditions were interwoven with heritage and culture, and therefore carried meaning beyond nutrition and diet. Food rituals were often perceived as providing 'comfort' central to a common culture and heritage. Mexico City: traditional gender roles limited effective self-care in men when there was no female household member present, and some men were unable or unwilling to provide diabetes support to others. Shanghai: denying hardship was culturally valorised. This attitude prevented people from seeking help from family, friends and healthcare professionals. Tianjin: belief in 'miracle cures' among some in the population created biological risks and psychological ill health.

Conclusion: 'Traditions and Conventions' impact vulnerability to type 2 diabetes. Where local traditions and conventions encourage specific individual behaviours, community-based interventions may prove ineffective, even if there are good local care providers present. Taking this cultural determinant into consideration and identifying any local variants may be a prerequisite for successful interventions.

Adherence to diabetes care process indicators in migrants as compared to non-migrants with diabetes: a population study

G. Seghieri[1], L. Policardo[1], P. Francesconi[1], C. Seghieri[2];
[1]ARS Tuscany, Pistoia, Italy, [2]Laboratorio Management e Sanità , Istituto di Management, Scuola Superiore Sant'Anna, Pisa, Italy, Pistoia, Italy.

Background and aims: According to previous studies the prevalence rate of diabetes is higher among migrants who have moreover been found to face a worse quality of care as compared with non_migrants. Whether migrants are correctly inserted into a standard quality of process care for diabetes by the regional health system and whether processes of care are adequately accomplished at follow up after being taken in charge, are the questions addressed by the present study which compares migrants with non-migrants (Italian residents) followed up since January 1st 2011 to December 31st2015 in Tuscany, a region of central Italy

Materials and methods: Diabetic patients living in Tuscany in the period January 1th 2011-31st December 2015 have been recruited according to a validated algorithm by administrative databases. Migrants were compared with Italian residents for the probability of fulfilling along this period at least one GCI (Guideline Composite Indicator, a process indicator including one annual assessment of HbA1c and at least two among eye examination, serum lipids measurement and microalbuminuria), through a logistic regression analysis and, for those with at least one GCI, the probability of having further GCIs through a truncated Poisson regression analysis. The analysis was finally completed by comparing two cohorts of migrants and Italian residents with diabetes, fully matched for main confounders by means of a *propensity score* ($N = 3{,}766$ for both).

Results: On January 1st 2011 a cohort of 130,648 diabetic patients has been identified of whom 3,766 composed by migrants. Migrants were on average younger (age: 51 ± 12 yr vs. 67 ± 13 yr; $p < 0.0001$), had a lower number of males (47% vs. 50%), a lower amount of previous comorbidities as testified by a higher Charlson Index (>1 in 9% vs. 26%) and finally a lower compliance to GCI significantly lower than among Italian residents (43% vs. 50%; OR = 0.776; 95%CI: 0.724–0.832); $p < 0.0001$ for all comparisons. After matching the two cohorts by propensity score, however, the probability of complying with at least one GCI was similar in migrants compared to Italian residents: OR:0.966 (95%IC:0.900–1.035; p = NS). On the contrary, even after matching cohorts by the propensity score the expected number of GCIs in those with at least one GCI was significantly reduced in migrants than in Italian residents with an Incidence Rate Ratio (IRR):0.86 (0.83–0.89); $p < 0.0001$.

Conclusion: These findings suggest that in Tuscany the regional health system can similarly intercept migrants and Italian residents with diabetes with regard to the expected adherence to guidelines. However, the quality of care seems to be impaired among migrant patients with diabetes, since they have a lower probability (by around 15%) of continuing to adhere to guidelines as evidenced by compliance to GCI.

Disclosure: **G. Seghieri:** None.

Area level deprivation and quality of care in type 2 diabetes: results from a disease management programme in North Rhine-Westphalia, Germany

B. Hagen, S. Groos, J. Kretschmann, C. Macare, A. Weber;
DMP-Projektbuero, Zentralinstitut fuer die kassenaerztliche Versorgung in Deutschland, Cologne, Germany.

Background and aims: Area level deprivation or socioeconomic status and its association with quality of care in type 2 diabetes (T2D) were addressed in a number of recent studies. Correlations were confirmed between low income and diabetes prevalence and diabetes-related mortality on the one hand, but higher referral rates on the other. In the context of a disease management programme (DMP) for T2D former analyses of the association between markers of socioeconomic status on a regional level and DMP-related indicators of quality of care showed ambiguous results. Therefore in a series of new analyses more detailed regional information was made accessible.

Materials and methods: For the 14 cities forming the metropolitan region of the central Ruhr area (approx. 3.36 millions of inhabitants, average population density 2.049 inhabitants/square kilometre) information on area level deprivation (income, migration status, educational level) was available on the level of small area city quarters. From the DMP documentation location of the practices as well as the results in the indicators of quality of care were known. An index of area level deprivation (1 = lowest grade of deprivation, 7 = highest) was used as a predictor of

specific indicators of quality of care in independent multivariate logistic regression models, adjusted for age, sex, comorbidities, duration of participation in DMP, and type of specialised care. All patient records of the years 2015 and 2016 from the region were analysed (*n* of patients = 206.903, mean age 68.1 + −12.6 yrs., female 50%).

Results: 4.0% of patients were assigned to the lowest level of area deprivation (1), 4.2% to the highest (7). 62.7% of patients were living in quarters characterised by medium level area deprivation (3–5). Comparing patients in index areas 1–5 with those assigned to 6 and 7 only marginal differences were seen with regard to HbA1c (<8,5%: 90.7% vs. 89.0%), blood pressure (<140/90 mmHg: 59.7% vs. 60.8%), assessment of renal function (92.4% vs. 91.6%) and prescription of metformin (87.8% vs. 87.7%). By contrast higher rates in patients from areas of lower deprivation were observed with regard to the achievement of the individual HbA1c aim (64.5% vs. 60.3%), regular eye examination (67.8% vs. 63.9%), referral to a specialist practice in case of severe feet lesions (50.6% vs. 44.3%; index areas 1–5 vs. 6–7, respectively), taking part in a recommended patient education (57.8% vs. 48.7%), and continuity of DMP participation (≥70% of all visits expected: 90.7% vs. 82.5%; index areas 1 vs. 7, respectively). Controlling for covariates patients in deprived areas had a significant lower chance to achieve their HbA1c aim (OR 0.90, 95%CI 0.88–0.92), to get an eye examination (0.84; 0.82–0.86), to take part in a patient education (0.67; 0.61–0.73) or to take part continuously (0.54; 0.48–0.61), and by trend to be referred to a specialist practice in case of feet lesions (OR 0.73; 0.50–1.05).

Conclusion: Data from a DMP for patients with T2D confirmed a strong influence of area level deprivation on specific indicators of quality of care, especially with regard to patient education and continuity of participation. As a consequence an intensification of supporting DMP patients in areas with high deprivation is required and intensified, cultural fair, and multilingual patient education programs must be implemented in those areas.

Diabetes knowledge, self-care behaviours, and metabolic control in Arabic-speaking adults with type 2 diabetes in Edmonton, Canada

R.O. Yeung[1], A. Belag[1], M. Alfaituri[2], F. Al-Sayah[3];
[1]Division of Endocrinology and Metabolism, University of Alberta, Edmonton, AB, Canada, [2]University of Alberta, Edmonton, AB, Canada, [3]School of Public Health, University of Alberta, Edmonton, AB, Canada.

Background and aims: The number of Arabic-speaking immigrants in Canada is growing, as is the prevalence of T2D (T2D) in this population. Understanding of T2D knowledge and self-care management in the Arabic-speaking population in Canada is lacking. The objective of this study was to examine diabetes knowledge, self-care behaviors, and health outcomes in Arabic-speaking adults with T2D in Canada.

Materials and methods: We conducted a cross-sectional study in Edmonton, AB between July 2017 and January 2018. Eligible adult Arabic-speaking participants with T2D were recruited from primary care settings and community centers in Edmonton. Data collection involved face-to-face interviews to complete an online survey via Research Electronic Data Capture (REDCap). The interviews were conducted in Arabic. Survey measures included diabetes knowledge (Michigan Diabetes Knowledge Test), self-care behaviours (Summary of Diabetes Self-Care Activates, SDSCA), medication adherence (Morisky medication adherence scale, MMAS8), and depressive symptoms (Patient Health Questionnaire 2, PHQ-2).

Results: A total of 114 individuals participated in this study. The mean age(±SD) of participants was 56 ± 16 years, and the majority were male (61.0%). The largest subset (37.7%) were of Lebanese origin. The mean diabetes duration was 11.8 ± 8.6 years. The majority (60.9%) had a BMI ≥25 kg/m^2 and 71.9% had a family history of diabetes. More than half of respondents reported having hypertension (58.8%) and dyslipidemia (54.4%). Less than the half (47.3%) had glycated hemoglobin less than the target range of 7%. Half (53.6%) had an average score (7 to 11 points) on their diabetes knowledge, and 25.4% scored poorly (<7 points). The poorest domain of self-care behaviours was exercise (mean 2.1 days/week). For those taking medication, 42.7% had moderate medication adherence (6–7), and 26.2% had poor medication adherence (score <6). One in five participants (19.3%) screened positive for depressive symptoms.

Conclusion: To the best of our knowledge, this is the first study describing diabetes-related knowledge, self-care management, depressive symptoms, medication adherence, and health outcomes in the growing Arabic-speaking population with T2D in Canada. We found significant gaps in knowledge and self-care behaviours. These findings have implications for the creation and implementation of culturally-tailored interventions to enhance diabetes knowledge, self-care behaviors, and clinical outcomes in the Arabic-speaking diaspora in Canada.

The impact of black ethnicity on performance of HbA_{1c} and 1 hour plasma glucose as screening modalities for impaired glucose tolerance

A. Ghafar, O. Bello, M. Ladwa, G. Alberti, S.A. Amiel, L. Goff;
Diabetes Research Group, School of Life Course Sciences, Faculty of Life Sciences and Medicine, King's College London, London, UK.

Background and aims: With a two-fold higher prevalence of type 2 diabetes (T2D) in people of Black compared with white European ethnicity, effective screening in this high-risk community is a public health priority. In the UK, HbA1c is used to detect risk of progression to T2D, with 42–47 mmol/mol as a criterion for entry into the new National Diabetes Prevention Programme. Ethnic-specific variations in HbA1c *vs* plasma glucose make these cut-offs of HbA1c for identification of pre-diabetes in people of Black ethnicity controversial. Furthermore, recent evidence favouring the 1 hour rather than the conventional 2 hour oral glucose tolerance test (OGTT) has not considered the possibility of ethnicity-related disparities in 1 hour plasma glucose concentrations (1hr PG). We aimed to compare the sensitivity and specificity of HbA1c and 1hr PG for the detection of impaired glucose tolerance (IGT) in men of Black West African (BWA) and White European (WE) ethnicity.

Materials and methods: Data were collected from participants undertaking a 75 g 2 hour OGTT during screening for entry into the South London Diabetes and Ethnicity Phenotyping Study between October 2015 and February 2018. Participants were male, aged 18–65 years and of BWA or WE ethnicity. Those with overt T2D or isolated impaired fasting glucose were excluded from analysis. IGT was diagnosed using WHO criteria (2 hour PG ≥7.8 mmol/L and <11.1 mmol/L). Sensitivity and specificity of HbA1c (42–47 mmol/mol) and 1hr PG (≥8.6 mmol/l) for detecting IGT in each ethnic group was tested using 2 hr PG values from the OGTT as the reference standard.

Results: 39 BWA and 56 WE men were recruited; IGT was found in 7.7% and 17.9% respectively. In the IGT group, HbA1c was significantly higher in BWA compared to WE men (45.0 ± 1.77 mmol/mol *vs* 38.0 ± 1.67 mmol/mol, $p = 0.014$), despite similar baseline characteristics (age 43.00 ± 3.61 years *vs* 52.50 ± 12.27 years, $p = 0.224$; BMI 33.35 ± 6.19 *vs* 29.93 ± 3.27, $p = 0.217$). In BWA men, sensitivity of HbA1c for detecting IGT was not significantly different in comparison to WE men (66.7%; 95% CIs [12.9, 98.2] *vs* 20.0%; 95% CIs [3.7, 40.9] $p = 0.125$) but specificity was lower (77.8%; 95% CIs [73.8, 80.4] *vs* 93.5%; 95% CIs [89.9, 98.0], $p = 0.038$). In BWA men, sensitivity of 1 hr PG for detecting IGT was not significantly different in comparison to WE men (66.7%; 95% CIs [13.0, 98.2] vs 88.9%; 95% CIs [53.5, 99.4] $p = 0.054$, but specificity was higher (81.8%; 95% CIs [76.9, 84.7] *vs* 60.9%; 95% CIs [54.0, 62.9] $p = 0.046$).

Conclusion: HbA1c levels of 42–47 mmol/mol have similar sensitivity but lower specificity in detecting IGT in BWA compared to WE men, whereas 1hr PG is more specific in detecting IGT in BWA compared to WE men and may offer a useful screening modality in people of Black ethnicity. Further work is needed to determine whether ethnic-specific HbA1c cut-offs are indicated.

Integration increases the risk of diabetes and obesity in the Filipino population resident in Rome

S. Pieralice[1], R. Del Toro[1], G. Pesce[1], K. Jansen[2], M. Khazrai[1], A. Maurizi[1], S. Manfrini[1], P. Pozzilli[1];
[1]Unit of Endocrinology and Diabetes, Department of Medicine, Campus Bio-Medico University, Rome, Italy, [2]The Hague University of Applied Sciences, Alphen aan den Rijn, Netherlands.

Background and aims: Italy is home to over 166,000 Filipino immigrants. However, dietary habits and predictors of risk of diabetes and metabolic disease within this immigrant group are not well investigated. Aims of the present study were to assess the dietary intakes and to evaluate the anthropometrical and metabolic characteristics of the Filipino population migrant to the Southern European city of Rome, Italy. Moreover, changes in metabolic characteristics between first-generation immigrants and their descendants were examined.
Materials and methods: A cross-sectional study was carried out in the city of Rome. A total of 132 first-generation immigrants (42 M/90 F, mean age: 49.3 ± 11.2 years, mean residence in Italy: 15.6 ± 10.6 years) and 27 descendants (12 M/15 F, mean age: 15.7 ± 3.2 years) were studied. Data were collected by standardized questionnaires; anthropometrical parameters and fasting capillary blood glucose (FCG) were measured. Paired t test (two tailed) and analysis of variance were used to evaluate differences in metabolic characteristics between the two groups. A Pearson's correlation analysis was performed to identify any significant correlation between BMI and life-style/eating habits.
Results: Impaired fasting glucose (FCG ≥110 mg/dl) was observed in 22.6% of first-generation immigrants and in 8% of descendants' group. Limited to the first-generation group, Toumilehto questionnaire showed a 10-year risk of developing diabetes >50% in 20% of subjects. BMI ≥25 kg/m^{2}was found in 41.7% of first-generation immigrants, while children's BMI-percentile-for-age >85% was recorded in 48.1% of second-generation group, with a significant different between the two populations ($p < 0.05$). Evaluation of dietary intake pattern showed that first-generation immigrants consumed traditional food more days x week compared to their descendants, who preferred western food, with a large consumption of eggs (>4 times/week: 96%), processed meat (>4 times/week: 74%) and sweet foods or beverages (>4 times/week: 96%). Body Mass Index (BMI) showed a positive correlation with the years spent in Italy ($R = 0.19$, $p = 0.03$) and with educational level ($R = 0.19$, $p = 0.04$). Limited to the first-generation women, the size of household was directly related to weight gain ($R = 0.40$, $p < 0.001$).
Conclusion: In the present study, substantial risk of developing diabetes within Filipino community was found. Moreover, the prevalence of obesity is higher in the second-generation, probably due to westernization in eating habits linked to an unfavourable socio-economic context.

Identification of novel loci associated with lipid levels in recent-onset type 1 diabetes

A.J. Overgaard[1], S. Kaur[1], A. Ali[1], J.M. Weir[2], K. Jayawardana[2], H.B. Mortensen[3], P.J. Meikle[2], F. Pociot[1];
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]Baker IDI Heart and Diabetes Research Institute, Melbourne, Australia, [3]Herlev Gentofte Hospital, Herlev, Denmark.

Background and aims: Multiple studies have identified panels of lipidomic biomarkers for increased cardiovascular risk and declining beta cell function in type 1 diabetes (T1D) patients. So far, single nucleotide polymorphisms (SNPs) at 157 loci have been robustly associated with blood lipids and several of these lipid loci are associated with cardiovascular and metabolic traits. However, shared genetic components between dyslipidemia and T1D are largely unknown. Here we aim to identify lipid-associated SNPs in children with recent onset T1D and examined their effects on glucose-related traits using global Lipidomics profiling.
Materials and methods: The plasma lipidome (352 lipids) in a cohort of children diagnosed with T1D from the Danish Remission Phase Study ($n = 106$) was profiled at 4 different time-points (1, 3, 6 and 12 months) using Agilent 1290 liquid chromatography system coupled to an Agilent 6490 triple quadrupole mass spectrometer. The cases were genotyped using ImmunoChip, a custom-made Illumina Infinium array, described previously. The lipid levels were quantile normalized and adjusted for covariates. The association with individual SNPs with lipids was tested using linear mixed models (FastLmm). Linkage disequilibrium (LD) analysis was performed to identify lead SNPs for each lipid-SNP association. Associations between lipid-associated SNPs and HbA1c were computed. Known lipid-loci were retrieved from Global Lipid Genetics Consortium (GLGC) cohort.
Results: We found 7 loci significantly associated with specific lipids at minimum 2 time-points (Table1). Among these, EVI5 locus has been previously shown to be associated with total cholesterol (TC) levels in GLGC cohort. Specific lipids that associated with EVI5 lead variants rs2065916 (OR = 1.31, p value = 2.9e-07), rs11164778 (OR = 1.29, p value = 7.0e-07) and rs6658232 (OR = 1.14, p value = 3.2e-06) in our analysis included CE:18:2 and COH at 6 months; DG(36:2), TG(50:2), TG(51:0), TG(54:1) and CE:22:0 at 12 months from lipid classes cholesteryl esters, free cholesterol, diacylglycerols, and triacylglycerols respectively. Interestingly, each copy of the risk alleles for EVI5 variant rs2065916 corresponded to up to 30% increase in the associated lipid levels. Furthermore, lead variants at 3 loci (EVI5, MAP3K8 and USP34) were associated with increased HbA1c at different time-points. Overlap with known lipid-loci identified FADS1/FADS2 lead variant rs174537 which has been previously shown to be associated with triglycerides, total cholesterol, LDL and HDL. In our analysis, rs174537 significantly associated with PC:36:4b at 6 months.
Conclusion: This study identified 7 loci that associate with lipid levels at multiple time-points in T1D patients. Three loci showed pleiotropic associations with lipids and HbA1c suggesting a complex genetic regulation and metabolic interplay.

Table: Lipid-SNP associations significant in at least 2 time-points

Lead SNP	MAF	Locus	Associated lipids, timepoints (months)	P-value	Odds Ratio	HbA1c ~ SNP

Genetic determinants of glycated haemoglobin in type 1 diabetes

A. Syreeni[1,2], N.K.A. Sandholm[1,2], J. Cao[3], I. Toppila[1,2], C. Forsblom[1,2], V. Harjutsalo[1,4], M. Parkkonen[1,2], E. Valo[1,2], A.D. Paterson[3], P.-H. Groop[1,2], the FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland, [2]Abdominal Center, Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland, [3]Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada, [4]The Chronic Disease Prevention Unit, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: HbA_{1c} is an important measure of glycemia in diabetes. Notably, HbA_{1c} is influenced not only by environmental but also by genetic factors, both in people with and without diabetes. For example, single nucleotide polymorphisms (SNPs) that affect erythrocyte turn-over or that modify glucose homeostasis may influence HbA_{1c}. Genetic variants for HbA_{1c} have mainly been studied in non-diabetic individuals, and only one genome-wide association study (GWAS) has previously been conducted in individuals with type 1 diabetes in the DCCT/EDIC cohort.
Materials and methods: Here we performed a GWAS for HbA_{1c} in The Finnish Diabetic Nephropathy Study (FinnDiane). A total of 4,622 individuals with type 1 diabetes were included. Human Core Exome Bead Chips were used for genotyping and imputation was performed. SNPs were analyzed with linear regression with covariates age, duration, sex, number of HbA_{1c} measurements, genotyping batch and principal components 1–10. Replication was performed in DCCT/EDIC divided into individuals with conventional (CON, $n = 667$) or intensive (INT, $n = 637$) treatment of diabetes during DCCT. The association between top SNPs and HbA_{1c} was further studied in non-diabetic cohorts from European, East Asian and South Asian origin with the data from a large meta-GWAS for HbA_{1c}.
Results: In the FinnDiane population, three tightly correlated SNPs on chromosome 13 near relaxin/insulin like family peptide receptor 2 (*RXFP2*) with minor allele frequencies (MAFs) 3.0–4.1% were associated with HbA_{1c} (Beta = 0.42 [95% CI 0.27, 0.56], $p = 1.5 \times 10^{-8}$ for the lead SNP rs2085277). The chromosome 13 top SNPs were not significantly associated with HbA_{1c} in the DCCT/EDIC and the MAFs were low. For example, MAF for rs2085277 was 0.2% and 0.5% in the DCCT/EDIC CON and INT cohorts, respectively. Interestingly, rs2085277 had a minor T-allele frequency of 38.5% in the 1000 Genomes East Asian population and this SNPs was associated with HbA_{1c} in non-diabetic subjects from East Asia (Beta = 0.02 [0.006, 0.03], $p = 0.005$). Further, rs1360072 on the chromosome 13 locus had MAF = 34.6% in East Asian and MAF = 9.0% in South Asian individuals and it significantly associated with HbA_{1c} in both Asian populations (Beta = 0.02 [0.003, 0.03], $p = 0.013$) with the consistent direction of the effect.
Conclusion: We identified variants near *RXFP2* that were associated with HbA_{1c} in Finnish individuals with type 1 diabetes as well as in individuals without diabetes. Detailed analysis of the involved genes and pathways may help understanding how this locus affects HbA_{1c} values and glycemia in diabetes.

Type 1 diabetes genetic risk score discriminates between monogenic and type 1 diabetes in patients with diabetes presented below five years of age in Iranian population

H. Yaghootkar[1], K. Patel[1], K. Colclough[1], A. Moleirinho[1], N. Ghaemi[2], S. Heidari[3], S. Vakili[2], S. Enayati[3], A. Rabbani[3], F. Abbasi[3], T. McDonald[1], S. Ellard[1], M.M. Amoli[3], R. Vakili[2], A.T. Hattersley[1];
[1]University of Exeter, Exeter, UK, [2]Mashhad University of Medical Science, Mashhad, Islamic Republic of Iran, [3]Tehran University of Medical Sciences, Tehran, Islamic Republic of Iran.

Background and aims: Previous studies of non-consanguineous white Europeans have indicated a type 1 diabetes genetic risk score (T1D-GRS) as a tool to discriminate between T1D and other non-autoimmune causes of diabetes. We aimed to assess the utility of T1D-GRS to distinguish monogenic from type 1 diabetes in predominantly consanguineous population.
Materials and methods: We collected 91 patients with diabetes diagnosed between 9 months and 5 years old from two centres in Iran. We analysed clinical features at referral, measured three islet autoantibodies (IA2, GAD and ZnT8) and generated T1D-GRS using 30 common genetic variants associated with T1D. All patients underwent a targeted next-generation sequencing of all known monogenic diabetes genes (35 genes).
Results: Our cohort included 44 females and 47 males, from 32 consanguineous families (37.7%). We identified monogenic diabetes in 6 patients (7%). Of these, 5 had homozygous mutations (4 in *WFS1* and 1 in *SLC19A2*) and 1 had heterozygous mutation in *GCK*. The frequency of mutations was different from monogenic diabetes in European population where mutations in *GCK* are the most common cause especially in children under 5 years old. T1D-GRS of the monogenic patients was lower (mean GRS 8.2, 95% CI [7–9.1]) than the rest of the patients (10.4 [7.4–12.9], $p_{difference} = 0.006$). Patients with monogenic cause did not have any antibodies but 80% of non-monogenic patients were positive for at least one of the antibodies. Age of diagnosis, birth weight, syndromic features, consanguinity and gender were similar in patients with monogenic cause and rest of the cohort (all $p > 0.05$). The T1D-GRS was highly discriminatory between monogenic and non-monogenic group (ROC area under the curve (AUC) 0.90 [0.82–0.98]). This is additive to the discriminatory power of islet autoantibodies (RUC AUC autoantibodies alone 0.81 [0.65–0.98] vs ROC AUC T1D-GRS and autoantibodies 0.94 [0.86–1.00], $p_{difference} = 0.018$).
Conclusion: Our study provides the first evidence that T1D-GRS can be used in the predominantly consanguineous Iranian population to distinguish monogenic from type 1 diabetes. Importantly, T1D-GRS was independent and additive to the widely available islet autoantibodies for identifying monogenic diabetes. This highlights the clinical utility of T1D-GRS in routine clinical practice.

IRS1genetic variants associated with glucose control and insulin resistance in type 2 diabetic patients from Bosnia and Herzegovina

L. Mahmutovic[1], T. Bego[2], M. Sterner[3], G. Gremsperger[3], E. Ahlqvist[3], Z. Velija Asimi[2], B. Prnjavorac[4], N. Hamad[1], A. Causevuc[2], L. Groop[5], S. Semiz[1];

[1]International University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [2]University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [3]Lund University Diabetes Centre, Malmoe, Sweden, [4]General hospital Tesanj, Tesanj, Bosnia and Herzegovina, [5]Lund University Diabeter Centre, Malmoe, Sweden.

Background and aims: Previous studies reported conflicting results regarding association of variation insulin receptor substrate 1 (*IRS1*) gene variation with Type 2 diabetes (T2D) and markers of insulin resistance (IR) in different ethnic groups. Here we examined the association of rs7578326 (G>A), rs2943641 (T>C), and rs4675095 (A>T) with T2D risk and its related traits in a population from Bosnia and Herzegovina (BH), which is among European countries with the highest T2D prevalence of 12.3%.
Materials and methods: Our study included 390 T2D patients and 252 unrelated nondiabetic control subjects. Biochemical parameters, including fasting glucose (FG), fasting insulin (FI), HOMA-IR, and HbA1c levels, were measured in all participants. We performed sensitivity analysis in a subgroup of 96 T2D patients not treated with any therapy (NT-T2D) to dissect the potential drug effects on phenotypic measures. Genotyping analysis was performed by Mass Array Sequenom iPlex platform in cooperation with Lund University Diabetes Centre, Malmo, Sweden.
Results: Our results demonstrated that upon adjustment for BMI, age, and gender, rs7578326 and rs4675095 variants were positively associated with FG ($B = 0.05295$% CI 0.004; 0.099, $p_{dom} = 0.034$; $B = 0.029$ 95% CI 0.002; 0.054, $p_{add} = 0.037$, respectively), thus, in opposite direction as compared to rs2943641 ($B = -0.17$ 95% CI −0.033; −0.002, $p_{add} = 0.030$). Strikingly, the risk allele of both, rs7578326 and rs2943641, were also associated with higher HbA1c ($B = 0.034$ 95% CI 0.003;0.065, $p_{dom} = 0.035$; and $B = 0.032$ 95% CI 0.002; 0.065, $p_{dom} = 0.040$, respectively). Furthermore, the risk A and C allele of these two polymorphisms were associated with HOMA-IR ($B = 0.316$, 95% CI 0.026; 0.607, $p_{rec} = 0.033$) and higher levels of FI ($B = 0.350$ 95% CI 0.022; 0.487, $p_{rec} = 0.033$) in NT-T2D patients. Interestingly, the rs7578326/rs2943641 haplotype was associated with FG ($p = 0.024$) and waist circumference ($p = 0.029$) in control subjects, while in NT-T2D patients it was associated with HOMA-IR ($p = 0.024$), thus confirming the observed individual effects of the risk alleles on FG and IR. Logistic regression analysis demonstrated that the odds of developing T2D in this sample of BH population were not associated with the presence of *IRS1* rs7578326, rs2943641, and rs4675095 variants after adjustment for gender and age.
Conclusion: Our results showed the association of the common *IRS1* genetic variants with insulin resistance markers and fasting glucose levels in the population of Bosnia and Herzegovina, indicating that *IRS1* is the common locus for insulin resistance across different populations. Importantly, here we report first here the association of *IRS1* variation with HbA1c levels, further strengthening its role in blood glucose control.

Does low birth weight and type 2 diabetes share a common genetic background?

O. Al-Allaf;
Exeter Medical School, Exeter, UK.

Background and aims: It has been shown, in observational epidemiological studies, that a low birth weight (BW) increases the susceptibility of type 2 diabetes (T2D) later in life. The Foetal Insulin Hypothesis proposes that these two phenotypes are of one genotype. We reviewed the literature providing evidence for the genetic factors linking low BW to T2D. Aim: To improve our understanding on the relationship of low BW and T2D at the genome level.
Materials and methods: We conducted a literature search on PubMed, Google Scholar and Springer-Link, using the search terms; 'Genetics', 'Birth Weight' and 'Type 2 Diabetes'. We found 314 publications and after applying our exclusion criteria we left with 4 papers to review (Figure 1).
Results: The publications we looked at had tested whether common genetic variants that predispose to T2D are also linked to low BW. Over the 4 papers (including 63,332 candidates in total) we looked at, we found a total of 6 Single Nucleotide Polymorphisms (SNPs) on 4 different loci that increase susceptibility to T2D and are associated with low BW. The CDKAL1-rs10946398 variant was associated with a reduction in BW by 41 g and 21 g in 2 different papers with *P* values of 0.034 and 2×10^{-5} respectively. The CDKAL1-rs7756992 variant showed a reduction in BW by 36 g and 22 g with *P* values of 0.048 and 0.04 respectively. The rs900400 SNP near CCNL1 reduced BW by 40 g ($P = 2 \times 10^{-35}$). The rs9883204 SNP on the *ADCY5 loci showed a 30 g reduction in BW* ($P = 7 \times 10^{-15}$) and the rs11708067 variant on the same loci showed a 33 g reduction with $P = 0.004$. Lastly, the HHEX-IDE-rs1111875 reduced BW by 14g ($P = 0.004$). (All figures for BW reduction stated are 'per risk allele'). Discussion: Insulin is vital for foetal growth and metabolism through life. SNPs in CDKAL1, HHEX-IDE, ADCY5 and near CCNL1 can affect the pancreatic beta cell function, resulting in low insulin mediated foetal growth and the increased risk of T2D in later life, which is strong evidence for the foetal insulin hypothesis. Clearly, the above-mentioned gene variants are associated with low BW, which was statistically significant ($P < 0.05$ in all of the above studies). On the other hand, these SNP's were found to increase susceptibility to T2D according to other studies previously done. This demonstrates that there is a clear overlap between the genetics of T2D and foetal growth which suggests that lower BW and T2D may be two phenotypes of one genotype. Also, low birth weight might be a predictor for future T2D.
Conclusion: Current studies showed clearly that low birth weight and future susceptibility to T2D share a common genetic background. This supports the Foetal Insulin Hypothesis.

Disclosure: **O. Al-Allaf:** None.

Variants in genes regulating vitamin D metabolism (DHCR7, CYP2R1 and GC) determine low vitamin D levels in type 2 diabetic patients

L. Bertoccini[1], D. Bailetti[1], I. Barchetta[1], C. Pibiri[1], F. Bagella[1], T. Filardi[1], E. Alessi[1], M. Incani[2], S. Carletti[3], S. Pezzilli[1], P. Piscitelli[4], G. Leanza[5], U. Di Folco[6], SUMMER Study Group, M.G. Baroni[1];
[1]Sapienza University of Rome, Rome, [2]University of Cagliari, Cagliari, [3]Pertini Hospital, Rome, [4]IRCCS CSS, S. Giovanni Rotondo, [5]Campus Biomedico, Rome, [6]San Camillo Forlanini Hospital, Rome, Italy.

Background and aims: Hypovitaminosis D is associated with an increased prevalence and incidence of metabolic syndrome and type 2 diabetes (T2D). Low vitamin D levels are constantly present in T2D patients. A large meta-analysis of GWAS of serum 25-hydroxyvitamin D identified variants in 3 genes involved in vitamin D metabolism (DHCR7, CYP2R1 and GC). So far, the association between these variants and vitamin D levels has been studied only in the general population, while no robust data are available in the context of T2D. Our aim was to investigate the role of variants in DHCR7, CYP2R1 and GC genes, considered either individually or in combination, on serum vitamin D concentrations in a large and very homogeneous cohort of Italian patients with T2D.
Materials and methods: The first 2165 consecutive study subjects of the "Sapienza University Mortality and Morbidity Event Rate (SUMMER)

study in diabetes" cohort were studied. Clinical data of all participants were collected. Centralised measurements of serum vitamin D levels were carried out in all patients. The following SNPs were studied: DHCR7 rs12785878 T>G, CYP2R1 rs10741657 G>A, GC rs4588 G>T.

Results: The rs12785878 SNP of DHCR7 gene was significantly associated with vitamin D levels (23.8 ± 10.2, 22.6 ± 10.1 and 21 ± 9.5 ng/ml in TT, TG and GG individuals, respectively, $p = 1.7 \times 10^{-4}$). The allelic OR for vitamin D insufficiency (<30 ng/ml) was 1.28 [CI = 1.09–1.51], $p = 3 \times 10^{-3}$. A similar tendency toward association was observed between the CYP2R1 rs10741657 SNP and vitamin D levels (24.7 ± 12.2, 23.3 ± 10.8 and 22.6 ± 9.4 ng/ml in AA, AG and GG individuals, respectively, $p = 0.20$). The allelic OR for vitamin D insufficiency was 1.18 [CI = 1–1.38], $p = 0.042$. The GC rs4588 SNP was significantly associated with vitamin D levels (24.1 ± 10.7, 22.3 ± 9.5 and 20.8 ± 8.7 ng/ml in GG, GT and TT individuals, respectively, $p = 3.5 \times 10^{-5}$). The allelic OR for vitamin D insufficiency was 1.36 CI = [1.14–1.61], $p = 4.7 \times 10^{-4}$. A weighted genotype risk score (w-GRS) was then calculated by summing the risk alleles of the 3 SNPs in each individual, weighting each risk allele with the effect size for risk of hypovitaminosis D (<30 ng/ml). We observed a strong association with vitamin D levels, decreasing significantly from the first to the last w-GRS category (24.3 ± 11, 24.8 ± 11.5, 22 ± 8.9, 21 ± 9 ng/ml respectively, $p = 1.0 \times 10^{-7}$), with an OR for the subgroup with 3+ risk alleles (vs. 0 alleles carriers) of 1.24 CI = [1.13–1.37], $p = 1.1 \times 10^{-5}$.

Conclusion: In this study, we observed a significant association between DHCR7 rs12785878 and GC rs4588 variants with lower vitamin D levels in T2D patients. When the 3 variants were considered together as GRS, a highly significant association was observed both with vitamin D levels and with the risk of hypovitaminosis D. These results provide strong evidence of the effects of variability in genes involved in vitamin D metabolism on vitamin D levels in patients with T2D.

Association of CUBN gene variants with type 2 diabetes and vitamin D levels in an elderly Greek population

X. Tsekmekidou[1], F. Tsetsos[2], S. Karras[1], M. Georgitsi[3,2], A. Roumeliotis[4], S. Panagoutsos[4], E. Thodis[4], M. Theodoridis[4], N. Papanas[5], D. Papazoglou[5], P. Pasadakis[4], E. Maltezos[5], P. Paschou[2], K. Kotsa[1];
[1]Division of Endocrinology and Metabolism, 1st Dept of Internal Medicine, AHEPA University Hospital, Aristotle University of Thessaloniki, Thessaloniki, [2]Department of Molecular Biology and Genetics, Democritus University of Thrace, Alexandroupolis, [3]Laboratory of General Biology-Genetics, Department of Medicine, Aristotle University of Thessaloniki, Thessaloniki, [4]Department of Nephrology, Democritus University of Thrace, Alexandroupolis, [5]Diabetes Centre, Second Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis, Greece.

Background and aims: Vitamin D has been shown to influence both insulin secretion and sensitivity. Genetic variations of *VDR* have been implicated in diabetes mellitus (DM) pathogenesis. Cubilin, encoded by the *CUBN* gene in humans, is involved in the conversion of 25-hydroxyvitamin D [25(OH)D] to biologically active 1α,25-dihydroxyvitamin D in the kidney. Thus, in this study, we aim to explore potential differences of *CUBN* variants in an elderly Type 2 DM (T2DM) population compared to non-diabetic subjects and assess potential effect of *CUBN* variants on 25(OH)D levels.

Materials and methods: In this case-control study, 1258 participants were categorized as T2DM patients ($n = 716$) by diabetes history, HbA1c and fasting plasma glucose levels and non-DM controls ($n = 542$) by absence of history of T2DM, HbA1c <6.5%, fasting glucose <126 mg/dl and age >65 years. Subjects on vitamin D supplementation were excluded. Informed consent was obtained and whole blood was collected for DNA extraction. Samples were analysed on Illumina Infinium PsychArray. After individual and SNP quality control, polymorphisms of *CUBN* were selected. For compound analysis, the PLINK software suite (v1.9) was used. Permutation test analysis was implemented to determine statistical significance ($p < 0.05$). Vitamin D levels [25(OH)D] were measured in a sub-group ($n = 276$) and *CUBN* variants were further analyzed. We also employed a correction method based on effective SNPs instead of Bonferroni, resulting to a $p = 0.05/115 = 4.434e^{-4}$ as significance cut-off.

Results: Female subjects predominated in study population (55.5%). Our results indicated a potential association of *CUBN* variants with T2DM. Permutation analysis associated rs11254375 ($p = 0.00049$, OR = 1.482), rs6602175 ($p = 0.016$, OR = 0.822), rs1801224 ($p = 0.025$, OR = 0.830), rs4366393 ($p = 0.028$, OR = 0.829) and rs7071576 ($p = 0.04$, OR = 1.219) with disease. Mean 25(OH)D levels were significantly lower in patients with T2DM than in the control group (16.705 ± 6.69 ng/ml vs 18.51 ± 6.71 ng/ml, $p < 0.05$), although both groups were vitamin D deficient. In a further quantitative analysis, rs41301097 was strongly associated with higher 25(OH)D levels ($p = 5.233e^{-6}$, beta = 15.95).

Conclusion: Our results indicate a potential role of *CUBN* in T2DM pathogenesis. Rs11254375 and rs7071576 exhibited a significant association with disease, whereas other variants show a potential protective role. These results may suggest an indirect effect of vitamin D metabolism in the pathogenesis of T2DM. Interestingly, in our quantitative analysis rs41301097 was associated with higher vitamin D levels, exhibiting a protective role against vitamin D deficiency. Further studies are required to replicate our findings and to further explore the role of cubilin in T2DM pathogenesis.

Novel roles of alpha-4, a non-canonical scaffolding subunit of protein phosphatase 2A, in the onset of beta cell dysfunction under glucotoxic conditions

A. Kowluru;
Wayne State University, Detroit, USA.

Background and aims: Despite a growing body of evidence suggesting key roles for protein kinases in islet beta-cell function, protein phosphatases remain an under studied class of signaling proteins in islet biology. The protein phosphatase 2A (PP2A), which accounts for 80% of total serine/threonine phosphatases, has been implicated in the regulation of cell proliferation, survival and apoptosis. The PP2A is a hetrotrimeric holoenzyme consisting of the structural (A), regulatory (B) and catalytic (C) subunits. Post-translational methylation (at Leu-309) and phosphorylation (at Tyr-307) of PP2Ac have been shown to increase and decrease the catalytic function of PP2A, respectively. We recently demonstrated sustained PP2A in beta-cell models of glucotoxicity, and proposed that hyperactivation of PP2A could lead to dephosphorylation of key proteins requisite for physiological insulin secretion and beta cell proliferation. Herein, we determined putative regulatory roles for alpha-4, a non-canonical adaptor regulatory subunit of PP2A, in the sustained activation of PP2A under glucotoxic conditions.
Materials and methods: Islets were isolated from Sprague-Dawley, Zucker lean control, and Zucker Diabetic rats by the collagenase digestion method. Human islets were from Prodo Labs (Aliso Viejo, CA). INS-1 cells, rat and human islets were cultured under basal (2.5 mM glucose) or glucotoxic (20–30 mM glucose; 24–48 hrs.) conditions. PP2A activity assay kit was from Millipore. Degree of cell death was detected by Annexin V/Propidium fluorescence staining.
Results: Glucotoxic conditions significantly promoted PP2A activity in INS-1 832/13 cells (~3 fold), rodent islets (~1.8 fold) and human islets (~2.2 fold). Sustained activation of PP2A was also seen islets derived from the pre-diabetic (7 weeks; ~1.4 fold) and diabetic (13 weeks; ~2 fold) Zucker diabetic rats. Western blot analysis indicated that alpha-4 is expressed in INS-1 832/13 cells, rat islets and human islets. Furthermore, glucotoxic conditions increased the expression of alpha-4 in INS-1 cells and human islets. siRNA-mediated knockdown of endogenous expression of alpha-4 resulted in significant inhibition (−60%) of high glucose-induced PP2A activity in INS-1 832/13 cells suggesting key regulatory roles for this scaffolding protein in the sustained activation of PP2A under glucotoxic conditions. Lastly, silencing of endogenous alpha-4 expression markedly attenuated high glucose-induced cell death in INS-1 832/13 cells.
Conclusion: Glucotoxic conditions promote activation of PP2A in *in vitro* and *in vivo* models of glucotoxicity and impaired insulin secretion. Alpha-4 is expressed in a variety of insulin-secreting cells including human islets and rat islets. Alpha-4 plays novel regulatory roles in promoting sustained activation of PP2A and associated dysfunction of pancreatic beta-cells. Studies are underway to further define putative signaling mechanisms underlying alpha-4 mediated regulation of PP2A activation including its role in facilitating post-translational modifications of PP2Ac and the holoenzyme assembly of PP2A.

Glutamine deprivation induces metabolic adaptations associated with beta cell dysfunction and exacerbate lipotoxicity

R. Carlessi, J. Rowlands, G. Ellison, H.H. de Oliveira Alves, P. Newsholme, C. Mamotte;
School of Pharmacy and Biomedical Sciences, Curtin Health Innovation Research Institute, Curtin University, Perth, Australia.

Background and aims: Circulating levels of the amino acid L-glutamine have been reported to be significantly reduced in type 2 diabetes (T2D) patients. Recent studies have demonstrated that supplementation with L-glutamine or the dipeptide L-alanyl-L-glutamine (Ala-Gln) has the potential to improve glycaemic control, although the mechanisms are still largely unknown. We hypothesized that L-glutamine is essential for a healthy beta cell bioenergetics, and deprivation of this amino acid could induce cell metabolic alterations capable of promoting insulin secretory dysfunction. Thus, we evaluated the bioenergetic and insulin secretory responses of beta cells to chronic L-glutamine deprivation in vitro. In addition, we also endeavoured to determine the impact of L-glutamine deprivation to the pathological mechanisms induced by lipotoxicity.
Materials and methods: BRIN-BD11 rat insulin secreting cells were submitted to 24h of either L-glutamine deprivation or treatment in the presence of the non-hydrolysable L-glutamine analogue 6-Diazo-5-oxo-L-norleucine (DON), a potent inhibitor of intracellular L-glutamine metabolism due to irreversible binding to glutaminases. Cellular bioenergetics was monitored by extracellular flux analysis using the XFe96 seahorse analyser. Several other cell metabolic outcomes, including glucose uptake and consumption, gene and protein expression of glycolytic enzymes, as well as determination of insulin production and secretion were evaluated. In addition, the responses of rat islets and BRIN-BD11 cells to palmitate treatment in combination with different levels of L-glutamine deprivation were assessed in terms cell viability, insulin secretion and activation of the apoptotic and endoplasmic reticulum (ER) stress response pathways.
Results: L-glutamine deprivation or inhibition of its intracellular metabolism for 24h induced striking metabolic adaptations. These included a potent reduction in mitochondrial oxidative phosphorylation, evident by marked decrease in oxygen consumption rates (OCR). Measurements of glucose consumption and uptake, however, indicated an increase in glucose utilization. This observation was supported by gene expression analysis, which evidenced a significant increase in several glycolytic enzymes, indicative of a compensatory metabolic adaptation to absence of L-glutamine as a fuel source. Such adaptations were paralleled by activation of the PERK/eIF2α/ATF4 pathway, responsible to drive global inhibition of protein synthesis during nutrient restriction and ER stress. Accordingly, this phenotype was associated with a striking impairment in β-cell function, as demonstrated by a markedly decreased insulin production and secretion. Treatment with palmitate, as expected, led to insulin secretory dysfunction, induction of ER stress, loss of viability and apoptosis in our experimental system. L-glutamine deprivation significantly exacerbated these phenotypes, which could be rescued by supplementation with Ala-Gln in a concentration dependent manner.
Conclusion: Altogether our data suggest that excessively low L-glutamine levels could participate in the process of beta cell dysfunction in T2D, warranting future nutritional strategies in order to re-establish normal levels of this amino acid as a therapeutic approach in T2D.

Proteasomal degradation of the histone acetyl transferase p300 contributes to beta cell injury in a diabetes environment

S. Costes[1], L. Ruiz[1], T. Gurlo[2], M.A. Ravier[1], A. Wojtusciszyn[3], J. Mathieu[1], M.R. Brown[4], C. Broca[3], G. Bertrand[1], P.C. Butler[2], A.V. Matveyenko[4], S. Dalle[1];
[1]Institute for Functional Genomics, Montpellier, France, [2]Larry L. Hillblom Islet Research Center, Los Angeles, USA, [3]Laboratory of Cell Therapy for Diabetes, Montpellier, France, [4]Mayo Clinic School of Medicine, Rochester, USA.

Background and aims: In type 2 diabetes (T2D), amyloid oligomers, chronic hyperglycemia, lipotoxicity and pro-inflammatory cytokines are detrimental to beta-cells, causing apoptosis and impaired insulin

secretion. The histone acetyl transferase p300, involved in remodeling of chromatin structure by epigenetic mechanisms, is a key activator of the transcriptional machinery. Whereas p300 appears as a central integrator of various signaling pathways, the regulation and biological actions of p300 in pancreatic beta-cells remain elusive. Here, we aimed to study the potential role of p300 in beta-cell survival and to investigate its mechanism of regulation in beta-cells exposed to stress situations known to be associated with T2D.

Materials and methods: Experiments were performed with the pancreatic beta-cell line (INS-1E), isolated mouse pancreatic islets and human pancreatic islets. p300, Pdx-1 and Nkx6.1 levels were evaluated by western blot. p300 mRNA levels were analyzed by RT-PCR. p300 protein levels were evaluated by immunofluorescence in pancreatic tissue obtained from human subjects with T2D versus BMI-matched control subjects. Apoptosis was evidenced by cleaved caspase-3 emergence and TUNEL staining in isolated mouse and human islets.

Results: Inhibition of p300 acetyl transferase activity by the inhibitor C646 in INS-1E cells and mouse islets led to an increase in caspase-3 cleavage ($p < 0.05$ and $p < 0.01$, respectively). The frequency of TUNEL staining in mouse beta-cells and human beta-cells was increased by 2.7 fold and 1.7 fold, respectively, in islets treated with C646 ($p < 0.05$). Inhibition of p300 also led to an alteration of beta-cell function as shown by the decreased insulin stimulation index and the diminished levels of the transcription factors Pdx-1 and Nkx6.1 ($p < 0.05$). Knock-down of p300 by siRNA further confirmed an altered beta-cell function and survival. Diabetes-related conditions (amyloid, glucolipotoxicity, pro-inflammatory cytokines) as well as T2D itself induced a loss of p300 protein levels in mouse and human beta-cells, whereas p300 mRNA levels remained unchanged under these conditions. Treatment of INS-1E cells with the proteasome inhibitor MG-132 prevented the decrease in p300 content induced by high glucose or pro-inflammatory cytokines exposure. Altogether these data point to a proteasomal degradation involved in p300 loss in pathological beta-cells. Finally, we found that activation of melatonin signaling restored p300 levels in beta-cells exposed to diabetic situations.

Conclusion: Our study demonstrates for the first time a key role of p300 in beta-cell survival and function and its alteration under pathological conditions in T2D. We further show that p300 proteasomal degradation plays a role in the pathophysiology of diabetes and constitutes a potential site for therapeutic intervention. Finally, melatonin signaling may represent a strategy for the maintenance of p300 integrity in order to preserve a functional beta-cell mass in T2D.

Omentin-1, a new adipokine influencing islet cells survival and function

S. Rutti[1], P. Heckman[1], W. Bietiger[1], C. Widmann[2], M. Pinget[1], K. Bouzakri[1];
[1]Centre Européen d'Etude du Diabète, Strasbourg, France, [2]Physiology Departement, University Lausanne, Lausanne, Switzerland.

Background and aims: Adipose tissue secretes a variety of bioactive molecules called adipokines that are now recognized as part of an "adipo-insular axis" whose dysregulation may contribute to beta-cell failure and hence to the development of type 2 diabetes. Omentin-1 is an adipokine that is predominantly expressed in visceral fat where it stimulates glucose uptake in response to insulin. Omentin-1 has also been shown to exert beneficial actions on endothelial cell function and survival and on vascular smooth muscle cells. In a recent study, we have shown that omentin expression in islet cells is positively regulated by IL-13, an interleukin protecting beta-cells from IL-1β induced apoptosis. However, the impact and mode of action of omentin-1 on primary human or murine beta-cell function and survival remain to be explored.

Materials and methods: Human and mouse dispersed islet cells were maintained in culture for 48 h in the presence of omentin-1 alone or in combination with a cytokine cocktail (IL-1β, IFNγ, and TNFα) known to be deleterious to islet cells. Insulin and glucagon secretion in response to glucose were measured by ELISA, proliferation by incorporation of BrdU over 48 h, cell death by TUNEL assay.

Results: Omentin-1 (100 ng/ml) decreased basal cell death in human (normalized to control: 0.62 ± 0.27) and mouse beta-cells (normalized to control: 0.56 ± 0.07) and protected them against cytokine induced cell death (normalized to control: cytokines: 2.24 ± 0.5; cytokines + omentin-1: 1.35 ± 0.4), without affecting beta-cell proliferation. Omentin-1 decreased glucose stimulated insulin secretion of mouse beta-cells (decreased to $1.6 \pm 0.3\%$ of total insulin content/h at 16.7mM from $3.4 \pm 0.7\%$) but did not affect human insulin secretion. Interestingly, omentin-1 increased glucagon secretion of human islets.

Conclusion: We show for the first time that omentin-1 improves primary beta-cell survival and protects them against cytokine induced beta-cell death without affecting proliferation. Omentin-1 also modulates insulin and glucagon secretion suggesting that this adipokine might influence beta and alpha cells secretory and survival capacities.

Activation of Ang II type 2 receptor (AT2R) protects pancreatic islets function via regulation of apoptosis and autophagy in obese rats

M. Liu[1], X. Li[2], A. Wang[2], S. Yin[1], Y. Mu[2];
[1]The First Affiliated Hospital of Chinese PLA General Hospital, Beijing, [2]Chinese PLA General Hospital, Beijing, China.

Background and aims: Activation of AT2R has been examined as a potential therapeutic strategy in cardiovascular and central nervous systems. However, there is few findings regarding the role of activation of AT2R in islets. In the current study, we evaluated the effects of Compound 21 (C21), a nonpeptide AT2R agonist, on the islets in obese rats induced by high-fat diet (HFD) to investigate the role of activation of AT2R in pancreatic islet.

Materials and methods: Adult male Sprague-Dawley (SD) rats were randomly assigned into four groups: normal (fed with normal diet), HFD and HFD respectively plus C21 (1 mg/kg/d) and telmisartan (Tel, AT1R antagonist, 1 mg/kg/d). Tel and C21 were continually given by oral administration for four weeks. After treatment, the rats received an intraperitoneal glucose tolerance test (IPGTT), and the pancreases were harvested to examine islet morphology and biochemical parameters of insulin secretion, apoptosis and autophagy by immunohistochemical, immunofluorescence and Western Blotting. Mitochondria and autophagy were observed by Electron microscope technique.

Results: We found that, compared with control HFD rats and HFD rats treated with Tel, those HFD rats treated with C21 displayed lower blood glucose lever, higher serum insulin concentration and improved glucose tolerance. These rats had more integrated islets, larger positive insulin-staining islet mass ratio and higher PDX-1, GLUT2 and GCK protein expressions. Western Blotting showed that anti-apoptosis factor Bcl-2 and p-Akt expression is up-regulated accompanied with down-regulated cleaved caspase-3 expression in the pancreas of those HFD rats treated with C21. Autophagy markers including LC-3B and Beclin-1 expression are also increased in those rats. Electron microscope showed that C21 treatment increased the autophagy and ameliorated the mitochondrial vacuolation against lipotoxicity in obese rats induced by HFD.

Conclusion: These data suggest that C21 protects pancreatic islets function against lipotoxicity via regulation of apoptosis and autophagy.

Overexpression of sphingosine-1 phosphate lyase sensitises insulin-secreting INS1E cells to lipotoxicity

E. Gurgul Convey, D. Kindler, H. Möller-Gnangra;
Institute of Clinical Biochemistry, Hannover School of Medicine, Hannover, Germany.

Background and aims: Lipotoxicity plays an important role in pancreatic beta cell dysfunction and failure in type 2 diabetes. Lipid oversupply has been shown to dysregulate formation of bioactive lipids and to induce oxidative stress in many cell types. An imbalance in the sphingolipid metabolism is a common feature during the development of many inflammatory diseases. The sphingolipid pathway is tightly regulated by a network of enzymes controlling generation and metabolism of various sphingolipids. The final step in this complex pathway is catalyzed by the enzyme sphingosine-1 phosphate lyase (SPL). The aim of this study was to analyze the role of SPL in insulin-secreting INS1E cells exposed to lipotoxic conditions.
Materials and methods: Insulin-secreting INS1E cells were stably transfected either with an empty pcDNA3.1 vector (INS1E-control) or with the pcDNA3.1-SPL vector (INS1E-SPL). Cells were treated with 250 μM palmitate (PA), 250 μM oleate (OA) or a combination of both fatty acids (FFA) for 24 h. Thereafter cell viability was estimated by a MTT assay, cell proliferation by BrdU ELISA, oxidative stress by DCFDA oxidation and gene expression analyses were performed by qRT-PCR.
Results: The expression of SPL was strongly increased by PA in INS1E cells. Exposure of INS1E-control cells to PA resulted in ~40% decrease of cell viability, an effect that was strongly potentiated by SPL overexpression (~70% cell viability loss, $p < 0.01$). OA was not toxic to INS1E-control cells and protected against PA-mediated cell viability loss. Interestingly, exposure of INS1E-SPL cells to OA led to a significant ~45% decrease of cell viability. Furthermore, in INS1E-SPL cells PA inhibited cell proliferation significantly more strongly than in INS1E-control cells. PA-exposed INS1E-SPL cells were also characterized by a higher level of oxidative stress as compared to INS1E-control cells. The toxicity of OA in INS1E-SPL cells was linked with reduced cell proliferation and increased oxidative stress. The expression of sphingolipid-4-delta-desaturase (SPL4dDes), an enzyme catalyzing the formation of ceramides, was enhanced by PA and OA in INS1E-SPL cells.
Conclusion: Our results showed that SPL overexpression sensitized insulin-secreting INS1E cells to PA toxicity and, interestingly, also induced OA toxicity. The mechanism was dependent on the reduction of cell viability and proliferation. These effects strongly correlated with the induction of oxidative stress and SPL4dDes expression, suggesting the involvement of SPL in the FFA-mediated ceramide generation. Thus, an imbalance in the sphingolipid metabolism may be an important mechanism of lipotoxicity in insulin-secreting cells.

High-fat diet accelerates pancreatic stellate cell activation and initiates islet fibrosis during pancreatogenic diabetes

X. Zhu[1], J. Sun[2], L. Li[1];
[1]Department of Endocrinology, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, [2]Shaoxing University Medical School, Shaoxing, China.

Background and aims: Epidemiological studies support strong links between obesity, diabetes, and chronic pancreatitis (CP). Risk factors for type 2 diabetes include overweight and obesity, which may accelerate the presentation of diabetes in the context of pancreatic disease. However, no direct evidence has supported the causal association between high-fat diet (HFD) and the risk of pancreatogenic diabetes. Here, we investigated the effects of HFD on the activation of pancreatic stellate cells (PSCs), development of pancreatic fibrosis, and destruction of pancreatic islets by using a CP mice model.
Materials and methods: A total of 40 male C57BL/6 mice were randomly selected and were divided into four groups, namely, Alc-Cer plus HFD, Alc-Cer plus normal chow diet (ND), saline plus HFD, and control (saline plus ND). CP was induced by intraperitoneally injecting mice with ethanol (3.2 g/kg, 30% v/v) and cerulein (50 μg/kg) for 6 weeks. The serum amylase activity was assayed after the last injection. HFD was given starting on the 56th day up to the fifth month in two cohorts (HFD and Alc-Cer plus HFD). The body weights and blood glucose levels were monitored every two weeks. At the end of the experiment, glucose tolerance and insulin-resistance tests were performed. Blood samples were collected to measure the lipid metabolism, insulin, and transforming growth factor β (TGF-β). The pancreas was collected to observe the pancreatic morphology by HE staining and to characterize the pancreatic fibrosis by Sirius red staining. Tissues were analyzed using immunofluorescence for insulin and α-smooth muscle actin (α-SMA) to visualize β cells and activate PSCs, respectively. The expression levels of collagen type I (Col-I), fibronectin (FN), and TGF-β were assayed using immunohistochemistry. The expression levels of Col-I, FN, TGF-β and α-SMA in the pancreas were assessed using real-time PCR or Western blot.
Results: Significant difference was observed in the amylase levels of the CP and control groups ($P < 0.05$). After 19 weeks, all mice fed with HFD gained significant increase in weight compared with those mice fed with ND ($P < 0.05$). Only a significant increase in total cholesterol concentrations in the plasma was observed in all HFD groups ($P < 0.05$). The mice in the Alc-Cer plus HFD cohorts developed hyperglycemia and hypoinsulinemia and exhibited elevated levels of TGF-β ($P < 0.05$). The mice with CP fed with HFD remained glucose intolerant and insulin resistant compared with the control mice. All mice that received Alc-Cer injections exhibited histopathological signs of CP with significant pancreatic atrophy, severe acinar architectural damage, and edema, especially the Alc-Cer plus HFD group. In comparison with the control group, the mice with CP fed with HFD for 3 months displayed extensive extracellular matrix deposition and activated PSCs in the islet and peri-islet exocrine pancreas. A decrease in the pancreatic islet numbers and size was exhibited in the pancreatic tissues of the Alc-Cer plus HFD mice. Western blot and RT-qPCR confirmed the enhanced expression of Col-I, FN, α-SMA, and TGF-β in the Alc-Cer plus HFD mice compared with those in the other three groups ($P < 0.05$).
Conclusion: HFD exerts a detrimental influence on the progression of pancreatogenic diabetes by inducing PSCs activation, pancreatic β cell dysfunction, and islet fibrosis.

MSCs improved insulin resistance and beta cell function in type 2 diabetes through modulation of macrophage polarisation and restoration of autophagy in insulin-targeted organs and islets

Y. Mu;
Department of Endocrinology, Chinese PLA General Hospital, Beijing, China.

Background and aims: Type 2 diabetes(T2D) has become one of the leading health problems in the world. T2D often is controlled by oral or injected therapeutics. However, till now, a considerable amount of diabetic patients didn't have adequate glycemic control. Thus alternative therapeutic approaches are urgent to be investigated. Insulin resistance and progressive β-cell dysfunction are recognized as fundamental pathologies of T2D. Mesenchymal stem cells (MSCs) are multipotent, and can be easily isolated from several human tissues such as bone marrow, adipose tissue, and umbilical cord. Small sample clinical trials showed that MSC infusion significantly decreased the levels of blood glucose and HbA1c and reduced daily insulin doses. Inspiringly, animal experiments

showed that MSCs infusion improved insulin resistance and β-cell function in T2D animal models. All this data makes MSCs a promising tool for the treatment of T2D. So our team was devoted to reveal the underlying mechanisms for MSCs in improving insulin resistance and β-cell function, and to develop new strategies to assist MSCs and enhance their efficiency in improving metabolic control in subjects with T2D.

Materials and methods: We induced a T2D model using a combination of a high-fat diet (HFD) with low-dose streptozotocin (STZ). Intravenously infused human umbilical cord-derived MSCs (UC-MSCs) promoted insulin sensitivity and islet function.

Results: On one hand, M1 macrophages in both adipose tissue and islets were directed towards an anti-inflammatory M2-like state after UC-MSC infusion. In vitro study also proved that UC-MSCs inhibited the activation of the M1 phenotype and induced the generation of the M2 phenotype via secretion of interleukin (IL)-6, blocking which by small interfering RNA (siRNA) largely abrogated the UC-MSCs effects on macrophages both in vitro and in vivo and resulted in dampened insulin sensitivity and β-cell function in T2D mice. On the other hand, MSC infusion upregulated LAMP2 expression and enhanced formation of autophagosomes and autolysosomes in hepatic cells and β-cells, which probably also contributed in the promotion of insulin sensitivity and β-cell function. In addition, combination of low-dose decitabine, an FDA-approved DNA methylation inhibitor, or increasing IL-6 secretion by preconditioning MSCs with high glucose and LPS, further promoted M2 macrophage polarization in adipose tissue and islets, enhancing the effects of MSCs on insulin sensitivity and β-cell function in T2D mice. Last but not the least, we first use low-dose STZ combined with long-term HFD to establish a late-stage T2D complication rat model, and multiple infusions of MSCs promoted the recovery of various targeted organs such as kidney, heart, lens, lung and liver in morphology and function.

Conclusion: In conclusion, MSCs improved insulin resistance and β-cell function in T2D through modulation of macrophage polarization and restoration of autophagy in insulin-targeted organs and islets. Combining MSCs with low-dose decitabine and pre-conditioning of MSCs prove to be effective strategies to improve metabolic control by promoting M2 macrophage polarization. Multiple infusions of MSCs also showed stunning therapeutic effects in late-stage T2D complications.

Characterisation of enteroendocrine transcription factors during development in the human duodenum and pancreas

J. Li, R. Wang;
Physiology & Pharmacology, The University of Western Ontario, London, Canada.

Background and aims: Pancreatic bud formation arises from the duodenal endoderm. Both the duodenum and pancreas share similar transcription factors (TFs) and hormone-secreting endocrine cells, and their major development stages occur from 8 to 21 weeks of fetal age. Growth factors produced by the enteroendocrine cells (EECs) of the duodenum and pancreas play a critical role in regulating islet cell proliferation and glucose metabolism. However, the temporal expression of shared EECs and TFs during human duodenal and pancreatic development are not fully documented. This study aimed to characterize common TFs and EECs present during development in the human fetal duodenum and pancreas

Materials and methods: Human fetal duodenum and pancreas samples were collected during the 1st (8–10 weeks of fetal age) and 2nd (19–21 weeks of fetal age) trimester of pregnancy. Microarray was performed with Affymetrix Gene Chip Human Genome U133 Plus 2.0 Array chips, and data for EECs and TFs were verified with qRT-PCR. The co-localization of TFs in EECs and epithelial cells were examined and quantified.

Results: 11 common TFs were expressed in both organs, with 7 TFs (ie. *PDX1, NGN3, PAX4*) expressed at a consistent level during development and only *NEUROD1* increased in both organs from the 1st to 2nd trimester. *PAX6*, *ISL1*, and *NKX2-2* increased significantly in the pancreas during the 2nd trimester, but reduced *ISL1* and *NKX2-2* expression was observed in the duodenum as development progressed. *NKX2-3*, required for duodenal development, was barely detected in the pancreas, while *ARX* expression increased 5-fold in the pancreas at the 2nd trimester. Chromogranin-A^{+} (EEC populations) staining showed EECs present in small villi and underdeveloped crypts of the duodenum and pancreatic duct-buds during the 1st trimester. The population of EECs increased in the crypt-villus structure and adult-like islet clusters at the 2nd trimester of development. 10 subtypes of EECs were found in both the duodenum and pancreas, while gastrin and CCK expression were exclusive to the developing duodenum. Co-localization of TFs with EECs was identified in both organs throughout the 1st and 2nd trimester of development and included GIP and GLP1 with PAX6, PC1/3 and PC2 with NKX2-2, and SST and PYY with ISL1. The percent of NKX2-2 in EEC populations was significantly reduced in the duodenum but increased in the pancreas by the 2nd trimester. The percent of PDX1^{+}/CK19^{+} cells was increased in the duodenum and reduced in the pancreas from the 1st to 2nd trimester of the development. A high number of SST^{+} and PC1/3^{+} cells was present in both organs, and clusters composed of SST or PC1/3 EECs were found in the submucosa of the developing duodenum.

Conclusion: This study has generated an extensive EEC gene expression profile of the human fetal duodenum and pancreas, confirming that common TFs are necessary for EEC development in both organs. The results from this study represent a small step towards the full understanding of all factors required for the regulation of duodenal and pancreatic endocrine development. Since duodenal and pancreatic hormone regulation are important for maintaining glucose homeostasis in postnatal life, understanding the shared transcription factors that regulate duodenal and pancreatic EEC development may benefit anti-diabetic and stem cell therapeutic targets.

A pancreas-specific ECM scaffold - human iPS cell culture and pancreatic differentiation goes 3D

C. Berger[1], Y. Bjørlykke[2], M. Mühlemann[1], H. Ræder[2,3], H. Walles[4,1], M. Metzger[4], D. Zdzieblo[1];
[1]Chair Tissue Engineering & Regenerative Medicine (TERM), University Hospital Wuerzburg, Wuerzburg, Germany, [2]Department of Pediatrics, Haukeland University Hospital Bergen, Bergen, Norway, [3]KG Jebsen Center for Diabetes Research, Department of Clinical Science, University of Bergen, Bergen, Norway, [4]Translational Center Regenerative Therapies (TLC-RT), Fraunhofer Institute for Silicate Research ISC, Wuerzburg, Germany.

Background and aims: Human induced pluripotent stem cell- (hiPSC) derived ß-cells display a great hope to treat diabetes mellitus. Current *in vitro* differentiation protocols enable the generation of immature ß-cells, which require additional *in vivo* maturation to achieve full functionality. Structural 3-dimensional (3D) characteristics, biophysical cues and biological components of the organ-specific extracellular matrix (ECM) are known to play important roles during organogenesis *in vivo* supporting cell survival, differentiation and function. Therefore, we hypothesize that β-cell differentiation of iPSCs could be improved using ECM-based cell culture systems mimicking the *in vivo* microenvironment. In this study, we report about a pancreas-specific ECM (PanMa) and its use as biological scaffold in 3D static bioreactor cultures for hiPSC maintenance culture and β-cell differentiation.
Materials and methods: The PanMa was generated by perfusion-decellularization of porcine pancreata with a chemical detergent. PanMa characterization was performed qualitatively by (immuno-)histochemical analyses and quantitatively by proteomics. Scanning electron microscopy (SEM) was performed to analyze PanMa ultrastructure. The generated matrix was used as liquid supplement in monolayer cultures (2D) or as biological scaffold in 3D bioreactor cultures. PanMa influence on hiPSC pluripotency and β-cell differentiation was assessed by analyzing cell type-specific gene and protein expression profiles under PanMa-based conditions.
Results: Matrix characterization studies demonstrate that the decellularized PanMa scaffold maintains key ECM components found in native tissue, such as Elastin, Laminin, Collagen I and IV. Furthermore, SEM analysis revealed preservation of ultrastructural features such as vascular structures. Human iPSCs cultured on PanMa scaffolds were viable for at least 12 days retaining cellular characteristics such as colony formation and proliferation. However, PanMa-based maintenance culture of iPSCs resulted in loss of pluripotency characterized by a diminished NANOG protein expression. Notably, iPSCs cultured on PanMa scaffolds under conditions allowing spontaneous differentiation revealed an altered gene expression pattern in comparison to typical embryoid body differentiation. Furthermore, β-cell differentiation under PanMa conditions resulted in the formation of insulin^{+}cell clusters and altered gene or protein expression for characteristic β-cell markers with a tendency for improved expression under ECM conditions.
Conclusion: In summary, we were able to establish a biological ECM from porcine pancreata termed PanMa that retains important ECM characteristics. Further, it is suitable as biological scaffold for hiPSC culture and differentiation in 3D. First *in vitro* experiments suggest that the organ-specific PanMa affects pluripotency and promotes differentiation towards the pancreatic lineage. Together, we hypothesize positive impacts of the organ-specific ECM on quality and function of iPSC-derived β-cells.

The epigenetic characteristics of liver to pancreas transdifferentiation

S. Ferber[1,2], H. Cohen[1], A. Har-Zahav[1,2], M. Szyf[3], D. Cheishvili[3], I. Meivar-Levy[1];
[1]The Sheba Regenerative Medicine, Stem Cell and Tissue Engineering Center, Sheba Medical Center, Tel-Hashomer, Israel, [2]Dept. of Human Molecular Genetics and Biochemistry, Tel-Aviv University, Tel-Aviv, Israel, [3]McGill University, Montreal, Canada.

Background and aims: Transdifferentiation is the direct reprogramming of adult cells into alternate cell types with different function. The efficiency of the process between most tissues analyzed is generally low. Liver to pancreas transdifferentiation (TD) induced by ectopic expression of pancreatic transcription factors (pTFs) is limited to up to 15% of the pTFs treated human liver cells in culture. Our previous data indicated that; The process is restricted to a sub-population of human liver cells that are persistently predisposed to undergo reprogramming while >85% of the cells resist TD. TD-resistant can be converted into TD-prone cells by overcoming the identified epigenetic barriers. Currently, we are analyzing the epigenetic characterization of the TD prone cells and of the TD process.
Materials and methods: A method for preselecting TD-predisposed liver cells by a lineage tracing approach based on the activation of a WNT response element, is suggested.
Results: The TD-propensity of the liver cells is stable and inherited to daughter cells upon proliferation. The separated WNT-responsive cells undergo efficient transdifferentiation and up to 70% of the pTFs treated cells produce and secrete insulin in a glucose-regulated manner. Continuously active WNT signaling is obligatory but insufficient for TD propensity to pancreas, since reconstruction of active WNT signaling does not allow the activation of the pancreatic lineage in TD-resistant liver cells. Our data suggest that pancreatic genes' chromatin is more transcrpition-permissive in transdifferentiation-predisposed than in recalcitrant liver cells. TD-predisposed liver cells display a reduced level of DNA methylation which further decreases upon the induction of reprogramming. Our data suggest a crucial role for epigenetic alterations induction in extending the transdifferentiation capacity to originaly transdifferentiation resistant cells.
Conclusion: Our results suggest that transdifferentiation is restricted to a specific population within the tissue, which harbors obligatory signaling patterns and specifically permissive epigenome. The efficient generation of insulin producing cells by adult cells reprogramming relies on the epigenetic landscape modulation. The extension of transdifferentiation capacity to most of the cells in culture, dramatically increase in transdifferentiation efficiency allowing the diabetic patient to serve also as the donor of his own therapeutic tissue

The global identification of glucose-regulated RNA binding proteins (RBPs) in pancreatic beta cells and their role in beta cell function and diabetes

T.P. Herbert, R. Wardman, J. Whitehead;
University of Lincoln, Lincoln, UK.

Background and aims: RNA-binding proteins (RBPs) play an essential role in regulating insulin gene expression, and coordinating complex biological and metabolic processes including cell replication, differentiation, and division. The aim of this study was to identify all RBPs within pancreatic β-cells and to quantify changes in their binding to RNA in response to glucose. We hypothesise that this will reveal unique insights into the role of RBPs in β-cell physiology and uncover hitherto unknown connections between RBPs and diabetes.
Materials and methods: Using 'interactome capture' RBPs (from 3 independent experiments) were isolated and purified from mouse clonal pancreatic β-cells (MIN6). The RBPs were identified and quantified

using Sequential Window Acquisition of all Theoretical Mass Spectra (SWATH-MS) and the data verified by Western blot analysis in both MIN6-cells and primary rodent islets. Ontological analysis and interrogation of published data sets were used to identify the RBPs potential roles in controlling metabolic pathways and molecular processes, and their putative importance in the development of β-cell dysfunction in diabetes.

Results: Using interactome capture we have determined system-wide changes in RBP interactions with RNA in response to glucose in β-cells. This revealed 398 RBPs of which the RNA binding activity of 55 was signficantly increased by glucose (>1.5 fold, $p < 0.05$). 122 RBPs were identified as having known function in ribosome biogenesis, RNA processing, export, or translation. Interestingly, 29 RBPs are enzymes involved in intermediatary metabolism, such as hexokinase, alpha enolase, and LDH, and over 22 RBPs were identified as being involved in secretion, such as RAB10 and SEC22. There is a precedent for enzymes 'moonlighting' as RBPs. For example, aconitase is an iron regulatory protein that has been shown to bind to the mRNA of genes involved in iron metabolism, including ferritin, to modulate their expression. Intriguingly, the expression of some of the RBPs identified, such as DDX5 an RNA helicase, LDH, and RAB10, are dysregulated in human β-cells isolated from subjects with type 2 diabetes.

Conclusion: As each RBP can potentially regulate the expression of a subset of mRNAs to coordinate a biological/metabolic process or pathway, our data has revealed new regulatory links between gene expression, nutrient metabolism and insulin secretion. We are now in the process of verifying changes in RBP binding in human EndoC-βH1 cells and identifying the RNAs that bind to specific RBPs using Photoactivatable Ribonucleoside-Enhanced Crosslinking and Immunoprecipitation (PAR-CLIP) in concert with RNA sequencing.

The E3 SUMO ligase PIASy is a novel interaction partner regulating the activity of diabetes associated hepatocyte nuclear factor-1 alpha

A. Kaci[1,2], M. Keindl[1], P. Njølstad[1,3], L. Bjørkhaug[4], I. Aukrust[1,2];
[1]KG Jebsen Center for Diabetes Research, University of Bergen, Bergen, [2]Department of Medical Genetics, Haukeland University Hospital, Bergen, [3]Department of Pediatrics and Adolescents, Haukeland University Hospital, Bergen, [4]Department of Biomedical Laboratory Sciences and Chemical Engineering, Western Norway University of Applied Sciences, Bergen, Norway.

Background and aims: The transcription factor hepatocyte nuclear factor-1 alpha (HNF-1A) is involved in normal pancreas development and function. Rare variants in the *HNF1A* gene can cause monogenic diabetes, while common variants confer type 2 diabetes risk. The precise mechanisms for regulation of HNF-1A, including the role and function of post-translational modifications, are still largely unknown. Since SUMOylation is a post-translational regulatory mechanism previously shown to regulate key proteins in glucose homeostasis, the aim of this study was to investigate the functional relevance of HNF-1A SUMOylation in various cell models.

Materials and methods: HNF-1A SUMOylation was assessed in HEK293 cells by immunoprecipitation analysis. A rat albumin promoter-linked luciferase reporter assay in MIN6 β-cells measured the effect of SUMOylation on HNF-1A transcriptional activity. The interaction between protein inhibitor of activated STAT (PIASγ) and HNF-1A, and its subsequent effect on nuclear distribution was investigated in HEK293 cells by co-immunoprecipitation and immunofluorescence experiments, respectively.

Results: Here, we present the first evidence for HNF-1A being a substrate for SUMOylation *in cellulo* identifying three lysine (K) residues (K205, K273 and K506) as SUMOylation sites. Overexpression of the E3 SUMO ligase, PIASγ, repressed the transcriptional activity of HNF-1A and was independent of HNF-1A SUMOylation. Furthermore, PIASγ was demonstrated to interact with HNF-1A, and sequestrate HNF-1A in the nuclear periphery.

Conclusion: SUMOylation of HNF-1A represents a novel post translational regulatory mechanism affecting HNF-1A function. Further, we have identified PIASγ is a new HNF-1A interaction partner that enhances HNF-1A SUMOylation and leads to re-localization of HNF-1A to the nuclear periphery, presumably restricting access to its target genes and thereby reducing the overall HNF-1A transcriptional activity. Our findings reveal potential new targets for drug development and precision medicine in diabetes.

The absence of melatonin during pregnancy impairs energy metabolism and maternal pancreatic remodelling: Is it the onset of type 2 diabetes in the mother?

P.R.L. Gomes[1], E.A. Leite[1], C.F. Lucena[1], A.C.M. Bonassa[1], E.A. Vilas-Boas[1], F.G. Amaral[2], A.R. Carpinelli[1], J. Cipolla-Neto[1];
[1]Physiology and Biophysics, University of Sao Paulo, Sao Paulo, [2]Physiology, Federal University of Sao Paulo, Sao Paulo, Brazil.

Background and aims: Circulating pineal melatonin, which is elevated at night, acts to synchronize physiological functions, including energy metabolism. Among its actions, this hormone promotes the timing of central and peripheral metabolic functions, playing an important role in the action of insulin and its secretion, as well as local action on trophism and endocrine pancreatic survival. Considering the maternal organism, studies indicate increasing serum concentrations of maternal melatonin during the gestational period in both humans and rodents, due to stimuli of placental hormones. In addition, there is a fine regulation of maternal-fetal energy metabolism, with the main consequence being the expansion of the maternal pancreatic islets during pregnancy, a result of the increase of the beta cell proliferation, returning to pre-gestational conditions around childbirth time. Thus, this study aims to evaluate the role of melatonin on energy metabolism and the remodeling of maternal pancreatic islets during pregnancy.

Materials and methods: Pregnant Wistar rats were divided into: P - pregnant rats, Pinx - pinealectomized pregnant rats, Mel.Fixed - pinealectomized pregnant rats with melatonin replacement at fixed concentrations (0.1 mg/kg for 21 days) and Mel.Dinamic - Pinealectomized pregnant rats with melatonin replacement at variable concentrations (0.1 mg/kg, 1–7 day of pregnancy, 0.2 mg/kg, 8–14 day of pregnancy and 0.5 mg/kg, 15–21 day of pregnancy). The animals were submitted to GTT, ITT on the 7th and 14th days. At the 21th day all groups were euthanized at ZT14 and pancreatic islets were isolated for GSIS, cell viability, apoptosis and cell death and production of ROS. The Ethics Committee for Animal Use approved the study, and complies with the Brazilian Society of Laboratory Animal Science.

Results: Improvement in glucose tolerance was observed in Pinx and Mel.Fixed in G7 ($P = 16718 \pm 1257$; Pinx = 13964 ± 502.4; Mel-Fixed = 13537 ± 1213 and Mel.Dinamic = 15392 ± 1530, $p < 0.05$) and in G14 ($P = 1013 \pm 72.4$; Pinx = 735 ± 85.4; Mel.Fixed = 779.2 ± 64.1 and Mel.Dinamic = 1043 ± 353.4, $p < 0.05$), as well as improvement in insulin sensitivity in G14 ($P = 1.9 \pm 0.8$; Pinx = 2.4 ± 0.3; Mel.Fixed = 3.2 ± 0.3 and Mel.Dinamic = 2.0 ± 0.6, $p < 0.05$). There was no difference in cell viability ($P = 73.9 \pm 7.8$; Pinx = 74.5 ± 8.4; Pinx.Fixed = 71.1 ± 8.2 and Pinx.Dinamic = 71.3 ± 3.9) and cell death ($P = 19 \pm 6$; Pinx = 19.1 ± 6.1; Pinx.Fixed = 21.7 ± 5.6 and Pinx.Dinamic = 18.9 ± 5.6) of the islets among the groups. However cellular apoptosis in the Mel.Dinamic presented apparent increase in relation to the others groups ($P = 7 \pm 3.5$; Pinx5 $\pm$ 1.1=; Pinx.Fixed = 6.3 ± 2.1 and Pinx.Dinamic = 9.7 ± 3.2). Lastly, maximum insulin response to glucose was higher in P rats

compared to the other groups, independent of replacement melatonin or not ($P = 0.2 \pm 0.1$; Pinx = 0.02 ± 0.00; Pinx.Fixed = 0.01 ± 0.00 and Pinx.Dinamic = 0.02 ± 0.00, $p < 0.05$).
Conclusion: Melatonin during pregnancy seems to be responsible for the fine regulation of energy metabolism to preserve adequate substrate for both mother and conception, characterizing it as a delicately architected period. In addition, the absence of melatonin impairs pancreatic remodeling at the end of pregnancy to the return of the tissue to non-gravid conditions, outlining a future setting for the onset of DM2 in the mother.

Identification of pancreatic elastase inhibitors with a potential to stimulate beta cell proliferation

G. Basile[1], A. Vetere[2], J. Hu[1], K.-C. Liu[3], Y. Zhang[1], O. Andersson[3], B.K. Wagner[2], R.N. Kulkarni[1];
[1]Islet Cell and Regenerative Biology, Joslin Diabetes Center, Boston, USA, [2]Chemical Biology and Therapeutics Science Program, Broad Institute of Harvard and MIT, Cambridge, USA, [3]Department of Cell and Molecular Biology, Karolinska Institutet, Stockholm, Sweden.

Background and aims: The identification of novel small molecules that can target endogenous factors to regulate β-cell proliferation is a desirable goal to counter Type 1 or Type 2 Diabetes. Recently, we have reported that serpinB1 (SB1), an endogenous protease inhibitor, can promote human β-cell proliferation by inhibiting elastase activity, and demonstrated that the elastase inhibitor, sivelestat, also induced β-cell proliferation. Hypothesizing the importance of blocking elastase activity within islet cells in order to selectively activate the proliferative pathways in β-cells, we employed high-throughput screening(HTS) assays to identify additional novel elastase inhibitors to evaluate their potential for inducing β-cell proliferation.
Materials and methods: We screened 16,320 compounds using a fluorescence-based porcine pancreatic elastase (pPE) assay, and confirmed inhibition of human neutrophil (hNE) and pancreatic (hPE) elastases using an absorbance-based assay. Mouse islets were isolated from ~10 week old C57BL6 mice and human islets were obtained from three healthy control donors from the IIDP. After treatment with increasing doses of the elastase inhibitors, β-cell proliferation was assessed using immunofluorescence techniques.
Results: We identified several compounds among which two emerged as powerful inhibitors of pancreatic elastase (PE): 1) an antiviral drug belonging to the protease inhibitor family, and 2) an antibiotic from the group of β-lactam antibiotics, which had not been previously associated with elastase inhibition and/or β-cell proliferation. Both compounds inhibited porcine PE with greater potency than sivelestat, a known elastase inhibitor, used as a positive control (IC_{50}: antiviral 33.9 nM, antibiotic 1.1 μM, sivelestat 2.4 μM; $n = 3$). The results were confirmed on hPE (IC_{50}: antiviral 15.7 nM, antibiotic 3.6 μM, sivelestat 2.3 μM; $n = 3$), while neither the antiviral nor the antibiotic blocked hNE activity. Evaluation of the mitogenic properties of the compounds in *in vitro* cultures of islets revealed that the antiviral and the antibiotic drugs each promoted proliferation of β-cells in rodent (~3-fold and ~1-fold increase, respectively; $n = 3$) and human islets (~5-fold and ~2.5-fold increase, respectively; $n = 3$) at 100 μg/ml concentration, compared to vehicle-treated islets. Furthermore, in an independent study, both compounds (at 10 μM), stimulated β-cell regeneration in a zebrafish model resulting in ~1.5-fold increase in insulin-positive cells in treated versus non-treated groups.
Conclusion: Taken together, these data, from independent studies, confirm the identification of novel compounds that can enhance mammalian β-cell proliferation, and highlight the therapeutic potential of pancreatic elastase inhibitors to stimulate human β-cell proliferation to treat all forms of diabetes.
Disclosure: **G. Basile:** None.

The impact of cilia-genes on pancreatic beta cell replication and the risk of type 2 diabetes

M. Stadion[1,2], O. Kluth[1,2], P. Gottmann[1,2], H. Aga[1,2], U. Krus[3], J. Gerdes[4,2], C. Ling[3], A. Schuermann[1,2];
[1]Experimental Diabetology, German Institute of Human Nutrition Potsdam-Rehbruecke (DIfE), Potsdam, Germany, [2]German Center for Diabetes Research (DZD), Neuherberg, Germany, [3]Department of Clinical Sciences, Lund University, Malmö, Sweden, [4]Institute for Diabetes and Regeneration Research, Helmholtz Center Munich, Garching, Germany.

Background and aims: Type 2 diabetes (T2D) results from a complex interplay between environmental stimuli and predisposing genes and is characterized by an insufficient adaptive beta-cell proliferation. Recent data suggest that primary cilia are implicated in beta-cell fuction and the susceptibiltly to T2D. Cilia are dynamic mikrotubule-based hair-like organelles located on almost all polarised mammalian cell types. They function as versatile sensory antennae regulating numerous cellular processes, but their role on beta-cell replication has not been investigated. This study aimed to examine islet cell ciliation and cilia-gene expression in two obese mouse models that differ in their susceptibility to T2D as well as in human pancreatic islets of non-diabetic and diabetic donors.
Materials and methods: Diabetes-resistant B6-ob/ob and diabetes-prone New Zealand Obese mice were fed a carbohydrate-free diet for 15 weeks followed by a diabetogenic carbohydrate-containing diet for two days. Islet ciliation and cilia-gene expression were analysed by immunohistochemistry and transcriptomics. Human pancreatic islets of 124 non-diabetic donors and 78 donors diagnosed with T2D were provided by the Nordic Network for Islet Transplantation and gene expression profiles were analysed by RNA sequencing. To directly investigate the impact of cilia on beta-cell replication, we repressed KIF3A, a subunit of the kinesin-II motor protein, via an adenovirus expressing *Kif3a*-specific shRNA in MIN6 beta-cells.
Results: Upon the carbohydrate challenge, exclusively B6-ob/ob mice exibited a massive induction of beta-cell division accompanied with cilia disassembly. Comparative islet transcriptomics identified a significant enrichment of 327 differentially expressed cilia-annotaded genes of which 81 human orthologues were also affected in islets of diabetic donors. Interestingly, in islets of non-diabetic mice and humans, we found a huge overlap of upregulated cilia-genes involved in cell-cycle progression. The shRNA-mediated supression of the cilia-gene KIF3A in MIN6 cells resulted in a decreased proliferation capacity in comparison with scrambled-shRNA transfected control cells as detected by a reduced incorporation of BrdU.
Conclusion: These findings provide direct functional evidence for the substantial role of cilia on compensatory beta-cell proliferation. We postulate that an impaired regulation of cilia-genes and a restricted capacity of cilia disassembly participate in the development of T2D in mice and men.

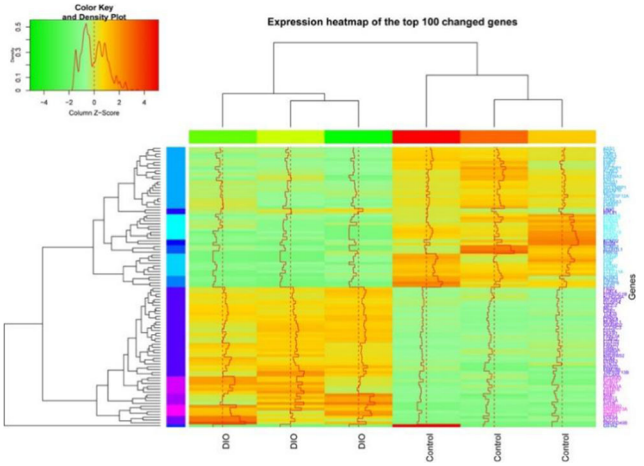
Protective effects of Clec11a on lipotoxicity induced islets injury via modulation of proliferation and secretion in mice

R. Shi[1], S. Zhao[2], Z. Sun[1];
[1]Department of Endocrinology, Zhongda Hospital, Institute of Diabetes, Medical School, Southeast University, Nanjing, [2]Department of Biochemistry and molecular biology, Medical School, Southeast University, Nanjing, China.

Background and aims: Glycemic dysregulation and insulin resistance are common threads in the progression from obesity to diabetes. The growth of beta cells and insulin secretion are essential to maintain blood

glucose homeostasis. Here we attempted to explore a new molecular mechanism mediated by Clec11a (C-type lectin domain family 11, member A) in prevention of islets disfunction during obesity.
Materials and methods: C57BL/6 mice aged 5 weeks fed a high-fad diet or standard diet for 14 weeks. Transcriptomic sequencing was performed with the islets of diet-induced obesity (DIO) C57BL/6 mice and normal food fed control mice. Differentiatial gene transcription was confirmed by real-time PCR, and protein translation was verified by western blot and immunofluorescence. The proliferation of MIN6 cells was measured by CCK8. The insulin secretion was measured by ELISA.
Results: The body weight (49.29 ± 0.79 g vs. 29.30 ± 0.54 g, $P < 0.01$, Fig 1.A), fasting blood glucose (7.58 ± 0.58 mmol/L vs. 3.90 ± 0.38 mmol/L, $P < 0.01$, Fig 1.B), and insulin level in plasma (1240.95 ± 92.30 pg/mL vs. 723.56 ± 74.33 pg/mL, $P < 0.01$, Fig 1.C) were higher in DIO mice than those of control mice. Moreover, the results of oral glucose tolerance test (OGTT) and insulin tolerance test (ITT) exhibited the impaired glucose tolerance and insulin resistance in DIO mice ($P < 0.05$, Fig. 1D,E). The mRNA of Clec11a significantly decreased in islets of DIO mice in RNA-Seq experiment by 5 folds (Fig. 1F) and confirmed by real-time PCR (Fig. 1G). The expression heatmap of the top 100 changed genes is shown in Fig. 1H. As shown in Fig. 2, Clec11a staining is localized in islets. Palmic acid (PA) treated cultured isolated islets expressed less Clec11a in a dose dependent manner (Fig. 3A,B). We then chose 0.5mM PA as the concentration in time course experiment. The protein expression of Clec11a demonstrated an waved trend with upregulated peak at 12 hours and then declined until a reversed level comparing to free fat acid (FFA-BSA) at 48h (Fig. 3C,D). The expression of Clec11a in MIN6 is also downregulated by PA in a dose dependent manner measured by real-time PCR (Fig. 4A) and western blot (Fig. 4B,C). Additionally, PA treatment inhibited the proliferation (Fig. 5A) and the secretion of insulin (Fig. 5B) in MIN6. The treatment of Clec11a protein containing medium rescued the proliferation (0.66 ± 0.05 vs. 0.42 ± 0.04, $P < 0.01$, Fig. 5C), the secretion of insulin in high glucose (22708.16 ± 2275.08 pg/mg/h vs. 11911.69 ± 1421.1 pg/mg/h, $P < 0.01$, Fig. 5D). Moreover, the phosphorylation level of Akt was elevated by Clec11a protein containing medium in PA treated MIN6 cells by 2 folds ($P < 0.05$, Fig. 5E).
Conclusion: Clec11a might protects the islets function injured by lipotoxicity via a mechanism of regulating pancreatic beta cell proliferation and secretion.



Disclosure: **R. Shi:** None.

PS 017 Insulin secretion

Evidence for differential role of beta-arrestin2 in GLP-1 and GIP signalling in mouse pancreatic beta cells

M.A. Ravier[1], J. Obeid[1], M. Leduc[1], S. Costes[1], P. Gilon[2], S. Dalle[1], G. Bertrand[1];
[1]Institut de Genomique Fonctionnelle, Montpellier, France, [2]Université Catholique de Louvain, Brussels, Belgium.

Background and aims: The scaffold protein beta-arrestin2 (ARRB2) is known to uncouple G protein coupled receptors (GPCR) from G protein and to recruit new signaling pathways (such as ERK1/2) to the activated GPCR. Several groups have reported a direct interaction of the GLP-1 receptor (GLP-1R) but not of the GIP receptor (GIPR) with ARRB2 in non beta cells. Nevertheless, we and others failed to detect any differences for insulin secretion in response to 20–100 nM GLP-1 from Arrb2$^{-/-}$ mouse pancreatic islets. Our aim was to determine if ARRB2 could be involved in GLP-1R and GIPR signaling in mouse beta cells.
Materials and methods: The experiments were carried out in beta cells from four-month-old Arrb2$^{+/+}$ and Arrb2$^{-/-}$ male mice. cAMP production (CAMPS-epac), endogeneous PKA (AKAR3) and ERK1/2 (EKAR) activations were measured after adenoviral infection of cells with FRET-based sensors of interest by live microscopy. ERK1/2 phosphorylation was also determined by immunofluorescence.
Results: Compared to Arrb2$^{+/+}$ mice, Arrb2$^{-/-}$ mice displayed a better oral glucose tolerance despite an impaired i.p. glucose tolerance and a decrease in beta cell mass. This was associated with a significant increase in plasma insulin concentration after the oral glucose administration ($p < 0.05$), suggesting a greater incretin effect in Arrb2$^{-/-}$ mice. Insulin secretion was then measured from isolated islets in response to both incretin hormones: GIP and GLP-1. Unexpectedly, whereas insulin secretion from Arrb2$^{-/-}$ isolated islets was significantly reduced in response to GIP (100 pM, $p < 0.05$), insulin secretion was larger with physiological concentrations of GLP-1 (1 and 10 pM GLP-1; $p < 0.05$). By contrast, supra-physiological concentrations of GLP-1 (1 nM–10 nM) induced similar insulin secretion in Arrb2$^{+/+}$ and Arrb2$^{-/-}$ islets. The larger insulin release with physiological concentrations of GLP-1 was associated with an increased cAMP production and PKA activation in Arrb2$^{-/-}$ beta cells, while cytosolic [Ca2+] increases and emptying of the endoplasmic reticulum were both similarly affected in Arrb2$^{+/+}$ and Arrb2$^{-/-}$ beta cells. Conversely, GLP-1-induced activation of ERK1/2 was strongly decreased (~50%, $p < 0.05$) in Arrb2-/- beta cells, but the re-expression of ARRB2 in Arrb2$^{-/-}$ beta cells, using an adenovirus encoding ARRB2-GFP, completely restored ERK1/2 phophorylation induced by GLP-1 ($p < 0.01$).
Conclusion: Our study revealed in living mouse beta cells, a differential role of ARRB2 in GLP-1R and GIPR signalling. For GLP-1R, ARRB2 contributes to a partial uncoupling for the production of cAMP, the activation of PKA and consequently insulin secretion in the pM range of GLP-1, which is the physiological circulating concentration of the incretin. On the other hand, ARRB2 is required for GLP-1-induced full activation of ERK1/2. For GIPR, ARRB2 is required for GIP-induced amplification of insulin secretion. Therefore, any variation in the expression of ARRB2, as observed in diabetic states, should affect differentially the signaling of GLP-1R and GIPR.

CB1 and CB2 antagonists stimulate insulin secretion and regulate human and mouse islet viability

I. Ruz-Maldonado[1], B. Liu[1], P. Atanes[1], A. Pingitore[1], G.C. Huang[1], D. Baker[2], S.J. Persaud[1];

[1]Department of Diabetes, King's College London, London, [2]Blizard Institute, Barts and The London School of Medicine and Dentistry, London, UK.

Background and aims: CB1, CB2 and GPR55 cannabinoid receptors are expressed by islets where they regulate insulin secretion. Some CB1 and CB2 antagonists are reported to also act as GPR55 agonists. In this study we evaluated the functional effects of the CB1 antagonists/GPR55 agonists SR141716A and AM251 and the CB2 antagonist JTE 907 in human and mouse islets.
Materials and methods: Islets from WT and GPR55KO mice and human donors were perifused in the absence and presence of 10 μM SR141716A, AM251 or JTE 907 alone, or SR141716A or AM251 in combination with JTE 907 and insulin secretion was determined by RIA. $[Ca^{2+}]_i$, cAMP and apoptosis were also quantified in islets by standard techniques.
Results: SR141716A potentiated insulin secretion from both WT and GPR55KO mouse islets (WT: 2.7 ± 0.3 pg/islet/min maximum increase (MXI) above 20mM glucose response (20GR); KO: 6.4 ± 0.3, $n = 20$). Similar effects were obtained with AM251 (WT: 4.4 ± 0.6 MXI above 20GR; KO: 2.3 ± 0.8, $n = 20$), JTE 907 (WT: 1.5 ± 0.8 MXI above 20GR; KO: 1.4 ± 0.3, $n = 4$) and SR141716A or AM251 in combination with JTE 907 (WT: 2.0 ± 0.1 MXI above 20GR; KO: 1.9 ± 0.7 and WT: 2.1 ± 0.9 MXI above 20GR; KO: 1.7 ± 0.7 respectively, $n = 4$). Stimulation of glucose-induced insulin secretion from human islets was also observed in response to SR141716A (control AUC: 671 pg insulin/20 min; +SR141716A: 1391, $p < 0.001$, $n = 4$); AM251 (control AUC: 524; +AM251: 1124, $p < 0.01$, $n = 4$); JTE 907 (control AUC: 16; +JTE 907: 29, $p < 0.05$, $n = 4$); SR141716A + JTE 907 (control AUC: 16; +SR141716A + JTE 907: 34, $p < 0.01$, $n = 4$) and AM251 + JTE 907 (control AUC: 16; +AM251 + JTE 907: 31, $p < 0.05$, $n = 4$). SR141716A and AM251 also elevated $[Ca^{2+}]_i$ in mouse islets (WT, SR141716A: 0.02 ± 0.01 fluorescence 340/380, MXI above 20GR, AM251: 0.04 ± 0.01; KO, SR141716A: 0.01 ± 0.01, AM251 0.05 ± 0.01, $n = 25$). However, SR141716A and AM251 did not promote cAMP generation (basal: 5 ± 0.8 nM cAMP; +SR141716A: 2 ± 0.7; +AM251: 6 ± 0.9, $p > 0.2$, $n = 6$) nor did they reduce elevated cAMP (1 μM forskolin: 90 ± 16.8 nM cAMP; +SR141716A: 122 ± 12.9; +AM251: 115 ± 11.1, $p > 0.2$, $n = 6$), indicating that they do not signal through G_s or G_i. The lack of effect of SR141716A and AM251 on cAMP was also observed in human islets, whereas 20 nM exendin-4 and 1 μM clonidine elevated ($p < 0.001$) and decreased ($p < 0.05$) cAMP respectively, $n = 6$. SR141716A and AM251 reduced cytokines-induced apoptosis in WT and GPR55KO islets (control WT: 8.9×10^4 LU/islet; +SR141716A: 4.6×10^4; +AM251: 5.8×10^4, $p < 0.001$; control KO: 6.2×10^4; +SR141716A: 3.9×10^4, $p < 0.001$; +AM251: 4.4×10^4, $p < 0.05$, $n = 8$). Conversely, in human islets, both antagonists induced apoptosis (control: 5.2×10^5 LU/islet; +SR141716A: 1.2×10^6, $p < 0.0001$; +AM251: 9.7×10^5, $p < 0.05$, $n = 8$). JTE 907 had no effect on apoptosis in human islets but it did induce apoptosis in mouse islets in a GPR55-dependent manner (WT: 13.2×10^4 LU/islet, $p < 0.001$, KO: 5.2×10^4, $p > 0.2$; $n = 8$).
Conclusion: Our data demonstrate that the CB1 and CB2 antagonism enhances glucose-induced insulin secretion from mouse and human islets in a GPR55-independent manner. This could be useful in the development of novel therapeutics that have dual actions to peripherally antagonise the obesogenic effects of cannabinoids while directly stimulating insulin secretion. However, the CB1 antagonists under investigation induced apoptosis in human islets, indicating that such compounds are not appropriate for therapeutic development.

The role of ER Ca^{2+} sensor, stromal interaction molecule 1 (STIM1) in GPR40-mediated potentiation of glucose-induced insulin secretion

R. Usui, D. Yabe, H. Goto, M. Fauzi, S. Tokumoto, H. Tatsuoka, Y. Tahara, M. Ogura, K. Nagashima, N. Inagaki;
Department of Diabetes, Endocrinology and Nutrition, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Background and aims: Long-chain fatty acid receptor GPR40 plays an important role in potentiation of glucose-induced insulin secretion (GIIS) from pancreatic β-cells. It was previously shown that GPR40 agonist fasiglifam (FAS) enhances Ca^{2+}-release from the endoplasmic reticulum (ER) by activating inositol 1,4,5-triphosphate (IP3) receptor 1 and enhances GIIS. However, it remains unknown how the enhanced Ca^{2+} release from the ER is linked to GIIS potentiation. We thus hypothesized that ER Ca^{2+}-sensor STIM1 senses decline of Ca^{2+} levels in the ER, translocate to the plasma membrane and triggers extracellular Ca^{2+} influx through Ca^{2+}-channel Orai1 to potentiate GIIS. To test the hypothesis, we examined the role of STIM1 in insulin-secreting MIN6 cells as well as isolated islets derived from β-cell specific STIM1-deficient mice.
Materials and methods: MIN6 cells were transfected with STIM1, IP3 receptor 1 (IP3R1) or scrambled siRNA; and analyzed for insulin secretion or intracellular Ca^{2+}-dynamics. MIN6 cells were also transfected with pEX-SP-YFP-STIM1(23-685) to monitor intracellular trafficking of STIM1 in response to glucose and FAS. Islets were also isolated from the β-cell specific STIM1-deficient (βSTIM1 cKO) or C57BL6/J mice; and analyzed for insulin secretion. In addition to FAS, Xestospongin C and GSK7975A were used as inhibitors for IP3 receptor and Orai1, respectively.
Results: STIM1 or IP3R1 knockdown in MIN6 cells similarly abolished FAS-mediated potentiation of GIIS, while they had little effects on GIIS itself. STIM1 knockdown in MIN6 cells also attenuated FAS-induced elevation of intracellular Ca^{2+} levels. STIM1-YFP was rapidly translocated from the ER to the plasma membrane in response to FAS. FAS-mediated potentiation of GIIS was also severely impaired in isolated islets from βSTIM1 cKO mice. In addition, FAS-mediated potentiation of GIIS was also severely impaired by Xestospongin C and GSK7975A.
Conclusion: STIM1 is essential for FAS-mediated potentiation of GIIS, possibly sensing decline of Ca^{2+} levels in the ER, translocate to the plasma membrane and triggers extracellular Ca^{2+} influx through Ca^{2+}-channel Orai1.

A genetically encoded low-affinity Ca^{2+}sensor unmasks autocrine purinergic signalling in beta cells

M. Yang, O. Idevall-Hagren, E. Gylfe, A. Tengholm;
Department of Medical Cell Biology, Uppsala University, Uppsala, Sweden.

Background and aims: Changes of the cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) play a critical role in the regulation of various cell functions including insulin secretion from β-cells. Ca^{2+} signalling has been studied for many years using low molecular-weight, organic fluorescent dyes. More recently, genetically encoded, fluorescent-protein-based Ca^{2+} sensors have been developed. Whereas the latter sensors have potential advantages, experience from their use in islet cells is limited. The aim of the present study was to compare the response of the red fluorescent protein-based sensor R-GECO with that of an organic dye with low affinity (fluo-5F; K_d 2.3 μM) to clarify if there are differences in the way they report temporal dynamics of $[Ca^{2+}]_i$ in β-cells.
Materials and methods: MIN6 β-cells, mouse islets and human islets were transfected with the red fluorescent protein-based sensor R-GECO and/or loaded with the organic fluorescent dye fluo-5F by 30 min incubation with 2 μM of its acetoxymethyl ester. Changes of $[Ca^{2+}]_i$ in response to glucose or K^+ depolarization were recorded using total internal reflection fluorescence microscopy. The Ca^{2+} dependence of the fluorescent sensor responses was determined in cells permeabilized with α-toxin.
Results: In all cell preparations, R-GECO and fluo-5F showed a rapid increase of fluorescence when voltage-gated Ca^{2+} influx was triggered by

depolarization of the β-cell membrane with 30 mM K^+ in the presence of 3 mM glucose. However, while fluo-5F most often reported stable elevations of $[Ca^{2+}]_i$, R-GECO usually showed repeated, transient, high-amplitude increases (spikes) from a sustained elevated level. Accordingly, protein sensor and dye remaining in the cytoplasm of MIN6-cells after plasma membrane permeabilization responded to elevations of the medium Ca^{2+}concentration with half-maximal increases of fluorescence at 3.0 ± 0.3 μM for R-GECO and 1.7 ± 0.1 μM for fluo-5F. This *in situ* value for R-GECO is around 6-fold higher than expected from previous studies of purified protein *in vitro*, but it seems unlikely that the distinct $[Ca^{2+}]_i$ signalling patterns reflect the relatively small differences in recorded Ca^{2+} affinities. The depolarization-triggered $[Ca^{2+}]_i$ spikes depended on release of the ion from intracellular stores and was consequently inhibited by depletion of endoplasmic reticulum Ca^{2+} with the SERCA pump inhibitor cyclopiazonic acid. The spiking was also suppressed by the purinergic $P2Y_1$-receptor antagonist MRS2179, indicating involvement of IP_3-gated Ca^{2+} mobilization in response to extracellular adenine nucleotides. Similar, MRS2179-sensitive $[Ca^{2+}]_i$ spikes were observed in R-GECO-expressing β-cells in mouse and human islets stimulated by a rise of the glucose concentration from 3 to 20 mM.

Conclusion: Voltage-gated Ca^{2+} influx in β-cells is tightly coupled to Ca^{2+} release from the endoplasmic reticulum triggered by autocrine feedback from adenine nucleotides co-released with insulin. The resulting $[Ca^{2+}]_i$ spiking with apparent significance for insulin secretion often escapes detection by traditional organic Ca^{2+} dyes but is readily revealed by R-GECO with apparent low affinity for Ca^{2+} in the cytoplasm.

The lipid phosphatase INPP5F regulates insulin secretion

P.M. Nguyen, N. Gandasi, O. Idevall-Hagren;
Uppsala University, Uppsala, Sweden.

Background and aims: NPP5F (Sac2) is a phosphatase that localizes to endocytic membranes where it dephosphorylates the lipid phosphatidylinositol 4-phosphate (PI[4]P), a key step in receptor recycling. PI(4)P levels are high in the Golgi membrane from which insulin granules are formed, and recent studies show changes in the phospholipid composition of insulin granules in response to glucose stimulation. It is not known if these changes are important for insulin granule maturation and release. The aim of this study was to investigate the potential involvement of INPP5F in these processes.

Materials and methods: A mouse β-cell line (MIN6) and live cell fluorescence microscopy was used to investigate the dynamic distribution of fluorescently tagged INPP5F and its colocalization with various markers of the secretory pathway. To assess the role of INPP5F in the regulation of insulin secretion, overexpression or siRNA/shRNA-mediated knockdown of INPP5F was combined with single cell TIRF microscopy imaging of insulin granule exocytosis and biochemical detection of insulin release using the AlphaLISA technique.

Results: Confocal microscopy imaging showed that GFP-tagged wild type INPP5F localized to small mobile structures. This localization became more pronounced when the enzyme was catalytically inactivated. Colocalization analysis revealed that INPP5F, in addition to localizing to early endosomes (60 ± 14% enrichment compared to random, $n = 96$, $P < 0.001$), was present on a subset of insulin granules positive for Rab3 (53 ± 9% enrichment, $n = 212$, $P < 0.001$) and Rab27 (46 ± 8% enrichment, $n = 220$, $P < 0.001$). siRNA-mediated knockdown of INPP5F resulted in 45 ± 9% ($n = 4$, $P < 0.01$) inhibition of glucose-stimulate insulin secretion, but was without effect on basal secretion or insulin content. Visualization of insulin granules with NPY-mCherry revealed 51 ± 3% ($n = 25$, $P < 0.001$) reduction in granule density at the plasma membrane in INPP5F knockdown cells. These cells also showed 70 ± 8% ($n = 87$, $P < 0.01$) reduction in K^+-stimulated exocytosis. This suppression was also observed when exocytosis was visualized by the plasma membrane insertion of the pH-sensitive, granule-localized protein VAMP2-pHluorin (34 ± 7% reduction, $n = 100$, $P < 0.01$).

Conclusion: INPP5F localizes to insulin granules and loss of this enzyme leads to reduced insulin granule density at the plasma membrane and to impaired insulin secretion. The exact mechanism of action remains to be determined, but the observation are consistent with INPP5F-mediated dephosphorylation of PI(4)P on the insulin granule membrane being a key step in granule maturation.

The inhibiton of protein biosynthesis diminishes insulin secretion in freshly isolated islets but not in cultured islets

T. Schulze, M. Morsi, I. Rustenbeck;
TU Braunschweig, Braunschweig, Germany.

Background and aims: In contrast to purely depolarizing insulin secretagogues nutrient secretagogues like glucose stimulate protein biosynthesis concomitantly with the stimulation of insulin release. The question is whether this dual role of nutrient secretagogues affects the kinetics of insulin secretion.

Materials and methods: NMRI mouse islets were used either freshly isolated or after overnight culture in RPMI 1640 with 10% FCS and 5 mM glucose. The kinetics of insulin secretion and the oxygen consumption rate (OCR) were measured in the same batch of perifused islets. Additionally, the kinetics of NAD(P)H- and FAD-autofluorescence and of the cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) were measured. The protein biosynthesis was inhibited by 10 μM cycloheximide (CHX), which was present during the entire perifusion, starting 60 min prior to the glucose stimulation.

Results: Raising the glucose concentration from 5 to 25 mM in the perifusion medium of freshly isolated islets led to a nearly continuous increase of the secretion rate (70 $pg \times min^{-1} \times islet^{-1}$ after 60 min). In the presence of CHX the secretion rates upon stimulation were smaller from the beginning on and reached only 57% of the control value. With cultured islets no such difference was noted. The diminishing effect of CHX on freshly isolated islets was accompanied by a retarded and less steep increase of the OCR during the first 15 min. Thereafter, the OCR of the control islets showed a continuous increase, whereas that of the CHX-exposed islets remained constant. After culture control islets and CHX-exposed islets showed a virtually identical pattern: the OCR increase was particularly steep during the first 10 min, remained constant thereafter and decreased only slowly. In freshly isolated islets the presence of CHX affected the mitochondrial energetics in response to high glucose as was visible by a continued increase of the NAD(P)H/FAD ratio. This was predominantly caused by a more marked decrease of the FAD-fluorescence. In cultured islets, in contrast, CHX had no appreciable effect on the NAD(P)H/FAD ratio. Finally, it was tested whether the effect of CHX on insulin secretion involved changes of $[Ca^{2+}]_i$. Both in freshly isolated and cultured islets CHX slightly diminished the steady state of elevated $[Ca^{2+}]_i$ by 25 mM glucose, whereas the resting $[Ca^{2+}]_i$ and the velocity of $[Ca^{2+}]_i$ changes was unaffected.

Conclusion: Glucose-induced insulin secretion is markedly diminished by the inhibition of protein biosynthesis in freshly isolated, but not cultured islets. This effect involves changes in mitochondrial energetics, but is not directly related to $[Ca^{2+}]_i$. Apparently, the relation between mitochondrial metabolism and insulin secretion (amplifying pathway) is changed by culturing isolated islets, in that a more stable supply of signalling compounds and metabolites is generated. It is unclear whether this reflects the in vivo working condition of the islets.

Selective disruption of the very long chain fatty acid elongase 2 (ELOVL2) in the pancreatic beta cell impairs insulin release during obesity

K. Meneyrol[1], L. Bellini[1], E. Georgiadou[2], B. Blondeau[3], N. Kassis[1], B. Thorens[4], G.A. Rutter[2], C. Cruciani-Guglielmacci[1], C. Magnan[1], H. Le Stunff[1];
[1]Université Paris Diderot, Sorbonne Paris Cité, Unité Biologie Fonctionnelle et Adaptative - CNRS UMR 8251, Paris, France, [2]Section of Cell Biology and Functional Genomics, Division of Diabetes, Endocrinology and Metabolism, Imperial College London, London, UK, [3]Inserm, Saint-Antoine Research Centre, Saint-Antoine Hospital, Sorbonne University, Pierre-and-Marie-Curie University Paris 06, Paris, France, [4]Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

Background and aims: Dietary ω3-polyunsaturated fatty acids, especially docosahexaenoic acid (DHA), are known to influence glucose homeostasis by modulating peripheral insulin sensitivity. We recently showed that expression of the very long chain fatty acid elongase 2 (*Elovl2*) gene in pancreatic beta cells, whose gene product ELOVL2 regulates the synthesis of endogenous DHA, is associated with glucose tolerance in mice. Moreover, we found that down-regulation of *Elovl2* in various beta cell lines is associated with a defect in glucose-induced insulin secretion. However the *in vivo* role of *Elovl2* in beta cells in the regulation of glucose homeostasis is not known. In this study, we developed mice inactivated selectively in the beta cell for *Elovl2* to determine its role in the regulation of insulin secretion and glucose homeostasis during the development of obesity.
Materials and methods: Homologous recombination of floxed *Elovl2* alleles was achieved by breeding carrier mice to animals bearing a beta cell-selective Cre recombinase (Ins1-Cre mice). Control and *Elovl2*-BKO mice were fed either a regular chow or a high fat diet (HFD) for 3 months. Body weight gain, glucose homeostasis (oral glucose tolerance test and insulin tolerance test) and insulin secretion in vivo and in vitro, gene expression and islet cell mass were measured using standard techniques.
Results: Ins1-Cre-based recombination led to efficient beta cell-targeted deletion of Elovl2 (87.5% of reduction $p < 0.01$) without affecting expression of the other elongases. Elovl2-BKO mice displayed normal body weight, fasting glycaemia and islet cell mass after maintenance on a HFD. Similar insulin resistance developed in control and Elov2-BKO mice under HFD. In contrast, after 3 months of HFD, Elovl2-BKO mice displayed a slightly impaired glucose tolerance compared to control mice. Control mice under HFD displayed increased basal and glucose-stimulated insulin secretion *in vivo*. In contrast, both basal and glucose-stimulated insulin secretion were significantly decreased by 48.7% and 30,9% ($p < 0.02$), respectively in Elovl2-BKO mice under HFD compared to control mice. Finally, glucose-stimulated insulin secretion *in vitro* was also significantly decreased (46.2% $p < 0.01$) in isolated islets from Elovl2-BKO mice maintained on HFD versus WT controls.
Conclusion: Taken together, these results demonstrate a cell-autonomous role for *Elovl2* in the control of pancreatic beta cell insulin secretion. We are presently exploring the potential mechanisms involved by assessing Ca^{2+} dynamics and beta cell connectivity.

Interactions between statins and the farnesoid-X-receptor inhibit positive effects of chenodeoxycholic acid on insulin secretion

T. Hoffmeister[1], J. Kaiser[2], G. Drews[2], M. Düfer[1];
[1]Institute of Pharmaceutical and Medicinal Chemistry, Department of Pharmacology, Münster, [2]Institute of Pharmacy, Department of Pharmacology and Clinical Pharmacy, Tübingen, Germany.

Background and aims: It is reported that statins affect expression and signaling of the farnesoid-X-receptor (FXR) in the liver. This study focuses on the interaction between statins and FXR in pancreatic islets. Bile acids are endogenous agonists of FXR and increase glucose-stimulated insulin secretion (GSIS). For this acute effect the cytosolic localization of FXR is required. Since statins increase the risk of developing type 2 diabetes mellitus, this study aims to elucidate whether they interact with FXR in pancreatic β-cells and thereby influence the insulinotropic effect of chenodeoxycholic acid (CDC).
Materials and methods: Islets or β-cells were isolated from wildtype and FXR-deficient mice of a C57BL/6N background. For culture (24 h), standard conditions (10 mM glucose) were used in the presence or absence of atorvastatin (1.5 and 15 μM) or pravastatin (50 and 200 μM). Insulin secretion was measured by radioimmunoassay and $[Ca^{2+}]_c$ was determined by fluorescence microscopy. Statistical significance was assessed by Student's t test or ANOVA followed by Student-Newman-Keuls test.
Results: Treatment of islets with atorvastatin for 24 h decreased insulin secretion stimulated by 15 mM glucose in a concentration-dependent manner (control: 4.9 ± 0.6 ng insulin/islet*h vs. 15 μM atorvastatin: 3.3 ± 0.3 ng insulin/islet*h, $n = 10$, $p \leq 0.05$). Atorvastatin abolished the stimulatory effect of CDC (500 nM) on GSIS (15 μM atorvastatin: 3.7 ± 0.3 ng insulin/islet*h vs. 15 μM atorvastatin + CDC: 3.1 ± 0.4 ng insulin/islet*h, $n = 6$, n.s.) and diminished the rise in $[Ca^{2+}]_c$ induced by acute application of CDC (CDC-mediated increase in $[Ca^{2+}]_c$, control: 36 ± 6%, $n = 55$ vs. 15 μM atorvastatin: 17 ± 5%, $n = 37$, $p \leq 0.05$). In addition, the bile acid receptor seems to be involved in negative effects of atorvastatin on GSIS as well: WT islets showing no elevation of insulin release in response to CDC ($n = 4$), pointing to translocation of FXR from the cytosol to the nucleus, were more sensitive to the inhibitory effect of atorvastatin (15 μM) compared to CDC-responsive preparations (statin-induced reduction of GSIS: 49 ± 8%, $n = 4$ vs. 10 ± 10%, $n = 6$, $p \leq 0.05$). Since the inhibitory effect of atorvastatin on GSIS persisted in islets of FXR-knockout mice (control: 5.2 ± 0.6 ng insulin/islet*h vs. 15 μM atorvastatin: 3.3 ± 0.5 ng insulin/islet*h, $n = 8$, $p \leq 0.05$), FXR is not required for the detrimental effect of atorvastatin but seems to influence it. The more hydrophilic pravastatin also decreased GSIS (control: 5.2 ± 0.6 ng insulin/islet*h vs. 200 μM pravastatin: 3.4 ± 0.4 ng insulin/islet*h, $n = 10$, $p \leq 0.05$) and abolished the stimulatory effect of CDC on GSIS (200 μM pravastatin: 3.6 ± 0.7 ng insulin/islet*h vs. 200 μM pravastatin + CDC: 3.1 ± 0.5 ng insulin/islet*h, $n = 5$, n.s.) or $[Ca^{2+}]_c$ (CDC-mediated increase in $[Ca^{2+}]_c$, control: 27 ± 7%, $n = 27$ vs. 200 μM pravastatin: 11 ± 4%, $n = 33$, $p \leq 0.05$).
Conclusion: Lipophilic and hydrophilic statins both reduce insulin release. This impairing effect does not require FXR but seems to be modulated by the nuclear receptor. In addition to their inhibitory effect on islet function, statins also prevent the positive effects of bile acids on $[Ca^{2+}]_c$ and insulin secretion indicating an interaction between statins and FXR. In patients treated with statins these two mechanisms would act in concert and progressively impair glycemic control.

Roles for the type 2 diabetes-associated genes C2CD4A and C2CD4B in the control of insulin secretion

N. Mousavy Gharavy, A. Martinez-Sanchez, G. Rutter;
Medicine, Imperial College London, London, UK.

Background and aims: Single nucleotide polymorphisms near the human *C2CD4A* and *C2CD4B* genes on chromosome 15q are associated with altered pro-insulin levels and Type 2 diabetes risk at genome-wide significance. Altered expression of both *C2CD4A* and *C2CD4B* has been reported in human islets in association with risk variants, particularly in female subjects. Both genes encode putative Ca^{2+} and phospholipid-

binding proteins thought to be localised to the nucleus. Here, we address their roles in the regulation of insulin secretion *in vitro* and of glucose homeostasis *in vivo.*

Materials and methods: *C2cd4b* null mice were generated by the International Mouse Phenotyping Consortium using CRISPR/Cas9-mediated genome editing. Intraperitoneal glucose tolerance (IPGTT) and glucose-stimulated insulin secretion (GSIS) were examined using standard protocols. Subcellular analysis of Flag-tagged constructs was performed by immunocytochemistry and confocal fluorescence microscopy using an inverted optics spinning disk microscope (Nikon ECLIPSE Ti).

Results: Animals deleted globally for *C2cd4b* (KO) showed mild dysglycaemia, and this effect was clearest in females (at 12 weeks: 15 min. IPGTT: WT, 11.5 ± 0.8 mmol/L; KO, 14.78 ± 1.05 mmol/L, $n = 7–11$, $p = 0.0129$, two-way ANOVA test). Whilst differences were still observed in female KO mice *versus* WT animals at 20 or 22 weeks of age, none were observed in males of the same age. Correspondingly, a tendency towards lower glucose-stimulated insulin secretion from isolated islets was observed in female, but not male, null mice compared to controls ($n = 6–9$ animals aged 24 weeks per genotype, $P = 0.177$, Student's t-test). Examined in human foetal pancreas-derived EndoC BH1 β-cells, C2CD4A (92.3% ± 3.3) and C2CD4B (79.22% ± 10.1) were located in both the cytoplasm and nucleus ($n = 100$ and 80 cells, respectively). Additional localisation to the plasma membrane was observed for C2CD4A in 3.6% ± 3.6, and for C2CD4B in 6.1% ± 3.1, of cells. Exclusive localisation to the nucleus was observed in only 0.37% ± 0.4 (C2CD4A) and 5.7% ± 2.1 (C2CD4B) of cells.

Conclusion: Our data suggest that altered *C2CD4B* expression may contribute to exaggerated disease risk conferred by variants at this locus by altering glucose homeostasis. This action may, at least in part, be due to altered glucose-regulated insulin secretion, particularly in females. Analysis of the sub-cellular localisation of C2CD4B suggests that this protein may play a role in extra-nuclear events in beta cells, conceivably including Ca^{2+} signalling, in contrast to earlier findings in other cell types.

Shotgun proteomic analysis and protein lysine-acetylation in cytokine exposed human pancreatic islets

F. Ciregia[1], F. Grano[1], M. Mazzoni[1], S. Mossuto[1], A. Lucacchini[1], M. Suleiman[1], L. Giusti[1], C. De Luca[1], S. Lacerenza[1], L. Marselli[1], M. Ronci[2], A. Urbani[3], P. Marchetti[1], M. Bugliani[1];
[1]University of Pisa, Pisa, [2]University G. d'Annunzio of Chieti-Pescara, Chieti, [3]Università Cattolica, Rome, Italy.

Background and aims: Type 1 diabetes is characterized by beta cell destruction also due to the action of proinflammatory cytokines. To shed further light on how cytokine-exposure affects the proteome of human islets and post-translational protein modifications, we performed a study using label free shotgun proteomics and 2D electrophoresis (2DE), and also evaluated the presence of protein lysine-acetylation dysregulation.

Materials and methods: Human islets were prepared by collagenase digestion and gradient centrifugation from the pancreas of five non-diabetic multiorgan donors and then cultured for 48h with or without 50 U/ml IL-1beta + 1,000 U/ml IFN-gamma. We used 250 μg of islet protein extracts for 2DE (n: 5) and 40 μg of extracts for shotgun (n: 3) analysis. Samples were loaded onto 12% acrylamide resolving gel. After separation, gel pieces (13 for lane) were excised and the proteins were identified by shotgun methodology after in-gel trypsin digestion and mass spectrometry analysis. To determine protein lysine-acetylation, 2DE of human islet protein samples coupled with Western blot was performed using specific anti-acetylated lysine antibody.

Results: Around 3,000 proteins were identified by the shotgun analysis, of which 307 resulted differentially expressed after cytokine exposure [184 upregulated (including chemokines, oxidative stress-related proteins and immunoproteasome proteins) and 123 downregulated (including cathepsins, antioxidant proteins, Krebs cycle enzymes). Ingenuity pathways analysis showed that some upstream regulators such as STAT1 and 2, NF-kB, JAK1 were activated, and others, such as MAPK1, atypical chemokine receptor 2, transcription intermediary factor 1-alpha and small ubiquitin-related modifier 3 were inhibited. The search for lysine-acetylated proteins revealed 151 spots; 6 of them showed statistically significant changes after cytokine culture (2 upregulated and 4 downregulated). Mass spectrometry identified peroxiredoxin 3 and superoxide dismutase 1 as the upregulated acetylated proteins and glutamate dehydrogenase, cathepsin D, acyl-CoA dehydrogenase family member 9 and EIF4A1 as the downregulated ones.

Conclusion: Novel human islet proteins regulated by cytokine exposure were found in the present study and the role of cytokines was shown in affecting post-translational lysine acetylation of proteins involved in cell function and survival.

An integrated multi-omics approach identifies the type I interferon-induced signature of human beta cells

M.L. Colli[1], E.S. Nakayasu[2], M. Ramos-Rodriguez[3], J.-V. Turatsinze[1], A. Coomans de Brachène[1], M. Lopes[1], R.S. dos Santos[1], J. Juan-Mateu[1], H. Raurell-Vila[3], R. Scharfmann[4], P. Marchetti[5], L. Pasquali[3], T.O. Metz[2], D.L. Eizirik[1];
[1]ULB Center for Diabetes Research, Universite Libre de Bruxelles (ULB), Brussels, Belgium, [2]Pacific Northwest National Laboratory, Richland, USA, [3]IGTP Health Sciences Research Institute of the Germans Trias i Pujol Foundation, Barcelona, Spain, [4]INSERM U1016, University Paris-Descartes, Cochin Institute, Paris, France, [5]Department of Endocrinology and Metabolism, University of Pisa, Pisa, Italy.

Background and aims: Overexpression of HLA class I, presence of markers of endoplasmic reticulum (ER) stress and beta cell apoptosis are hallmarks of the pancreatic islets in early type 1 diabetes (T1D). Interferon-α (IFNα) is expressed in islets from T1D patients, and we have recently shown that human beta cells exposed to it recapitulate all the hallmarks observed during T1D development (PMIDs 28062922, 29305625). We presently used an integrated multi-omics approach to systematically characterize the IFNα responses induced in pancreatic human beta cells.
Materials and methods: Human EndoC-βH1 insulin-producing cells were exposed or not to IFNα (2000 U/ml) for 2h, 8h and 24h ($n = 5$). These cells were evaluated in parallel by: a. ATAC-seq to determine the chromatin accessibility and regulatory regions; b. RNA-seq with a high coverage (>220 millions reads) to determine gene expression, including spliced variants; c. Proteomics using liquid chromatography-mass spectrometry (LC-MS). Key findings were validated in EndoC-βH1 cells and primary human islet cells by real-time RT-PCR, Western Blot, and additional chromatin studies. Baricitinib (0.1–4 μM) was added to the cells 1h before IFNα exposure.
Results: IFNα-treated EndoC-βH1 cells showed >4400 gained open chromatin regions at 2h (False Discovery Rate (FDR) <0.05, fold change (FC) >2) but only 1000 at 24h. IFNα changed the mRNA expression (Up/Down) of 489 (411/78), 1659 (1173/486) and 1416 (872/544) genes at 2h, 8h and 24h, respectively, (FDR <0.05, FC >1.5). There were around 20.000 alternative splice events modified by IFNα (FDR <0.05, Percentage Splicing Index (PSI) >|5%|, minimal exon counts: 5). Analysis of the differentially abundant proteins by protein-protein interaction (PPI) tools identified ER protein processing, antigen presentation, type I interferon signaling, apoptosis and MDA5/RIG-I activation. Integration of the PPI networks with the DrugBank database identified the kinase JAK1 as both a hub for IFNα signaling and a target for the JAK inhibitor baricitinib, in test for rheumatoid arthritis treatment. Pretreatment of EndoC-βH1 or human islet cells with Baricitinib decreased IFNα-induced expression of HLA class I, the chemokine CXCL10 and the ER stress marker CHOP ($P < 0.01$).
Conclusion: Exposure of human beta cells to IFNα induces early modifications in chromatin structure and consequent modifications in the expression of thousands of mRNAs and proteins. IFNα activates signaling pathways promoting beta cell autoantigen(s) presentation and potentially neoantigen generation by parallel activation of the alternative splicing machinery and ER stress. The use of an integrated omics approach, coupled to novel bioinformatics tools, allowed us to identify Baricitinib as a potential new drug for beta cell protection in T1D.

The type 1 diabetes candidate gene CTSH protects against cytokine-induced beta cell apoptosis via Rac2 GTPase

T. Fløyel[1], A.H. Mirza[2], S. Kaur[1], J. Størling[1], F. Pociot[1];
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]Department of Pharmacology, Weill Cornell Medicine, New York, USA.

Background and aims: Genome-wide association studies have identified more than 50 risk loci for type 1 diabetes (T1D), including chr15q25.1 with the candidate gene *CTSH* (lysosomal protease cathepsin H). We previously showed that T1D-associated risk variants in *CTSH* affect the expression of CTSH, and that CTSH regulates β-cell function and disease progression in children with newly-diagnosed T1D. Overexpression of *CTSH* protected INS-1 cells against cytokine-induced apoptosis. By global gene expression analysis, the aim of this study was to identify the genes and mechanisms through which CTSH mediates its protective effect.
Materials and methods: INS-1 cells ($n = 3$) stably transfected with a plasmid encoding CTSH (pCTSH) or an empty vector (pcDNA) were stimulated with IL-1β and IFNγ for 0, 6 and 16 hours. Microarray analysis was performed on the extracted RNA using Affymetrix Rat Genome 230 array. Data were analyzed using the Bioconductor affy package and limma in R. Pathway analysis was performed using ROntoTools in R which takes into account the log fold changes and p values for the differentially expressed genes as well as pathways topology in order to assess the abnormal perturbation of the pathways in the condition under study. Two pathways were validated functionally by siRNA-mediated knockdown of *Gna15*, *Cav1* and *Rac2* in the pcDNA and pCTSH cells ($n = 5$) to examine the effect on CTSH-mediated protection against apoptosis using the Caspase-Glo 3/7, the CytoTox-Fluor, and the Cell Death Detection ELISA assays. Knockdown was verified by real-time qPCR.
Results: A total of 56 annotated genes were differentially expressed between the pCTSH and pcDNA cells (abs fold change >1.2 and FDR-adjusted $p < 0.05$). Six pathways were significantly perturbed by *CTSH* overexpression ($p < 0.05$): "Serotonergic synapse" with the differentially expressed gene *Ptgs1*, "Calcium signaling" with *Gna15*, "Amoebiasis" with *C9* and *Gna15*, "Chagas disease" with *Ccl5* and *Gna15*, "Focal adhesion" with *Cav1* and *Rac2*, and "Insulin resistance" with *Ppargc1a*, *Ppp1r3c* and *Trib3*. The three genes from the "Calcium signaling" and "Focal adhesion" pathways (*Gna15*, *Cav1* and *Rac2*) were all upregulated in response to *CTSH* overexpression ($p < 0.05$) and therefore knockdown experiments were done individually to evaluate their potential as mediators of the protective effect of CTSH against apoptosis. Knockdown of *Rac2* reversed the protective effects of *CTSH* overexpression on cytokine-induced apoptosis ($p < 0.05$), whereas knockdown of *Gna15* and *Cav1* had no effect.
Conclusion: The current data suggest that CTSH may mediate its protective effect on cytokine-induced apoptosis through the Rho family small GTPase Rac2, which itself is a T1D candidate gene located at the chr22q12.3 risk locus. Interestingly, Rac1, which has 92% sequence homology with Rac2, is also expressed in insulin-secreting cells, where it has been implicated in both glucose-stimulated insulin secretion and apoptosis. Further experiments are needed to evaluate if higher CTSH and Rac2 levels in β-cells protect against immune-mediated damage and preserve β-cell function, thereby representing possible targets for β-cell therapy in T1D.

The type 1 diabetes candidate gene Src kinase associated phosphoprotein 2 (SKAP2) controls beta cell sensitivity to pro-inflammatory cytokines

J. Størling[1], K. Meyerovich[2], T. Fløyel[1], H.B. Mortensen[3], L.B. Nielsen[3], D.L. Eizirik[2], A.K. Cardozo[2], F. Pociot[1];
[1]T1D Biology, Steno Diabetes Center Copenhagen, Gentofte, [2]ULB Center for Diabetes Research, Université Libre de Bruxelles, Bruxelles, [3]Department of Pediatrics E, University Hospital Herlev, Herlev, Denmark.

Background and aims: The gene encoding *Src kinase associated phosphoprotein 2 (SKAP2)* is a type 1 diabetes (T1D) candidate gene, but the causal mechanisms are unknown. We previously showed that pro-inflammatory cytokines believed to cause β cell destruction in T1D modulate the expression of *SKAP2* in human pancreatic islets. Here, we aimed to establish the functional role of SKAP2 in pancreatic β cells with focus on its potential regulatory effect on cytokine-mediated β cell apoptosis.
Materials and methods: Rat INS-1E cells, purified primary rat β cells, and the newly established insulin-secreting human cell line 1.1B4 were used to study the function of SKAP2. Cells were transfected with small interfering RNAs (siRNAs) to knockdown the expression of SKAP2. Overexpression experiments were performed on either stably-

transfected clones of INS-1E cells or in transiently-transfected cell pools. Gene expression and protein analyses were examined by real time PCR and immunoblotting, respectively. Apoptosis in response to cytokines (IL-1β + IFNγ ± TNFα) was determined by caspase 3/7 activation, nucleosome detection or Hoechst/propidium iodide staining. Nitric oxide (NO) production was determined by Griess assay. The clinical relevance of SKAP2 genotypes was evaluated in a cohort of newly-diagnosed children with T1D by HbA1c and insulin dose-adjusted HbA1c (an estimate of residual β cell function) analyses.

Results: Knockdown of SKAP2 aggravated cytokine-induced apoptosis in both INS-1E cells, primary rat β cells and 1.1B4 cells. On the contrary, SKAP2 overexpression in INS-1E cells afforded protection against cytokine-induced apoptosis. The protective effect of SKAP2 overexpression correlated with reduced iNOS expression and NO production and decreased the expression of the endoplasmic reticulum (ER) stress marker CHOP. In a cohort of children with newly diagnosed T1D, we found that the single nucleotide polymorphism (SNP) *rs7804356* in *SKAP2* could predict residual β cell function at 12 months after diagnosis.

Conclusion: The present findings reveal that the T1D candidate gene *SKAP2* plays a critical role in the β cells by controlling their vulnerability to cytokine-mediated apoptosis possibly by regulating ER stress.

Characterisation of CXCL10 expression pattern in pancreatic islets of NOD mice and type 1 diabetic patients: a new role for alpha cells in T-lymphocytes recruitment

L. Nigi[1], F. Mancarella[1], L. Krogvold[2], L. Marselli[3], G. Sebastiani[1], G. Ventriglia[1], G.E. Grieco[1], N. Brusco[1], C. Gysemans[4], P. Marchetti[3], C. Mathieu[4], K. Dahl-Jørgensen[2], F. Dotta[1];
[1]Diabetes Unit, Dept. of Medicine, Surgery and Neuroscience, University of Siena; Umberto Di Mario Foundation ONLUS, Toscana Life Sciences, Siena, Italy, [2]Division of Pediatric and Adolescent Medicine, Oslo University Hospital, Oslo, Norway, [3]Dept. of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, [4]Laboratory of Clinical and Experimental Endocrinology, KU Leuven, Leuven, Belgium.

Background and aims: in type 1 diabetes (T1D) the pro-inflammatory chemokine CXCL10 is involved in recruitment of autoreactive T-lymphocytes in pancreatic islets, contributing to beta(β)-cells destruction. CXCL10 has been described to be expressed by murine and human pancreatic islets in autoimmune diabetes. However, the specific expression pattern distribution among pancreatic endocrine cell subtypes has not been clarified yet. Therefore, the purpose of our study was to shed light on the pancreatic islet expression pattern of CXCL10 both in NOD mice and in T1D patients.

Materials and methods: we analyzed formalin-fixed paraffin embedded pancreatic sections obtained from C57Bl/6J 8 weeks ($n = 4$), C57Bl/6J 15–20 weeks ($n = 3$), NOD-SCID 2–3 weeks ($n = 4$), NOD normoglycemic (NG) 22 weeks ($n = 4$), NOD recent diabetic (RD) 12–21 weeks old ($n = 4$) mice and from new-onset T1D patients ($n = 6$) participating in Diabetes Virus Detection (DiViD) study, compared to non-diabetic organ donors ($n = 3$) from European Network for Pancreatic Organ Donors with Diabetes (EUnPOD) cohort. Immunofluorescence and confocal microscopy analysis were performed to study the expression of CXCL10, insulin and glucagon. Colocalization analysis between insulin and CXCL10 (INS-CXCL10) and between glucagon and CXCL10 (GCG-CXCL10) was performed by using LAS AF software. In mice, total CXCL10 positive volume was analyzed and normalized per islet volume; moreover, extent of islet inflammation (measured by lymphocytic infiltrates area) was correlated to CXCL10 expression.

Results: CXCL10 was not expressed in pancreatic islets of C57Bl/6J and NOD-SCID mice indicating that CXCL10 expression occurs together with inflammation. Total CXCL10 positive volume was increased in pancreatic islets of RD compared to NG NOD mice ($p < 0.01$) and was positively correlated to extent of islet inflammation ($r = 0.44$, $p = 0.02$). Both in NG and RD NOD mice CXCL10 was expressed in pancreatic islets and in RD NOD mice GCG-CXCL10 colocalization rate was increased compared to INS-CXCL10 ($p < 0.01$). Surprisingly, INS-CXCL10 colocalization rate was similar between NG and RD NOD mice, while GCG-CXCL10 was increased in RD compared to NG NOD mice ($p < 0.001$). The analysis of CXCL10 expression pattern performed on human sections revealed that this chemokine was expressed in pancreatic islets of T1D patients but not in non-diabetic donors. GCG-CXCL10 colocalization rate was increased compared to INS-CXCL10 ($p = 0.003$) and, interestingly, was similar between insulin-containing and insulin-deficient islets ($p = 0.6$); it suggests that CXCL10 expression in alpha(α)-cells is not driven by residual β-cells and may represent an independent effect.

Conclusion: we showed that CXCL10 is preferentially expressed by α-cells both in NOD mice and in T1D patients, thus opening to the possibility of a new role for α-cells in the recruitment of autoreactive T-lymphocytes in pancreatic islets and a primary function in β-cell damage.

Disclosure: **L. Nigi:** None.

Studies of insulin-related peptides in pancreas and plasma support the existence of two distinct aetiological subtypes of type 1 diabetes associated with age at diagnosis

P. Leete, R. Oram, T.J. McDonald, C. Ziller, B. Shields, T. Tigi Study Team, A.T. Hattersley, S.J. Richardson, N.G. Morgan;
University of Exeter, Exeter, UK.

Background and aims: Immunopathological analysis of insulitis in pancreas tissue studied soon after the onset of type 1 diabetes (T1D) in patients diagnosed <7 y or ≥13 y has suggested two different aetiological subtypes. We sought to assess whether the distribution of proinsulin and mature insulin in the insulin-containing islets (ICI) remaining at disease onset in these two groups, as well as the secretion of insulin-related peptides in people with longstanding T1D, further support the existence of 2 discrete subtypes.

Materials and methods: 4 μm sections of pancreas tissue from 21 patients studied within 1y of T1D onset (4 < 7 y, 11 7–12 y; 6 ≥ 13 y) and 8 controls, were stained with antisera directed specifically against proinsulin or insulin and visualised via confocal microscopy. Images were analysed in a blinded manner to assess the extent of antigen co-localisation. In parallel, 90 minute plasma C-peptide and proinsulin levels were measured after a mixed meal tolerance test in 191 T1D patients (87 diagnosed <7 y and 84 ≥ 13 y) studied >5 y (median 13.3 y) post diagnosis.

Results: In common with earlier work revealing that two immune cell phenotypes can be distinguished at diagnosis of T1D, two distinct patterns of proinsulin/insulin localisation were also seen, which differed markedly between children diagnosed <7 y and those ≥13 y. Prohormone processing was aberrant in the younger group, as evidenced by abnormally high co-localisation of proinsulin and insulin (72 ± 4% vs 28 ± 1% in controls; $p < 0.0001$) in almost all islets. This phenomenon was much less evident in those ≥13 y where, in 78% of islets, proinsulin did not co-localise with mature insulin and was restricted solely to a perinuclear (Golgi) compartment within beta cells ($p < 0.0001$ vs <7 y). Importantly when the islets of children who had been diagnosed in the middle age range (between 7–12 y) were studied in a blinded manner, islets with aberrant proinsulin processing were found, but their proportion correlated precisely with the assigned immune cell profile of each individual patient; as expected if two distinct disease processes are operative. In patients with longstanding T1D and diagnosed <7 y, C-peptide levels were much lower than in those diagnosed ≥13 y (median (IQR) <3 (<3–<3) v 34.5 (<3, 151)pmol/l; $p < 0.0001$) despite a similar duration (12.4 v

15.8 y $p = 0.07$). In contrast, the proinsulin/C-peptide ratio (PI/CP) was increased in those with onset <7 y compared to people diagnosed ≥13 y (0.18 (0.10, 0.31) v 0.01 (0.009, 0.10) nmol/mmol; $p < 0.0001$). No differences in C-peptide or PI/CP ratio were found in those diagnosed 13–18 y or >19–30 y (all $p > 0.5$), arguing against a continuous effect of age at diagnosis.

Conclusion: These findings strongly support the proposition that two distinct aetiological subtypes of Type 1 diabetes exist, which can be identified clinically by age at diagnosis. These subtypes differ according to their insulitic profiles, numbers of residual insulin-containing islets and the proportion of islets with aberrant proinsulin processing, at diagnosis. These differences are reflected over the longer term in the circulating C-peptide and proinsulin concentrations. Understanding the link between the differences in immune cell infiltration and proinsulin processing may provide clues as to the distinct disease processes in the 2 subtypes.

Prevascularisation of pseudo-islets: a new strategy to improve the engraftment of transplanted islets

L. Nalbach[1], E. Ampofo[1], V. Becker[1], W. Metzger[2], N. Wilhelm[3], M.D. Menger[1], M.W. Laschke[1];
[1]Institute for Clinical and Experimental Surgery, Saarland University, Homburg/Saar, [2]Department of Trauma, Hand and Reconstructive Surgery, Saarland University, Homburg/Saar, [3]Biomedical Engineering, Frauenhofer Institute, St. Ingbert, Germany.

Background and aims: Pancreatic islet transplantation is a clinically applied strategy to restore physiological blood glucose levels in diabetic patients. However, successful islet engraftment still represents the main critical issue for this surgical approach. To overcome this, we incorporate adipose tissue-derived microvascular fragments (adMVF) into pseudo-islets (PI) to ameliorate the revascularization process of transplanted islets

Materials and methods: Prevascularized PI were generated by liquid overlay cultivation of pancreatic islet cells and adMVF isolated from C57BL/6 donor mice. Native islets and non-prevascularized PI served as controls. Scanning electron microscopy was performed to analyze the morphology of the grafts. The cellular composition was determined by immunhistochemical stainings of insulin, glucagon and CD31. Neutral red/trypane blue stainings, flow cytometric analyses and immunhistochemical stainings of KI67- and caspase3-positive cells were used to investigate the cellular viability. The angiogenic activity of the grafts was evaluated by sprouting assays. In vivo, prevascularized PI, non-prevascularized PI and native islets were transplanted into dorsal skinfold chambers of C57BL/6 mice to investigate their engraftment and vascularization. All values are presented as mean ± SD.

Results: The liquid overlay technique allowed the generation of stable prevascularized and non-prevascularized PI within 5 days. Scanning electron microscopy revealed a more heterogeneous surface pattern of prevascularized PI when compared to non-prevascularized PI and native islets. The analysis of cellular composition indicated that the fraction of CD31-positive endothelial cells was significantly higher in prevascularized PI (23 ± 6%) when compared to native islets (10 ± 2%) and non-prevascularized PI (0 ± 0%). The number of insulin-, glucagon- and somatostatin-positive cells was not affected. Neutral red/trypane blue stainings demonstrated that the incorporation of adMVF did not reduce the grafts viability, which was confirmed by additional flow cytometric and immunhistochemical analyses. In addition, 23 ± 6% of the endothelial cells were positive for KI67 indicating a high proliferative potential. In vitro, prevascularized PI exhibited a high number of sprouts in a length of 120 μm, whereas no sprouts were detected in the control groups after 24 hours. Importantly, the incorporation of adMVF in PI markedly accelerated the process of vascularization and the onset of microvascular perfusion when compared to non-prevascularized PI and native islets in vivo.

Conclusion: The present study demonstrates that the incorporation of adMVF in PI markedly enhances the angiogenic activity of the grafts in vitro and in vivo. Accordingly, this prevascularization approach may represent a promising future strategy to increase the success rate of clinical islet transplantation.

Donor body mass index does not affect short term clinical islet transplant outcomes

K.J. Potter[1], A. Lam[1], D. O'Gorman[2], T. Kin[2], S. Forbes[3], A. Malcolm[1], A. Haqq[1], A. Shapiro[1], P. Senior[1];
[1]University of Alberta, Edmonton, Canada, [2]Alberta Health Services, Edmonton, Canada, [3]University of Edinburgh, Edinburgh, UK.

Background and aims: Clinical islet transplantation is limited by availability and quality of donor organs. Obese donors are generally avoided in whole pancreas transplants. They have, however, been suggested as ideal for islet transplantation based on isolation outcome studies demonstrating improved islet yields. There remains a concern that islets isolated from obese donors have suboptimal function. Further, the effect of donor obesity on clinical outcomes post islet transplantation remains unknown. The aim of this study was to compare short term clinical outcomes in islet transplant recipients who received islets from obese (BMI >30 kg/m^2) compared to non-obese (BMI 18.5–30 kg/m^2) donors.

Materials and methods: Subjects receiving their first single-donor islet infusion at a single center, between 1999 and 2017, were included. We excluded recipients of islets from a donor with BMI <18.5 kg/m^2 or a second islet transplant after less than a month. There were 233 donor-islet pairs. 128 subjects received islets from non-obese BMI donors and 90 from obese donors. Clinical outcomes at one month post-transplant included insulin independence, insulin dose reduction, fasting C-peptide, blood glucose and BETA-2 score. Time to second transplant was compared using Kaplan-Meier analysis.

Results: There was no difference between obese and non-obese donors in terms of either donor age (49.7 ± 12.4 v 47.3 ± 12.8, $p = 0.174$) or donor sex (41.4% v 37.8% female, $p = 0.590$). The average BMI for non-obese donors and for obese donors were 25.6 ± 2.6 kg/m^2 and 35.1 ± 5.2 kg/m^2, respectively. The number of islet equivalents (IEQ) isolated from obese donors was significantly greater (437,588 ± 12,004 v 496,939 ± 19,701 IEQ, $p = 0.007$) but there was no difference in islet particle number (IPN) (412,193 ± 12,966 v 429,723 ± 18,777 particles, $p = 0.428$). The correlation between donor BMI and islet yield (IEQ) was moderate ($r = 0.30$, $p < 0.0001$) and weak for IPN ($r = 0.15$, $p = 0.02$). The number of islets transplanted per kilogram of recipient body weight was similar in non-obese and obese donors (6185 ± 142 vs 6662 ± 264 IEQ, $p = 0.08$). The proportion of islet recipients who achieved single-donor insulin-independence at one month was similar between recipients of non-obese and obese donor islets (13.3% vs 20.2%, $p = 0.1934$). Similarly, reduction in insulin dose was not associated with donor BMI ($r = 0.12$, $p = 0.095$). At one month following transplantation, there was no relationship between donor BMI and fasting plasma glucose ($r = 0.094$, $p = 0.1515$), fasting C-peptide ($r = 0.111$, $p = 0.1027$), or HbA1c ($r = 0.118$, $p = 0.0827$). In recipients of obese donor islets there was a relationship between BMI and BETA2 score ($r = 0.2$, $p < 0.0001$) but not after controlling for number of islets transplanted per kg recipient body weight. Kaplan-Meier analysis of time to second transplant was similar between recipients of islets from non-obese and obese donors ($p = 0.8991$).

Conclusion: This large dataset provides robust confirmation that pancreata from obese donors yield greater islet mass (IEQ) but similar numbers of islet particles. Reassuringly, short-term clinical outcomes were similar between obese donors and non-obese donors and suggest that an elevated BMI in carefully selected donors does not adversely affect islet graft function. The relative importance of islet mass or particle number should be examined in more detail.

Background and aims: Type 1 diabetes is an autoimmune disease characterized by progressive decline in pancreatic beta cell mass (BCM) that culminates in beta cell destruction and insulin deficiency. The extent and evolution of BCM is difficult to quantify due to lack of accurate techniques for *in vivo* determination of pancreatic islet loss. We have recently identified, by a combined RNA sequencing and systems biology approach, Dipeptidyl Peptidase 6 (DPP6) as a new biomarker suitable for *in vivo* imaging of human pancreatic cells. We presently validated its use for the imaging of different amounts of human beta cells implanted in immunodeficient mice.
Materials and methods: The identification of new biomarkers was based on RNA-sequenced human pancreatic islets, treated and untreated with IL-1β and IFN-γ, and on 16 healthy human tissues (Illumina Body Map 2.0:GSE30611). The specificity of the expression of the target was validated at the protein level by immunohistochemistry on human tissue arrays. A ^{99m}Tc- camelid single-domain antibody (nanobody) targeting this protein was developed and used to quantify different kinds of intramuscular or subcutaneous grafts in NOD-SCID mice by SPECT-CT, including insulin-producing human EndoC-βH1 cells and primary human islets. The linearity of SPECT signal was evaluated by performing imaging on mice transplanted with different EndoC-βH1 amounts (2.5, 5 and 10 million cells). The effect of the nanobody on cell viability and basal insulin secretion was assessed in EndoC-βH1 cells by using nuclear dyes (Hoechst/Propidium Iodide) and anti-insulin ELISA, respectively.
Results: DPP6 is a human-specific biomarker present only in beta and alpha cells. At the protein level, DPP6 was detected in alpha and beta cells, as well as in some brain regions, but not in other tissues. By using a ^{99m}Tc-nanobody for SPECT-CT imaging we successfully detected grafts composed of EndoC-βH1 cells, or primary human islets. Graft radioactivity levels were specific, with tumour-to-blood and tumour-to-muscle ratios of 2.5 ± 0.4 and 9.9 ± 2.2 respectively, in EndoC-βH1-bearing mice ($n = 5$, $P \leq 0.05$). Similar results were obtained for primary human islets, while exocrine tissue provided limited or no signal. The SPECT-CT signal seemed to be linearly correlated to the number of cells transplanted ($n = 5$, $R^2 = 0.95$). The probe did not induce beta cell death or alter basal insulin secretion of EndoC-βH1 cells ($n = 4$–5, $P > 0.05$).
Conclusion: We have identified and validated a novel beta and alpha cell biomarker and developed a tracer for its use in *in vivo* islet imaging. This represents a useful tool to non-invasively follow up islet grafts and, pending future development, islet mass in diabetic patients.

Orphan G-protein coupled receptors (GPC) expression profiling in human islets revealed novel genes for type 2 diabetes

J. Taneera[1], A. Mohammed[1], N. Sulaiman[1], M. Hamad[1], A.S. Salehi[2];
[1]University of Sharjah, Sharjah, United Arab Emirates, [2]Lund University Diabetes Center, Malmoe, Sweden.

Background and aims: G-protein coupled receptors (GPCRs) regulate pancreatic insulin secretion through various signaling pathways. To date there are several hundred GPCRs have been identified, of them 100 are known to lack a defined ligand and are named as orphan receptors. Little is known about the roles of these receptors, expression or implication in insulin secretion in human pancreatic. As almost 50% of the current pharmaceutical agent are based on GPCRs, therefore, studies on uncharacterized orphan receptors are of great importance to expand the therapeutic targets for diabetes. In here, we used microarray gene expression data to compare the expression level of orphan GPCRs in isolated human pancreatic islets from non-diabeitc (ND) and type 2 diabetic (T2D) organ donors. The expression magnitude of orphan GPCRs in ND islets was also compared to frequently used clonal rat INS-1 (832/13) cells.
Materials and methods: Human Islets from cadaver donors were provided by the Nordic Islet Transplantation Program, Uppsala University. The microarrays (GeneChip® Human Gene 1.0 ST and Rat Gene 2.0 ST) were performed using the Affymetrix standard protocol. The array data were summarized and normalized with Robust Multi-array Analysis method. Gene silencing was done using siRNA and transfection efficiency was assessed by qRT-PCR. Secreted insulin was measured in the incubation medium (1 h) with an ELISA assay. Insulin gene expression was analyzed by qRT-PCR and cAMP by ELISA assay.
Results: Of the 90 analyzed orphan GPCR genes, 50 were in the boundary of detection in human islets, 36 had moderate expression level and 4 (GPR125, GPR56, GPRC5B, and LGR4) displayed a high expression. In INS-1 cells, GPR158 was the highest expressed orphan GPCR transcript. (for more details see Figure 1). Differential expression analysis in diabetic vs. non-diabetic islets revealed 14 differently expressed GPCR transcripts, while 4 GPCRs showed a differential expression pattern in hyperglycemic vs. norm-glycemic donors. GPR75 and GPR183 were found to overlap in both comparisons. GPR75 expression was correlated significantly with insulin secretion and with HbA1c, while GPR183 expression was correlated only with HbA1c. siRNA knockdown of GPR75 and GPR183 in INS-1 cells was associated with a significantly decreased in glucose-stimulated insulin secretion, insulin mRNA expression and cAMP content.
Conclusion: Our study provides a comprehensive expression pattern for orphan GPCRs transcripts in human pancreatic islets and INS-1 cells. The modulatory impact of GFP75 and GPR183 activation on pancreatic B-cell function by specific agonists is of utmost interest for the future treatment of T2D although more functional studies are required.

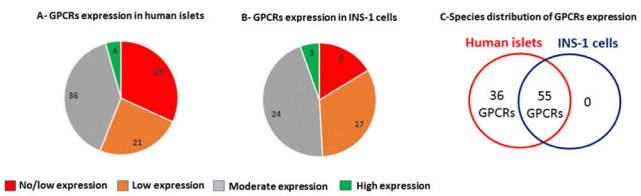

Figure 1: Summary of orphan GPCRs mRNA expression in human pancreatic islets (A) and rat INS-1 (832/13) (B). The color coding represents the expression abundance of GPCRs for each species. (C) Distribution of GPCRs expression in human islets and INS-1 cells. 55 GPCRs were overlapped between the two species, while 35 GPCRs were restricted only to human islets.

Proteomic analysis on human islets shows-up new markers of cellular and metabolic dysfunction

C.M.A. Cefalo[1], T. Mezza[1], S. Alfieri[2], W.-J. Qian[3], R.N. Kulkarni[4], A. Giaccari[1];
[1]Policlinico A. Gemelli, Rome, Italy, [2]Department of digestive an Hepatobiliary surgery, Policlinico A. Gemelli, Rome, Italy, [3]Pacific Northwest National Laboratory, Richland, USA, [4]Joslin Diabetes Center, Boston, USA.

Background and aims: The pathogenesis of type 2 diabetes is characterized by a progressive beta cell dysfunction resulting in both quantitative and qualitative loss of insulin secretion. However, the molecular mechanisms underlying this progressive functional loss are still unknown. The aim of the study is to highlight changes in the proteome of pancreatic islets that can anticipate and eventually predict the onset of diabetes.
Materials and methods: High performance liquid chromatography-mass spectrometry (HPLC-MS) analysis was applied to islets isolated by laser capture microdissection (LCM) from human samples of both diabetic and no diabetic subjects, underwent to duodeno-cefalopancreatectomy for extra-pancreatic and low grading tumors. The subjects were classified on the basis of glucose tolerance assessed by a oral glucose tolerance test before surgery in normal tolerant (NGT, n:7), glucose intolerant (IGT, n:5) and diabetic subjects (T2DM, n:2). Qualitative and quantitative analysis were performed to detect differential protein expression among the three study's groups.
Results: Sixty-seven proteins were found to be significantly different regulated in diabetic subjects compare to NGT, with 29 upregulated and 38 downregulated proteins, while ninety-five proteins were differentially expressed in IGT compare to NGT with 49 upregulated and 46 downregulated. These proteins are mainly involved in cellular and metabolic processes. In particular IGT and DM, compared to NGT, showed a lower expression of proteins involved in cell proliferation such as PURA and NAP1L1, as well as proteins involved in the insulin cleavage process, like ERO1B or in gluconeogenesis process like PG3 and PGK1. While other proteins involved in endoplasmic reticulum stress, CASP14, ERP27 and PDIA3, resulted upregulated in both IGT and DM compare to NGT. A protein, SE1L1, already shown to be potentially involved in the differentiation of pancreatic epithelium resulted upregulated in IGT and downregulated in the DM2 subjects.
Conclusion: Our data suggest that metabolic and cellular processes of islet cells are already dysregulated in patients with impaired glucose tolerance, highlighting some proteins as potential early markers of beta cell dysfunction and novel therapeutic targets to slow the progression to type 2 diabetes.

The glutamate receptor GLUK2 plays a role in glucose homeostasis

M. Abarkan[1], F. Lebreton[1,2], R. Perrier[1], M. Jaffredo[1], J. Gaitan[1], C. Magnan[3], M. Raoux[1], J. Lang[1];
[1]Cell Biology and Biosensors, Univ. Bordeaux, Pessac, France, [2]Université de Genève, Genève, Switzerland, [3]Unité de Biologie Fonctionelle et Adaptative (BFA), Univ. Bordeaux, Paris, France.

Background and aims: Islet hormone secretion is fine-tuned by neurotransmitters and A- as well as B-cells express the ionotropic glutamate receptor Gluk2 according to immunocytochemistry, qPCR and RNAseq. To gain insight into the potential role of Gluk2 in glucose homeostasis we have investigated corresponding knockout mice. These mice have been previously characterized only at the level of the central nervous system and without regard to glucose homeostasis.
Materials and methods: Wild-type C57BL/6 GLUK2$^{+/+}$ mice born on similar dates as C57BL/6 GLUK2$^{-/-}$ mutant litter mice were analyzed (both genotyped by PCR). Adult (week 14–20) and old (week 40–52) mice were investigated. Glucose, pyruvate or insulin tolerance tests were performed according to standard procedures, hormones determined by ELISA. For electrophysiological analysis, islets were isolated and seeded on multielectrode arrays (MEA, 60 electrodes; MCS, Tuebingen). 4 days later signals were recorded (10 kHz) and analyzed offline in terms of slow potential frequency with a commercial software (MC_Rack, MCS).
Results: No statistical differences were apparent in islet mass, beta- or alpha-cell volume or liver glycogen stores between the WT and KO mice. The subsequent functional experiments suggested in essence that old WT mice handled glucose less well than adult (either WT or KO) mice, whereas old KO mice ressembled more to adult mice (WT or KO). Indeed, ip glucose tolerance tests (GTTs) yielded similar values in adult WT or KO mice, whereas old WT mice showed diminished glucose tolerance (1.5 increase in AUC, $P < 0.001$, $n = 7–10$) from 30 min onwards. In contrast, old KO mice behaved as adult WT or KO mice. Insulin levels in-vivo were similar in old mice, except for lower basal values in KO animals (1.18 vs. 0.75 pmol/l; $2p < 0.02$, $n = 7$). Interestingly, fasting glucagonemia was reduced by 39% in old KO mice (compared to old WT). In OGTTs, old KO mice exhibited a far better glucose tolerance than old WT mice from 30 min onwards with a 50% decrease in glycemia (AUC, $n = 14–16$, $2p < 0.05$). Similar results were obtained in pyruvate tolerance test (which mainly reflects neoglucogenesis) where again old KO behaved as adult WT or KO mice, in contrast to augmented glycemia in old WT mice (old WT vs KO, $P < 0.05$ or smaller, $n = 7–9$). Insulin tolerance tests (ip) showed no differences among adult mice (KO or WT) but a marked loss in sensitivity in old WT mice ($P < 0.02$ vs young mice, WT or KO), whereas old KO mice remained as sensitive as the adult ones ($P < 0.001$, all $n = 6$ as compared to old WT). Islet activity of old mice was directly tested in-vitro using MEAs. Stimulation with glucose (8.2 mM, 50 min) resulted in a biphasic pattern of electrical activity in terms of slow potential (SP) frequencies. SPs mainly translate activity of coupled intra-islet beta-cell units. In the second phase, KO mice islets exhibited a 40% higher frequency. Islet insulin and glucagon secretion assays are underway.
Conclusion: Old GLUK2$^{-/-}$ mice exhibited an improved glucose tolerance and insulin sensitivity as compared to WT mice. This is accompanied by a slightly higher glucose-induced electrical islet activity in-vitro mainly during the second phase. These observations suggest a negative effect of Gluk2 on glucose homeostasis especially during aging and which may be due to effects on islets although extra-islet actions are not excluded.

Inhibition of insulin secretion by the chemokine Cxcl14 via a cAMP-independent pathway

P. Atanes, R.G. Hawkes, I. Ruz-Maldonado, O. Olaniru, B. Liu, S. Amisten, S.J. Persaud;
Diabetes Research Group, Department of Diabetes, King's College London, London, UK.

Background and aims: Cxcl14 is a secreted peptide that belongs to the CXC-class chemokine family, acting as a ligand for an unknown receptor. Previous studies have shown that Cxcl14 levels in serum and white adipose tissue are increased in obese mice, whilst Cxcl14 knockout mice are protected from obesity-induced hyperglycaemia and show improved insulin responsiveness. We have identified CXCL14 mRNA expression by islets, but its function in islets has not been elucidated yet. We here explore the role of Cxcl14 on islet and β-cell function and the underlying mechanisms mediating these effects, and attempt to identify the GPCR through which it acts.

Materials and methods: Cxcl14 mRNA expression and the mRNA expression profiles of all CXC-receptors were quantified by qPCR in MIN6 β-cells and mouse islets. Distribution of Cxcl14 in mouse islets was determined by immunohistochemistry (IHC), with insulin, glucagon and somatostatin co-staining. The effects of exogenous Cxcl14 on glucose-stimulated insulin secretion (GSIS) were quantified by radioimmunoassay. Cxcl14 effects on cAMP accumulation, glucose uptake, ATP generation and intracellular calcium levels were assessed by standard techniques using mouse islets and/or MIN6 cells. Activation of Cxcr4 and Cxcr7 receptors was assessed using β-arrestin assays.

Results: Cxcl14 mRNA was not detected in MIN6 β-cells but it was present in mouse islets, and IHC indicated that it was mainly localised to δ-cells. Cxcl14 induced a concentration-dependent inhibition of GSIS from mouse islets (20 mM glucose: 1.93 ± 0.4 ng/islet/hr; +Cxcl14: 1, 2, 10, 20 and 40 ng/mL: 1.59 ± 0.5, 1.31 ± 0.2, 1.08 ± 0.2, 1.00 ± 0.2 and 0.43 ± 0.1 ng/islet/hr, $n = 8$, $p < 0.05$), and a similar trend was observed in MIN6 cells. Cxcl14 (0.01–512 ng/mL) did not reduce forskolin-induced elevation in cAMP in β-cells, whereas the α2-adrenergic agonist clonidine did (10 μM forskolin: 20.3 ± 1 nM cAMP; +512 ng/mL Cxcl14: 23.4 ± 1.5 nM; $p > 0.05$; +1 μM clonidine: 1.4 ± 0.2 nM, $p < 0.001$). However, Cxcl14 inhibited glucose uptake into islets (20 mM glucose: 100 ± 38.3%; +Cxcl14: 1, 10, 20, 40 and 80 ng/mL: 64.7 ± 38, 33.9 ± 20.5, 35.3 ± 16.4, 31.6 ± 14.4 and 18.2 ± 6.1%, $n = 6$, $p < 0.05$; 50 μM cytochalasin B: 12.3 ± 4.0%; $n = 6$, $p < 0.001$), inhibited ATP generation (20 mM glucose: 100 ± 24.7%; +Cxcl14: 1, 20, 40 and 80 ng/mL: 89.2 ± 16.8, 76.7 ± 23.4, 45.9 ± 8.6 and 35.5 ± 8.8%; 5 μM oligomycin A: 14.6 ± 3.8%; $n = 8$, $p < 0.001$) and it also reduced glucose-stimulated elevation in intracellular calcium. CXC-receptor mRNA expression profiling indicated that Cxcr4 and Cxcr7 are the most abundant family members in islets, and β-arrestin experiments demonstrated that these receptors are activated by the native ligand Cxcl12 (Cxcr4, % relative to basal: 100 ± 6.4%; +1 μM Cxcl12: 491.4 ± 37.2%. Cxcr7, % relative to basal: 100 ± 8.3%; +1 μM Cxcl12: 891.3 ± 53% $p < 0.001$). However, Cxcl14 did not promote β-arrestin recruitment at Cxcr4 or Cxcr7 and it did not antagonise Cxcl12 activation of these receptors.

Conclusion: Cxcl14 is expressed by islet δ-cells where it may have paracrine effects to inhibit GSIS through inhibition of glucose uptake, leading to reductions in intracellular ATP and calcium levels. It does not signal via the highly expressed islet Cxcr4 or Cxcr7 receptors. These observations, together with the previously reported association of Cxcl14 with obesity and glucose homeostasis, suggest that Cxcl14 down-regulation could be explored as a novel approach to treat type 2 diabetes.

Beta cell resident hypoxia inducible factor prolyl 4-hydroxylase PHD3 is involved in the regulation of glucose homeostasis

F. Cuozzo, D. Nasteska, A. Thakker, D.A. Tennant, D.J. Hodson;
University of Birmingham, Birmingham, UK.

Background and aims: The prolyl 4-hydroxylase PHD3 belongs to the α-ketoglutarate-dependent dioxygenase family of enzymes involved in oxygen-dependent regulation of cell phenotype. While its role in tumorigenesis and cancer growth has been extensively studied, scarce reports exist regarding the impact of PHD3 on insulin secretion. We have generated β-cell-specific PHD3 knockout mice ($\beta PHD3^{-/-}$) and investigated the phenotype under normal and diabetogenic diet conditions with a purpose of providing the first blueprint for PHD3-regulated glucose homeostasis.

Materials and methods: $\beta PHD3^{-/-}$ mice were generated by crossing Ins1Cre animals with those bearing a floxed *Egln3* gene (encoding for PHD3). Male and female $\beta PHD3^{-/-}$ mice and wild type (WT) littermates were kept on standard chow and/or high fat diet containing 60% fat (HFD). Gene and protein levels were detected by qPCR and western blot, respectively. Insulin secretion *in vitro* was measured by HTRF assay. Islet Ca^{2+}, ATP/ADP and cAMP dynamics were captured by high-speed spinning disk microscopy. Body weight was measured weekly. Glucose tolerance was assessed by intraperitoneal glucose tolerance test (IPGTT), with a glucose load of 1–2 g/kg body weight.

Results: $\beta PHD3^{-/-}$ mice exhibited reduced islet *Egln3* (0.55-fold *vs* WT, $p < 0.01$) and reduced PHD3 protein expression (0.6-fold *vs* WT, $p < 0.05$). When fed standard chow, $\beta PHD3^{-/-}$ mice had similar body weight to WT and showed no changes in glucose tolerance. Glucose- and fatty acid-stimulated insulin secretion, Ca^{2+} fluxes, as well as glucose-stimulated ATP and cAMP levels were all unaffected by PHD3 deletion. HFD induced similar weight gain in male $\beta PHD3^{-/-}$ and WT mice. Glucose levels during IPGTT were higher at 60 and 90 min after 4 weeks of HFD (60 min: 25.6 *vs*19.7 mmol/L, $\beta PHD3^{-/-}$ *vs* WT; 90 min: 20 *vs* 14.5 mmol/L, $\beta PHD3^{-/-}$ *vs* WT $p < 0.01$), and at 30 and 60 min after 8 weeks of HFD (30 min: 23.8 *vs* 20.2 mmol/L, $\beta PHD3^{-/-}$ *vs* WT; 60 min: 19.2 *vs* 15.8 mmol/L, $\beta PHD3^{-/-}$ *vs* WT $p < 0.05$). *In vitro* insulin secretion at 4 weeks of HFD was increased following stimulation with glucose (4.8 *vs* 2.6 ng/ml, $\beta PHD3^{-/-}$ *vs* WT; $p < 0.05$) and incretin mimetic (12 *vs* 7.2 ng/ml, $\beta PHD3^{-/-}$ *vs* WT; $p < 0.05$), although ATP/ADP rises were blunted ($\Delta F = 0.02$ *vs* 0.06 AU, $\beta PHD3^{-/-}$ *vs* WT; $p < 0.01$). However, by 8 weeks of HFD, glucose was unable to significantly stimulate insulin from isolated islets in $\beta PHD3^{-/-}$ animals (3 mM glucose: 8.8 vs 9 ng/ml, $\beta PHD3^{-/-}$ *vs* WT; 16.7 mM glucose: 14 *vs* 19.8 ng/ml, $\beta PHD3^{-/-}$ *vs* WT) and this was accompanied by defective glucose-stimulated Ca^{2+} fluxes ($\Delta F = 0.19$ *vs* 0.21 AU, $\beta PHD3^{-/-}$ *vs* WT; $p < 0.05$).

Conclusion: PHD3 expression in β-cells appears to be critical in preventing β-cell failure under metabolic stress, such as high fat diet. Elucidating the mechanisms by which PHD3 maintains insulin secretion and glucose homeostasis may be useful for designing new drug therapies for type 2 diabetes mellitus.

Fetuin-A impairs islet differentiation and function via inhibition of TGFbeta-1 signalling

F. Gerst[1,2], A.-K. Fritz[3], E. Lorza Gil[1,2], G. Kaiser[1,2], E. Wolf[4], H.-U. Haering[1,2], S. Ullrich[1,2], E. Kemter[4];
[1]University of Tuebingen, IDM of the Helmholtz Center Munich, Tuebingen, [2]German Center for Diabetes Research (DZD e.V.), Tuebingen, [3]Department Endocrinology, Diabetology, Angiology, Nephrology and Clinical Chemistry, Internal Medicine IV; University of Tuebingen, Tuebingen, [4]Molecular Animal Breeding and Biotechnology, Faculty of Veterinary Medicine; LMU Munich, Munich, Germany.

Background and aims: Fetuin-A is a foetal glycoprotein sustaining cell proliferation. Plasma concentration of fetuin-A declines towards the end of gestation and its expression is restricted to hepatocytes throughout adulthood. During obesity, fetuin-A is upregulated in the fatty liver. Previous observations suggest that fetuin-A impairs glucose-induced insulin secretion (GIIS) of isolated adult human islets. In contrast to the adult islets, the new born islets are largely glucose unresponsive and proliferative. Beta-cell differentiation is accompanied by activation of TGFβR signalling, a pathway sustaining also GIIS. This study aims to assess whether fetuin-A impairs islet cell differentiation and function via inhibition of TGFβR signalling.

Materials and methods: Freshly isolated, glucose-unresponsive pig neonatal islet cell clusters (NICCs) were maturated for 10 d in serum-free Ham's F10 medium containing 10 mM glucose, 50 μM IBMX, 2 mM L-glutamine, 10 mM nicotinamide, 1.6 mM $CaCl_2$, 0.6 mg/ml human serum

albumin (HSA) and supplemented for the last 4 d with 0.6 mg/ml fetuin-A or HSA (as control). Adult human islets obtained from the ECIT Centers were cultured for 1 h or 2 d in serum-free CRML1066 medium containing 5 mM glucose and supplemented with fetuin-A or HSA. Insulin secretion was assessed in static incubations. Gene expression was analysed by RT-PCR, protein expression by western blotting and their subcellular localisation by confocal microscopy.

Results: The maturation of NICCs was accompanied by increased expression of PDX1, insulin, glucagon and somatostatin. SMAD2/3 phosphorylation, the mRNA level of TGFBI, an extracellular matrix component which sustains beta-cell function, and p16/INK4a protein, a beta-cell maturation marker, were upregulated in the matured NICCs suggesting activation of TGFβR signalling. Moreover, PDX1 and p16/INK4a proteins accumulated in the nuclei upon maturation. Matured NICCs displayed a modest GIIS (1.35-fold of basal secretion) which was potentiated by palmitate (2-fold) and forskolin (3-fold). When maturation was carried out in the presence of fetuin-A, the NICCs acquired no glucose responsiveness. Forskolin-mediated potentiation of GIIS was compromised while palmitate still stimulated GIIS. The mRNA levels of PDX1, insulin and glucagon remained low. TGFβR signalling was inhibited in NICCs exposed to fetuin-A, as suggested by the reduced phosphorylation of SMAD2/3 and TGFBI mRNA level. Furthermore, the transcript of RanBP3L, a protein mediating the nuclear export of SMADs, was increased. In addition, fetuin-A counteracted the nuclear accumulation of PDX1 and p16/INK4a. In adult human islets, fetuin-A inhibited GIIS and reduced phosphorylation of SMAD2/3 and SMAD1/5/8 in a TLR4 independent manner.

Conclusion: These observations suggest that fetuin-A impairs beta-cell maturation, differentiation and function via inhibition of TGFβR signalling.

Characterisation of a mechanotransductive signalling pathway in human islets of Langerhans: implications for beta cell fate

A. Galli[1], E.S. Di Cairano[1], E. Maffioli[2], E. Sogne[3], F. Bertuzzi[4], P. Milani[3], C. Lenardi[3], G. Tedeschi[2], C. Perego[1];
[1]Pharmacological and Biomolecular Sciences, University of Milan, Milan, [2]Veterinary medicine, University of Milan, Milan, [3]Physic, University of Milan, Milan, [4]Niguarda Cà Granda Hospital, Milan, Italy.

Background and aims: The interaction between cells and extracellular environment plays a pivotal role in the control of cell differentiation and fate, both in physiological and pathological conditions. Like other cells, β-cell behaviour is strongly influenced by extracellular matrix (ECM) interactions. While the involvement of the extracellular environment "chemistry" in this process has been greatly investigated, the contribution of the ECM physical properties has not been completely clarified. Taking advantage of the ability of our group to fabricate transition metal oxide nanostructured surfaces with multiscale controlled disorder as substrates to study the effect of nanoscale topography, aim of the proposed research was to characterize the mechanotransductive signalling complexes in human islets of Langerhans and verify their involvement in the regulation of β-cell fate.

Materials and methods: Cluster-assembled zirconia nanotopographies with specific roughness parameters were produced by Supersonic cluster beam deposition. Human islets were grown on these substrates for up to 15 days and the mechanotrasductive signalling complexes were isolated and characterized by proteomic analysis and super-resolution imaging techniques. β-cell function was assessed by measuring insulin secretion by ELISA assay under basal and stimulated conditions.

Results: β-cell viability and function was improved on nanostructured substrates as revealed by TUNEL assay and insulin secretion. Immunofluorescence analysis revealed modification of cell-substrate adhesion complexes, reorganization of the actin cytoskeleton and modification of the nuclear architecture. Proteomic changes were congruent with cell morphological and functional changes and showed that β-cells respond to environmental mechanical forces through a number of mechanosensors, including integrins and mechanosensitive ion channels (upregulation of Gene Ontology terms GO:0005925). Activation of mechanosensors in turn, caused the up-regulation of proteins important for actin polymerization (GO:0005856), nuclear architecture (GO:0031891) and import/export, thus modifying the program of gene transcription and cellular modeling.

Conclusion: Characterizing the mechanotrasductive signalling pathways may offer a unique possibility to identify potential targets of intervention in diabetes mellitus.

The mechanism of impaired incretin responsiveness in the pancreatic islets of obese type 2 diabetes: a study of the ZFDM rat

N. Yokoi, T. Hayami, S. Hidaka, A. Kawabata, H. Takahashi, S. Seino;
Kobe University, Kobe, Japan.

Background and aims: The sensitivity of the pancreatic islets to the actions of the incretin hormones is often decreased in obese type 2 diabetes. However, the mechanism of impaired incretin responsiveness remains unknown. In this study, we tried to elucidate the mechanism of impaired incretin responsiveness in the pancreatic islets of an animal model of obese type 2 diabetes, the Zucker fatty diabetes mellitus (ZFDM) rat.

Materials and methods: Eight- and twelve-week-old male lean (*fa/+*) and fatty (*fa/fa*) rats were used. Pancreatic islets of *fa/fa* rats were further divided into non-large and large islets (diameter more than 300 μm). Histological analysis of the pancreas, insulin secretion experiment, transcriptome analysis, metabolome analysis, and western blotting of isolated islets were performed.

Results: In *fa/fa* male rats, the number of large islets increased with age. Incretin-induced insulin secretion was diminished in the large islets at 12 weeks of age. Expressions of glycolysis- and lactate production-related genes were increased while those of the TCA cycle- and the malate-aspartate shuttle-related genes were decreased in the large islets. Glycolysis-related metabolites and lactate were increased but glutamate production from glucose was decreased in the large islets. O-GlcNAcylation of proteins, which may compete with serine/threonine phosphorylation by PKA, was increased in the large islets.

Conclusion: An age-dependent increase of large islets exhibiting dysregulated glucose metabolism, defective glutamate production, and increased O-GlcNAcylation may cause impaired incretin responsiveness in obese type 2 diabetes.

The selective serotonin reuptake inhibitor fluoxetine improves glucose homeostasis in mice and humans: effects on insulin secretion and functional beta cell mass

B. Liu[1], C.D. Moulton[2], I. Ruz-Maldonado[1], K. Toczyska[1], G.C. Huang[1], M.G. Zariwala[3], K. Ismail[2], P.M. Jones[1], S.J. Persaud[1];
[1]Department of Diabetes, Faculty of Life Sciences & Medicine, King's College London, London, [2]Department of Psychological Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, [3]Faculty of Science & Technology, University of Westminster, London, UK.

Background and aims: We have previously reported that therapeutically relevant concentrations of fluoxetine (Prozac) are well tolerated by isolated β-cells and acute exposure to fluoxetine stimulated insulin secretion, increased β-cell proliferation and reduced apoptosis *in vitro*. The aim of the current study was to investigate the effect of fluoxetine on β-cell function and glucose homeostasis in obese mice and humans with impaired glucose homeostasis.

Materials and methods: Groups of 5 male ob/ob mice (56.0 ± 0.8 g) were administered 4 doses of fluoxetine (10 mg/kg body weight) or DMSO (vehicle) intraperitoneally over 2 weeks before being subjected to intraperitoneal glucose tolerance tests (2 g/kg glucose). BrdU (1 mg/ml) was provided in drinking water for 7 days prior to sacrifice and β-cell proliferation was identified in pancreas sections by immunohistochemistry using antibodies against BrdU and insulin. Glucose-dependent insulin secretion from islets isolated from these mice was assessed in perifusion and quantified by radioimmunoassay. The effects of 1 μM fluoxetine on insulin secretion from islets isolated from an obese (BMI = 36 kg/m^2) human donor was also determined by perifusion and radioimmunoassay. In a multi-ethnic primary care cohort with newly diagnosed type 2 diabetes (T2D), patients prescribed fluoxetine (n = 14) were compared with controls (n = 615) for 1-year changes in plasma insulin and HbA1c; linear regression analysis was used to adjust for potential confounders.

Results: Fluoxetine improved glucose tolerance in ob/ob mice (blood glucose concentrations, control vs fluoxetine; T = 0: 6.7 ± 0.8 mM glucose vs 6.5 ± 0.5; P > 0.5; T = 210 min: 36.3 ± 8.5 mM vs 16.5 ± 2.4; P < 0.05; n = 5), most likely a consequence of increased β-cell proliferation (BrdU positive β-cells/islet: 0.30 ± 0.17 vs 12.15 ± 2.88; n = 20; P < 0.001) and enhanced insulin secretion in response to 20 mM glucose (AUC, pg insulin/20 min: 304.8 ± 28.7 vs 464.7 ± 34.2; n = 4; P < 0.001). Acute exposure of obese donor islets to 1 μM fluoxetine resulted in rapid and reversible potentiation of glucose-stimulated insulin secretion (AUC: 20 mM glucose: 202 ± 23; +1 μM fluoxetine: 316 ± 25; n = 4; P < 0.05). Patients with newly diagnosed T2D who were prescribed fluoxetine for depression showed significant improvement in plasma insulin at one year compared to controls [β = 13.35 (1.84–23.85), p = 0.023] after adjustment for age, gender, ethnicity vascular risk factors and change in depressive symptoms. Fluoxetine treatment was also associated with non-significant reduction in HbA1c (fluoxetine: −0.54% [SD 2.02]; control: −0.05% [SD 1.24]).

Conclusion: These data support a role for fluoxetine in improving β-cell function in obese conditions and in patients with early T2D, and *in vitro* assessments in isolated human islets indicate that fluoxetine directly stimulates insulin secretion. Repurposing of fluoxetine thus represents a novel therapeutic strategy for the management of T2D.

Prolactin protects beta cells against oxidative stress through HSPB1

L. Labriola[1], R.A.M. Wailemann[1], A.F. Dos Santos[1], V.M. Gomes[1], R.P. Silva[1], A. Laporte[2,3], F.C. Meotti[1], W.R. Terra[1], G. Palmisano[1], S. Lortz[2], L.F. Terra[1];
[1]University of Sao Paulo, Sao Paulo, Brazil, [2]Institute of Clinical Biochemistry, Hannover Medical School (MHH), Hannover, Germany, [3]Institute of Medical Biochemistry and Molecular Biology, University Medicine Greifswald, Greifswald, Germany.

Background and aims: Maintaining islet cell viability in vitro, although challenging, appears to be a strategy for increasing the outcome of pancreatic islet transplantation. We have shown that heat shock protein B1 (HSPB1) mediates prolactin (PRL) beta-cell inhibition of apoptosis. Since the role of HSPB1 in beta-cells is still unclear, we explored the molecular mechanisms by which HSPB1 mediates PRL-induced beta-cell cytoprotection.

Materials and methods: Wild type, HSPB1 silenced or overexpressing MIN6 cells were used as beta-cell models. Biochemical and cell biology parameters such as protein levels, oxidative stress quantification and cell viability were analysed by HPLC-mass spectrometry, western blotting, and fluorescent bioassays among other techniques.

Results: Lysates from PRL and/or cytokine-treated MIN6 beta-cells were subjected to HSPB1 immunoprecipitation. Of the 130 client proteins identified by mass spectrometry, 60 were interacting with HSPB1 under both situations whereas 49 were only detected in the presence of PRL and cytokines. Of note were oxidative stress resistance proteins such as MnSOD, CuZnSOD and PRDXs. We then investigate whether HSPB1-knocked down cells would show a different sensibility towards oxidative stress. Our results indicated not only that PRL was able to protect both control MIN6 cell lines against menadione-induced toxicity (EC50: 11.88 and 14.97 μM for control and PRL treated cells respectively), but also that this effect was mediated by HSPB1, since its silencing completely abrogated PRL's effect on cytoprotection (EC50: 11.61 and 11.91 μM for control and PRL, respectively). Using cells expressing cytosolic or mitochondrial variants of the D-amino acid oxidase (DAAO), we observed that HSPB1 was important mainly for the protection against ROS produced in mitochondria displaying an even greater (around 40%) decrease in the EC50 of MIN6-shHSPB1 cells when compared to that of control cells. HSPB1 silenced cells presented a higher mitochondria-targeted hydroethidine mean fluorescence signal than control cells (at 14 μM menadione. MIN6: 363.7%: MIN6-Sc: 347.7%; MIN6-shHSPB1 cells: 705.4%). HSPB1 overexpression led to opposite effects such as a significant increase of the EC50 of both menadione (16.0 μM vs. 14.49 μM for control cells) and H2O2 (32.58 μM vs. 26.2 μM for control cells) and also a reduced overall oxidative stress shown by DCF fluorescence. PRL treatment, HSPB1 silencing or overexpression did not change the expression of antioxidant enzymes; but influenced glutathione cell content reduction state (GSH/GSSG ratio was decreased in shHSPB1 cells by 50% compared to control cells) and glucose-6-phosphate dehydrogenase (G6PD) activity (MIN6-shHSPB1 cells displayed approximately 40% lower levels of G6PD activity).

Conclusion: We have shown that HSPB1 is important for pro-survival effects against ROS-induced beta-cell death. Altogether our results outline the importance of further studies investigating the importance of HSPB1 for beta-cell viability, since this could lead to the mitigation of beta-cell death through the up-regulation of an endogenous protective pathway.

A novel prolactin-receptor target in pancreatic beta cells

C. Huang[1], G. Makkar[1], V. Shrivastava[1], B.D. Kyle[2], A.P. Braun[2], F.C. Lynn[3];
[1]Biochemistry and Molecular Biology, University of Calgary, Calgary, [2]Physiology and Pharmacology, University of Calgary, Calgary, [3]Surgery, University of British Columbia, Vancouver, Canada.

Background and aims: Pancreatic islets adapt to the increase in insulin demand during pregnancy by upregulating insulin synthesis and secretion. One of the most highly up regulated genes in the islets during pregnancy is Lrrc55, an auxiliary protein, or γ-subunit of the large conductance, Ca^{2+}-activated (BK) channel. BK channel activity contributes to the regulation of insulin secretion; it also regulates apoptosis, as beta cells of BK channel-null mice have increased susceptibility to apoptosis. While BK channel activity is increased in the presence of Lrrc55, whether Lrrc55 participates in the regulation of insulin secretion and apoptosis in pancreatic islets is unknown. The aim of this study is to determine the role of Lrrc55 in pancreatic beta cells.
Materials and methods: Lrrc55 was overexpressed in INS-1 cells, MIN-6 cells, and isolated mouse islets using an adenovirus vector; adenoviral expression of GFP was used as a control. Beta cells were treated with 33mM glucose (HG) and 0.5 mM palmitate (PA) to induce cell death. Expression of pro-apoptotoc and pro-survival molecules of the ER signaling pathways were determined by qPCR or Western immunoblotting. Dead cells were measured by TUNEL. Intracellular calcium store was measured by Fura-4.
Results: Under non-pregnant condition, Lrrc55 expression is barely detectable in the pancreatic islets. During pregnancy, Lrrc55 expression was upregulated by >60-fold in islets isolated from the wild type mice but in heterozygous prolactin receptor null mice, it was only up regulated by 30-fold. Furthermore, this increase in Lrrc55 expression was only detected in islets and not in other tissues. Overexpression of Lrrc55 in beta cells protected them from glucolipotoxicity-induced apoptosis, accompanied by up regulation of pro-survival signals and down regulation of pro-apoptotic signals of the ER stress pathway. Expression of Lrrc55 prevented calcium depletion induced by glucolipotoxicity, which may contribute to its anti-apoptotic effect. Lastly, although Lrrc55 can facilitate BK channel activity, overexpression of Lrrc55 had minimal effect on glucose-stimulated insulin secretion, although it prevented the glucolipotoxicity-induced reduction in insulin synthesis.
Conclusion: Lrrc55 is a novel pro-survival factor that is up regulated in islets during pregnancy and it prevents conversion of adaptive unfolded protein response to unresolved ER stress and apoptosis in beta cells. Lrrc55 could be a potential therapeutic target in diabetes as it could reduce ER stress and promote beta-cell survival.

Impact of mitochondrial dysfunction on pancreatic islet cell composition in a mouse model of premature ageing

X. Yu[1], C. Arden[1], C. Chen[2], M. White[1], D. Turnbull[2], L. Greaves[2], M. Walker[1];
[1]Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, [2]Institute of Neuroscience, Newcastle University, Newcastle upon Tyne, UK.

Background and aims: Inherited mitochondrial DNA mutations can lead to maternally inherited diabetes and deafness (MIDD). There is evidence that mitochondrial mutations accumulate with age, and contribute to the ageing process. The $PolgA^{D257A}$ mutator mouse is a model of premature ageing due to the accelerated accumulation of mitochondrial DNA mutations, and has been previously shown to develop impaired insulin secretion with age. The aim of this project was to measure pancreatic islet cell mitochondrial protein expression and islet cell composition in aged PolgA mutator mice and age matched wild type controls.
Materials and methods: Quantitative quadruple immunofluorescence was used to detect the OXPHOS deficiency by measuring the expression of mitochondrial respiratory chain proteins. A triple immunofluorescence was applied to study the endocrine cell composition and endocrine function in pancreatic islets. Experiments were conducted in pancreas tissue from 44 week old PolgA mutator mice ($n = 5$) and their age-matched wild type controls ($n = 5$).
Results: We found evidence of mitochondrial complex I deficiency in islets from PolgA mice compared to their age-matched controls (Unpaired t test, $P < 0.05$). Triple immunofluorescence showed that the PolgA mutator mice had a lower β-cell percentage (mean ± SEM; 71.8 ± 4% vs 89.3 ± 4% $P < 0.05$) and a higher α-cell percentage (29.6 ± 4% vs 12.5 ± 5%; $P < 0.05$) compared to the wild type controls. However, there was no difference in islet size between the mutator and control mice. We also found that the level of insulin expression in the pancreatic β-cells was decreased in the PolgA mutator versus wild type control mice ($P < 0.05$).
Conclusion: This study shows that age-related mitochondrial dysfunction is associated with a change in islet cell composition towards more α-cells, fewer β-cells with decreased insulin expression. These changes are predicted to predispose to diabetes. Further work is required to determine whether the changes in islet cell composition are due to transdifferentiation driven by mitochondrial dysfunction.

Pancreatic beta cell-specific deletion of CR6-interacting factor-1 (CRIF1) causes blunted first phase insulin secretion and altered islet morphology

H. Hong[1], K. Joung[2], Y. Kim[3], J. Chang[1], J.-H. Park[4], H. Kim[2], M. Shong[1,2];
[1]Medical Science, Chungnam National University School of Medicine, Daejeon, Republic of Korea, [2]Internal Medicine, Chungnam National University Hospital, Daejeon, Republic of Korea, [3]University of Colorado Denver Anschutz Medical Campus Barbara Davis Center for Diabetes, Aurora, USA, [4]Physiology, Keimyung University School of Medicine, Daegu, Republic of Korea.

Background and aims: A common factor in the etiology of type 2 diabetes mellitus (T2DM) is insufficient pancreatic beta cell function to meet peripheral insulin demand. The emphasis on pancreatic beta cells is reinforced by genome-wide association studies (GWAS) of T2DM which show that the beta cell is the main culprit in T2DM. The basic function of pancreatic beta cells is to regulate glucose homeostasis by secreting insulin. Mitochondrial function in beta cells plays an important role in controlling insulin secretion and beta cell mass. However, the mechanisms underlying progressive beta cell failure caused by mitochondrial OxPhos dysfunction are largely unknown. To investigate whether mitochondrial OxPhos dysfunction gradually leads to diabetes through progressive dysfunction of beta cells, we developed knockout mice with reduced mitochondrial OxPhos function by deleting *Crif1*, a critical protein for translation of OxPhos polypeptides within the mitochondria.
Materials and methods: The study has been carried out along the "Principles of laboratory animal care" and according to the national law, if applicable. Mice bearing islet beta cell-specific mitochondrial dysfunction were developed by breeding CRIF1 flox/flox mice with RIP2-cre mice. Metabolic parameters such as body weight and glucose tolerance were measured. The mitochondrial oxygen consumption rate (OCR) was measured using a Seahorse XF-24 extracellular flux analyzer for determining mitochondrial function. The GSIS (glucose stimulated insulin secretion) assay perifusion experiment was used to determine islet function. Also, Histomorphological analysis of islets was performed to examine the change of islet structure and composition.
Results: Heterozygous *Crif1*-deficient mice ($Crif1^{beta+/-}$) showed no difference in body weight or glucose tolerance compared to control mice ($Crif1^{beta+/+}$). In ex-vivo islets, basal and maximal respiratory capacity measured by OCR was not different between the two groups. However, glucose-induced OCR was significantly lower in $Crif1^{beta+/-}$ mice than $Crif1^{beta+/+}$ mice at 11 weeks. Induction of first phase insulin secretion by raising glucose from basal (5 mmol/l) to 11 mmol/l was blunted in

Crif1$^{beta+/-}$ mice compared to *Crif1*$^{beta+/+}$ mice at 14 and 22 weeks. In *Crif1*$^{beta+/-}$ mice at 18 and 22 weeks, islet area was enlarged, resulting from increased beta cell proliferation. In addition, islets of *Crif1*$^{beta+/-}$ mice had an increased alpha to beta cell ratio, with alpha cells located within the central portion of islets. We propose that beta cell dysfunction may increase alpha cell number through increased alpha cell proliferation or trans-differentiation from beta cells.

Conclusion: Beta cell specific Crif1 haploinsufficiency resulted in defect of first phase insulin secretion, and caused islet cell composition change as well as proliferation of beta cell for a compensation to maintain metabolic homeostasis. These results suggest that mitochondrial OxPhos function of beta cell has roles for cell composition of islet as well as insulin secretion

The KINGS Ins2$^{+/G32S}$ mouse: a novel model of diabetes

A.L.F. Austin, C. Gentry, D. Andersson, S. Sharp, S. Bevan, P.M. Jones, A.J.F. King;
King's College London, London, UK.

Background and aims: Spontaneous hyperglycaemia was discovered in male mice in a C57Bl/6 colony at King's College London (KCL). Through gene screening, a spontaneous polymorphism of the *Ins2* gene (*Ins2*$^{+/G32S}$) was found with a substitution of glycine to serine at position 32 of the B chain of the preproinsulin molecule. We have named this mouse the **K**CL **in**sulin **G**32**S** (KINGS mouse). The human heterozygous variant of this mutation causes neonatal diabetes. To fully establish the phenotype of these mice, animals were monitored from weaning and assessed at different ages to determine onset and extent of hyperglycaemia, glucose tolerance, islet function and islet morphology.

Materials and methods: Random blood glucose concentrations were measured from weaning at 3 weeks to 20 weeks of age and animals with blood glucose above 16.7mmol/l deemed hyperglycaemic. Intraperitoneal glucose tolerance tests were performed at 4 weeks, 10 weeks and 20 weeks. Islet function was measured in isolated islets from 10 week old mice by static incubation. Islet morphology was investigated at 10 weeks using transmission electron microscopy to define islet ultrastructure.

Results: *Ins2*$^{+/G32S}$ males showed onset of hyperglycaemia at 30 ± 1.5 days and by 10 weeks blood glucose concentrations were 26.7 ± 0.9 mmol/l vs 9.4 ± 0.5 mmol/l in wild type littermates ($p < 0.001$, t-test, $n = 9$–11). Blood glucose levels in female *Ins2*$^{+/G32S}$ mice at 10 weeks were elevated but not hyperglycaemic (12.3 ± 0.8 mmol/l vs 8.9 ± 0.5 mmol/l in wild type littermates ($p < 0.007$, t-test, $n = 9$–10). Area under the curve from glucose tolerance tests showed that *Ins2*$^{+/G32S}$ males have impaired glucose tolerance at 4, 10 and 20 weeks compared to wild type controls. This progressively worsened from 4 to 10 weeks and from 10 to 20 weeks (4 weeks = 2503 ± 80 mmol/l/120 mins; 10 weeks = 3318 ± 167 mmol/l/120 mins; 20 weeks = 4022 ± 216 mmol/l/120 mins; $p = 0.022$ (4 vs 10 weeks), $p = 0.02$ (10 vs 20 weeks); $n = 5$–7, One-way ANOVA, Holm-Sidak post-hoc). Wild type mice showed no significant change over time with an average area under the curve of 1869 mmol/l/120 mins. Female *Ins2*$^{+/G32S}$ mice were glucose intolerant by 4 weeks (area under the curve = 2483 ± 145 mmol/l/120 mins vs 1438 ± 41 mmol/l/120 mins in wild types, $p < 0.001$) which did not deteriorate over time. *Ins2*$^{+/G32S}$ males at 10 weeks had a 95% reduction in glucose stimulated (20 mmol/l) insulin secretion (0.04 ± 0.01 ng/islet/h vs wild type: 0.86 ± 0.16 ng/islet/h; $p < 0.001$, $n = 5$) and a 97% reduction in insulin content (1.19 ± 0.15 ng vs wild type: 37.3 ± 4.9 ng; $p < 0.001$, $n = 5$). *Ins2*$^{+/G32S}$females at 10 weeks had a 63% reduction in glucose stimulated (20 mmol/l) insulin secretion (0.205 ± 0.014 ng/islet/h vs wild type = 0.552 ± 0.07 ng/islet/h; $p < 0.001$, $n = 5$) and a 69% reduction in insulin content (6.1 ± 0.6 ng vs wild type = 19.4 ± 1.5 ng; $p < 0.001$, $n = 5$). Transmission electron microscopy revealed ultrastructure disturbances in both genders with the *Ins2*$^{+/G32S}$ males in particular showing a depletion of insulin granules within the beta cells. They also presented with swollen mitochondria and a reduction in mitochondrial cristae, indicative of endoplasmic reticulum stress.

Conclusion: KINGS *Ins2*$^{+/G32S}$ mice have impaired glucose homeostasis with the male mice showing a more severe and progressive phenotype. In particular these mice show signs of impaired islet function and morphology as well as signs of endoplasmic reticulum stress. These mice represent a novel preclinical model of human diabetes with enhanced translational validity.

Overexpression of eukaryotic translation initiation factor 2A (eIF2A) in pancreatic beta cells attenuates diabetes progression in Akita mice

E. Panzhinskiy[1], G. Soukhatcheva[2], S. Skovsø[1], D.A. Dionne[1], J.S. Wildi[1], S. Marcil[1], X. Hu[1], C.B. Verchere[2], E. Jan[3], J.D. Johnson[1];
[1]Cellular and Physiological Sciences, University of British Columbia, Vancouver, [2]Surgery, University of British Columbia, Vancouver, [3]Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada.

Background and aims: Endoplasmic reticulum (ER) is a key mechanism mediating beta-cell apoptosis in diabetes. Previously, we demonstrated that overexpression of an alternative translation initiation factor eIF2A, that can initiate translation despite inhibition of protein synthesis during ER stress, protects beta cells *in vitro* from ER stress-induced apoptosis. Therefore, we investigated the protective mechanism of eIF2A in beta cells *in vivo* using Akita mice, which carry a mutant *Ins2*allele that produces an insulin protein which cannot fold properly, leading to spontaneous diabetes due to ER stress-induced apoptosis.

Materials and methods: For beta-cell specific overexpression,we designed adeno-associated virus 6 (AAV6), encoding either eIF2A-GFP or control GFP and driven by an insulin promoter. 1.5 x 10^11 viral particles were injected into the pancreatic duct of 6-week old *Ins2*$^{Akita/WT}$ female mice randomized into two groups. Two independent cohorts of 5–6 mice per group were used. Body weight and 4h fasting blood glucose levels were monitored weekly. Glucose tolerance and glucose-stimulated insulin secretion were assessed 3 weeks after AAV injection. Plasma insulin and proinsulin levels were measured using ELISA. Pancreatic islets or perfused pancreas sections were collected for RNA or immunofluorescent staining 4 weeks post AAV injection.

Results: As expected, *Ins2*$^{Akita/WT}$mice given GFP-control AAV6 showed increased fasting blood glucose levels with age, but this increase was attenuated by eIF2A overexpression in beta cells. *Ins2*$^{Akita/WT}$mice with eIF2A overexpression ($n = 10$) had lower fasting blood glucose levels compared to GFP control mice ($n = 11$) at 2 weeks (12.1 ± 1.1 vs 16.8 ± 0.7 mmol/l, $p = 0.0017$) and 3 weeks (11.5 ± 1.0 vs 17.0 ± 0.8 mmol/l, $p = 0.0005$) after AAV6 ductal injections. Beta-cell specific overexpression of eIF2A had no effect on body weight gain at any time point when compared to GFP controls. Three weeks after viral injection, *Ins2*$^{Akita/WT}$mice overexpressing beta-cell specific eIF2A showed significantly improved glucose tolerance when compared with controls transduced with AAV6-GFP alone (AUC 1631 ± 140 vs 2222 ± 85 respectively, $n = 10$–11, $p = 0.0067$). Overexpression of eIF2A in *Ins2*$^{Akita/WT}$ was associated with increased insulin secretion at 15 min post glucose challenge (0.73 ± 0.09 vs 0.47 ± 0.07 ng/ml, $n = 4$, $p = 0.04$) in comparison to GFP overexpressing *Ins2*$^{Akita/WT}$mice. In the fed state, no significant difference in plasma insulin or proinsulin levels were detected between eIF2A-GFP and control GFP groups. qPCR analysis revealed 35 ± 12% ($n = 4$, $p = 0.04$) decrease in mRNA levels of pro-apoptotic ER stress marker CHOP in pancreatic islets isolated from *Ins2*$^{Akita/WT}$ mice with eIF2A overexpression compared to GFP control. Furthermore, we observed 22.7 ± 8% ($n = 5$) decrease in intensity of immunofluorescent staining for ER stress marker BiP in pancreatic islets of *Ins2*$^{Akita/WT}$mice overexpressing beta-cell specific eIF2A compared to controls, despite no difference in beta-cell area between groups.

Conclusion: We conclude that overexpression of eIF2A in pancreatic beta cells preserves beta cell function in *Ins2*$^{Akita/WT}$ mice.

Metallothionein 1 inhibits glucose-stimulated insulin secretion and is differentially regulated in conditions of beta cell compensation and failure

M. Bensellam[1], Y.-C. Shi[2], J. Chan[2], D.R. Laybutt[2], J.-C. Jonas[1];
[1]IREC, EDIN, Université catholique de Louvain, Brussels, Belgium, [2]Garvan Institute of Medical Research, Sydney, Australia.

Background and aims: The mechanisms responsible for β cell compensation in obesity and for β cell failure in type 2 diabetes (T2D) are poorly defined. Metallothioneins play a role in both Zn^{2+} homeostasis and the regulation of cellular redox state. The mRNA levels of several metallothionein genes are upregulated in islets from subjects with T2D, but their role in β cells is not clear. Here we examined: 1) the temporal changes of islet *Mt1* and *Mt2* gene expression in models of β cell compensation and failure, and 2) the role of *Mt1* and *Mt2* in β cell function and glucose homeostasis.
Materials and methods: *Mt1* and *Mt2* expression was assessed in islets from control lean (chow diet) and diet-induced obese (DIO) mice (8 weeks high fat diet), and prediabetic (6-week-old) and diabetic (16-week-old) *db/db* mice and age-matched *db/+* (control) mice. *Mt1-Mt2* double knockout (KO) mice, *Mt1* overexpressing transgenic mice (Tg-*Mt1*) and corresponding control mice were studied. *Mt1* and *Mt2* were inhibited in MIN6 cells by small interfering RNAs. mRNA levels were assessed by real-time RT-PCR, plasma insulin and islet metallothionein levels by ELISA, glucose tolerance by *i.p.* glucose tolerance tests (*ip*GTT) and fasting-1h refeeding tests, insulin secretion by RIA, cytosolic free Ca^{2+} with Fura-2 LR, NAD(P)H by autofluorescence and cytosolic thiol redox state using roGFP1 ratiometric thiol redox probe.
Results: Increased plasma insulin levels (β cell compensation) correlated with marked downregulation of *Mt1* and *Mt2* mRNA levels in islets of DIO mice (*Mt1*: ~4-fold, $p < 0.01$ and *Mt2*: ~4.5-fold, $p < 0.05$), and prediabetic *db/db* mice (both by ~2-fold, $p < 0.01$). These findings were confirmed in β cells of DIO mice (β cell-specific translating ribosome affinity purification model). In contrast, β cell failure in islets from diabetic *db/db* mice correlated with a tendency for increased *Mt1* (~1.3-fold) and significantly upregulated *Mt2* (~1.6-fold, $p < 0.05$) mRNA levels. *Ex vivo* treatment of islets for 18–48h in high glucose (10–30 mM *vs.* 2–5 mM) strongly downregulated *Mt1* and *Mt2* mRNA and protein levels in parallel with increased insulin secretion. Interestingly, KO mice displayed markedly improved glucose tolerance during *ip*GTT ($p < 0.01$) and fasting-refeeding tests ($p < 0.01$), in association with increased plasma insulin levels (30 min following *ip*GTT, $p < 0.05$). Glucose-stimulated insulin secretion (GSIS) was potentiated in islets isolated from KO mice *vs.* control islets while insulin content was unchanged. In MIN6 cells, knockdown of *Mt1*, but not *Mt2*, potentiated GSIS by ~1.8-fold ($p < 0.01$). The potentiation of GSIS in KO islets occurred despite similar rises in intracellular Ca^{2+} and NAD(P)H levels, and the mRNA levels of β cell enriched genes preproinsulin, *Pdx1*, *Glut2* and *Pc* and stress response genes *Hmox1*, *Hspa5* and *Ddit3* were unchanged. Nevertheless, basal and acute H_2O_2-induced cytosolic roGFP1 oxidation was slightly lower in KO islets. On the other hand, overexpression of *Mt1* in islets from Tg-*Mt1* inhibited GSIS by ~1.5-fold ($p < 0.01$). Moreover, treatment of control islets with $ZnCl_2$, a potent inducer of metallothioneins, reduced GSIS. This effect was absent in KO islets.
Conclusion: We identified *Mt1* as a novel negative regulator of GSIS in mouse β cells. Our studies suggest a role for *Mt1* downregulation in β cell compensation in obesity, and for *Mt1* upregulation in β cell failure in T2D.

PS 021 Clinical and experimental immunology in type 1 diabetes

425

Older age of diagnosis is the major feature of persistent long term endogenous insulin secretion in type 1 diabetes

R.A. Oram[1,2], T.J. McDonald[1,3], S. Sabbah[4], S. Bloem[5], B. Shields[1], A. Hill[1], R. Bolt[1], S. Begom[4], L. Khatri[4], T. Tree[4], B.O. Roep[5,6], A.T. Hattersley[1], The TIGI Study Group;
[1]NIHR Exeter Clinical Research Facility, University of Exeter Medical School, Exeter, UK, [2]Academic Kidney Unit, Royal Devon and Exeter NHS Foundation Trust, Exeter, UK, [3]Blood Sciences, Royal Devon and Exeter NHS Foundation Trust, Exeter, UK, [4]Immunobiology, King's College London, London, UK, [5]Leiden University Medical Centre, Leiden, Netherlands, [6]Department of Diabetes Immunology, City of Hope, Duarte, USA.

Background and aims: The majority of people with long term (>5 years) type 1 diabetes (T1D) have a small number of functioning beta-cells, and a small proportion have relatively high C-peptide despite longstanding T1D. The clinical correlates and mechanisms for persistent beta cell function are not known. We aimed to investigate the mechanisms of persistent beta cell function by studying the clinical, genetic, serological and immune associations of persistent endogenous insulin in the TIGI study.
Materials and methods: We identified T1D patients in the top and bottom 20% of C-peptide secretion for their duration of diabetes, assessed using a post meal urine C-peptide creatinine ratio(UCPCR) in a cross sectional regional study of 1005 patients. A median of 3 years later we confirmed their C-peptide status using a MMTT (90-minute serum C-peptide >40 pmol/L (CpHi) or undetectable (<3 pmol/L, CpLo). We measured GAD, IA-2 and ZnT8 autoantibodies and T1D genetic risk score (T1D GRS). Detailed immunophenotying of cryopreserved PBMC was performed including assessment of circulating leucocyte subsets, islet specific CD4 and CD8 T cells, and CD4 Treg.
Results: We investigated 48 CpHi and 65 CpLo with markedly different 90 min C peptide (median(IQR) 144(92,301) v <3(<3,<3)pmol/L, $p < 0.0001$), despite similar duration (12.2(7.5,22.0) v 10.9(8.2,15.4)y $p = 0.4$). Age of diagnosis was older in CpHi (16(13,22) v 6(3,10)y $p < 0.0001$). HbA1c was similar (69.5(63.0,81.0) v 69(57.0,79.0) mmol/mol $p = 0.4$) but insulin doses lower (0.69(0.55,0.96) v 0.83(0.74,1.01)$p = 0.003$)u/kg/24 hr. CpHi had more autoantibody positive (83 v 63% ≥1 autoantibody positive, $p = 0.025$) but no difference in T1D GRS (mean(SD) 0.274(0.025) v 0.275(0.026), $P = 0.9$), HLA DR3/DR4 status ($p = 0.7$) or individual proportion of T1D associated loci (30 individual loci all $p > 0.10$). Following age adjustment, there was no difference in total frequencies of circulating leucocyte populations, FOXP3 Treg function or the total frequency of autoreactive CD8 T cells with specificity for a range of islet antigens. Proliferation of CD4 T cells in response to islet antigens GAD65 or Proinsulin, was similar, however, the quality of response differed, with individuals from the CpHi group producing a higher level of the anti-inflammatory cytokine IL-10 in response to proinsulin (12.0(2,23) v 4.9l(2,11)mg/mL, $p = 0.01$).
Conclusion: A persistently high C-peptide in long standing T1D is a feature of an older age of diagnosis. It is associated with a higher proportion of islet autoantibodies and little evidence of increased genetic susceptibility or a less severe T cell mediated autoimmunity apart from an enhanced signature of islet specific immune regulation. The strong association of age of diagnosis and long term endogenous insulin secretion allows extrapolation from studies at diagnosis supporting a different immune phenotype in the islets at diagnosis.

Repeat BCG vaccination creates lasting HbA_{1c} reductions in adult subjects with longstanding type 1 diabetes

D. Faustman[1], W.M. Kühtreiber[1], L. Tran[1], M. Dybala[1], S. Plager[1], S. Janes[1], A. Defusco[1], H. Zheng[2];
[1]Massachusetts General Hospital/Harvard Medical School, Boston, [2]Massachusetts General Hospital, Boston, USA.

Background and aims: The bacillus Calmette-Guerin (BCG) vaccine, originally developed for tuberculosis, is being trialed globally for new immune indications including allergy, autoimmunity and infection. A randomized, placebo-controlled, Phase I study of adult subjects with longstanding type 1 diabetes (T1D) who received the BCG vaccine (2 vaccinations 4 weeks apart) previously revealed potential disease-modulating, but not clinical, effects of the vaccine with 20 weeks of follow up (i.e., death of autoreactive T cells, transient and modest restoration of insulin secretion, induction of regulatory T cells [Tregs]). Here we report long-term follow up of subsequent study groups, including original Phase I trial subjects at year 08 and additional subjects up to year 05.
Materials and methods: This analysis includes data on 282 human research participants in both *in vivo* BCG vaccine clinical trial studies (n = 52) and *in vitro* mechanistic studies (n = 230). Of these research subjects, 211 had T1D and 71 were non-diabetic control subjects. Adults subjects with T1D were followed for 8 years (Phase I trial subjects) or up to 5 years (additional subjects) after BCG vaccinations. All subjects with T1D had disease >10 years duration without complications at enrollment. Mechanistic studies of RNAseq, metabolomics and epigenetics were performed in parallel to track the systemic and mechanistic effects of BCG vaccinations.
Results: Starting after year 03 of follow up, only BCG vaccinated subjects had lowered HbA1c for 1 year (Year 05 data: BCG-treated HbA1c 6.18 ± 0.34 [n = 9], placebo 7.07 ± 0.41 [n = 3], reference subjects with type 1 diabetes 7.22 ± 0.17 [n = 34, p = 0.02]). Follow-up of 6 Phase I trial subjects who have been followed for a total of 8 years, 4 years after the first documented lowering of HbA1c, confirms the ability of repeat BCG vaccination to maintain lowered HbA1c levels without hypoglycemia in long-term disease (BCG-treated HbA1c 6.65 ± 0.26 vs placebo 7.22 ± 0.38, p = 0.0002) for a total of 5 continuous years. For all BCG-treated subjects, the stable reductions in HbA1c were not associated with hypoglycemia. BCG-treated subjects had no change in their enrollment use of insulin pumps and none utilized a CGM device. The impact of BCG on blood sugars appeared to be driven by a novel systemic and blood sugar lowering mechanism in diabetes. We observed a systemic shift in glucose metabolism from oxidative phosphorylation to aerobic glycolysis, a state of high glucose utilization, and major epigenetic effects on the immune system related to Treg tolerance.
Conclusion: Repeat BCG vaccination in this trial was associated with stable and long-term lowering of HbA1c without hypoglycemia for over 5 years after an onset delay. The apparent stable and long-lasting impact of BCG on blood sugars in humans with T1D appears to be the result of a novel mechanism, as documented with metabolomics, mRNAseq, and epigenetic methods; namely, a systemic shift in glucose metabolism from oxidative phosphorylation to aerobic glycolysis. BCG via epigenetics resets Treg genes for genetic reprogramming of tolerance. The identification of a novel mechanism for significant blood sugar lowering with BCG opens the door for future trials in both type 1 and 2 diabetes with a safe, novel and affordable approach.
Disclosure: **D. Faustman:** None.

GAD65 autoantibodies are associated with incident diabetes in mid-life: the EPIC-InterAct study

O. Rolandsson[1], C.S. Hampe[2], S.J. Sharp[3], C. Langenberg[3], N. Wareham[3], EPIC-Interact Group;
[1]Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden, [2]Department of Medicine, University of Washington, Seattle, USA, [3]MRC Epidemiology Unit, Institute of Metabolic Science, University of Cambridge School of Clinical Medicine, Cambridge, UK.

Background and aims: Type 1 diabetes (T1D), is characterized by autoimmune destruction of beta cells. The autoimmune response manifests itself in T cell reactivity and autoantibody responses directed against at least four beta-cell autoantigens including the 65kDa isoform of glutamic acid decarboxylase (GAD65). Although the pathogenesis of Type 2 diabetes (T2D) is different to that of T1D, there is some overlap as up to 40% of T2D patients demonstrate an autoimmune element revealed by the presence of autoantibodies, predominantly directed against GAD65. As is the case for T1D, it has been suggested that the presence of GAD65Ab preceeds the development of T2D, albeit with a lower prevalence. Susceptibility for development of GAD65Ab and T1D is at least in part mediated by risk alleles located within the HLA region on chromosome 6. However, the association between T2D-associated genes and autoantibody positive diabetes in adults remains to be established. Thus, our aim was to assess the association between GAD65Ab, genetic risk scores for T1D and T2D, and the development of diabetes.
Materials and methods: We investigated the associations in adults in EPIC-InterAct, a case-cohort study in 8 countries nested in the European Prospective Investigation into Cancer and Nutrition cohort (n = 340,234). GAD65Ab were analysed at baseline by radioligand binding assay in a random subcohort (n = 15,802) and in all incident cases ascertained and verified as T2D (n = 11,981). T1D and T2D genetic risk scores (GRS) were calculated. Associations were estimated using Prentice-weighted Cox regression (GAD65Ab/incident diabetes) and logistic regression (genetic risk/GAD65Ab positivity); all models accounted for country.
Results: GAD65Ab positivity at baseline was associated with development of diabetes (median follow-up: 11.7 years) (HR GAD65Ab positive vs negative 1.78, 95% CI 1.43–2.20) after adjustment for sex, center, physical activity, smoking status and education. T1D-GRS, but not T2D-GRS, was associated with GAD65Ab positivity in both the subcohort (OR 1.24 per SD 95% CI 1.03–1.50), and incident diabetes cases (OR 1.97 per SD 95% CI 1.72–2.26) when adjusted for sex and age. Of the five SNPs in the T1D GRS that are associated with HLA, three were associated with GAD65Ab positivity in the subcohort after adjustment for sex and age; the odds ratios for GAD65Ab positivity were 4.07 (95% CI 2.01–8.26) for DR3/DR3, 2.42 (95% CI 1.32–4.43) for DR3/DR4 - DQ8, and 3.93 (95% CI 1.78–8.68) for DR4-DQ8/DR4-DQ8. There was no overall association between T1D GRS and incident diabetes (HR 1.02 per SD T1D GRS, 95% CI 0.99–1.06) when adjusted for age, sex, physical activity, smoking status, education, and BMI. Because of the relationship between T1D GRS and antibody status, we stratified the analysis by GAD65Ab status. In GAD65Ab positive individuals, there was a significant association between T1D GRS and incident diabetes (HR 2.42 per SD (95% CI 1.84–3.21)), which was not evident in GAD65Ab negative individuals (HR 1.00 per SD T1D GRS, 95% CI 0.97–1.04).
Conclusion: Our findings suggest that a sub-group of individuals who present with incident diabetes in mid-life have an underlying autoimmune aetiology.

Exogenous IL-33 prevents diabetes induction in mice

N. Jovicic[1], I. Petrovic[2], S. Pavlovic[3], B. Ljujic[4], M. Miletic Kovacevic[1], N. Pejnovic[2], N. Arsenijevic[5], M.L. Lukic[5];
[1]Department of Histology and embryology, Faculty of Medical Sciences, University of Kragujevac, Kragujevac, [2]Department of Pathophysiology, Faculty of Medical Sciences, University of Kragujevac, Kragujevac, [3]Department of Microbiology and immunology, Faculty of Medical Sciences, University of Kragujevac, Kragujevac, [4]Department of

Genetics, Faculty of Medical Sciences, University of Kragujevac, Kragujevac, [5]Center for Molecular Medicine and Stem Cell Research, Faculty of Medical Sciences, University of Kragujevac, Kragujevac, Serbia.

Background and aims: Type 1 diabetes is an autoimmune disease caused by the immune-mediated destruction of pancreatic β-cells. Prevention of type 1 diabetes requires early intervention in the autoimmune process against beta-cells of the pancreatic islets of Langerhans, which is believed to result from disordered immunoregulation. $CD4^+Foxp3^+$ regulatory T cells (Tregs) participate as one of the most important cell types in limiting the autoimmune process. We have previously shown that IL-33R (ST2) deletion enhanced susceptibility to multiple low dose streptozotocin (MLD-STZ) induced diabetes. The aim of this study was to investigate the preventive and therapeutic effect of IL-33 in MLD-STZ induced diabetes and to delineate the mechanisms of its influence on autoimmune attack.
Materials and methods: For the induction of diabetes C57BL/6 mice were treated with five doses of 40 mg/kg STZ, and 0.4 μg rIL-33 was administrated per mouse, four times, every second day from the day of disease induction. Glycemia, glycosuria and HbA1c levels were measured after diabetes induction and histological and immunohistochemical parametars in pancreatic islets were evaluated on day 28. Cellular make up of the pancreatic lymph nodes and islets were evaluated by flow cytometry.
Results: IL-33 was given simultaneously with the application of STZ and completely prevented the development of hyperglycemia, glycosuria and attenuated islet mononuclear cells infiltration. IL-33 treatment enhanced the bias toward Th2 immune response and increased the frequency and number of $ST2^+$ Tregs. This was accompanied by higher number of IL-13 and IL-5 producing $CD4^+$ T cells and increased presence of $ST2^+Foxp3^+$ regulatory T cells (Tregs) in pancreatic lymph nodes and islets. Using IL-33 also promotes islet infiltration with M2 macrophages.
Conclusion: We provide the first evidence that exogenous IL-33 completely prevents the development of T cell mediated inflammation of pancreatic islets and consecutive development of diabetes in C57BL/6 mice.

Immunomodulatory therapies with anti-IL-6 and anti-IL-17 combined with anti-TCR to regain normoglycaemia in the LEW.1AR1-iddm rat as a model for human type 1 diabetes

A. Joerns[1], H. Teraoku[2], T. Yoshimoto[2], D. Wedekind[3], S. Lenzen[2];
[1]Institute of Clinical Biochemistry, Hannover Medical School, Hannover, [2]Institute of Experimental Diabetes Research, Hannover Medical School, Hannover, [3]Institute of Laboratory Animal Science, Hannover Medical School, Hannover, Germany.

Background and aims: In other autoimmune diseases, such as psoriasis and rheumatoid arthritis, antibodies against IL-6 and IL-17 showed very promising therapy success. Combination therapies with both antibodies alone or combined with anti-TCR, a T cell antibody, have not yet been performed in type 1 diabetes mellitus (T1DM). The aim of the study was to elucidate the protection potential of these antibodies for the survival of the remaining beta cells from autoimmune destruction after onset of diabetes. The IDDM (LEW.1AR1-*iddm*) rat, a model of human T1DM, was used for these studies. In this model other combination therapies have been successfully evaluated.
Materials and methods: Animals were treated with anti-IL-17 (0.1 mg/kg b. wt.), anti-IL-6 (0.01 mg/kg b. wt.) alone or in combination with anti-TCR (0.5 mg/kg b. wt.) in a double or triple fashion consecutively over 5 days immediately after diabetes manifestation. Besides biochemical parameters changes in the pancreas were analysed quantitatively by biopsies at the time point of diabetes manifestation, at the end of therapy, and 60 days after the end of therapy for beta cell survival and immune cell infiltration on the gene and protein expression level.
Results: Prevention therapies in combination of anti-TCR with anti-IL-17 or/and anti-IL-6 starting immediately after disease manifestation reversed diabetes to normoglycaemia until 60 days without therapy. The therapy effectiveness in the triple combination was successful in the widest range of blood glucose concentrations between 8–18 mmol/l, followed by the combination with anti-IL-17 and thereafter with anti-IL-6. Monotherapies with both antibodies showed no therapeutic effect. Thereby the C-peptide concentrations increased from 1/3 of the normal control values of around 1000 pg/ml, to 2/3 in the double and nearly to the control values in the triple combination treated IDDM rats. In parallel, beta cell mass in the pancreas was nearly doubled after combination with anti-IL-6 in comparison to the diabetic control (4.38 ± 0.19 vs. 2.21 ± 0.30) and reached values close to normal in the double and triple combination with anti-IL-17 (double 5.41 ± 0.18; triple 5.50 ± 0.17 vs. 6.25 ± 0.20). The beta cell proliferation rate showed a fourfold increase in the double combination and a twofold increase in the triple combination with anti-IL-17, whereas the beta cell apoptosis rate was markedly reduced only in the combination with anti-IL-6 alone or additionally with anti-IL-17. Severe islet immune cell infiltration in the pancreas was abolished after all combination therapies in normoglycaemic IDDM rats. Residual infiltrating CD68 macrophages were observed in the islet periphery, whereas CD8 T cells and γ, δ T cells were only found in the double combination with anti-IL-17.
Conclusion: Anti-IL-6 reduced islet immune cell infiltration and anti-IL-17 possessed the strongest beta cell proliferation potential. Combining both anti-inflammatory cytokine antibodies with anti-TCR in the triple therapy revealed an optimal effect with a regain of stable normoglycaemia.

Gut microbiome signatures in LEW.1AR1-iddm rats during time course of beta cell autoimmunity

T. Schoeppe[1], J.-H. Sachs[1], B. Kreikemeyer[2], D.P.R. Herlemann[3], M. Tiedge[1];
[1]University Medical Center Rostock, Institute of Medical Biochemistry and Molecularbiology, Rostock, [2]University Medical Center Rostock, Institute of Medical Microbiology, Virology and Hygiene, Rostock, [3]Leibniz-Institute for Baltic Sea Research Warnemünde, Rostock, Germany.

Background and aims: The gut microbiome plays an important role in the pathogenesis of type 1 diabetes mellitus. It is still unknown how the gut microbiome affects the time course of beta cell autoimmunity from islet infiltration to overt diabetes. In this study we analyzed changes of the gut microbiome in LEW.1AR1-*iddm* rats during the process from islet infiltration (day 40) to complete beta cell loss and diabetes manifestation (day 60–70).
Materials and methods: Stool samples were collected from normoglycaemic (blood glucose <7.8 mmol/l) LEW.1AR1-*iddm* ($n = 68$) and diabetes resistant LEW.1AR1 ($n = 20$) rats at day 40, 50, 60 after birth and at the timepoint of diabetes manifestation. Total chromosomal DNA was isolated from ~200 mg frozen stool samples using the Qiagen QIAamp DNA stool extraction kit. The 16S rRNA genes were amplified on the V3 - V4 regions and sequenced on using the paired end Illumina MiSeq platfrom. The taxonomic classification of resulting sequences were performed and quality controlled using QIIME and SILVA_NGS.
Results: The analysis showed a different development of gut mirobiome communities in LEW.1AR1-*iddm* and LEW.1AR1 rats. While microbial diversity increased in both strains between day 40 and day 60, the diversity was significantly lower in LEW.1AR1-*iddm* rats than in LEW.1AR1 controls. In LEW.1AR1-*iddm* rats we also observed increased abundancies of Firmicutes, *Prevotella* and *Clostridium*. Heatmap analysis were used to rank most abundant bacteria species and confirmed a lower microbial diversity in LEW.1AR1-*iddm* rats with high abundancy of

*Lachnospiraceae*and *Clostridia*, which were formerly described as a trigger for inflammatory gastrointestinal diseases.
Conclusion: Microbial species with proinflammatory characteristics were increased at the beginning of islet infiltration in diabetes susceptible LEW.1AR1-*iddm* strain. These proinflammatory species constanly decreased up to the timepoint of diabetes manifestation. The data may have several implications for gut microbiome analysis in humans: (1) Microbiome analysis has a higher prognostic value in young individuals with high family risk of T1D and low autoantibody titres. (2) Age-dependent changes of microbial diversity and abundancies require repeated analyses of stool samples. (3) Probiotic interventions should start early in life before detection of autoantibodies.

HERV-W-Env is involved in type 1 diabetes pathogenesis: new insights from mouse models

S. Levet[1], J. Medina[1], J. Joanou[1], N. Queruel[1], J. Pierquin[1], H. Perron[1,2]; [1]Geneuro Innovation, Lyon, France, [2]Geneuro, Plan-les-Ouates, Switzerland.

Background and aims: Human endogenous retroviruses (HERVs), known to represent 8% of the human genome, have been associated with several autoimmune diseases. In particular, the envelope protein of HERV-W family (HERV-W-Env), which has been involved in the pathogenesis of Multiple Sclerosis (MS), displays pro-inflammatory and autoimmune properties. This has initially been demonstrated in an MS context, but it subsequently turned out to be relevant for Type 1 Diabetes (T1D). We recently observed that HERV-W-Env protein and RNA are detected respectively in sera and PBMC of more than 50% of T1D patients. We demonstrated that this pathogenic protein is expressed by acinar cells in human T1D pancreas, and is associated with the recruitment of macrophages within the pancreas of these patients. HERV-W-Env also displays direct pathogenic properties, as it inhibits insulin secretion by human Langerhans islets.
Materials and methods: Two transgenic mouse models in which HERV-W-Env transgene is expressed under the control of HERV LTR and CAG promoter have been developed. In a first model, these transgenic mice have been generated in a C57Bl6/J background and have been challenged with 5 multiple low-dose streptozotocin (STZ, 40 mg/kg). In a second model, transgenic mice are currently backcrossed in a NOD/ShiLtJ background. Glycemia, insulinemia and pancreas histology are studied in both models.
Results: HERV-W-Env transgenic mice in the C57Bl6/J background were challenged by repeated STZ injections. We observed that transgenic mice are more susceptible to STZ-induced diabetes as they developed a more severe hyperglycemia ($P < 0.01$) and hypoinsulinemia ($P < 0.01$) than wild-type C57Bl6/J mice. These observations are consistent with endocrine pancreatic damage observed in HERV-W-Env-STZ transgenic mice which developed more severe insulitis ($P < 0.0001$) than wild-type-STZ mice. Interestingly, HERV-W-Env transgenic mice also displayed huge abnormalities in their exocrine pancreas, consisting in immune ($P < 0.0001$) and fatty infiltrates ($P < 0.0001$), which are not modified by STZ injections. These pre-existing exocrine abnormalities observed in HERV-W-Env transgenic mice could explain the pancreatic susceptibility to environmental insults, such as the ones caused by STZ. In a second model, transgenic mice are currently backcrossed in a NOD/ShiLtJ background. Preliminary results revealed that NOD transgenic males start to develop a hyperglycemia as soon as 4 weeks old compared to their controls littermates.
Conclusion: Early results from these transgenic mouse models support a role for HERV-W-Env in human T1D pathogenesis, in a sub-group of patients expressing this pathogenic protein. They provide additional rationale for the ongoing phase IIa clinical trial, which is designed to neutralize HERV-W-Env in T1D patients using a monoclonal antibody named GNbAC1. Six months interim results of this new therapeutic approach will be available 3rd quarter 2018.

EMC-D virus-induced diabetes in DBA/2 mice

K. Mine[1], S. Nagafuchi[2], H. Takahashi[2], Y. Yoshikai[1], H. Mori[2], Y. Matsuta[2], K. Anzai[2];
[1]Division of Host Defense, Medical Institute of Bioregulation, Kyushu University, Fukuoka, [2]Division of Metabolism and Endocrinology, Department of Internal Medicine, Saga University, Saga, Japan.

Background and aims: Human type 1 diabetes (T1D) research has suggested the close link between viral infections and T1D. In experimental animal model, D variant of encephalomyocarditis virus (EMC-D) induces T1D in male SJL, SWR, and DBA/2 mice within five days after infection. It was reported that a single autosomal-recessive gene, which is inherited in a Mendelian manner, controls susceptibility to EMC-D virus-induced diabetes (VID)(Nature, 1978). The natural susceptible gene(s) had been unknown until we reported that natural mutations of tyrosine kinase 2 (tyk2) gene determined susceptibility to EMC-D VID in SJL and SWR mice (Nat commun, 2015). It was also revealed that DBA/2 mice that lack tyk2 gene mutations should have other VID susceptibility gene(s). In this study, we assessed the pathogenesis of EMC-D VID in DBA/2 mice to explore the role of susceptibility gene(s) in DBA/2 mice.
Materials and methods: To analyze the mechanisms to develop EMC-D VID in mice, we carried out intraperitoneal challenge with 1.0×10^3 PFU of EMC-D virus to VID-resistant C57BL/6(B6) and DBA/2 male mice. Immunohistochemical analysis, islet isolation, and cell death assay, were performed.
Results: The levels of serum type 1 interferon (IFN) in virus infected DBA/2 mice were comparable to that of resistant-strain B6 mice, while virus titer in pancreas of DBA/2 mice was significantly higher than that of B6 mice at three to five days after infection. High dose of type 1 IFN transfer did not alter the outcome of EMC-D VID in DBA/2 mice indicating that increased levels of type 1 IFN did not possess biological significance to resist against VID in DBA/2 mice. Histopathological analysis showed that both B6 and DBA/2 mice had mild CD45-positive cell-infiltration around the islets at three days after infection, while insulin-negative areas were widely observed in DBA/2-islets. These observations indicated that islets of DBA/2 mice were destroyed by EMC-D virus before immune cell-infiltration. At five days after infection, B6 mice had CD45-positive cell-infiltration around, but not into the islets. In contrast, DBA/2 mice developed severe CD45-positive cell-infiltration in the islets concomitant with extensive destruction of the islets. Mouse embryonic fibroblasts (MEF) showed comparable anti-viral responses between DBA/2 and B6 mice at 100 U/ml IFN-β stimuli. On the other hand, the virus-induced β-cell death was significantly increased in DBA/2 β-cells than B6 β-cells by the stimulation with 100 U/ml IFN-β. Annexin V, a marker of apoptosis, positive β-cells were significantly increased in DBA/2 β-cells. In addition, caspase3, another marker of apoptosis, positive cells were noticeably detected in DBA/2-islets at five days after infection. These observation suggested that reduced β-cell defense against virus infection in DBA/2 mice determined susceptibility to EMC-D VID.
Conclusion: These observations suggested that virus-induced islet cell lysis is the first step of islets destruction and enhanced by inflammatory cell-infiltration in the islets. The weakness of antiviral responses and of type 1 IFN dependent reactivity within three days after infection may determine susceptibility to EMC-D VID in DBA/2 mice. Thus, it was suggested that gene(s) associated with early anti-viral responses or cell-survival associated genes in β-cells may involve EMC-D VID susceptibility gene(s).

Effectiveness and applicability of an aggressive management of insulin therapy and CHO-integration strategy during prolonged endurance competition in athletes with type 1 diabetes

E. Gamarra[1], A. Benso[1], L. Nollino[2], M. Miccio[3], C. Agnoli[4], M. Sudano[5], M. Vasta[5];
[1]Medical Science, Endocrinology, Diabetology and Metabolic Unit, University of Turin, Turin, [2]UOC Malattie Endocrine, del Ricambio e della Nutrizione, AULSS 2 della Marca Trevigiana, Treviso, Italy, [3]freelance Nutritionist, Garda (Vr), [4]Fellow Athlete with Type 1 Diabetes and former President of Italian Non-Profit Organization "Diabetenolimits", Garda (Vr), [5]Diabetes and Endocrinology Unit AV1, General Hospital, Urbino, Italy.

Background and aims: General recommendations for T1DM athletes are usually focused on reducing insulin dose and/or defensive carbohydrates (CHO) eating to prevent hypoglycemia, independently of duration and intensity of the activity and fitness and nutritional status of the athlete. On the other hand, high CHO supplementation is strongly suggested in order to maximize performance in healthy endurance athletes. Aim of the present study was to investigate the effectiveness and applicability of an aggressive management of insulin therapy and CHO integration strategy, focused on maximizing the performance, during prolonged endurance race in T1DM athletes.

Materials and methods: 8 T1DM amateur athletes experienced in endurance sports (6 on MDI, 2 on CSII) participated to a trail running competition of approximately 3 hours, performing 3 or 4 laps of a 6 km muddy track, average 250 m d+ in rainy and windy weather conditions. Diabetes duration ranged from 9 to 37 yrs (mean 20 yrs), A1c values from 6.7 to 7.8% (mean 7.3%) and total insulin requirement from 0.26 to 0.59 U/kg/die (mean 0.46 U/Kg/die). Athletes were asked not to reduce their insulin dose profile before and during the race and, at the same time, to maintain an aggressive CHO approach, accordingly to their experience and medical staff advices. Clinical and athletic evaluations were performed before the race and at the end of each lap. Glucose values were evaluated with fingersticks (Abbott®).

Results: Mean capillary glycaemic value was 201 ± 31 mg/dl (range 161–242) before the first lap and 118 ± 51 mg/dl (range 78–217) at the end of the last lap, showing a trend toward decrease (−83 mg/dl vs baseline), in front of constant mean CHO integration (57 ± 19 g/h or 0.825 ± 0.24 g/kg/h, range 30–83 g/h or 0.42–1.18 g/kg/h), that was slightly less than recommendations for this kind of effort (>60–90 g/h). No cases of severe hypo- or hyperglycemia occurred (min 62 mg/dl, max 242 mg/dl). None of the athletes, both in MDI and CSII, modified his basal insulin profile, neither the bolus and insulin/CHO ratio was varied with respect to CHO supplementation during the race. Heart rate (maintained in zone 2–3 for most of the time and in zone 4 only for very short time) and mean lactate levels (3.5 ± 1.7 mmol/l, range 1.7–9.6) indicated that the effort of the athletes was mainly supported by aerobic metabolism.

Conclusion: The T1DM athletes evaluated safely and successfully completed a prolonged trail running endurance competition, following an aggressive management of insulin therapy and CHO integration strategy. The present data support the hypothesis that, differently from general sports recommendations in T1DM, essentially focused on avoiding hypoglycemia and severe hyperglycemia, in case of endurance T1DM athletes, the combination of exercise physiology, duration and intensity of the activity, fitness and nutritional status of the athlete should carefully be kept in consideration in the management of insulin therapy and CHO supplementation, in order to maximize performance.

Assessment of glycaemic changes and parameterisation of physical exercise during football matches in adolescents with type 1 diabetes

[1]Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poznań, [2]Department of Pediatrics, Oncology, Hematology and Diabetology, Medical University of Lodz, Lodz, [3]The Academic Laboratory of Movement and Human Physical Performance DynamoLab, Medical University of Lodz, Lodz, [4]Department of Paediatrics and Endocrinology, Medical University of Warsaw, Warsaw, Poland.

Background and aims: Maintaining normoglycemia throughout football matches is difficult for young players with type 1 diabetes mellitus (T1DM). Moreover, it is not clear whether two similar games elicit the same glycemic response in a particular player. The aim of this study was to parametrize physical activity and glycemic variability of adolescents with T1DM during two football matches.

Materials and methods: During summer camp for adolescents with T1DM, two football matches (each lasting 80 minutes +10-minute break) were organized for two 9-players adolescent teams (mean age 14.9 ± 1.4 years old, diabetes duration 7.2 ± 3.9 years, HbA1c 7.1 ± 0.6% [54 ± 0.32 mmol/mol]). The meetings were separated by a 4-day rest period. During the matches, players wore chest straps heart rate (HR) monitors coupled with GPS, which allowed for continuous tracking of their position and movement. To assess glycemic and metabolic response to exercise, lactate and blood glucose (BG) in capillary blood were measured at rest, after the first half and at the end of each match. Moreover, some players used continuous glucose monitoring (CGM) systems which allowed to measure glucose level every 5 or 15 minutes, depending on the CGM device.

Results: Mean BG before and after each match were as follows - match: no.1: 139 ± 61 mg/dl, 151 ± 95 mg/dl; no.2: 164 ± 80 mg/dl and 131 ± 78 mg/dl. No significant difference in BG between the matches ($p = 0.32$) or during each match ($p = 0.5$) was noted, changes between matches were also similar ($p = 0.9$). Hypoglycemia <70 mg/dl was observed in four players during the first match, two of them experienced glycemia <54 mg/dl. Similar proportions were noted for the second meeting (<70 mg/dl in four players, <54 mg/dl in one). No episode of glycemia <54 mg/dl lasted ≥15 min in CGM was observed. Recorded HRs (match no. 1: 77 ± 7% of maximum HR for a given age; match no. 2: 76 ± 8%) revealed a mixed aerobic-anaerobic character of exercise and were similar between the meetings ($p = 0.58$). During both matches, significant rise in capillary blood lactate was observed (match: no.1: 2 ± 0.6 do 6 ± 4.9; no.2: 1.9 ± 07 do 4 ± 2, $p = 0.005$), similar during both events ($p = 0.46$) although with tendency toward higher concentrations in match no 1 ($p = 0.051$). Mean distance covered by the players was comparable in both matches (match no.1: 6.1 ± 1 km, no.2: 6.2 ± 1.4 km, $p = 0.89$). No significant differences were noted regarding velocities and accelerations reached by each player during both matches.

Conclusion: HR monitoring coupled with GPS-based tracking can effectively parametrize physical activity during a football match. Under similar exercise workload particular participants displayed comparable changes in glycemia which gives hope for creating uniform guidelines for young football players with T1DM.

Variability and reproducibility in the rise in blood glucose levels in response to high intensity interval training (HIIT) in type 1 diabetes: the FIT reproducibility study

M.C. Riddell[1], R. Pooni[1], R.E. Brown[2], L. Yavelberg[1], Z. Li[3], C. Kollman[3], R. Aronson[2];

[1]School of Kinesiology and Health Science, York University, Toronto, Canada, [2]LMC Diabetes & Endocrinology, Toronto, Canada, [3]Jaeb Center for Health Research, Tampa, USA.

Background and aims: Hyperglycemia can occur when individuals with type 1 diabetes (T1D) perform high intensity interval training (HIIT). However, the reproducibility of the glycemic response to a HIIT session has not been definitively tested. The objective of this study was to investigate the reproducibility of the glycemic response to a HIIT session in physically active patients with T1D.
Materials and methods: Seventeen patients with T1D, all using insulin glargine 300 U/mL as basal insulin, were asked to perform four separate in clinic HIIT sessions in an overnight fasted state. HIIT consisted of two bouts of cycling at 90% peak power, separated by a series of 'CrossFit'-type activities, spanned over a 25 min period (~75–95% of maximal heart rate). Plasma glucose (YSI) was measured pre-exercise (−10 min) and at 5- and 15-min into the HIIT session, as well as at 5- and 15-min in recovery.
Results: A total of 64 HIIT sessions were compiled. Pre-exercise blood glucose levels were similar among the four HIIT visits (8.8 ± 1.0 mmol/L, mean SD), as were the rise in glucose levels in response to HIIT (+3.9 ± 1.6; +3.8 ± 1.8; +3.9 ± 2.3; +3.9 ± 1.5 mmol/L, in visits 1-4, respectively). In almost all occasions (63 of 64 sessions), HIIT produced a rise in glycemia, but the inter-individual responses did vary, ranging from −0.3 to +9.0 mmol/L. The change in glucose during HIIT was not influenced by the baseline glucose concentration and was predictable within an individual based on the measured response in visit 1 (composite correlation with post-exercise glucose rise among the four visits was 0.56 [0.33–0.79, 95% CI]).
Conclusion: Following HIIT, there appears to be a consistent increase from the pre-exercise glucose concentration in patients living with T1D and the degree of response is moderately reproducible within a given patient. Individualized insulin correction strategies, which take into account the rise in glucose observed and the patient's sensitivity to insulin, may be helpful in restoring glucose control after HIIT in patients living with T1D.

Optimal insulin correction factor (ICF) for post-exercise hyperglycaemia following high intensity training in adults with type 1 diabetes: the FIT Study

R. Aronson[1], R.E. Brown[1], M.C. Riddell[2];
[1]LMC Diabetes & Endocrinology, Toronto, [2]School of Kinesiology and Health Science, York University, Toronto, Canada.

Background and aims: The phenomenon of post-exercise hyperglycemia following high-intensity training (HIT) in patients with type 1 diabetes (T1D) has led to debate of corrective therapy options but has not been definitively investigated to date. The aim of this study was to investigate the optimal bolus insulin correction factor to correct for post HIT exercise in physically active patients with T1D.
Materials and methods: The FIT study was a randomized, cross-over investigation of 4 post-HIT bolus insulin correction strategies in patients with T1D. Patients with T1D ($n = 17$) using multi-daily injections (MDI) were enrolled and underwent an 8-week insulin optimization period using insulin glargine 300 U/mL as their basal insulin. On 4 separate days, each subject performed 25 minutes of structured HIT in the morning. If hyperglycemia (>8.0 mmol/L) resulted, subjects received a bolus insulin correction 15 minutes post-HIT, based on their own ICF, adjusted by one of 4 commonly used multipliers: 0%, 50%, 100%, or 150%.
Results: At 180 minutes following bolus correction, change in plasma glucose (PG) was greatest in both the 100% (−4.7 mmol/L) and 150% (−5.3 mmol/L) ICF arms, vs 50% (−2.3 mmol/L, $p < 0.05$) and 0% (+1.0 mmol/L, $p < 0.05$) (Figure). Percent time in euglycemia (4.0–8.0 mmol/L) progressively increased with each increasing correction factor. Both the 100% and 150% ICF arms spent significantly less time in hyperglycemia (>8.0 mmol/L), and significantly more time in euglycemia, compared to both the 0% and 50% ICF arms ($p < 0.05$). Hypoglycemia was rare and only seen in the 100% arm (percent time 1.9%) and 150% arm (percent time 4.4%).
Conclusion: In correction of post-exercise hyperglycemia following HIT in patients with T1D, correction based on a patient's usual ICF is safe and effective. Optimal PG reduction, with very little hypoglycemia, occurred in the 100% ICF correction arm.

Aerobic exercise training improves hepatic insulin sensitivity but lowers splanchnic glucose uptake in obese type 2 diabetic humans

J.J. Winnick[1], J.M. Gregory[2];
[1]Department of Internal Medicine, University of Cincinnati, Cincinnati, [2]Pediatric Endocrinology and Diabetes, Vanderbilt University, Nashville, USA.

Background and aims: Exercise improves hepatic insulin sensitivity in people with type 2 diabetes (T2D); manifest by diminished endogenous glucose production (EGP) during the fasting state and improved suppression of EGP in response to hyperinsulinemia. Hepatic insulin action is also known to augment splanchnic glucose uptake (SGU) in response to an oral glucose challenge, although the effect of exercise-induced gains in hepatic insulin sensitivity on SGU remain unclear.
Materials and methods: Obese humans with T2D were recruited to undergo 15 ± 1 weeks (mean ± sem) of aerobic exercise training (AEX; $n = 6$; 70% VO2 max; 4–5 days/week; 50 min per session) or remain sedentary for 15 ± 2 weeks (SED; $n = 5$). Prior to intervention, each subject underwent an isoglycemic/hyperinsulinemic clamp (ISO-clamp) to assess basal EGP and hepatic insulin sensitivity at insulin infusion rates of 20 and 40 mU/m^2/min. Each subject also underwent a 75 g oral glucose load clamp (OGL-clamp) to assess SGU. After the intervention, each subject underwent both the ISO-clamp and OGL-clamp a second time, thereby allowing us to assess pre-post changes in hepatic glucose metabolism.
Results: Age, BMI, body fat, HbA_{1C} and VO_2 max were similar in both groups at baseline. In response to the intervention, HbA_{1C} remained unchanged in SED but was reduced from 7.5 ± 0.4 to 7.1 ± 0.2% in AEX ($p < 0.05$). During the basal (i.e., fasting) period of the pre-intervention ISO-clamp, plasma glucose (151 ± 12 mg/dl), insulin (22 ± 2 uU/ml) and EGP (2.2 ± 0.2 mg/kg/min) were similar in both groups, and these values did not change in response to the 15 week intervention in either group.

Likewise, during the 20- and 40-mU/m^2/min insulin infusion periods of all ISO-clamp studies, glucose continued to be clamped at isoglycemia and insulin was also similar among groups at each time point (51 ± 3 and 92 ± 6 uU/ml, respectively). The hyperinsulinemia during the low-insulin period of the pre-intervention study suppressed EGP similarly in SED and AEX (70 ± 5%) and also suppressed EGP by 71 ± 2% in SED during the post-intervention clamp. However, EGP suppression was increased to 80 ± 6% in AEX during the post-intervention clamp ($p < 0.05$). Likewise, while the pre-intervention suppression of EGP during the high-insulin period was indistinguishable between SED and AEX, and similar to what was observed during the post-intervention ISO-clamp in SED, it was also greater in AEX post-intervention ($p < 0.05$). During the OGL-clamp, no differences in hepatic glucose metabolism were observed between groups or over time during the euglycemic/ hyperinsulinemic lead-in period, with average plasma glucose and insulin levels of 96 ± 1 mg/dl and 270 ± 9 uU/ml, respectively. This hormonal milieu, as expected, completely suppressed EGP in each group both before and after the intervention period (0.04 ± 0.09 mg/kg/min). The plasma glucose responses to the 75 g oral glucose challenge were similar between groups at baseline and did not change over time, while insulin levels remained elevated and similar over time in both groups. In response to this challenge, pre-post SGU increased by 22 ± 8% in SED, which was in marked contrast with AEX, which exhibited a 30 ± 20% decrease ($p < 0.05$).

Conclusion: Despite improved hepatic insulin action during the fasted state, aerobic exercise training reduces SGU in response to an oral glucose challenge.

Plasma branched-chain amino acids predict change in insulin sensitivity after exercise training

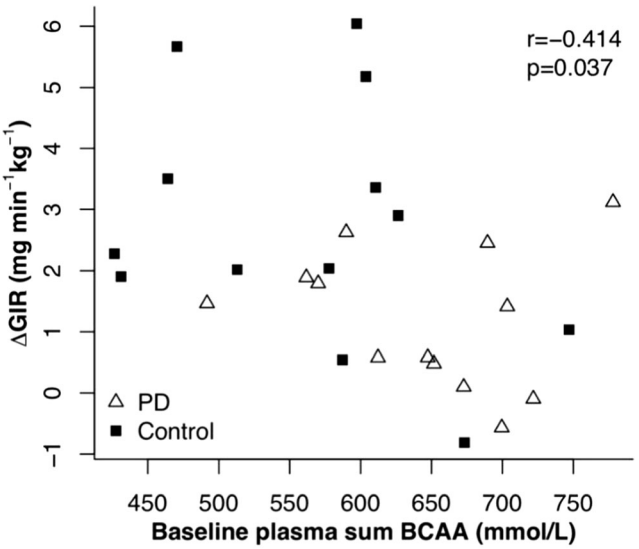
S. Lee[1,2], T.M. Langleite[1], H. Refsum[1], H.L. Gulseth[2], C.A. Drevon[1], K.I. Birkeland[2,1];
[1]University of Oslo, Oslo, [2]Oslo University Hospital, Oslo, Norway.

Background and aims: Insulin resistance (IR) is a hallmark of type 2 diabetes mellitus (T2DM), and it is related to physical inactivity and dietary energy surplus. Recently, branched-chain amino acids (BCAAs) were implicated in IR and T2DM. Physical exercise improves insulin sensitivity perhaps via effects on BCAAs. Our aim was to investigate relationships between BCAAs and IR in dys- ($n = 13$) and normoglycemic ($n = 13$) men during different modalities of physical exercise.

Materials and methods: Insulin sensitivity was estimated as the glucose infusion rate (GIR) during a euglycemic-hyperinsulinemic-clamp, skeletal muscle (SkM) and adipose tissue (AT) transcriptomics by mRNA-sequencing, liver fat by magnetic resonance spectrometry, plasma BCAAs by HPLC, in addition to VO_2max and %-mitochondrial volume in SkM. Tissue samples were obtained at rest, directly after and 2 h after a bicycle ergometer challenge of 70% VO_2max before as well as after 12 w of combined endurance- and strength training intervention. GIR and VO_2max were measured before and after the intervention.

Results: GIR, VO_2max and both AT and SkM BCAA catabolism (based on transcriptomics) were lower, whereas liver fat and plasma BCAAs were higher in dys- vs. normoglycemic men at baseline. GIR, liver fat, %-mitochondrial volume in SkM, both AT and SkM BCAA catabolism, and VO_2max improved similarly for both groups after 12 w exercise intervention. Baseline plasma BCAAs concentration correlated with improvements in GIR and VO_2max after 12 w exercise, independent of several baseline covariates such as age, group, and BMI. However, no net change in plasma concentration of BCAAs was observed after 12 w of exercise. Whereas changes in liver fat and AT BCAA catabolism correlated with reduced plasma concentration of BCAAs, the opposite was observed for plasma creatine kinase (representing muscle micro injury).

Conclusion: BCAAs metabolism seems dysregulated in men with dysglycemia, and baseline plasma BCAAs predicted change in GIR after 12 w exercise training. Although GIR improved after 12 w of exercise, no net change was observed in plasma BCAAs, perhaps because exercise influence several processes with opposite effects on plasma BCAAs.



Baseline plasma BCAAs concentrations correlated with change in insulin sensitivity after 12 w of exercise. Spearman's correlation was performed. PD, prediabetes; GIR, glucose infusion rate; BCAA, branched-chain amino acids represent the molar sum of leucine, iso-leucine and valine.

Resistance training improves neuromuscular health in the elderly with type 2 diabetes: a randomised clinical trial

C.E. Botton[1], R.S. Pinto[2], L. Helal[3], B.D. Schaan[4], D. Umpierre[3];
[1]Health Technology Assessment Institute, Federal University of Rio Grande do Sul, Porto Alegre, [2]Graduate Program in Movement Human Sciences, Federal University of Rio Grande do Sul, Porto Alegre, [3]Graduate Program in Cardiology and Cardiovascular Sciences, Federal University of Rio Grande do Sul, Porto Alegre, [4]Graduate Program in Endocrinology, Federal University of Rio Grande do Sul, Porto Alegre, Brazil.

Background and aims: Elderly with type 2 diabetes mellitus (T2DM) have a 3-fold increased risk to physical disability as well as reduced muscle mass and strength compared with healthy individuals. Resistance training may lead to functional and muscular benefits. Thus, we aimed to assess the efficacy of resistance training in neuromuscular parameters in this population.

Materials and methods: This study is a 3-month randomized controlled clinical trial. Forty-four elderly (69.7 ± 6.9; 26 women) were randomly allocated (1:1), stratified by sex to either (1) a 12-week resistance training program (3 times a week), or (2) an active control group with stretching classes (once a week). Variables were assessed at baseline and after 12 weeks, as follows: quadriceps muscle thickness and muscle quality (assessed by ultrassonography), maximal strength (assessed by knee extension) and $HbA1_c$. Generalized

estimating equations were used to analyses based on intention-to-treat and *per protocol* (sessions adherence ≥70%) approaches.
Results: No differences were found between intervention and control groups at baseline; rectus femoris muscle quality after 12 weeks was also similar among groups ($P = 0.37$). Maximal strength and quadriceps muscle thickness increased in the resistance training group ($P < 0.001$) (Table 1). Lastly, the $HbA1_c$ levels did not significantly change for intervention (7.1 ± 1.0 to 6.8 ± 0.6) and control groups (7.2 ± 1.2 to 7.3 ± 0.2).
Conclusion: A 12-week resistance training program was efficacious to counteract the maximal muscle strength and thickness impairments in elderly with T2DM, although no improvement in metabolic control and muscle quality were found.

Metabolic response of skeletal muscle tissue to three-month exercise intervention in sedentary non-diabetic men

L. Szczerbinski[1], E. Siewiec[1], A. Citko[2], U. Puchta[1], J. Zapolska[3], M. Gorska[1], A. Kretowski[1,2];
[1]Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Bialystok, Bialystok, [2]Clinical Research Centre, Medical University of Bialystok, Bialystok, [3]Department of Dietetics and Clinical Nutrition, Medical University of Bialystok, Bialystok, Poland.

Background and aims: Physical activity is a well-established tool in prevention and treatment of Type 2 Diabetes. Exercise-mediated remodelling of skeletal muscle is associated with improved metabolic health, but unfortunately its mechanisms are still poorly understood. The rapid development of "omics" technologies, including metabolomics, has introduced new opportunities for mapping molecular adaptations to exercise and indicating novel pathways involved in that process. The aim of the study was to assess changes in skeletal muscle metabolome under three-month exercise intervention.
Materials and methods: We performed global untargeted metabolomics by GC-TOF MS, HILIC-QTOF MS/MS and lipidomics by CSH-QTOF MS/MS to evaluate changes in skeletal muscle metabolism under three-month, highly supervised exercise intervention. Skeletal muscle samples were obtained from 37 sedentary, non-diabetic men (mean ± SD age: 47.51 ± 6.97 yrs; BMI: 30.01 ± 6.97 kg/m^2; fasting plasma glucose: 105.57 ± 13.89 mg/dl) before and after three months of exercise intervention, consisting of mixed trainings with endurance and strength exercises three times per week. Exercise intervention was highly supervised, monitored by MyWellness system (Technogym, Italy). To assess the effect of exercise on metabolites we compared metabolites concentrations before and after the intervention, summarizing metabolome-wide responses to exercise with Partial Least Squares Discriminant Analysis (PLS-DA) and Principal Component Analysis (PCA). To define significantly altered chemical classes, we performed chemical enrichment analysis using ChemRICH, which classifies metabolites by structural similarity.
Results: From a total of 663 detected metabolites (120 for GC, 426 for Lipidomics and 117 for HILIC), we found that 78 compounds were significantly altered in skeletal muscle tissue following exercise intervention. Significantly altered metabolites included fatty acids, amino acids, carnitines, complex lipids, and energy metabolites. The enrichment analysis identified eight significantly altered metabolite clusters: acidic amino acids, saturated fatty acids, and unsaturated triglycerides significantly increased and phospholipid ethers significantly decreased. Phosphatidylethanolamines were significantly altered with most species increased and one decreased. Unsaturated phosphatidylcholines were significantly altered with most species decreased and two increased, while carnitines and purines were also significantly altered with equal numbers of increased and decreased metabolites.
Conclusion: In summary, in this study we found significant global alterations in the human skeletal muscle metabolome following three-month exercise intervention. The largest observed changes in metabolite levels were observed in lipids species, especially in glycerophospholipids and glycerolipids. Further studies are required to determine how these changes impact exercise-induced health benefits.

High intensity interval training improves insulin sensitivity in individuals with prediabetes

P. Mensberg[1], C. Frandsen[1], E. Espersen[1], T. Leineweber[1], H. Storgaard[1], K.S. Schlawitz[2], T.H.D. Petersen[2], J.N. Poulsen[2], F. Sørensen[3], J.L. Forman[3], F.K. Knop[1,4], T. Vilsbøll[1,4];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Hellerup, [2]Center for Prevention and Health, Gentofte Municipality, Gentofte, [3]Department of Public Health, Section of Biostatistics, Copenhagen, [4]Department of Clinical Medicine, Faculty of Health and Medical Sciences, Copenhagen, Denmark.

Background and aims: Lack of physical activity in the general population remains a major health issue. Recently, extremely low volume, high intensity interval training (HIIT), as low as 3 min per week, was demonstrated to improve insulin sensitivity and glycaemic control in young healthy individuals. We evaluated the effects of 12 weeks HIIT vs. no training on insulin sensitivity in individuals with prediabetes.
Materials and methods: Seventy sedentary obese middle-aged individuals with prediabetes (women $n = 36$; age: 60.8 ± 11.3 years (mean ± SD); BMI: 31.6 ± 4.4 kg/m^2; fasting plasma glucose (FPG): 6.6 ± 0.8 mmol/l; HbA1c: 39.0 ± 4.3 mmol/mol) were randomised to one of four groups: 1) HIIT (3 × 20 second's cycle sprint 3 times per week, 2) HIIT+walking (HIIT plus >10,000 steps per day), 3) walking (>10,000 steps per day) or 4) no exercise (control group). At baseline and after intervention insulin sensitivity indices were assessed during an OGTT and peak oxygen uptake during an incremental exercise test.
Results: Increased muscle insulin sensitivity (Cederholm index) was observed in the HIIT and HIIT+walking group vs. the control group (Table 1). Muscle insulin sensitivity remained unchanged in the walking only group. Whole body insulin sensitivity (Matsuda index) was unchanged with HIIT, but improved significantly with HIIT+walking and walking only, compared to the control group. Peak oxygen uptake increased from baseline to end of trial in the two HIIT groups and in the HIIT only group, peak oxygen at end of trial was higher compared to the control group (Table 1).

Conclusion: In individuals with prediabetes twelve weeks of HIIT as well as HIIT plus 10,000 daily steps significantly improved muscle insulin sensitivity and the latter also resulted in significantly greater whole body insulin sensitivity compared to no training. HIIT may constitute a time-efficient way to improve insulin sensitivity in individuals with prediabetes.

Table 1

	HIIT n=13		HIIT+walking n=14		Walking n=15		Control n=15	
	Baseline n=13	Change from baseline	Baseline n=14	Change from baseline	Baseline n=15	Change from baseline	Baseline n=15	Change from baseline

Ghrelin in rat pancreatic islets decreases islet blood flow and impairs insulin secretion

C.J. Drott[1], P. Franzén[1], P.O. Carlsson[1,2];
[1]Medical Cell Biology, Uppsala University, Uppsala, [2]Medical Sciences, Uppsala, Sweden.

Background and aims: The peptide ghrelin is mainly produced in some of the epithelial cells in the stomach, but also, during starvation, by the ε-cells in the endocrine pancreas. Ghrelin, as an endogenous ligand for the growth hormone secretagogue receptor (GHS-R1α), exerts a variety of metabolic functions including stimulation of appetite and weight gain. Its complete role is not yet fully understood, including whether it has any vascular functions. The present study evaluated if ghrelin may affect pancreatic and islet blood flow, and insulin secretion.
Materials and methods: Ghrelin and the GHS-R1α receptor antagonist GHRP-6 were injected intravenously in rats followed by blood flow measurements using a microsphere technique. The physiological effect exerted by ghrelin and GHRP-6 in vivo on glucose homeostasis was evaluated by intravenous glucose tolerance test and intraperitoneal insulin tolerance test, and in vitro through glucose-stimulated insulin release experiments.
Results: Ghrelin decreased islet blood flow (50.5 ± 4.4 (control) vs. 34.8 ± 4.2 (ghrelin) μl × min^{-1} × g $pancreas^{-1}$; $P < 0.05$), while GHRP-6 in fasted, but not fed, rats selectively increased islet blood flow fourfold (fed rats 50.5 ± 4.4 (control) vs. 52.3 ± 4.8 (GHRP-6); fasted rats 35.5 ± 6.7 (control) vs. 203 ± 38 μl × min^{-1} × g $pancreas^{-1}$(GHRP-6); $P < 0.05$). GHS-R1α was identified not only on glucagon producing cells, but also in the islet arterioles through PCR and immunohistochemistry. GHRP-6 in fasted rats, only, also improved the peak insulin response to glucose *in vivo* (235 ± 56 pmol/l(control) vs. 534 ± 108 pmol/l (GHRP-6); $P < 0.05$), thereby substantially blunting the hyperglycemia. GHRP-6 doubled glucose stimulated insulin release *in vitro* of both islets obtained from fed rats (35.7 ± 3.9 (control) vs. 64.8 ± 4.7 pmol/l (GHRP-6); $P < 0.05$) and fasted rats (35.9 ± 5.0 (control) vs. 66.2 ± 6.7 pmol/l (GHRP-6); $P < 0.05$).
Conclusion: Our results indicate a novel role for endogenous ghrelin as a local vasoconstrictor in the islets during fasting, thereby restricting the insulin response to hyperglycemia. This is to the best of our knowledge the first report that shows this physiological mechanism to restrict insulin delivery from the islets by acting on the vasculature.

C-terminal plasma degradation of PYY(1-36) and PYY(3-36) severely curtails effects on insulin secretion, beta cell mass and satiety

P.R. Flatt, R.A. Lafferty, N. Irwin;
Ulster University, Coleraine, UK.

Background and aims: Peptide YY (PYY) is known to exist in two major circulating forms, PYY(1-36) and PYY(3-36). PYY(3-36), generated by the action of DPP-4, has well documented anorectic actions with possible therapeutic implications for obesity, whereas the importance of PYY(1-36) for the regulation of pancreatic beta-cell survival has been described recently. Further to this, enzymatic C-terminal truncation of PYY related peptides has been reported, but the physiological impact of this C-terminal processing remains uncertain. The present study has therefore characterised plasma C-terminal degradation products of PYY(1-36) and PYY(3-36), and evaluated their effects on function, proliferation and survival of beta-cells as well as feeding behaviour and glucose homeostasis.

Materials and methods: PYY(1-36) and PYY (3-36) were incubated with murine plasma (4 h, $n = 4$) and evaluated by HPLC/MS to assess enzyme stability. BRIN-BD11 beta-cells ($n = 8$) were used to evaluate the acute (20 min) effects on insulin release (10^{-12}–10^{-6} M) of PYY(1-36), PYY(3-36) plus their related C-terminal degradation products. Actions of PYY peptides (10^{-8} and 10^{-6} M) on beta-cell proliferation, by Ki-67 antibody staining, and protection against cytokine-induced (IL-1β 100 U/ml, IFN-γ 20 U/ml, TNF-α 200 U/ml) apoptosis, by TUNEL assay, were examined in clonal rodent BRIN BD11 and human 1.1B4 cells ($n = 4$). Acute effects of the peptides (25 nmol/kg; i.p.) on food intake, glucose and insulin concentrations were evaluated in overnight fasted (12 h) mice ($n = 8$). In addition, the impact of the ACE inhibitor captopril (50 mg/kg, i.p.) on PYY(3-36) induced appetite suppression was also assessed in mice ($n = 8$).
Results: C-terminal degradation products, PYY(1-34) and PYY(3-34), were detected by HPLC and mass spectrometry analyses following incubation of PYY(1-36) and PYY(3-36) in murine plasma. PYY(1-36) and PYY(3-36) inhibited ($P < 0.05$–$P < 0.001$) glucose-stimulated insulin secretion (GSIS) from BRIN-BD11 beta-cells, whereas PYY(1-34) and PYY(3-34) had no effect on GSIS. All peptides examined, namely PYY(1-36), PYY(3-36), PYY(1-34) and PYY(3-34), lacked effects on glucose tolerance or glucose-induced insulin release. However, both PYY(1-36) and PYY(3-36) significantly ($P < 0.05$–$P < 0.001$) enhanced proliferation of BRIN BD11 and 1.1B4 beta-cells, and also fully protected ($P < 0.01$–$P < 0.001$) these cells against cytokine-induced apoptosis. The C-terminal degradation products, PYY(1-34) and PYY(3-34), were entirely ineffective in this regard. As expected, PYY(3-36) induced clear acute reductions ($P < 0.05$–$P < 0.01$) of food intake in mice, but these effects were eliminated by removal of the C-terminal dipeptide from PYY(3-36). Interestingly, captopril significantly ($P < 0.05$) augmented the appetite suppressive actions of PYY(3-36).
Conclusion: PYY is an enteroendocrine derived peptide hormone with an important role in metabolism linked to regulation of energy expenditure and pancreatic beta-cell survival. The impact of C-terminal degradation of both PYY(1-36) and PYY(3-34) on receptor interaction and subsequent bioactive profile at islet and hypothalamic sites of action needs further consideration, as it appears to dramatically diminish biological activity.

A novel exendin-4/gastrin/xenin-8-Gln fusion peptide, in combination with a stable GIP agonist, substantially improves metabolic control in high fat fed mice

N. Irwin, A. Hasib, M.T. Ng, P.R. Flatt, V.A. Gault;
Ulster University, Coleraine, UK.

Background and aims: Enteroendocrine derived hormones such as gastrin, glucagon-like-peptide-1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP) and xenin are known to exert complementary beneficial metabolic effects in diabetes. The present study characterised a novel fusion peptide, exendin-4/gastrin/xenin-8-Gln, and evaluated therapeutic utility in combination with the GIP receptor agonist, ($DAla^2$)GIP, in high fat fed mice.
Materials and methods: Exendin-4/gastrin/xenin-8-Gln was synthesised by coupling residues 1–28 of exendin-4, with gastrin-6 and xenin-8-Gln, using 8-amino-3,6-dioxaoctanoic acid linker molecules. The peptide was incubated with murine plasma ($n = 4$) to assess enzyme stability. BRIN-BD11 cells were used to evaluate insulinotropic activity of exendin-4/gastrin/xenin-8-Gln (10^{-12}-10^{-6} M), with GLP-1, neurotensin, and CCK-B receptor antagonists employed to ascertain insulin secretory receptor balance. Acute effects of the fusion peptide on food intake, glucose and insulin concentrations were examined in lean mice ($n = 8$). High fat fed (HFF) mice ($n = 8$) were used to assess chronic effects of exendin-4/gastrin/xenin-8-Gln alone, and in combination with ($DAla^2$)GIP, (each peptide at 25 nmol/kg; *ip*) using a twice-daily injection regimen for 21 days. Body weight, glucose and insulin concentrations were measured every 3 days. Oral glucose tolerance (18 mmol/kg), metabolic response to GIP (25 nmol/kg; *ip*) and insulin sensitivity (10 U/kg; *ip*) were determined at the end of the study. Plasma lipid, glucagon and amylase activity were also assessed on day 21.
Results: Exendin-4/gastrin/xenin-8-Gln was enzyme resistant and enhanced ($P < 0.001$) insulin secretion from BRIN-BD11 cells, with GLP-1 and neurotensin receptor pathways being important. Acute injection of exendin-4/gastrin/xenin-8-Gln in combination with glucose significantly ($P < 0.001$) lowered glucose and increased insulin concentrations in mice, with antihyperglycaemic effects evident ($P < 0.001$) 8 h post-injection. Exendin-4/gastrin/xenin-8-Gln also induced significant ($P < 0.001$) appetite suppressive effects. Administration of exendin-4/gastrin/xenin-8-Gln alone, or in combination with ($DAla^2$)GIP, twice daily for 21 days in HFF mice, reduced ($P < 0.01$) percentage body fat compared to saline controls. The treatment regimens significantly ($P < 0.05$–$P < 0.001$) decreased circulating glucose and increased insulin concentrations, with no impact on glucagon levels or amylase activity. Exendin-4/gastrin/xenin-8-Gln in combination with ($DAla^2$)GIP also reduced ($P < 0.05$) LDL-cholesterol levels. In addition, the combined treatment group presented with clear improvements in glucose tolerance, which was superior to either treatment alone. Similarly, GIP-induced reductions in blood glucose and elevations of insulin were enhanced ($P < 0.05$–$P < 0.01$) by treatment with exendin-4/gastrin/xenin-8-Gln in combination with ($DAla^2$)GIP. All treatment groups had superior ($P < 0.05$–$P < 0.001$) glucose-lowering actions in response to exogenous insulin administration.
Conclusion: Exendin-4/gastrin/xenin-8-Gln is a fusion peptide with clear antidiabetic potential. Efficacy was improved through concurrent administration of a stable GIP molecule, adding support to the promise of multi-targeting peptides for the treatment of diabetes.

Differential efficacy of a GLP-1R/GCGR dual agonist versus a GLP-1R agonist in diet-induced obese mice

M.P. Valdecantos[1], L. Ruiz[1], M.J. Obregon[1], A. Dos Santos[2], M.A. Bednarek[2], J. Grimsby[2], C. Rondinone[2], A.M. Valverde[1];
[1]Metabolismo y Señalización Celular, Instituto de Investigaciones Biomédicas Alberto Sols, Madrid, Spain, [2]MedImmune Inc, Gaithersburg, USA.

Background and aims: The increasing incidence of obesity and type 2 diabetes worldwide has prompted the need for new therapies. In this study we have designed a pharmacological intervention protocol with a GLP-1R or dual-acting GLP-1R/ GCGR agonist aimed to investigate their differential effects and the mechanism of action involved in preventing diet-induced obesity in mice.
Materials and methods: Eight week-old male C57BL/6 mice were fed chow or HFD for 10 weeks. HFD-fed mice were subsequently s.c. injected every 2 days with vehicle or a GLP-1R agonist (10 nmol/kg) or G49, a GLP-1R/GCGR dual agonist, (4 mg/kg) for 6 weeks. Another group of animals were administered a single dose of G49 (4 mg/kg). Parameters that assess obesity, BAT activation, lipolysis, glucose homeostasis and insulin sensitivity were analyzed at 6 weeks of treatment and after 6, 12, 24 and 48 hours post G49 treatment.
Results: After 6 weeks of treatment, body weight loss was greater in mice injected with G49 (20.05% ± 5.94) compared to animals treated with the GLP-1R agonist (6.61% ± 5.29; $p < 0.001$). Indirect calorimetry revealed an increase in energy expenditure in G49 treated animals, but not in mice injected with the GLP-1R agonist in both the dark (16.7 ± 1.57 vs 13.9 ± 0.63 Kcal/h/Kg) and light cycles (14.6 ± 1.4 vs 11.8 ± 0.26 Kcal/h/Kg) ($p < 0.001$). G49 was more effective than the GLP-1R agonist in increasing mRNA levels of BAT activation-related genes, as well as in the induction of browning-related genes in iWAT ($p < 0.05$–$p < 0.001$). Furthermore, G49 increased BAT type II deiodinase (Dio2) mRNA and DIO2 activity, T3 and T4 concentration, effects not observed after treatment with GLP-1R agonist ($p < 0.001$). Moreover, a single dose of G49 reduced body weight at 6 h (4.6

± 1.4% of the initial BW) concomitant with a reduction in eWAT ($p < 0.001$) and iWAT ($p < 0.001$) depots and a transient elevation in plasma free fatty acids (0.81 ± 0.09 vs 0.59 ± 0.06 mmol/L in vehicle-treated mice) relative to vehicle treatment. Lipolysis was stimulated in ex vivo eWAT explants isolated from mice treated with a single dose of G49. The analysis of BAT revealed an increase in UCP-1 immunostaining and protein levels at 48 h post-single injection, reflecting rapid BAT activation. Treatment with G49 for 4 h induced lipolysis in both differentiated 3T3L1 and brown adipocytes (BA) ($p < 0.01$). Gene expression analysis of BA treated with G49 for 16 h showed an increase in *Ucp1*, mitochondrial biogenesis and beta oxidation-related genes ($p < 0.05$–$p < 0.01$). Interestingly, G49 treatment during differentiation of BA increased protein levels of UCP1 and mitochondrial-biogenesis-related genes.
Conclusion: Our results strongly suggest a novel role of G49, an oxyntomodulin-like dual acting GLP-1R/GCGR agonist, in reducing obesity by increasing energy expenditure due to its effects in BAT and browning of WAT. Moreover, the results revealed an acute effect of G49 in inducing lipolysis in eWAT and activation of BAT with a similar pattern in white and brown adipocytes in culture. These data suggest that G49 might trigger a cross-talk between eWAT and BAT which is mediated by the release of FFA which are fuels for BAT thermogenesis

Increasing the cellular populations secreting incretins improves glucose homeostasis and beta cell regeneration

M. Terasaki[1,2], C.L. Mattsson[1], K.-C. Liu[1], J. Charbord[1], Q. Zhou[3], T. Hirano[2], O. Andersson[1];
[1]Cell and Molecular Biology, Karolinska Institutet, Stockholm, Sweden, [2]Diabetes, Metabolism and Endocrinology, Showa University School of Medicine, Tokyo, Japan, [3]Stem Cell and Regenerative Biology, Harvard University, Cambridge, USA.

Background and aims: Glucagon-like peptide-1 (GLP-1) receptor agonists and dipeptidyl peptidase-4 (DPP-4) inhibitors are widely used in patients with type 2 diabetes. However, their use could lead to tonic supraphysiological levels of incretins. We speculated that it might be advantageous to expand the cellular populations secreting GLP-1 and glucose-dependent insulinotropic polypeptide (GIP), such that one has the capacity to secrete more incretins upon food ingestion, instead of constantly having increased levels of circulating incretins.
Materials and methods: Using a transgenic zebrafish model, we performed an *in vivo* screen of 1,300 small molecules for stimulators of GIP expression by measuring luciferase activities. We then evaluated whether the hit-compounds can increase the number of GIP-expressing K-cells in the intestine by using immunohistochemistry, and subsequently examined whether the hits also increase L-cell numbers. The glucose levels and related gene expression levels were determined by a glucose assay kit and by SYBR-based RT-PCR, respectively. We also evaluated the effect of the hit-compounds on pancreatic β-cells in transgenic zebrafish with or without β-cell ablation using metronidazole. Moreover, we examined whether the effects were conserved to the mouse, using wild-type (C57BL/6J) mice and diabetic *db/db* (C57BLKS/J Iar- +*Leprdb*/+*Leprdb*) mice, which were administered with the hit-compounds *in vivo.*
Results: We identified small molecules that converge on a fatty acid signaling pathway with a common downstream transcriptional regulator, to increase the number of incretin-expressing cells originating from Neurog3-expressing enteroendocrine progenitors. This did not only lead to an increased number of incretin-expressing cells, but also to reduced glucose levels and promoted β-cell regeneration by increasing β-cell proliferation, effects that were accompanied with increased insulin mRNA levels. Consistent with these findings, our identified compounds increased incretin-expressing cell numbers in the mouse intestine with augmented plasma levels of GIP and GLP-1, and improved oral glucose tolerance tests and HbA1c levels in diabetic *db/db* mice.
Conclusion: Our identified compounds increased incretins-expressing cell numbers in both zebrafish and mouse intestine with improved glucose homeostasis *in vivo*, indicating the effect of the hits is conserved across species.

Transcriptional factor pancreatic duodenal homeobox-1 (Pdx1) is involved in age-related glucose-dependent insulinotropic polypeptide (GIP) hypersecretion in mice

E. Ikeguchi[1], N. Harada[1], Y. Kanemaru[1], A. Sankoda[1], S. Yamane[1], K. Iwasaki[1], M. Imajo[2], Y. Murata[1], K. Suzuki[1], E. Joo[1], N. Inagaki[1];
[1]Department of Diabetes, Endocrinology and Nutrition, Graduate School of Medicine, Kyoto University, Kyoto, [2]Laboratory of Bioimaging and Cell Signaling, Graduate School of Biostudies, Kyoto University, Kyoto, Japan.

Background and aims: Fat accumulation with aging is a serious problem. Glucose-dependent insulinotropic polypeptide (GIP) is an incretin secreted from enteroendocrine K cells in response to glucose and fat ingestion. GIP potentiates insulin secretion through the GIP receptor (GIPR) expressed in pancreatic β-cells. GIP plays an important role in maintaining blood glucose levels by inducing hypersecretion of insulin in high-fat diet (HFD)-induced obesity. GIPR expressed in adipose tissue is involved in HFD-induced insulin resistance. Thus, GIP is a key hormone for fat accumulation. GIPR-knockout mice show reduced fat mass and improved insulin sensitivity associated with aging. Therefore, GIP could be involved in fat accumulation and insulin resistance with aging. However, age-related changes of GIP secretion remain unclear. The present study aimed to elucidate age-related changes of GIP secretion and K cells under normal diet condition using GIP reporter mice.
Materials and methods: Male GIP reporter (GIP-GFP knock-in heterozygous) mice were divided into two groups: 3–4 months old (young) mice and 1 year old (aged) mice. Their body composition, GIP secretion, and insulin tolerance were evaluated. Immunohistochemical and flow cytometry analyses were performed to assess K cell number. The expression levels of GIP mRNA and transcriptional factors in sorted K cells were measured. A target gene expression in small intestine was suppressed by intestine-specific gene transfer (iGT). K cell number, GIP mRNA expression and content in small intestine, and GIP secretion were estimated after the suppression of the target gene by the introduction of siRNA.
Results: Body weight of aged mice was significantly higher than that of young mice. Aged mice accumulated more body fat, and blood glucose reduction was significantly less in aged mice during insulin tolerance test, indicating that aged mice exhibit the phenotype of fat accumulation and insulin resistance. Aged mice showed hypersecretion of GIP and insulin during oral glucose tolerance test and under free feeding, while blood glucose levels did not differ between the two groups. K cell number was increased in small intestine of aged mice. In aged mice, the mRNA expression levels of GIP and transcriptional factor pancreatic and duodenal homeobox-1 (Pdx1) were increased in sorted K cells. K cell number, GIP mRNA expression and GIP content in small intestine were decreased in the mice after posteriori suppression of Pdx1 using iGT, resulting in reduced GIP secretion after glucose ingestion.
Conclusion: Pdx1 increases K cell number and GIP mRNA expression in small intestine of aged mice, which results in GIP hypersecretion with aging.
Disclosure: **E. Ikeguchi:** None.

GLP-1 releaser D-allulose effectively and glucose-dependently corrects hyperglycaemia

T. Yada[1], M. Sendo[2], M. Yoshino[2], Y. Yamada[3], D.J. Drucker[4], M. Tokuda[5], Y. Iwasaki[6];
[1]Integrative Physiology, Kansai Electric Power Medical Research Institute, Kobe, Japan, [2]Physiology, Jichi Medical University, Shimotsuke, Japan, [3]Endocrinology, Diabetes and Geriatric Medicine, Akita University, Akita, Japan, [4]Lunenfeld Tanenbaum Research Institute, Mt. Sinai Hospital, Toronto, Canada, [5]Cell Physiology, Kagawa University, Kagawa, Japan, [6]Animal Science, Kyoto Prefectural University, Kyoto, Japan.

Background and aims: We previously reported that oral administration of D-allulose (Allu), a rare sugar with sweetness but not calorie, induced release of GLP-1 and promoted glucose tolerance in normal B6J mice and those fed high fat diet (HFD). The Allu-induced promotion of glucose tolerance was blunted in GLP-1R deficient mice and in mice receiving vagal afferent denervation. Allu enhanced both initial insulin secretion in glucose tolerance test and insulin action. Type 2 diabetes is featured with elevation of casual blood glucose (cBG) as well as postprandial blood glucose. This study aimed (1) to clarify the effect of Allu on cBG levels, and its dependency on glycemic levels or healthy vs diabetic states. Moreover, Allu serves as GLP-1 releaser, providing a novel category of incretin medicine. Hence it is of relevance to compare the effects of Allu and conventional inctretin medicine. This study aimed (2) to compare Allu and GLP-1R agonist, exentine-4 (Ex4), in the efficacy of lowering cBG and potential of causing hypoglycemia in normoglycemic and hyperglycemic mice.
Materials and methods: Lean B6J mice with body weight (BW;25 g), obese B6J mice fed HFD for 80–90 days (40 g), and obese db/db mice (45 g) were used. Male mice ($n = 5–6$ for each experiment) were mildly fasted for 4 hours from 9:00 to 13:00. Allu (1 g/kg) (Matsutani Chem.) or saline was per oral (po) administered and blood glucose was measured at 0, 1, 2 and 3 hr. GLP-1R agonist Ex4 (Abcam) was subcutaneously (sc) administered at 0.5 nmol/kg, a dose that suppressed food intake. Statistical analysis was performed by one-way or two-way ANOVA followed by Dunnett's, Tukey's or Bonferroni's post hoc test. $P < 0.05$ was considered significant. All data were expressed as means ± SEM.
Results: (1) In B6J mice with cBG levels around 100 mg/dL, po Allu failed to significantly alter cBG at 1–3 hr after Allu administration. In contrast, Allu reduced cBG from 200 to 150 mg/dL (ΔcBG;50) at 1–3 hr in HFD fed diabetic B6J mice, and from 400 to 220 mg/dL (ΔcBG;180) at 1–5 hr in db/db mice. (2) In B6J mice, Ex4 significantly reduced cBG from 110 to 65 mg/dL (ΔcBG;45) at 1 hr. In HFD fed B6J mice, Ex4 significantly reduced cBG from 185 to 160 mg/dL (ΔcBG;25) only at 1 hr, and in db/db mice it reduced blood glucose from 400 to 300 mg/dL (ΔcBG;100) only at 1 hr.
Conclusion: Allu exhibited greater cBG-lowering effect at higher cBG levels, and no effect at normal glucose levels. This result indicates glucose-dependent ability of Allu to attenuate hyperglycemia. In contrast, Ex4 induced mild hypoglycemia in normal B6J mice and ameliorated hyperglycemia only transiently in HFD fed B6J and db/db mice. The results demonstrate that Allu ameliorates hyperglycemia with greater efficacy and longer-lastingly than Ex4 in type 2 diabetic mice. Oral Allu, as a GLP-1 releaser, may provide a novel category of incretin-based medicine with high efficacy and safety to correct hyperglycemia.

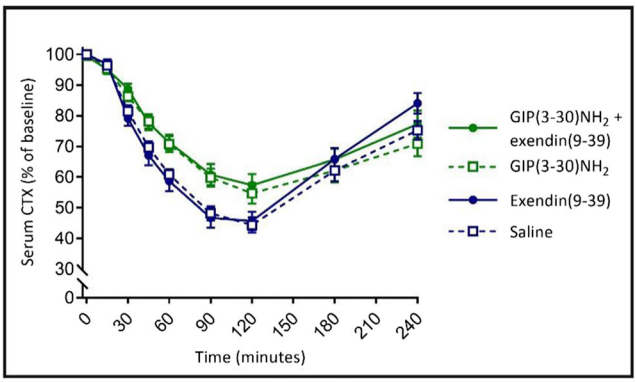
The role of the incretins in the postprandial bone remodelling

M.M. Helsted[1,2], L.S. Gasbjerg[1,2], A.R. Lanng[1], S. Stensen[1], B. Hartmann[2], M.B. Christensen[3,4], J.J. Holst[2], T. Vilsbøll[1,2], M.M. Rosenkilde[2], F.K. Knop[1,2];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Hellerup, [2]Department of Biomedical Sciences and Novo Nordisk Center for Metabolic Research, University of Copenhagen, Copenhagen, [3]Department of Clinical Pharmacology, Bispebjerg Hospital, Copenhagen, [4]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Glucose-dependent insulinotropic polypeptide (GIP) is, like glucagon-like peptide 1 (GLP-1), an incretin hormone and thus potentiates glucose-induced insulin secretion in healthy subjects. Furthermore, GIP is known to affect bone metabolism and has been suggested as an important mediator in an entero-osseous axis. We used a novel high-affinity competitive GIP receptor antagonist, GIP(3-30)NH_2, and the competitive GLP-1 receptor antagonist exendin(9-39) to examine the contributions of the endogenous GIP and GLP-1, respectively, to postprandial suppression of bone resorption, measured by carboxy-terminal collagen crosslinks (CTX), and postprandial bone formation, measured procollagen type 1 amino-terminal propeptide (P1NP), in healthy subjects.
Materials and methods: In two randomised and double-blinded cross-over sub-studies, the separate and combined impact of endogenous GIP and GLP-1 was investigated. In sub-study 1, 18 healthy men (age 20–70 years, body mass index (BMI) 22–34 kg/m^2) received four oral glucose tolerance tests (OGTT). In sub-study 2, 12 healthy men (age 19–65 years, BMI 20–25 kg/m^2) received four liquid mixed meal tests. In both studies, subjects received combinations of infusions of GIP(3-30)NH_2 (800 pmol/kg/min), exendin(9-39) (20 min of 1000 pmol/kg/min, then 450 pmol/kg/min), and/or matching volumes of saline. Thus, subjects received: A) GIP(3-30)NH_2 + exendin(9-39), B) GIP(3-30)NH_2 + saline, C) exendin (9-39) + saline; D) saline + saline. The antagonist concentrations were chosen based on respective inhibitory potencies in vitro. We measured serum levels of CTX, P1NP, and parathyroid hormone (PTH).
Results: CTX decreased on all study days. Significant differences in baseline-subtracted area under the curve (bsAUC) between day B1 and D1 ($p = 0.009$), A1 and D1 ($p = 0.012$), B2 and C2 ($p = 0.020$) and B2 and D2 ($p = 0.030$) were evident. During infusion with GIP(3-30)NH_2, CTX decreased significantly less than during placebo infusion (42 ± 3.7% (B1) vs 56 ± 2.5% (D1) and 52 ± 2.8% (B2) vs 63 ± 3.5% (D2)) (Figure shows results from sub-study 1). There was no effect of exendin(9-39) (A1 vs B1, C1 vs D1, A2 vs B2, and C2 vs D2). In both sub-studies, the interventions did not affect P1NP or PTH.
Conclusion: Endogenous GIP contributes significantly to postprandial suppression of bone resorption in humans whereas an effect of endogenous GLP-1 could not be demonstrated using exendin 9-39.



Sub-study 1. Serum CTX levels in percent of baseline during OGTT in healthy male subjects (n=18). Infusions of GIP(3-30)NH_2 + exendin(9-39), GIP(3-30)NH_2, exendin (9-39), and saline.

The thromboxane A2 receptor modulates glucose metabolism in skeletal muscle

A.M. Abdelmoez[1], A. Krook[1], J.R. Zierath[2], N.J. Pillon[1];
[1]Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, [2]Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Obesity and type-2 diabetes are associated with chronic low grade inflammation. Activation of immune responses and infiltration of immune cells in the adipose tissue, liver and skeletal muscle contribute to the development of insulin resistance. Skeletal muscle is the major contributor to post-prandial regulation of glucose levels and therefore a key player in the development of type 2 diabetes. However, inflammatory responses occurring within skeletal muscles that affect myocytes metabolic responses are poorly characterized.
The thromboxane A2 receptor (TBXA2R) is a G-protein coupled receptor present at the cell surface of platelets but we also discovered that it is expressed in skeletal muscle cells. In addition, phosphoproteomic data has shown increased TBXA2R phosphorylation in skeletal muscle after an acute exercise bout. TBXA2R responds to prostaglandins and thromboxane, compounds known to activate inflammation, but its role in skeletal muscles metabolic responses has not been studied. We hypothesize here that TBXA2R affects skeletal muscle cells glucose metabolism, as part of skeletal muscle cells response to exercise.
Materials and methods: L6 rat skeletal muscle cells and primary human myoblasts were grown and differentiated into myotubes. Cells were incubated with the thromboxane A2 receptor agonists U46619 or I-BOP for four hours, then incubated with/without insulin for 20–30 minutes before adding ^{3}H- or ^{14}C-labeled glucose for 15 or 90 minutes for the glucose uptake and glucose incorporation into glycogen (glycogen synthesis) assays respectively. Proteins were extracted, and glucose and glycogen metabolism, insulin signalling, and inflammatory pathways were investigated.
Results: Incubation with the thromboxane A2 agonists significantly increased basal and insulin-stimulated glucose uptake and glycogen synthesis in L6 and human myotubes. Human cells were more responsive than rat L6 cells, which corresponds with higher expression of the TBXA2R receptor in human cells. Preliminary data showed that activation of TBXA2R triggered an increase in protein kinase C (PKC) phosphorylation as well as a large decrease of the inhibitory phosphorylation of glycogen synthase (GS), which corresponds with the increase in glycogen synthesis. Activation of TBXA2R did not increase phosphorylation of MAPK pathways (p38 and JNK), while the phosphorylation of p65/NFκB (nuclear factor κB) was decreased. Phosphorylation of Akt and AS160 (Akt substrate of 160 kDa) was unaffected, which indicates that the metabolic effects of TBXA2R were independent from insulin signaling pathway.
Conclusion: Our data suggests that TBXA2R modulates glucose metabolism in skeletal muscle, and mapping of its signaling network will likely identify novel targets to improve insulin-independent glucose uptake. TBXA2R modulation in skeletal muscle may represent an interesting approach for the improvement of glucose control in metabolic diseases.

Background and aims: Recently, extracellular vesicles (EVs) such as exosomes and microvesicles are indicated the possibility of a signal transmitter in intercellular network, because they include DNA, miRNAs and proteins. We have reported that mechanical stretch improved insulin-stimulated glucose uptake through the insulin-independent signaling mechanism in C2C12 myotubes. We hypothesized that EVs secreted by mechanical stretch affected on glucose uptake mechanism and improved insulin sensitivity by the means of paracrine or autocrine systems. Therefore, this study aimed to investigate the functions of EVs derived from mechanical stretched myotubes on insulin-stimulated glucose uptake in vitro.
Materials and methods: C2C12 myoblasts were grown on an elastic silicone chamber and induced differentiation. Differentiated C2C12 myotubes were stimulated by cyclic uniaxial stretch (10% of initial length, 10 cycle/min) for 5 hours. EVs were isolated from supernatants with Mag-capture isolation kit and co-incubated with well differentiated C2C12 myotubes or 3T3L1 adipocytes before insulin stimulation. The cells were stimulated with 10nM insulin for 10 minutes and then glucose uptake experiment was performed. The amount of 2-deoxyglucose uptake was measured by enzymatic assay. And the signaling pathway was examined by western-blotting.
Results: EVs were isolated in basal and stretched condition and the protein amount of EVs was not seen any differences between them by protein assay. These EVs expressed exosomes biomarker, CD81 equally in each condition. EVs from mechanical stretch statistically increased insulin-stimulated glucose uptake by 22% and Akt phosphorylation in C2C12 myotubes. Interestingly, this ameliorating of insulin sensitivity was observed in 3T3L1 adipocytes by stretch-induced EVs from C2C12 myotubes. Glucose transporter 4 (Glut4) expression was elevated in both C2C12 myotubes and 3T3L1 adipocytes co-incubated with stretch-induced EVs.
Conclusion: These results suggest that mechanical-stretch induced extracellular vesicles from muscle cells have the potential for improvement insulin sensitivity of muscle cells and adipocytes and the target for treatment of diabetes.

Caveolin and clathrin mediate insulin receptor internalisation and are associated with high-insulin induced insulin resistance in muscle cells

H. Cen[1], L. Abraham[2], M. Gold[2], J.D. Johnson[1];
[1]Department of Cellular and Physiological Science, University of British Columbia, Vancouver, [2]Department of Microbiology and Immunology, University of British Columbia, Vancouver, Canada.

Background and aims: InsR internalization upon insulin binding enables the InsR signaling from endosomal compartments and is a possible mechanism to selectively activate different downstream signaling pathways. InsR endocytosis through either clathrin- or caveolin-mediated pathways have been observed in different cell lines, but the specific internalization routes and insulin dose-dependent dynamics of InsR have not been determined in skeletal muscle cells. Hyperinsulinemia thought to be a compensation for peripheral insulin resistance may be the cause. The mechanism by which high insulin exerts its deleterious effects on insulin signaling remains unclear. We are determining the InsR internalization routes and dynamics in muscle cells and the associated mechanisms of high insulin-induced insulin resistance.
Materials and methods: The interaction of InsR with Cav3 or clathrin in response to insulin were assessed by co-immunoprecipitation (Co-IP)

using skeletal muscles from mice injected with 1.5 U insulin. The localization and trafficking of inter-domain tagged InsR around cell membrane were imaged by TIRF microscopy. Diffusion coefficient was calculated from the single particle tracking of InsR domains to determine the dynamics of InsR. Differentiated C2C12 myotubes were treated with 200 nM insulin for ~16 hours to establish an *in vitro* cell model for high insulin-induced insulin resistance. Surface biotinylation assay, which allows the isolation of labeled surface or internalized proteins and their interacting proteins, was used to illustrate the distribution and internalization kinetics of InsR at normal and insulin resistance conditions.

Results: InsR had increasing interaction with Caveolin 3 (Cav3) at 5 and 10 min after insulin stimulation in mouse skeletal muscle, while clathrin had elevated interaction with InsR at 5 min, determined by Co-IP. Inter-domain tagged InsR co-localized with both caveolin and clathrin in C2C12 myoblasts. The presence of 2 nM insulin resulted in the higher diffusion coefficient of InsR, which suggested a positive effect of insulin on accelerating the movement of the insulin receptor. High insulin-treated C2C12 myotubes exhibited attenuated insulin signaling highlighted by moderated Akt and ERK phosphorylation. The baseline Akt phosphorylation was also decreased. The InsR level was significantly downregulated by ~50%, and the total Akt and ERK levels were unaltered. The surface InsRs were also decreased by ~40%, while the surface to total InsR ratio was unaffected. Interestingly, both Cav3 and AP2, the adaptor protein that binds to receptors and initiates clathrin-mediated endocytosis, were increased in high insulin-treated cells, while surface-bound Cav3 had no apparent difference. The internalization kinetics of InsR were not significantly affected by different insulin concentrations or high-insulin treatment.

Conclusion: InsR internalization may be mediated by both clathrin and caveolin is skeletal muscle cells. The mechanisms of high-insulin induced insulin resistance may involve the downregulation of both total and surface InsR, which is associated with upregulation of Cav3 and AP2. We are investigating the role of dual internalization routes on InsR signaling in normal and high-insulin induced insulin resistant cells.

Prdx6 reduced the risk of type 2 diabetes-associated sarcopenia by improving skeletal muscle cells differentiation

F. Pacifici[1], B. Capuani[1], F. Piermarini[1], D. Pastore[1], R. Arriga[1], A. Coppola[1], S. Rea[1], G. Donadel[1], A. Bellia[1], D. Della-Morte[1,2], D. Lauro[1]; [1]University of Rome Tor Vergata, Rome, [2]Università Telematica San Raffaele Roma, Rome, Italy.

Background and aims: Diabetes Mellitus (DM) is a group of metabolic disorders characterized by a state of hyperglycemia resulting from altered insulin secretion by pancreatic beta cell, insulin action (insulin resistance) or both. This pathological condition is frequently associated with muscle mass loss, a condition defined as sarcopenia, and with diabetic myopathy, represented by an impairment of the regenerative power of muscle fiber and by an altered differentiation of progenitor cells. Oxidative stress has been identified among the main causes of muscular decline typical of diabetic patients. We reported that Peroxiredoxin6 (Prdx6), a relatively new antioxidant enzyme belonging to the Peroxiredoxin's family, has a central role in controlling glucose homeostasis by exerting a potent antioxidant role. Therefore, in the present study, we aimed to investigate whether Prdx6 may be implicated in Type 2 DM (T2DM)-sarcopenia pathological link.

Materials and methods: Wild type (wt) and Prdx6 knockout ($Prdx6^{-/-}$) three-months old male mice were used for this study. Moreover, a murine myoblasts cell line (C2C7) stably silenced for Prdx6 ($Prdx6^{KD}$) was generated and compared with control scramble (scr) cells. Four limbs GRIP test was achieved in mice model to assess muscle strength. Gene expression of myogenic and atrophy-associated factors was evaluated by performing qRT-PCR on muscle. Protein extracts from $Prdx6^{KD}$ C2C7 cell line was processed by performing western blot analysis. Sera levels of biomarkers of sarcopenia were evaluated by Luminex assay.

Results: We observed significant reduced muscle strength in $Prdx6^{-/-}$ mice compared to control group by performing GRIP test, suggesting presence of sarcopenia in this mice model. In order to investigate possible influencers responsible for this phenomenon, we analyzed gene expressions of the main factors involved in the differentiation of myogenic muscle cells, such as MyoD and Myogenin. We observed significant decreased levels of both genes in $Prdx6^{-/-}$ mice compared to control group, suggesting an impairment of the regenerative potential of muscle fibers in these mice. Muscle atrophy was studied by evaluating the gene expression of MuRF1 and Atrogin-1 that finely regulate protein degradation at skeletal muscle level. According to our hypothesis, the expression levels of both enzymes were significantly increased in $Prdx6^{-/-}$ mice, confirming the presence of muscle atrophy. To further confirm sarcopenia, we evaluated sera levels of IGF-1, GDF-15 and TNF-alpha, a well-established markers of muscle loss. We observed a significant pathological modulation of these factors validating the presence of T2DM-sarcopenia associated noxious link. An *in vitro* cellular model of murine muscle cell $Prdx6^{KD}$ was used to confirm the reduction of myogenic factors. A significant decrease in proteins expression of MyoD and Myogenin, which could be regulated by specific muscle miRNA up-regulation, was evident.

Conclusion: Our study, innovatively, highlights a fundamental role of the antioxidant enzyme, Prdx6, in the mechanism of diabetes-associated sarcopenia, suggesting how Prdx6 can be considered a potential therapeutic target for restore muscle loss in these patients. Further studies are needed in order to understand molecular mechanisms underlying this phenomenon.

The novel adipokine Wnt1-inducible signalling pathway protein-1 (WISP1) associates with insulin resistance and impairs insulin action

Background and aims: Wnt1-inducible signalling pathway protein-1 (WISP1) was recently identified as a pro-inflammatory adipokine. We examined whether WISP1 expression and circulating levels are altered in type 2 diabetes, and whether WISP1 affects insulin signalling in muscle cells and hepatocytes.
Materials and methods: Serum and visceral adipose tissue (VAT) biopsies for analysis of circulating WISP1 levels by ELISA and *WISP1* mRNA expression by qPCR were collected from normal-weight control men ($n = 33$), and obese men with ($n = 56$) and without type 2 diabetes ($n = 46$) undergoing surgery. Insulin signalling was analysed in primary human skeletal muscle cells (hSkMC) and murine AML12 hepatocytes following incubation with WISP1 and insulin by Western blotting. WISP1 effects on insulin-stimulated glycogen synthesis and gluconeogenesis were investigated in hSkMC cells and murine hepatocytes, respectively.
Results: Circulating WISP1 levels were higher in obese men independent of type 2 diabetes than in controls (70.8 (55.2–86.4) ng/l vs. 42.6 (28.5–56.6) ng/l; $p < 0.05$, respectively). VAT *WISP1* expression was 1.9-fold higher in morbidly obese men versus controls ($p < 0.05$). Circulating WISP1 levels were positively associated with blood glucose in the oral glucose tolerance test and circulating heme oxygenase-1 but negatively with adiponectin levels. In hSkMC cells and AML12 hepatocytes, recombinant WISP1 impaired insulin action by inhibiting the phosphorylation of insulin receptor, Akt, and its substrates glycogen synthase kinase 3β, FOXO1 and p70S6 kinase, as well as insulin-stimulated glycogen synthesis and suppression of gluconeogenic genes.
Conclusion: Circulating WISP1 and *WISP1* expression in VAT are increased in obesity independent of glycaemic status. Furthermore, WISP1 impaired insulin signalling in muscle and liver cells.

Plasma methylglyoxal is associated with insulin resistance and induces impairment of insulin-induced akt-phosphorylation in microvascular endothelial cells

T.A. Chimhanda[1], D.E.M. Maessen[1], N. Hanssen[1], M.K.C. Hasselink[2], P. Schrauwen[2], C.D.A. Stehouwer[1], C.G. Schalkwijk[1];
[1]Internal Medicine, Maastricht University Medical Center, Maastricht, [2]Human Biology, Maastricht University Medical Center, Maastricht, Netherlands.

Background and aims: Insulin resistance (IR) is a major mechanism in the pathological progression of diabetes, in which skeletal muscle cells and endothelial cells play key roles. The dicarbonyl methylglyoxal (MGO), the major reactive precursor in the formation of advanced glycation endproducts (AGEs), has been linked to the development of IR. However, the underlying mechanism through which MGO contributes to IR is unknown. Therefore, we investigated first in humans, whether increased plasma and muscular MGO levels were associated with insulin resistance. Next, we studied the effect of MGO on the insulin-signaling cascade *in vitro* in cultured muscle and microvascular endothelial cells.
Materials and methods: Plasma samples and biopsies of the vastus lateralis muscle from 11 insulin resistant individuals and 11 age-matched controls were obtained in the fasted state. Whole body insulin sensitivity was determined by the glucose infusion rate (GIR) during a hyperinsulinaemic euglycaemic clamp. The dicarbonyls MGO, glyoxal (GO) and 3-deoxyglucosone (3-DG), a panel of AGEs and insulin modifications were determined by UPLC-MS/MS. The effect of MGO and AGEs on insulin-induced phosphorylation of Akt was determined in mature cultured C2C12 myotubes and in microvascular endothelial cells (MVEC) by western blotting. Glyoxalase-1 activity was measured by spectrophotometry. Independent two-sample t-tests were used to compare data between healthy controls and insulin resistant individuals. One-way ANOVA was used for comparing the *in vitro* effects of MGO on Akt-phosphorylation and a $p < 0.05$ value was considered statistically significant.
Results: At baseline, IR individuals (GIR 54 ± 12 μmol/min/kg) showed significantly elevated plasma MGO (316 ± 10 nmol/L vs 457 ± 29; $p < 0.001$), GO (698 ± 48 nmol/L vs 1593 ± 175; $p < 0.001$) and 3-DG (1205 ± 36 nmol/L vs 2909+/187; $p < 0.001$), but not AGEs levels, as compared to age-matched healthy controls (GIR 179 ± 20 μmol/min/kg). In addition, intramuscular levels of the dicarbonyls, AGEs and the glyoxalase-1 activity were similar between the two groups. Extracellular supplementation of MGO-derived AGEs and MGO (up to 200 μM) to mature cultured C2C12 myotubes did not affect insulin-induced phosphorylation of Akt, while supplementation of MGO, but not MGO-derived AGEs, to MVECs inhibited significantly insulin-induced Akt-phosphorylation in a time and concentration-dependent manner up to ~30% at maximum. In addition, we found that MGO could directly modify insulin, accompanied by an impaired insulin-induced phosphorylation of Akt.
Conclusion: Overall, MGO contributes to impaired insulin sensitivity through direct modification of insulin and through modulation of the insulin-signaling cascade in endothelial cells but not muscle cells, highlighting MGO as a potential target in the treatment of insulin resistance.

Effect of glycated albumin in the expression of glucose transporter GLUT4 in adipocytes: potential participation of transcription factor NF-kB

M.L.E. Michalani[1], M. Passarelli[2], U.F. Machado[1];
[1]Physiology and Biophysics, University of Sao Paulo, Sao Paulo, [2]University of Sao Paulo, Sao Paulo, Brazil.

Background and aims: The loss of glucose homeostasis, a feature of diabetes, is related to insulin resistance that leads to reduced peripheral glucose uptake. In this process, the insulin-sensitive glucose transporter isoform 4 (GLUT4) encoded by the *Slc2a4* gene, plays a decisive role. In fact, reduced levels of GLUT4, in insulin-sensitive territories, such as adipose and skeletal muscle tissues, contributes for hyperglycemia. Increasing circulating glucose levels results in increased production of advanced glycation end products (AGEs) which, by interacting with their receptor (RAGE), activate the nuclear factor NF-kappa-B (NFKB) pathway. NFKB has been well described to inhibit *Slc2a4* gene expression, contributing to a vicious circle of impaired glucose utilization by GLUT4-expressing tissues. Although AGEs are well studied in the pathogenesis of diabetes complications, little is known about their potential contribution to impair insulin-stimulated glucose uptake. Clarifying this mechanism, we may reveal a regulatory role for AGEs not only in the development of chronic complications of diabetes, but also in the loss of glycemic homeostasis.
Materials and methods: Differentiated 3T3-L1 adipocytes were treated with bovine serum albumin without modification or conjugated with glycolaldehyde, at different concentrations (0.4, 3.6 and 5.4 mg/mL) and periods (24 and 72 hours). Expression of the *Slc2a4*, *Nfkb1* and *Rela* mRNAs by RT-qPCR and GLUT4, p50 and p65 proteins by Western blotting were evaluated. The statistical test used was two-tailed unpaired Student's t test.

Results: In 3T3-L1 cells, glycated albumin in short term (24 hours) and low dose (0.4 mg/mL) increased *Slc2a4* mRNA (99%, $P < 0.001$) and GLUT4 protein (52%, $P < 0.05$) expression, however, in long term (72 hours) and high dose (5.4 mg/mL) it reduced the gene (57.5%, $P < 0.001$) and protein (37%, $P < 0.01$) expression. In addition, glycated albumin during 24 hours and at all three doses had a stimulatory effect on the expression of *Rela* (22%, $P < 0.05$; 28%, $P < 0.01$; 45%, $P < 0.001$) and *Nfkb1* (12%, $P < 0.05$; 30%, $P < 0.01$; 69%, $P < 0.001$) genes, indicating an increase in proinflammatory activity. This was accompanied by an increase in the nuclear content of p50 and p65 proteins, at long term and high dose (98%, $P < 0.05$; 29%, $P < 0.01$, respectively). **Conclusion:** The results indicate that glycated albumin, in a time/dose-dependent manner, can induce proinflammatory activity in the adipocyte, reducing *Slc2a4*/GLUT4 expression. This characterizes a hormetic effect of AGEs, which in chronic condition contributes to impair glycemic homeostasis.

Skeletal muscle contraction protects against hyperglycaemia-induced insulin resistance and associated transcriptomic (dys) regulation

S. Carter, J.P. Barlow, T.P.J. Solomon;
University of Birmingham, Birmingham, UK.

Background and aims: Skeletal muscles represent a major site of glucose uptake. Insulin serves as a potent stimulus to increase glucose uptake to maintain normoglycaemia. Therefore, impairment in responsiveness to insulin contributes to increasing hyperglycaemia and, if untreated, the progression towards type 2 diabetes. Exercise enhances skeletal muscle insulin sensitivity and therefore serves as a key intervention to prevent type 2 diabetes. Dissecting the molecular mediators controlling this protective effect will aid understanding which could be targeted to prevent insulin resistance and associated metabolic abnormalities. Therefore, we set out to characterise the underlying transcriptional changes responsible for these exercise-mediated protective effects.

Materials and methods: Differentiated C2C12 myotubes were exposed to 24 hours of contractile activity (electrical pulse stimulation; EPS) or rest, followed by 0, 6, 18 or 24 hours of normo- (5 mM) or hyperglycaemic (25 mM) conditions. We evaluated the functional (basal and insulin-stimulated glucose uptake) and molecular (RNA sequencing followed by analysis of differential gene expression using NOISeq) responses to these conditions of rest *vs.* contraction and/or normo- *vs.* hyperglycaemia. Follow-up annotation and pathway enrichment analysis was conducted on differentially expressed genes. Data are presented as mean ± SEM.

Results: Data demonstrates the time-course for functional and molecular responses to different durations of a) hyperglycaemia (6, 18 and 24 hours) and b) rest following contraction cessation (0, 6, 18 and 24 hours). In non-EPS treated cells, 24 hours of hyperglycaemia significantly impaired insulin-stimulated glucose uptake *vs.* control (fold increase over basal: 1.00 ± 0.24 *vs.* 1.91 ± 0.20, $P < 0.05$), and this impairment coincides with differential expression of 115 transcripts (58 up-regulated; 57 down-regulated). Interestingly, prior skeletal muscle contraction ameliorated this hyperglycaemia-induced insulin resistance (fold increase over basal: 1.57 ± 0.34, $P > 0.05$ *vs.* control), and prevented the (dys) regulation of several transcripts otherwise induced by hyperglycaemia. In particular, prior contractile activity prevented the hyperglycaemia-induced (dys) regulation of several non-coding RNAs that were otherwise up-regulated (e.g. miR-27a, miR-125a and SNORD70) or down-regulated (e.g. miR-378a and miR-194-1) by 24 hours of hyperglycaemia.

Conclusion: The present study combines functional and transcriptomic profiling of hyperglycaemia and/or contraction treated skeletal muscle cells. Our data demonstrate that skeletal muscle contraction *per se* protected skeletal muscle cells against hyperglycaemia-induced insulin resistance, and that this protective effect coincides with contraction-mediated normalisation of several hyperglycaemia-responsive transcriptional changes. Our ongoing experiments will define possible causal roles for these novel contraction-responsive transcripts, and establish whether they can be targeted to modulate skeletal muscle insulin sensitivity in human skeletal muscle cells from individuals with widely varying insulin sensitivity.

Endurance exercise training in the fasted or fed state in male patients with type 2 diabetes: safe and equally effective

K. Verboven[1], I. Wens[1], B. Lapauw[2], P. Calders[2], D. Hansen[1];
[1]Rehabilitation Research Center (REVAL), Biomedical Research Unit (BIOMED), Hasselt University, Hasselt, [2]Department of Endocrinology, Ghent University Hospital, Ghent, Belgium.

Background and aims: Exercise training is a cornerstone in the care of patients with type 2 diabetes mellitus (T2DM). A possible role for nutritional state, either being in the fed or fasted state, is of particular interest during exercise training interventions in T2DM patients. The present study investigates the impact of endurance exercise training in the fasted versus the fed state on clinical outcome measures, glycemic control and skeletal muscle characteristics in male T2DM patients.
Materials and methods: Twenty male T2DM patients (age 60 ± 2 years, BMI 29.2 ± 0.8 kg/m², HbA1c 7.4 ± 0.3% (57 ± 4 mmol/mol)) participated in a randomized clinical trial in which individuals performed a supervised endurance exercise intervention for 12 weeks. Training sessions (including walking and cycling) were performed in the fasted state (FAST, $n = 10$) or after having a breakfast (FED, $n = 10$) (groups matched for age, BMI and glycated hemoglobin level). Before and after the exercise intervention, patients were evaluated for glycemic control, blood lipid profile, body composition and physical fitness and a fasting skeletal muscle biopsy was obtained for gene expression analyses.
Results: Exercise training intervention was well tolerated, with no difference between FAST and FED with respect to adherence (91 ± 1% vs. 94 ± 1%, respectively; $P = 0.280$) or mean Borg score (11 vs. 12, respectively; $P = 0.052$) and without any incident of hypoglycemia. In both FAST and FED, exercise training significantly decreased BMI ($P_{TIME} = 0.014$), body fat percentage ($P_{TIME} = 0.002$), whole-body fat mass ($P_{TIME} < 0.001$) and significantly improved VO_2peak ($P_{TIME} = 0.042$) and Wpeak/lean tissue mass ($P_{TIME} = 0.005$), without any interaction effects ($P_{TIME*GROUP} > 0.05$, respectively). Exercise training reduced respiratory exchange ratio during different levels of submaximal exercise (*i.e.* 20%, 40% and 60% VO_2peak) in both groups (for all levels $P_{TIME} < 0.050$; $P_{TIME*GROUP} > 0.050$). HDL significantly increased in both FAST and FED ($P_{TIME} = 0.028$; $P_{TIME*GROUP} = 0.435$). Glycated hemoglobin levels significantly decreased after exercise training ($P_{TIME} < 0.001$), with the greatest reduction (−0.36%) in the FED compared to the FAST group (−0.07%) ($P_{TIME*GROUP} = 0.004$). At skeletal muscle level, no interaction effects were observed for genes related to lipid metabolism or oxidative capacity ($P_{TIME*GROUP} > 0.05$).
Conclusion: Exercise training in the fasted or in the fed state were both safe and effective in improving glycemic control, body composition, physical fitness and HDL in male patients with T2DM.

Time dependence of glucagon under hypoglycaemic conditions

C. Pedersen[1], G. Kraft[2], D. Laneve[2], M. Scott[2], M.N. Najdowski[2], B. Farmer[2], P. Williams[2], A.D. Cherrington[2], D.S. Edgerton[2];
[1]Novo Nordisk A/S, Maaloev, Denmark, [2]Vanderbilt University, Nashville, USA.

Background and aims: Glucagon's (GGN) effect on hepatic glucose production (HGP) is time dependent under hyperglycemic conditions. It is not known whether this is also the case under hypoglycemic conditions. This question was addressed using adrenalectomized animals to avoid the confounding effects of other counterregulatory hormones.
Materials and methods: Nine dogs were subjected to adrenalectomy and catheter placement in the femoral artery, portal vein and hepatic vein, as well as flow probes on the hepatic artery and portal vein. Mineralocorticoid therapy was initiated pre-surgery (desoxycorticosterone pivalate, 1.2 mg/kg) and after surgery hydrocortisone was administered (12.5 mg) twice daily for glucocorticoid maintenance. On the day of the study, basal infusions of epinephrine (7.25 ng/kg/min) and cortisol (0.6 μg/kg/min) were started. After the control period, somatostatin was infused to disable the endocrine pancreas, and insulin was infused in a leg vein (800 μU/kg/min). After 30 minutes, when plasma glucose started to fall, GGN was infused at a basal rate (1 ng/kg/min, BaGGN group, $n = 4$) or a rate 8 fold basal (8 ng/kg/min, HiGGN group, $n = 5$) for 4 hours. Studies were paired and glucose was infused to match the arterial glucose levels between groups.
Results: Epinephrine and cortisol were basal throughout the study in both groups. Insulin rose to ≈40 ± 3 μU/mL in both groups ($P > 0.05$), while GGN dropped to ≈21 ± 3 pg/mL when somatostatin started, then rose to 39 ± 3 and 227 ± 11 pg/mL in the BaGGN and HiGGN groups, respectively ($P < 0.05$). To maintain a glucose level of 41 mg/dL in both groups, the glucose infusion rate averaged 2.5 ± 0.3 and 0.5 ± 0.4 mg/kg/min in BaGGN and HiGGN, respectively ($P < 0.05$). Net hepatic glucose output (NHGO) was similar in both groups during the basal period and prior to GGN infusion. During GGN infusion NHGO rose to 5.6 ± 1.3 mg/kg/min by 15 min in the HiGGN group but stayed at 0.7 ± 0.2 mg/kg/min in the BaGGN group. NHGO fell in the HiGGN group ≈50% over 60 min and plateaued at 2.3 ± 0.2 mg/kg/min for the last 120 min of study, while NHGO in the BaGGN group remained at 0.4 ± 0.1 mg/kg/min (Figure). Importantly, the hypoglycemic induced rise in norepinephrine (334 ± 40 and 244 ± 19 pg/mL, $P = 0.08$) and plasma glycerol (225 ± 15 and 152 ± 6 μmol/L, $P = 0.05$) were significantly smaller when GGN was elevated despite plasma glucose being identical in the groups.
Conclusion: The effect of GGN on HGP during hypoglycemia is biphasic, characterized by an initial burst occurring over about 60 min followed by a reduced but sustained effect over the last 120 min of the experiment. Of note, the sympathetic nervous system response to the hypoglycemia was blunted when GGN was elevated, resulting in a decrease in lipolysis. This finding suggests that there is reciprocity between GGN and the sympathetic neural system such that when GGN is increased the sympathetic nervous system response to hypoglycemia is downregulated.

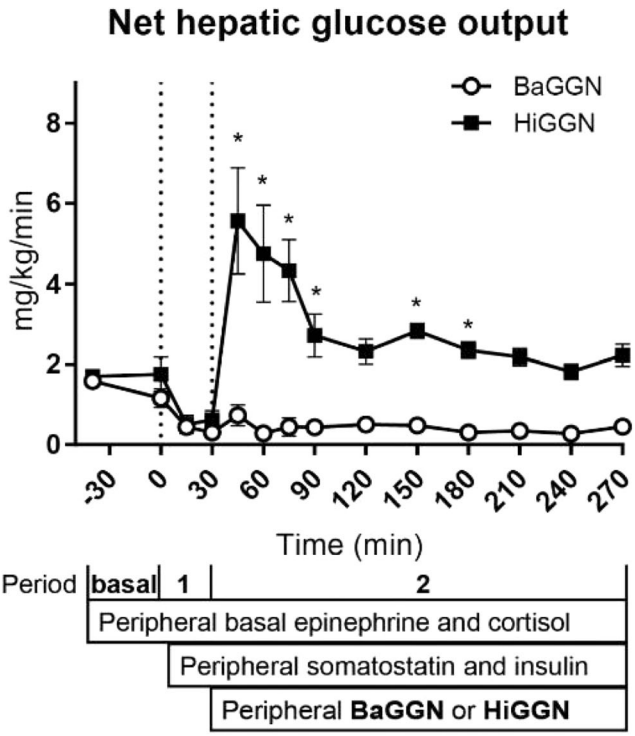

Figure: Net hepatic glucose output during a hyperinsulinemic hypoglycemic clamp in adrenalectomized dogs with basal (BaGGN n=4) or an 8 fold basal (HiGGN, n=5) infusions of glucagon. Values are mean ± SEM, *p < 0.05 compared to the BaGGN group.

Afternoon exercise is more efficacious than morning exercise at improving blood glucose levels in men with type 2 diabetes

M. Savikj[1,2], B.M. Gabriel[1], P. Alm[1], J. Smith[1], K. Caidahl[3,4], M. Björnholm[1], T. Fritz[3,4], A. Krook[1], J.R. Zierath[1,3], H. Wallberg-Henriksson[1];
[1]Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden, [2]Faculty of Medicine, University of Oslo, Oslo, Norway, [3]Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden, [4]Department of Clinical Physiology, Karolinska University Hospital, Stockholm, Sweden.

Background and aims: Exercise is a recommended intervention for prevention and treatment of type 2 diabetes. Low-volume High Intensity Interval Training (HIIT) remodels skeletal muscle and the cardio-respiratory system to a similar or greater extent than continuous moderate-intensity training, with reduced time commitment and exercise volume. Even though perturbed circadian rhythms are associated with metabolic dysfunction, time of day at which most robust adaptions to exercise can be achieved is unknown. We compared the efficacy of morning and afternoon HIIT in lowering blood glucose levels in participants with type 2 diabetes.
Materials and methods: Eleven men with type 2 diabetes underwent a randomized cross-over trial with either 2 weeks morning or afternoon HIIT (3 bouts/week), followed by a 2-week washout period and a subsequent period of the opposing training regime. Continuous glucose monitoring (CGM) based blood glucose levels were recorded throughout the study and hourly time-point means were compared. Blood samples were collected pre-training and after both training regiments.
Results: During week 1 of training, afternoon HIIT reduced CGM-based glucose levels as compared to either pre-training (mean change 0.9 mmol/l, $p < 0.05$) or morning HIIT (1.1 mmol/l, $p < 0.05$) at 4 and 10 time-points throughout the day, respectively. Conversely, during week 1 of training, morning HIIT increased CGM-based glucose levels as compared with pre-training (1.2 mmol/l, $p < 0.05$) at 4 time-points throughout the day. During week 2 of training, afternoon HIIT reduced CGM-based glucose levels as compared to either pre-training (0.9 mmol/l, $p < 0.05$) or morning HIIT (0.9 mmol/l, $p < 0.05$) at 4 and 6 time-points throughout the day, respectively. Conversely, during week 2 of training, morning HIIT increased CGM-based glucose levels as compared with pre-training (0.9 mmol/l, $p < 0.05$) at 2 time-points throughout the day. The elevated glucose concentration with morning HIIT persisted even into the subsequent days after exercise. Additionally, plasma T_4 was decreased and TSH was increased following the training as compared with pre-training, suggesting a hormonal mechanism behind the differing responses, as these changes were potentiated following afternoon HIIT. Plasma triglycerides levels were elevated following morning HIIT as compared with pre-training, suggesting changes in fuel utilization with morning training.
Conclusion: This was a field-based study in 'free-living' individuals, thus the specific factors responsible for the differing blood glucose levels between morning and afternoon exercise remain to be elucidated. Afternoon HIIT is more efficacious than morning HIIT in controlling blood glucose levels in type 2 diabetic men whereas morning HIIT may even be deleterious for optimal blood glucose control. Our data highlight the importance of optimizing the timing of exercise bouts to improve glycaemic control in people with type 2 diabetes.

Carbohydrates standard breakfast as a more physiological test of glucose tolerance than the OGTT in obese patients: glycaemic variability and insulin secretion indexes

I. Banu, A. Rezki, M. Fysekidis, S. Chiheb, E. Cosson, P. Valensi;
AP HP Jean Verdier Hospital, Department of Endocrinology-Diabetology-Nutrition, CRNH-IdF, CINFO, Bondy, France.

Background and aims: Glycemic variability (GV) may play a role in diabetic complications. We recently showed that GV is more marked in non-diabetic patients with elevated HbA1c level. The aim was here to examine the glycemic and insulinemic response profile to a standard breakfast including 75 g of carbohydrates and the relationship with GV in obese patients with different glycemic status (normal, NGT or impaired glucose tolerance, IGT, or type 2 diabetes, T2D).

Materials and methods: We included 82 obese patients without known dysglycemia we separated in 34 NGTs, 38 IGTs and 10 T2Ds according to oral glucose tolerance test (OGTT). During OGTT, the insulinogenic index (IGI = insulin T120-insulin T0)/(glucose T120-glucose T0) and the oral disposition index (ODI=IGI/insulin T0) were calculated. A "French" standard breakfast including 75 g of carbohydrates was given with plasma glucose and insulin measurements for 2 hours. The area under curve (AUC-glucose) was calculated for 2 hours after breakfast. GV was evaluated by calculating SD-glucose, CONGA, J index and MAGE from 24-h continuous glucose monitoring including the standard breakfast.
Results: IGTs and T2Ds were older than NGTs (51 ± 13 and 54 ± 12 *vs* 41 ± 13 years, $p = 0.002$). They had lower IGI and ODI, and higher HbA1c and GV indexes than NGTs ($p < 0.05$ to $p < 0.0001$). After the standard breakfast, they had higher AUC-glucose. In all patients, AUC-glucose correlated positively with HbA1c and GV indexes and negatively with ODI ($p < 0.02$ to $p < 0.0001$), independently of age and BMI.
Conclusion: In obese patients without known dysglycemia, the magnitude of post-prandial excursion (AUC-glucose) after the carbohydrates standard breakfast is in line with the severity of glycemic disorder identified by OGTT. AUC-glucose correlates positively with greater 24h glycemic variability and negatively with insulin secretion. This breakfast could be proposed as a more physiological test than OGTT.

Fructose contributions to hepatic triglyceride synthesis in the presence of glucose during overnight feeding in mice

J. Jones[1,2], J. Silva[1], F. Martins[3], I. Viegas[1], C. Marques[1], M. Macedo[3,2];
[1]Center for Neurosciences, Cantanhede, [2]Portuguese Diabetes Association (APDP), Lisbon, [3]Chronic Diseases Research Center (CEDOC), Lisbon, Portugal.

Background and aims: Fructose is considered to be a potent lipogenic substrate and its increased consumption may be associated with soaring NAFLD incidence rates. However, its precise contribution to hepatic *de novo* lipogenesis (DNL) is not well characterized. Moreover, fructose is typically accompanied by equivalent amounts of glucose, which can also contribute to DNL. Current stable-isotope tracer methods quantify the fractional synthetic rate of triglyceride fatty acids and glycerol moieties from all precursors but cannot resolve contributions from individual substrates. We combined deuterated water (^2H_2O) and [U-^{13}C]fructose to measure the specific contribution of exogenous fructose to newly-synthesized triglyceride fatty acids and glycerol in the presence of an equivalent amount of exogenous glucose under natural feeding conditions.
Materials and methods: At the start of the dark period in a 12h/12h dark/light cycle, seven adult male C57/BL6 mice fed with standard chow were given an intraperitoneal injection of 99.9% ^2H_2O/0.9% NaCl to raise body water ^{2}H-enrichment to ~4%. The drinking water was supplemented with 5% ^2H_2O, 17.5% w/w unlabeled glucose and 17.5% w/w fructose enriched to 20% with [U-^{13}C]fructose. Animals were allowed to feed naturally overnight and then sacrificed at the end of the dark cycle. Livers were freeze-clamped and triglycerides were extracted and purified from other lipid species. Triglycerides were analyzed for ^{2}H and ^{13}C-

enrichment in the terminal fatty acid methyls and the glyceryl moiety by ^{2}H and ^{13}C NMR at 11.7T and 14.1T, respectively.
Results: ^{2}H-enrichment of the terminal fatty acid methyl hydrogens measured by ^{2}H NMR showed that the fraction of newly-synthesized triglyceride fatty acids from all lipogenic precursors was 18 ± 3% (mean ± S.E.). From the ^{13}C NMR analysis the contribution of exogenous fructose to total triglyceride fatty acids was found to be 5 ± 1% and its contribution to newly-synthesized fatty acids was calculated to be 27 ± 3%. For the triglyceride glycerol moiety, 29 ± 5% was newly synthesized and fructose contributed 77 ± 12% of this newly synthesized fraction.
Conclusion: The integration of $^{2}H_2O$ and ^{13}C-enriched substrates coupled to $^{2}H/^{13}C$-NMR analysis of triglyceride allows contributions of specific substrates to triglyceride fatty acid and glycerol synthesis to be determined. In the presence of equimolar amounts of glucose, fructose contributed modestly to hepatic triglyceride fatty acid synthesis but was the dominant precursor for synthesis of the glyceryl moiety.

An essential role of ghrelin in circadian rhythmicity of voluntary exercise under constant darkness

Y. Tajiri[1], Y. Sakai[1], T. Sato[2], M. Kojima[2], M. Nomura[1], H. Mifune[1];
[1]Kurume University School of Medicine, Kurume, [2]Kurume University, Kurume, Japan.

Background and aims: We previously reported a diurnal rhythm of ghrelin with its peaks at the beginning and at the end of the dark period concomitant with an increase of voluntary exercise in the wild type (WT) mice. Those accelerations of exercise were severely attenuated in the ghrelin knockout (GKO) mice, suggesting the relevance of ghrelin surge to the motivation for voluntary exercise (52nd EASD annual meeting). Exercise is also known to be essential for the entrainment to circadian rhythmicity, separate of light-entrained oscillator, suggesting the crucial role of ghrelin as exercise-entrained oscillator. In the present study, we compared exercise patterns in the WT and GKO mice under constant darkness to evaluate the relevance of ghrelin to the entrainment of circadian clock independent of light on-off rhythmicity.
Materials and methods: Eight-week-old male WT (n = 6) and GKO (n = 10) mice were individually housed in cages with SW-15 running wheels under a 12 h light: 12 h dark cycle (L/D, light on 7:00–19:00) at a controlled ambient temperature and provided with food and water ad libitum until 13 weeks old. Then, both groups of mice were subjected to wheel running under constantly dark condition (D/D) for the next 60 days to measure the free-running period of voluntary exercise. At 21 weeks old, light was turned on at 7:00 and the L/D condition was resumed for the next 10 days. The number of revolutions was acquired every 15 minutes. The obtained data of actogram was subjected to Fast Fourier Transform to obtain the spectrum, and the period of the absolute value was calculated to obtain the periodogram using ClockLab Analysis Software Ver. 6.
Results: Body weight of WT and GKO mice were comparable at 8 and 22 weeks old. A marked increase of wheel-running activity was observed especially at the beginning of dark period in either WT or GKO mice under L/D condition. Under D/D condition, actograms of both groups showed free-running periods of less than 24 hours in terms of the onset of voluntary exercise. However, regarding the termination (offset) of exercise, clearly irregular rhythmicity and dispersed pattern was observed in the GKO mice in contrast to the WT mice (Figure). Analysis by periodgram revealed that a dominant free-running period was significantly shorter in the GKO mice compared to that in the WT mice (16.6 ± 1.5 vs. 22.7 ± 1.8 hours, means ± S.E. $P < 0.05$), in agreement with other various and irregular rhythmicity observed in GKO mice under D/D condition. Both WT and GKO mice were immediately re-entrained after the resumption of L/D condition.
Conclusion: Ghrelin in itself is not relevant to the maintenance of the exercise pattern under L/D condition because of the immediate re-entrainment in either WT or GKO mice. In contrast, under D/D condition ghrelin is quite essential for the maintenance of circadian rhythmicity of voluntary exercise, especially in the termination of it, suggesting a crucial role of this peptide as exercise-entrained oscillator independent of light-entrained rhythmicity.

Changes in mitochondrial morphology lead to disruption of circadian rhythms in skeletal muscle

L. Sardon Puig[1], B. Gabriel[1], N.J. Pillon[1], J. Smith[1], R. Sjögren[1], C. Cantó[2], A. Krook[1], J. Zierath[1];
[1]Karolinska Institutet, Stockholm, Sweden, [2]Nestlé Institute of Health Science, Lausanne, Switzerland.

Background and aims: Circadian rhythms modulate fundamental physiological processes and are mainly regulated by day-night cycles. However, most cells of the body also follow an endogenous clock. Disruption of circadian rhythms is associated with the development of metabolic disorders, but the pathways involved have not been fully elucidated. Mitochondrial morphology is directly linked to mitochondrial function, which include satisfying the metabolic demands of the cell and ensuring the removal of damaged organelles. For that reason, proper regulation of the fusion and fission process is required to maintain a functional reticular mitochondrial network. Mitofusin1 (Mfn1), Mitofusin2 (Mfn2) and Opa1 are key proteins in the outer and inner

mitochondrial membrane orchestrating fusion processes, and their ablation causes mitochondrial fragmentation that leads to impaired metabolism in skeletal muscle. Very little is known about the interactions between mitochondrial fragmentation and circadian rhythms and how metabolic challenges might regulate this interaction. We therefore hypothesized that impairment of mitochondrial fusion leads to the disruption of the muscle internal clock.

Materials and methods: Primary skeletal muscle cells from healthy (NGT) and type 2 diabetic (T2D) volunteers were grown and differentiated into myotubes. After synchronization by serum shock (50%FBS, 2h), cells were exposed to palmitate (0.4mM) and samples were collected every 6h up to 56h. RNA was extracted and used for RNA sequencing. Silencing of Mfn1, Mfn2 or Opa1 was performed to differentiated C2C12 and primary skeletal muscle cells using siRNA. Cells were synchronized and exposed to different nutrient challenges for up to 48h. Samples were collected every 6h for further analysis. RNA from tibialis anterior from Mfn2 muscle knock out (MKO) mice on low and high fat diet was extracted and clock gene expression analysed and compared to the expression of their littermates.

Results: Differential expression analysis comparing cells treated with palmitate and controls lead to the identification of pathways related to mitochondria and lipid metabolism suggesting a link between palmitate and mitochondrial fragmentation. Silencing of Mfn2 and Opa1 in C2C12 and primary human skeletal muscle cells lead to a disrupted rhythm of clock gene expression. Similar effect was observed in Mfn2 MKO mice which exhibited impaired clock gene expression compared to wildtype littermates. This effect was accentuated on a high fat diet and paralleled the effect of palmitate in muscle cells in vitro.

Conclusion: Our data suggest that nutritional challenges, such as palmitate, can induce mitochondrial dysfunctions that can lead to dysregulation of skeletal muscle internal clock and might provide a link between metabolic dysregulation in obesity and type 2 diabetes mellitus and impaired circadian rhythms.

Dietary methionine restriction protects from type 2 diabetes in NZO mice

T. Castaño-Martinez[1,2], W. Jonas[1,2], T. Laeger[1,2];
[1]Department of Experimental Diabetology, German Institute of Human Nutrition Potsdam-Rehbruecke (DIfE), Nuthetal, [2]German Center for Diabetes Research (DZD), München-Neuherberg, Germany.

Background and aims: In general, diets low in protein or methionine have been shown to reduce the body weight by increasing energy expenditure and insulin sensitivity. Protein restriction prevented type 2 diabetes in diabetes-susceptible New Zealand obese (NZO) mice despite hyperphagia and increased fat mass. An elevated concentration of circulating FGF21 has been implicated as a potential underlying mechanism. Therefore, we tested in NZO mice whether a methionine restriction (MR) in a high-fat regimen protects against diabetes.

Materials and methods: After weaning, male NZO mice were placed on isocaloric high-fat diets (protein, 16 kcal%; carbohydrate, 52 kcal%; fat, 32 kcal%) that provided methionine at control (0.86%; CON) or low levels (0.17%; MR) for 9 weeks. Glucose homeostasis, energy expenditure, food intake and other metabolic endpoints were assessed. Six weeks after the diet switch, an oral glucose tolerance test (OGTT) was performed after a 6-hour period of fasting.

Results: Despite no differences in the ratio of body fat, lean mass, and in food intake between the groups, MR prevented the onset of hyperglycemia, whereas CON-fed mice exhibited a rise of blood glucose (blood glucose at week 9; mean ± SEM; CON = 15.5 ± 1.7 mM, MR = 7.4 ± 0.3 mM) which was associated with elevated plasma insulin concentrations (week 9; CON = 4.6 ± 1.3 μg/l, MR = 0.6 ± 0.1 μg/l). MR-fed mice did not improve glucose clearance during the OGTT but exhibited an increased insulin sensitivity (Matsuda index; CON = 16.8 ± 2.4, MR = 80.1 ± 14.6). At week 9, mice on MR showed an elevated hepatic FGF21 secretion (plasma FGF21; CON = 0.6 ± 0.1 ng/ml, MR = 8.7 ± 0.9 ng/ml), higher plasma adiponectin levels (CON = 23.0 ± 1.1 μg/ml, MR = 33.4 ± 2.0 μg/ml), and an increased energy expenditure (CON = 9.1 ± 0.5 kcal h^{-1} body weight kg^{-1}, MR = 12.5 ± 0.9 kcal h^{-1} body weight kg^{-1}) during both the dark and light periods not associated with an increase in locomotor activity. Interestingly, neither the final mass of subcutaneous white adipose tissue nor of brown adipose tissue was different between the groups. Final liver weight was lower in the MR-fed mice than in the CON-fed mice, due to decreased hepatic triacylglycerol and glycogen concentrations.

Conclusion: NZO mice are protected from hyperglycemia through methionine restriction, which elevates FGF21 secretion by the liver and increases adiponectin secretion by the adipose tissues. These effects might improve hepatic insulin sensitivity. A protective effect of methionine restriction is independent of food intake and adiposity.

Medium-chain triglyceride oil does not induce GIP secretion and induces less body weight and fat mass gain compared with long-chain triglyceride oil

Y. Murata, N. Harada, S. Yamane, K. Iwasaki, Y. Kanemaru, T. Harada, A. Sankoda, E. Ikeguchi, S. Kuwahara, E. Joo, H. Poudyal, N. Inagaki;
Department of Diabetes, Endocrinology and Nutrition, Graduate School of Medicine, Kyoto University, Kyoto, Japan.

Background and aims: Glucose-dependent insulinotropic polypeptide (GIP) is an incretin secreted from enteroendocrine K-cells and potentiates

glucose-dependent insulin secretion from pancreatic β-cells. GIP plays an important role in maintaining postprandial blood glucose levels under long-chain triglyceride (LCT) diet-induced obesity. GIP also enhances LCT diet-induced obesity and insulin resistance. Medium-chain triglyceride (MCT) consists of medium chain fatty acids and long-term intake of MCT diet induces less body weight and fat mass gain than that of LCT diet. LCT oil and LCT diet strongly stimulate GIP secretion from K-cells but the effect of MCT oil and MCT diet on GIP secretion is unknown. In this study, we evaluated GIP secretion after MCT oil and MCT diet ingestion in wild-type (WT) mice and investigated the effect of long-term MCT diet-induced GIP secretion on body weight, fat mass, and glucose tolerance using WT and GIP-knockout (GIP KO) mice.
Materials and methods: Oral LCT (lard oil) and MCT oil tolerance tests were performed in WT mice and plasma total GIP levels were measured. 6-week old mice (WT and GIP KO mice) were divided into the three groups [Control fat (CF) diet (10% fat), LCT diet (45% fat), and MCT diet (45% fat)] and long-term food tolerance tests were performed. Non-fasting GIP levels and body weights were weekly measured during experiments. Oral glucose tolerance test (OGTT) and CT scan analysis were performed to evaluate glucose tolerance and fat mass, respectively.
Results: Single administration of LCT oil increased plasma GIP levels in WT mice but that of MCT oil did not. Long-term LCT diet feeding significantly increased non-fasting GIP levels compared with CF diet feeding in WT mice. There was no significant difference in GIP levels between MCT diet-fed and CF diet-fed WT mice. In GIP KO mice, non-fasting GIP levels were not detectable in the three diet groups. Body weight of LCT and MCT diet-fed WT mice was 47.0% and 10.7% higher than that of CF diet-fed WT mice after 24-week diet feeding, respectively. In GIP KO mice, body weight of LCT diet and MCT diet-fed mice was 28.1% and 7.5% higher than that of CF diet-fed mice, respectively. Visceral fat mass was 7.5 and 2.4-fold larger in LCT diet and MCT diet-fed WT mice than CF-diet fed WT mice, respectively. In GIP KO mice, the fat mass was 5.5-fold larger in LCT diet group than that in CF diet group but the mass was not significantly difference between MCT diet and CF diet groups. In WT mice, Area under the curve (AUC) of blood glucose (BG) during OGTT was not different among the three diet groups. AUC-insulin in LCT and MCT diet groups was higher compared with that in CF diet group. AUC-insulin in LCT diet group was the highest among the three diet groups. In GIP KO mice, AUC-insulin was significantly increased in LCT diet group than that in CF diet group but AUC-BG in LCT group was significantly higher than that in CF diet group. There was no statistical difference in AUC-BG and AUC-insulin between MCT diet and CF diet groups.
Conclusion: Long-term intake of LCT diet induced GIP hypersecretion but that of MCT diet did not. Therefore, GIP contributes to adiposity and preservation of postprandial glucose levels under long-term LCT diet feeding but the effect of GIP is smaller under MCT diet feeding.
Disclosure: **Y. Murata:** None.

High fat diet induces a blunted antihyperglycaemic effect of the neuropeptide 26RFa in mice

G. Prevost[1,2], J. Bons[2,1], A. Arabo[3], M. Picot[1], J. Maucotel[3], H. Berrahmoune[1,2], M. El Mehdi[1], S. Cherifi[1], M. Coeffier[4], J. Leprince[1], V. Brunel[5], P. Dechelotte[4], H. Lefebvre[1,2], Y. Anouar[1], N. Chartrel[1];
[1]Normandie Univ, UNIROUEN, INSERM U1239, Laboratory of Neuronal and Neuroendocrine Differentiation and Communication (DC2N), Rouen, [2]Normandie Univ, UNIROUEN, Rouen University Hospital, Department of Endocrinology, Diabetes and Metabolic Diseases, Rouen, [3]Normandie Univ, UNIROUEN, Rouen, [4]Normandie Univ, UNIROUEN, INSERM U1073 "Nutrition, Inflammation and dysfunction of gut-brain axis", Rouen, [5]Normandie Univ, UNIROUEN, Rouen University Hospital, Department of Biochemistry, Rouen, France.

Background and aims: The neuropeptide 26RFa also referred to as QRFP (for pyroglutamilated RFamide peptide) is the latest member of the RFamide peptide family discovered. 26RFa was identified as the cognate ligands of the human orphan G-protein-coupled receptor, GPR103. 26RFa stimulates food intake via a modulation of the NPY/POMC network in the arcuate nucleus. Recently, we have also shown that 26RFa regulates glucose homeostasis by acting as an incretin. As type 2 diabetes is associated with a reduced incretin effect of the two other incretins GLP-1 and GIP, we have investigated in the present study whether an eventual dysfunction of the 26RFa incretin effect and/or production occurs in diabetic conditions.
Materials and methods: A model of high fat diet mice and human β cell line exposed to palmitate were used to analyze the 26RFA effect in diabetic conditions. Q-PCR and immunohistochemistry for GPR103 were also performed in the insulin target tissues. 26RFa blood level and tissue content were performed using a radioimmunoassay
Results: In high fat diet mice with diabetes , we first found a loss of the anti-hyperglycemic effect of 26RFa during IPGTT which is associated with a total loss of its insulinotropic activity. Moreover, we reported a marked reduction of the insulin-sensitive effect of the neuropeptide and during insulin tolererance test. Insulin secretion induced by the 26RFa neuropeptide is also completely blunted in human β cell line exposed to palmitate. Q-PCR and immunohistochemical experiments revealed a down-regulation of the 26RFa receptor in insulin target tissues of diabetic mice. Finally, our data show that the kinetic of release of 26RFa after an oral glucose challenge is profoundly altered in diabetic conditions both for plasma level and 26RFa intestine content.
Conclusion: the present data indicate that high fat diet in mice is associated with a significant reduction of the antihyperglycemic effect of the neuropeptide 26RFa.

Murine lipid-induced hepatic insulin resistance is not pathway-selective

D.F. Vatner, L. Goedeke, X. Li, M.C. Petersen, J.C. Rogers, G. Casals, G.W. Cline, V.T. Samuel, G.I. Shulman;
Yale University School of Medicine, New Haven, USA.

Background and aims: Insulin suppresses hepatic glucose production and increases hepatic de novo lipogenesis (DNL). Paradoxically, hepatic DNL remains elevated in insulin-resistant subjects, leading to the hypothesis that hepatic insulin resistance is pathway-selective. Prior studies of DNL in hepatic insulin resistance are complicated by confounders, such as use of markedly unphysiologic animal models or comparison of animals on different diets and thus different availability of DNL precursors. We sought to determine the effect of lipid-induced hepatic insulin resistance *per se* on insulin-stimulated lipogenesis.
Materials and methods: We measured DNL using the deuterated water method in Insulin receptor T1150A knockin (*KI*) mice, a strain protected from diacylglycerol-mediated hepatic insulin resistance, and in littermate controls (WT). Diets were matched: 60% high fat diet (HFD) with 1% dextrose in drinking water.
Results: After two days of fat-feeding, before the development of significant insulin resistance, *KI* and WT mice displayed similar rates of DNL (*KI* 24.3% ± 3.6; WT 22.2% ± 3.5). After 9 days of HFD, when WT but not *KI* mice have developed hepatic insulin resistance, rates of DNL were reduced in WT mice but preserved in *KI* mice (*KI* 16.4% ± 2.4; WT 7.4% ± 1.3; $P < 0.01$). After 4 weeks of HFD, with the development of skeletal muscle resistance, rates of DNL increased in WT mice to reach those observed in *KI* mice (*KI* 19.3% ± 2.6; WT 15.9% ± 2.3). Consistent with the insulin-resistant phenotype, Sterol regulatory element-binding protein-1c (Srebp-1c) cleavage was reduced in the setting of hepatic insulin resistance in WT mice; this effect was attenuated in *KI* mice. The Srebp-regulated lipogenic proteins Fatty acid synthase and Stearoyl-CoA desaturase-1 were both reduced in 9d HFD fed livers regardless of

genotype; at 4 weeks, protein abundance remained suppressed in WT mice but was restored in *KI* mice. Pyruvate kinase L/R, a protein associated with DNL but not regulated by Srebp, was unaffected by HFD-induced hepatic insulin resistance.
Conclusion: Regulation of DNL is subject to lipid-induced hepatic insulin resistance, challenging the selective hepatic insulin resistance hypothesis. Increased DNL seen in insulin resistant subjects may be due to hyperinsulinemia and diversion of substrate from the insulin resistant periphery.

CD44 plays a key role in regulating high fat diet induced muscle insulin resistance

A. Hasib[1], C.K. Hennayake[1], D.P. Bracy[2], D.H. Wasserman[2], L. Kang[1]; [1]Division of Molecular and Clinical Medicine, School of medicine, University of Dundee, Dundee, UK, [2]Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, USA.

Background and aims: Increased extracellular matrix (ECM) hyaluronan is associated with diet-induced insulin resistance (IR). Reduction of muscle hyaluronan by PEGPH20 (PEGylated human recombinant hyaluronidase-PH20) ameliorates IR in diet-induced obese mice. CD44, the main cell-surface hyaluronan receptor, is positively correlated with type 2 diabetes. This study determines the role of CD44 in skeletal muscle IR. The hypotheses that *1*) genetic deletion of CD44 improves diet induced skeletal muscle IR and *2*) improved IR by PEGPH20 treatment is dependent on the presence of CD44 were tested in the present study.
Materials and methods: Global CD44-deficient ($CD44^{-/-}$) mice and their wild-type littermates ($CD44^{+/+}$) were fed chow-diet or 60% high-fat-diet (HFD) for 16 weeks. HFD-fed $CD44^{-/-}$ mice were also treated with PEGPH20 (1 mg/kg) for 3 weeks to evaluate its CD44-dependent action. Insulin sensitivity was measured by hyperinsulinaemic-euglycaemic clamp.
Results: HFD feeding increased muscle CD44 protein expression in $CD44^{+/+}$ mice ($p = 0.001$). Male HFD-fed $CD44^{-/-}$ mice exhibited reduced diet-induced obesity, adiposity and fasting insulin levels compared to HFD-fed $CD44^{+/+}$ ($p < 0.05$,$p < 0.01$). During hyperinsulinaemic-euglycaemic clamp, glucose infusion rate (GIR), glucose disappearance rate (Rd) and glucose uptake in gastrocnemius (Rg) were similar between $CD44^{+/+}$ and $CD44^{-/-}$ mice, in both chow and HF-fed state. However, $CD44^{-/-}$ mice exhibited lower clamp insulin levels (6.8 ± 0.8 vs 4.6 ± 0.4, $p > 0.01$, chow-fed; 14.5 ± 1.8 vs 7.0 ± 1.0, $p > 0.001$, HFD-fed), suggesting that $CD44^{-/-}$ mice were responding to lower insulin for glucose disposal compared to $CD44^{+/+}$ mice. Therefore, the insulin sensitivity indices were normalized to insulin concentrations during clamp. After normalization, there was no notable change in whole body insulin sensitivity of chow-fed $CD44^{-/-}$ mice, however HFD-fed $CD44^{-/-}$ mice exhibited higher GIR {5.9 ± 1.2 vs 2.3 ± 0.3 [mg/kg/min/(ng/mL insulin)]; $p < 0.01$}, Rd {6.4 ± 1.0 vs 2.9 ± 0.3 [mg/kg/min/(ng/mL insulin)], $p < 0.01$} and gastrocnemius Rg {3.0 ± 0.8 vs 1.0 ± 0.2 [umol/100 g/min/(ng/mL insulin)]; $p < 0.05$} than HFD-fed $CD44^{+/+}$ mice, suggesting ameliorated systemic and muscle IR. Reduced muscle insulin resistance in HFD-fed $CD44^{-/-}$ mice was associated with increased gastrocnemius vascularization (CD31 protein expression: $1.8 \pm 0.0.2$ vs 1.1 ± 0.2, $p < 0.05$), rather than insulin signalling. PEGPH20 treatment in HFD-fed $CD44^{-/-}$ mice increased energy expenditure and decreased respiratory exchange ratio (RER) compared to vehicle-treated HFD-fed $CD44^{-/-}$ mice ($p < 0.05$), despite no changes in body weight, food intake, glucose tolerance, insulin tolerance or locomotor activity. The hyperinsulinaemic-euglycaemic clamp showed similar GIRs and muscle glucose uptake between vehicle- and PEGPH20-treated $CD44^{-/-}$ mice.
Conclusion: Global CD44 deletion ameliorates skeletal muscle IR possibly via increased vascularization and the beneficial effects of PEGPH20 are CD44-dependent. These results suggest a critical role of CD44 in promoting hyaluronan-mediated muscle IR, therefore representing a potential therapeutic target for diabetes.

Long-term hypercaloric diet consumption exacerbates age-induced metabolic dysfunction: beneficial effects of CSN denervation

J.F. Sacramento, B.F. Melo, C.S. Prego, S.V. Conde;
CEDOC, NOVA Medical School|Faculdade de Ciências Médicas, Lisbon, Portugal.

Background and aims: We have previously described that carotid body (CB), a peripheral O_2 sensor, that controls energy homeostasis, is involved in the genesis of insulin resistance and glucose intolerance, since the abolishment of its activity restores these features in young animal models of prediabetes and type 2 diabetes. Knowing that ageing itself is associated with deregulation of glucose homeostasis, we have evaluated the long-term intake of hypercaloric diet on age-induced metabolic dysfunction. Additionally, the beneficial effects of carotid sinus nerve (CSN), the CB sensitive nerve, resection on metabolic dysfunction were evaluated. Finally, and since we have previously described that metabolic dysfunction is associated with CB overactivation, we tested CB function in hypercaloric aged animals.
Materials and methods: Two groups of Wistar rats (8–10 weeks) were used: the control group fed a sham diet and the high-fat high-sucrose (HFHSu) group fed a 60% lipid-rich diet with 35% sucrose in drinking water. The groups were randomly divided and submitted to 14, 25 and 44 weeks of respective diets. In this last group when the animals reached 1 year, they were submitted to CSN resection or to a sham surgery. Follow-up of the animals was made until 9 weeks post-surgery. Insulin sensitivity was evaluated through an insulin tolerance test and glucose tolerance by an OGTT. Fasting glycemia, insulinemia and ventilatory responses to hypoxia were also monitored. At a terminal experiment, blood pressure and sympathetic nervous system activity were evaluated and fat depots were analyzed. CB dysfunction was evaluated thought the morphometric analysis of tyrosine hydroxylase (TH) and GFAP in CBs.
Results: Age decreased insulin sensitivity in control animals by 59.11% (K_{ITT} CTL = 4.50 ± 0.36%glucose/min). HFHSu diet during 14, 25 and 44 weeks decreased insulin sensitivity by 55.98, 51.39 and 58.30%, respectively (K_{ITT} HFHSu before diet = 4.13 ± 0.19%glucose/min). CSN resection completely restored insulin sensitivity in control and HFHSu old animals, an effect that was maintained until 9 weeks after surgery. HFHSu diet decreased glucose tolerance, an effect that was exacerbated in HFHSu old animals (AUC HFHSu 14 weeks diet = 23803 ± 586 mg/dl*min; AUC HFHSu 44 weeks diet = 27449 ± 1265 mg/dl*min ($p < 0.05$)). In contrast, age did not alter glucose tolerance in control animals. CSN resection in HFHSu old animals decreased glucose intolerance by 13.23% (AUC HFHSu 9 weeks after CSN resection = 24392 ± 558 mg/dl*min). The increase in fat depots was proportional to the period of time that animals underwent HFHSu consumption. In contrast, in the control animals, only perienteric fat increased with age (CTL = 10.14 ± 0.76 g/kg; CTL Old = 19.82 ± 3.58 g/kg). CSN resection in HFHSu old animals did not modify fat depots. The expression of TH in the CB increased with HFHSu diet by 82.55% and, in contrast, was decreased in control old animals.
Conclusion: Ageing induces insulin resistance in rats and long-term hypercaloric consumption in old animals did not modify age-induced insulin resistance, while exacerbates glucose intolerance. Moreover, CSN resection in old animals restored insulin sensitivity and ameliorates glucose intolerance, effects that were not mediated by amelioration of fat deposition. Our results suggest that modulation of CB activity might be also important in age induced insulin resistance as well as in age-induced metabolic dysfunction exacerbated by diet.

GIP-xenin hybrid peptide enhances the metabolic benefits of exenatide in high fat fed and db/db diabetic mice

V.A. Gault, A. Hasib, M. Ng, R.A. Perry, P.R. Flatt, N. Irwin;
Ulster University, Coleraine, UK.

Background and aims: Metabolic and body weight benefits of GLP-1 mimetics, such as exenatide, in type 2 diabetes are not as impressive as first predicted from preclinical studies. Thus, methods to augment antidiabetic effects of GLP-1 compounds are highly sought after and therapeutically relevant. In the present study we evaluated therapeutic utility of combined treatment with exenatide and a recently characterised GIP-xenin hybrid peptide, namely (DAla^2)GIP-xenin-8-Gln (GIP-XEN), in high fat fed (HFF) and *db/db* diabetic mice. This combined treatment approach should lead to positive modulation of both arms of the incretin axis with improved metabolic effects.
Materials and methods: Groups of mice ($n = 8$) received twice-daily injections (09:30 and 17:30 hr) of saline vehicle, GIP-XEN, exenatide or a combination of both peptides (each at 25 nmol/kg bw; *ip*) for 32 days in HFF mice and 30 days in *db/db* mice. Energy intake, body weight, circulating glucose and insulin concentrations were measured at regular intervals. At the end of each study, glucose tolerance (18 mmol/kg bw; *ip*), biological response to GIP (25 nmol/kg; *ip*) in combination with glucose and peripheral insulin sensitivity (10 U/kg in HFF mice and 30 U/kg in *db/db* mice; *ip*) were examined. In addition, pancreatic islets were isolated at the end of the treatment period in both HFF and *db/db* mice by collagenase digestion, and effects of various secretagogues on insulin secretion determined.
Results: Twice-daily administration of GIP-XEN, exenatide or combination of both peptides had no impact on energy intake or body weight in HFF mice, although all exenatide treated *db/db* mice had reduced ($P < 0.001$) energy intake compared to saline controls by the end of the study. Circulating glucose concentrations and HbA1c values were significantly ($P < 0.05$-$P < 0.001$) decreased and insulin levels increased by treatment with GIP-XEN in combination with exenatide in both HFF and *db/db* mice, compared to respective control mice. Oral glucose tolerance ($P < 0.05$) was also improved by combined GIP-XEN and exenatide treatment in both diabetic mouse models, and insulin sensitivity was substantially enhanced ($P < 0.001$) in HFF mice. Circulating and glucose-stimulated insulin concentrations were elevated ($P < 0.05$) in mice treated with the GIP-XEN and exenatide combination when compared to either treatment alone. Interestingly, GIP-mediated glucose-lowering effects were improved ($P < 0.05$) by treatment with GIP-XEN in combination with exenatide in HFF, but not *db/db* mice. None of the treatment interventions augmented GIP-induced insulin secretion in either mouse model. Pancreatic islets isolated from HFF mice did not display any differences in glucose-stimulated insulin secretion between control and treatment groups, however mice treated with GIP-XEN in combination with exenatide had augmented ($P < 0.01$–$P < 0.001$) insulin secretory responsiveness to Ca^{2+}, IBMX, KCl and PMA.
Conclusion: Prolonged twice-daily treatment with GIP-XEN and exenatide induced an impressive profile of beneficial metabolic effects in both HFF and *db/db* diabetic mice, including improvements of glucose tolerance, augmentation of the glucose-lowering action of GIP and overall beta-cell responsiveness. These data highlight the potential to enhance the antidiabetic properties of clinically approved GLP-1 mimetics, especially with hybrid peptides such as GIP-XEN that merits further clinical consideration.

Postnatal loss of pancreatic beta cell insulin receptor affects insulin secretion observed under long-term high-fat diet

A. Oakie[1,2], L. Zhou[1], S. Rivers[1], C. Cheung[1], J. Li[1,3], R. Wang[1,3];
[1]Children's Health Research Institute, London, [2]Department of Pathology and Laboratory Medicine, University of Western Ontario, London, [3]Department of Physiology and Pharmacology, University of Western Ontario, London, Canada.

Background and aims: The presence of insulin receptor (IR) on insulin-secreting beta cells is required for proliferation, survival, and up-regulation of insulin production, and its expression suggests an autocrine role in insulin signalling. Congenital beta cell -specific *IR* knockout (βIRKO) mouse studies have demonstrated the development of age-dependent glucose intolerance and decreased insulin secretion. However, it is not known if the loss of beta cell IR signalling postnatally interferes with insulin release. In this study, we examined the effects of reduced postnatal IR signalling on maintaining insulin release under normal and high-fat diet feeding.
Materials and methods: We utilized a tamoxifen-inducible *mouse insulin 1* promoter driven Cre-recombinase *IR* knockout mouse model (MIP-βIRKO) to determine the functional role of beta-cell IR in adult mice. Knockdown of IR was induced in postnatal male mice at 4 weeks of age, and mice were placed on either a chow diet or a high fat diet (HFD, 60% kcal) for an 18-week period at 6 weeks of age. Metabolic tests for glucose tolerance and insulin secretion were completed in both diet groups. Histological analyses of islets were performed to examine islet morphology and expression of beta cell transcription factors and proteins involved in glucose-induced insulin release (SNAREs). The INS-1 832/13 cell line was used to examine *in vitro* effects of insulin stimulation (100 nM for 1 hour) on SNARE proteins.
Results: Using western blot analysis, we demonstrated an approximately 50% reduction of IR protein level in isolated MIP-βIRKO islets in comparison to control groups. MIP-βIRKO mice that were fed chow diet for 18 weeks did not develop a change in glucose tolerance and had normal islet morphology when compared to control litter-mates. However, HFD MIP-βIRKO mice demonstrated significantly impaired glucose tolerance compared to HFD control mice. HFD MIP-βIRKO mice showed reduced insulin release with *in vivo* GSIS, and *ex vivo* GSIS of HFD MIP-βIRKO islets identified decreased insulin secretion at low (2.2 mM) glucose levels when compared to HFD control mice. Histological analyses showed no change in beta cell mass or proliferation between HFD control or MIP-βIRKO mice, yet decreased Glut2 and pAkt^{S473} levels were found in HFD MIP-βIRKO mice. The examination of the exocytotic SNARE proteins revealed that Munc18-1, Snap25, and Vamp2 were down-regulated in HFD MIP-βIRKO mouse islets. Preliminary INS-1 cell studies demonstrated that 100 nM insulin induced increased Snap25 with no change in other SNARE proteins.
Conclusion: The results from this study demonstrate that IR knockdown in adult beta cells affects insulin release under HFD stress due to the decreased expression of proteins involved in glucose-sensing and insulin exocytosis. This data indicates that beta cell autocrine IR signalling is required to maintain sufficient insulin secretion against hyperglycemic stress and that the IR-insulin signalling pathway may be directly linked to the regulation of exocytotic proteins.

Corticotropin-releasing hormone: a novel signal for regulating the islet adaptation to pregnancy

S.J.S. Simpson, L.I.F. Smith, T.G. Hill, P.M. Jones, J.E. Bowe; Department of Diabetes, King's College London, London, UK.

Background and aims: Corticotropin releasing hormone (CRH) is the neuroendocrine hormone released from the hypothalamus into the pituitary portal system to regulate adrenal glucocorticoid production via the pituitary. It is generally present at trace levels in the periphery. Despite this lack of CRH in the circulation, both CRH and CRH receptors are present on mouse and human islets. Furthermore, CRH treatment directly affects islet function and has been shown to improve islet transplantation outcomes. However the physiological relevance of CRH action on the islets is currently unclear. Whilst circulating CRH is generally low, during gestation maternal levels rise exponentially due to placental release, which correlates with the islet adaptation necessary to overcome maternal insulin resistance. This study therefore examined the effects of CRH as a potential signal involved in the islet adaptation to pregnancy.
Materials and methods: Expression of CRH and both CRH receptors (CRHR1/2) was confirmed in isolated CD1 mouse islets via qPCR. Effects of exogenous CRH (50 nM) on insulin secretion was assessed using both a dynamic perifusion system and static incubations, with insulin release measured by radioimmunoassay. Pregnant mice were implanted subcutaneously with osmotic minipumps containing saline or CRH receptor antagonist (α helical $CRH_{9\text{-}41}$) to test the effects of endogenous CRH during pregnancy. Intraperitoneal glucose tolerance tests (IPGTT) and insulin tolerance tests (IPITT) were performed in these animals at day G.16 and G.18 respectively. Statistical significance was determined by students T-test or two way ANOVA followed by Sidak's multiple comparisons as appropriate.
Results: Male and female islets express CRH, CRHR1 and CRHR2 mRNA (female CRHR1: 0.007 ± 0.003 vs CRHR2: 0.001 ± 0.001, male CRHR1: 0.003 ± 0.0004 vs CRHR2: 0.0008 ± 0.0004 mRNA expression relative to GAPDH). In perifusion experiments 50 nM CRH potentiated glucose stimulated insulin secretion (GSIS) in male and female islets by 264 ± 79% and 75 ± 22% respectively compared to 20 mM glucose alone, $p < 0.001$). In static incubations CRH caused a similar potentiation of GSIS (0.20 ± 0.04 vs 0.64 ± 0.15 ng $islet^{-1}$ h^{-1}; 20 mM glucose vs 20 mM glucose +50 nM CRH; $n = 7$ observations). The stimulatory effect of CRH was inhibited by the addition of both CRHR1 (Antalarmin) and CRHR2 (Astressin $_2$B) specific antagonists respectively (20 mM glucose +50 nM CRH: 0.64 ± 0.15; 20 mM glucose +50 nM CRH + 1 μM Antalarmin: 0.22 ± 0.03; 20 mM glucose +50 nM CRH + 1 μM $Astressin_2B$: 0.51 ± 0.01 ng $islet^{-1}$ h^{-1}; $n = 7$ observations). Pharmacological blockade of both CRHR1 and R2 *in vivo* during pregnancy resulted in significantly impaired glucose tolerance ($p = 0.0078$; control vs α-helical $CRH_{9\text{-}41}$; $n = 8$–9), which was most pronounced at 15 minutes post glucose (control: 12.98 ± 1.24 vs α-helical $CRH_{9\text{-}41}$: 16.83 ± 1.60 mM; $p = 0.0017$; $n = 8$–9). Insulin sensitivity was unaffected by α-helical $CRH_{9\text{-}41}$ treatment (AUC, control: 359 ± 21 vs α-helical $CRH_{9\text{-}41}$: 395 ± 21; $p = 0.237$; $n = 8$–9).
Conclusion: Both CRHR subtypes are present in mouse islets. Stimulation with CRH results in significant potentiation of GSIS, an effect which appears to be primarily mediated by CRHR1 although CRHR2 may also play a role. Pharmacological blockade of endogenous CRH, through inhibition of both CRH receptors, impairs glucose tolerance but not insulin sensitivity. These results are consistent with a novel physiological role for CRH in regulating the islet adaptation to pregnancy.

Effect of sustained hyperglycaemia on insulin sensitivity and beta cell function in normal glucose tolerant subjects with and without family history of type 2 diabetes

D. Tripathy[1], A. Merovci[2], X. Chen[2], E. Maldonado-Corchado[2], R. DeFronzo[2];
[1]Medicine/Diabetes, South Texas Veteran's Health Care System, San Antonio, [2]Medicine/Diabetes, The University of Texas Health Science Center at San Antonio, San Antonio, USA.

Background and aims: Short-term hyperglycemia induces insulin resistance and beta cell dysfunction in rodents. However the effect of chronic physiological hyperglycemia on beta cell function in humans is not clear. The aim of the present study was to evaluate effect of a sustained (72 hr) physiologic increase in plasma glucose concentration on insulin secretion in healthy NGT individuals with (FH+) and without (FH-) a family history of T2DM.
Materials and methods: 20 NGT subjects: 12 without family history of T2DM (FH-), (9M/3F, age = 50 ± 4 yrs, BMI = 27 ± 1 kg/m^2) and 8 with FH (FH+) (4M/4F, Age = 48 ± 3 yrs, BMI = 26 ± 1 kg/m^2) participated in a OGTT and 2 step hyperglycemic (+125 and + 300 mg/dl) clamp followed by IV arginine (5 g) bolus clamp before and after a 72 hour glucose infusion to increase plasma glucose conc by ~50 mg/dl above baseline. The acute insulin response ($AIR_{0\text{-}10}$min), 2nd phase (SP) insulin secretion ($SPIS_{10\text{-}80}$ and $SPIS_{90\text{-}160}$ minutes) responses during each hyperglycemic step and following arginine (AIR_{Arg}) were assessed. Insulin sensitivity was assessed as the glucose infusion rate/steady state plasma insulin (M/I) during the hyperglycemic clamp.
Results: There was no difference in FPG, 2-h Glucose, fasting, and 2-h insulin concentrations between FH+ and FH- subjects. The FPG increased from 97 ± 4.5 to 140 ± 4.9 mg/dl during 72 hours of glucose infusion. The first phase insulin secretion (0–10 min) increased by 80% and 60% respectively in FH- and FH- subjects, while the second phase insulin secretion (10–80 min) increased by 3 fold (>300%) in both FH- and FH+ subjects respectively following chronic glucose infusion. The insulin sensitivity M/I declined in FH- (21 ± 5 to 8.1 ± 2.03, mg/kg.MU.l, $p = 0.02$) and in FH+ (16 ± 3 to 7 ± 1, mg/kg.MU.l, $p = 0.03$) following chronic glucose infusion. The insulin secretion/insulin resistance (disposition index, $ACR_{0\text{-}10}$ X M/I) did not significantly change in FH+ or FH- subjects before and after sustained hyperglycemia. However the disposition index ($SPIR_{90\text{-}160}$ X M/I), was reduced in FH- (9591 ± 1941 to 4198 ± 938, $p = 0.02$) and FH+ (6775 ± 1280 vs 2397 ± 640, $p = 0.01$) following chronic glucose infusion.
Conclusion: These results demonstrate that sustained physiologic hyperglycemia (i) impairs insulin sensitivity, (ii) increases absolute insulin secretion (iii) only impairs second phase insulin secretion. This suggests that healthy individuals are able to compensate for insulin resistance induced by short-term glucotoxicity.

The increment of noradrenergic fibers correlates with the density of dedifferentiated beta cells and impairs beta cell function in humans

F. Cinti[1], T. Mezza[1], I. Severi[2], M. Suleiman[3], C. Cefalo[1], G. Sorice[1], S. Moffa[1], F. Impronta[1], S. Alfieri[4], A. Pontecorvi[1], L. Marselli[3], S. Cinti[2], P. Marchetti[3], A. Giaccari[1], D. Accili[5];
[1]Center for Endocrine and Metabolic Diseases, Fondazione Policlinico Universitario A.Gemelli, Catholic University of Sacred Heart, Rome, Italy, [2]Department of Experimental and Clinical Medicine, Center of Obesity, University of Ancona (Politecnica delle Marche), Ancona, Italy, [3]Department of Experimental and Clinical Medicine, University of Pisa,, Pisa, Italy, [4]Digestive Surgery, Fondazione Policlinico Universitario A.Gemelli, Catholic University of Sacred Heart, Rome, Italy, Rome, Italy, [5]Department of Medicine, Naomi Berrie Diabetes Center, Columbia University, New York City, USA.

Background and aims: β cell dedifferentiation has recently been indicated as the main mechanism responsible for the functional "disappearance" of β cells from the islets of diabetic individuals. Given the results obtained in a mouse model of type 2 diabetes (T2D), which found a

significant increase in the density of noradrenergic fibers in diabetic compared to non-diabetic mice, we attempted to replicate the study in humans, examining the possible involvement of noradrenergic fibers in the process of dedifferentiation.

Materials and methods: We analyzed human pancreas samples from organ donors (8 non diabetic and 9 with type 2 diabetes) and 11 patients undergoing pancreatoduodenectomy, who previously underwent an Oral Glucose Tolerance Test [Normal Glucose Tolerance - NGT (5), Impaired Glucose Tolerance - IGT (3) and T2D (3)] and a 2h hyperglycemic clamp. The dedifferentiation score was calculated as the percentage of synaptophysin positive cells negative for the four major pancreatic hormones. Tyrosine hydroxylase (TH) was used as a marker for the evaluation of noradrenergic fiber expression. Transmission electron microscopy was performed to localize fibers inside the islet. β cell glucose sensitivity (GS) was calculated as the ratio of insulin secretion and glucose increments, during the hyperglycemic clamp.

Results: The islets of diabetic subjects were about 3 times more innervated than controls (0.32 ± 0.12 vs. 0.90 ± 0.21 n.fibersTH+/islet; $p < 0.01$), with a stepwise increase from NGT-IGT to T2D; the increase of these fibers correlated positively with the dedifferentiation score ($p < 0.001$; $r = 0.69$). Moreover, the increase of noradrenergic fibers negatively correlated with GS, supporting the possibility of their functional role ($p = 0.018$, $R = -0.84$).

Conclusion: In conclusion, our data show an increase in the number of sympathetic nerve fibers, potentially able to transmit inhibitory signals on insulin secretion in the islets of diabetic subjects. The important correlation with the glucose sensitivity and dedifferentiation score suggests a significant role of noradrenergic fibers in the dedifferentiation process and β cell dysfunction, introducing the possibility of new future strategies for the preservation of cellular mass/secretion and, therefore, for the prevention and/or treatment of diabetes.

Disclosure: **F. Cinti:** None.

477

The role and mechanism of TXNIP in aging related proliferation and secretion dysfunction of pancreatic beta cells

Y. Li, D. Liu, G. Yang;
Department of Endocrinology, The Second Affiliated Hospital Chongqing Medical University, Chongqing, China.

Background and aims: Thoredoxin interacting protein (TXNIP) is the interacting protein of Thioredoxin, that can reduce insulin secretion of pancreatic β cells. Thioredoxin was confirmed as an anti-aging gene, but there is little known about the relationship between TXNIP and pancreatic β cells aging. The present study was designed to explore it.

Materials and methods: Three aged-periods (youth, mid-aged, elderly) human normal pancreas tissue and serum were collected, the expression of TXNIP protein was measured by Immunofluorescence and ELISA. 4-week-old C57BL/6J mice($n = 48$) and TXNIP$^{-/-}$ mice($n = 48$) were randomly assigned into 2 groups respectively, fed on a normal chow diet(NC) or a high fat diet(HFD) separately, each group was fed for four periods (3 months, 9 months, 12 months, 18 months). At each period of all groups , GTT, ITT, serum insulin and basic physiological metabolic indexes were measured; the mass of pancreatic β-cell was counted; the expression of TXNIP and aging marker protein (p21, p16) of pancreatic β cells were measured by Immunofluorescence and Western blot. Proliferation capacity of pancreatic β-cell was assessed by ki67 expression in insulin+ cells from 3 months mice. Ultrastructural changes of pancreatic β-cell were visualized and compared by electron microscopy in 12 months mice. Meanwhile, primary pancreatic β-cell were isolated and cultured from 3 and 18 months mice. Ex vivo glucose-insulin secretion level of primary pancreatic β-cell incubated in medium containing 2.8mM or 16.7mM glucose was measured by ELISA. The expression of TXNIP, p21, p16 of primary pancreatic β-cell were also measured by Immunofluorescence and Western blot.

Results: The expression of TXNIP protein was gradually increased with aging in the human normal pancreatic β-cells and serum. Compared with the age-diet-matched C57 groups, the FBG was lower, the insulin secretory function was better, and the insulin resistance was milder, among each TXNIP$^{-/-}$ groups, significantly. The serum TC,LDL were lower, insulin and HDL were higher in TXNIP$^{-/-}$ groups, compared with the age-diet-matched C57 mice. Among 3,9,12,18 months period in C57 NC/HFD groups, the mass of pancreatic β-cell was down-regulated and the protein expression of TXNIP, p16, p21of pancreatic β-cells were up-regulated with aging. Compared with the age-matched C57 NC group, the mass of pancreatic β-cell was down-regulated and the expression of TXNIP was up-regulated in 9, 12, 18 months C57 HFD groups. The mass of pancreatic β-cell were larger and the expression of protein p16, p21 were lower obviously in 9, 12, 18 months TXNIP$^{-/-}$ groups than those in the age-diet-matched C57 mice. Meanwhile, proliferation capacity of pancreatic β-cell was better in 3-month-old TXNIP$^{-/-}$ group than that in the age-diet-matched C57 groups. Mitochondrial and the endoplasmic reticulum became more swell, mitochondria decreased more seriously, in 12-month-old C57 HFD group as compared with 12-month-old TXNIP$^{-/-}$ HFD group. In TXNIP$^{-/-}$ group, ex vivo glucose-insulin secretion level was better and the protein expression of p16, p21 were lower in 18-months-old primary pancreatic β-cell, as compared with the age-diet-matched C57 group.

Conclusion: TXNIP could be a pro-aging gene of pancreatic beta cells, aggravates the aging-induced proliferation and secretion dis-function of pancreatic beta cells, meanwhile accelerates metabolic disorders.

Mitochondrial respiratory chain complex IV dysfunction and beta cell failure is associated with a novel mutation in the mitochondrial assembly factor NDUFAF5

S. Weksler-Zangen[1], A. Kogot-Levin[1], G. Aharon Hananel[1], E. Gurgul-Convey[2], I. Raz[1], A. Saada[3];
[1]Diabetes Unit, Hadassah University Hospital, Jerusalem, Israel, [2]Institute of Clinical Biochemistry, Hannover Medical School, Hannover, Germany, [3]Monique and Jaques Roboh Department of Genetic Research and of Genetic and Metabolic diseases, Hadassah University Hospital, Jerusalem, Israel.

Background and aims: Mitochondrial respiratory chain (MRC) function is a major determinant of insulin secretion from pancreatic β-cells. The Cohen diabetic sensitive (CDs) rat is a unique model of cytochrome c oxidase (COX, MRC, complex-IV) deficiency, developing hyperglycemia when fed a diabetogenic high sucrose, copper-deficient diet (DD). Copper is a key-element for the catalytic activity of complex-IV. Yet, the precise mechanisms leading to mitochondrial dysfunction are unknown. A mutation in NDUFAF5, the gene encoding MRC complex I assembly factor 5 was associated with MRC complex I & IV deficiencies in Leigh-syndrome patients. However, the role of NDUFAF5 in β-cell function is not yet defined. Aim: We examined the role of COX and NDUFAF5 in β-cell failure.

Materials and methods: Blood glucose and insulin concentrations were measured before and during oral glucose tolerance tests performed at different periods on DD or copper supplemented DD. Islets complex I and complex IV activity were measured spectrophotometrically. Whole genome sequencing was performed in blood-DNA using Illumina HiSeq2500 followed by in-silico variant-analysis. The effect of NDUFAF5 gene silencing (siRNA) on glucose stimulated insulin secretion (GSIS) was assessed in rat (INS1E) and human (EndoCβH1) β cells.

Results: Complex IV & I activity were significantly reduced in CDs rat islets as compared to control rat islets ($P < 0.01$). A highly significant positive correlation between COX activity and GSIS and an inverse correlation with blood-glucose-levels ($R^2 = 0.984$ and $R^2 = -0.915$, $P <$

0.0001 respectively) were found in islets of CDs rats fed DD or copper supplemented-DD. Whole-genome-sequencing identified a *novel* homozygous missense variant, p.P318L (c.C1002T), in the NDUFAF5 gene predicted to be pathogenic by in-silico analysis. NDUFAF5 protein levels were significantly decreased in CDs rat islets vs. control rat islets. siRNA suppression of NDUFAF5 in rat INS1E and human EndoCβH1 β-cells reduced GSIS by ~20%.

Conclusion: We demonstrate a tight correlation between impaired mitochondrial function and β-cell dysfunction in CDs rats. NDUFAF5 may play an important role in the CDs mitochondrial defect and genetic susceptibility to develop diabetes. Our data emphasize a crucial role for mitochondria defect in the pathogenetic processes culminating in type 2 diabetes.

The increase in calcium by arginine, but not by strong potassium depolarisation is different between pancreatic alpha and beta cells

E.-H. Frueh, I. Rustenbeck;
University of Braunschweig, Braunschweig, Germany.

Background and aims: Pancreatic alpha-cells release their peptide hormone by depolarization-triggered exocytosis. Since alpha-cells express glucokinase and K_{ATP} channels, one might expect that the increase but not the decrease of glucose stimulates glucagon secretion. To explain the inverse glucose dependence of glucagon secretion it has been suggested that the alpha cell Ca^{2+} channels desensitize at strong depolarization, thus abrogating stimulated Ca2+ influx. Here, we have compared the effect of depolarizing stimuli on alpha- and beta-cells.

Materials and methods: Insulin and glucagon were determined by ELISA (Mercodia) from the fractionated efflux of batch-perifused NMRI mouse islets. Alpha-cells were isolated from such islets by incubation with alloxan for 10 min. Thereafter, these islets were dissociated by incubation in Ca2+ free solution. The surviving cells were cultured for 24 h in RPMI 1640 with 5 mM glucose. The same procedure without alloxan treatment was used to isolate beta cells. The cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) was measured by microfluorometry of Fluo-4. The plasma membrane potential was measured by patch-clamping using the perforated patch mode.

Results: Decreasing the glucose concentration from 10 to 1 mM led to a transient increase of glucagon secretion before the insulin secretion was diminished. Raising subsequently the glucose concentration from 1 to 30 mM increased the insulin secretion before the glucagon secretion was diminished. 1 mM glucose is thus a glucose concentration which is compatible with stimulated glucagon secretion. In the presence of 1 mM glucose all of the non-beta cells (survivors of alloxan treatment) reacted to 20 mM arginine by increasing $[Ca^{2+}]_i$, but only 50% did so in response to 1 mM glutamate or 1 mM glutamine. All cells which responded to glutamate also increased $[Ca^{2+}]_i$, in response to KCl. The strongly depolarizing concentration of 40 mM KCl was more effective than the moderately depolarizing concentration of 15 mM KCl. The response pattern caused by 40 mM KCl showed the typical fast increase followed by a decrease to moderately elevated plateau. 20 mM arginine caused a similarly strong, but more sustained elevation of $[Ca^{2+}]_i$, clearly higher than the beta-cell response to arginine. All non-beta cells failed to increase $[Ca^{2+}]_i$ in response to a maximally effective concentration of tolbutamide (500 μM). 15 mM KCl depolarized alpha-cells (defined as those, which survived alloxan treatment and responded to arginine and glutamate) by 14 mV, 40 mM KCl depolarized them by 34 mV. With beta-cells the depolarizing effect of 15 mM KCl was 21 mV and that of 40 mM KCl was 40 mV.

Conclusion: The clear concentration dependence of the KCl-induced $[Ca^{2+}]_i$, increase argues against a desensitization of Ca2+ influx as the underlying mechanism of the inverse glucose dependence of glucagon secretion. This view is supported by the sustained elevation of $[Ca^{2+}]_i$, in response to 20 mM arginine.

Endocytosis occurs right after fusion pore open and plays crucial roles in granule collapse

W. Ma[1], J. Tong[1], J. Chang[2], P. Thorn[1];
[1]Charles Perkins Centre, University of Sydney, Sydney, [2]University of Queensland, Brisbane, Australia.

Background and aims: Exocytosis is the process of granule fusion and release of granule content. Current models propose that, coincident with loss of content, the granule collapses into the cell membrane. This is then followed by the recruitment of endocytic machinery, such as clathrin, to the cell membrane and the endocytic recovery of the granule membrane and membrane proteins. Recent studies question this temporal sequence with evidence that endocytosis occurs much more rapidly after exocytosis than has been thought. However, the time course of recruitment of endocytic machinery and their roles remain unknown. Our study aims to find out when the endocytic machinery is recruited to the fused granule and whether they play any role in the granule fusion process.

Materials and methods: 2-Photon microscopy was used to image the exocytosis of insulin granules in β-cells. SRB extracellular dye was used to label fused granules. Primary β-cells were prepared from Lifeact-GFP mice to study the actin remodeling during granule fusion. Primary β-cells from WT mice were infected with Proinsulin-GFP adenovirus to study the content release during secretion. Stable Min6 cell-lines were generated by infecting with lentivirus expressing Clathrin-GFP, Arp3-GFP and Dynamin-GFP to trace the corresponding proteins' translocalization. Drugs including Arp3 inhibitor CK666 and CK689 (control); Clathrin inhibitor Pitstop2 and Dynamin inhibitor Dyngo 4a were utilized to study the effect on granule fusion dynamics.

Results: In our study of pancreatic β-cells, it is observed during glucose stimulated insulin secretion, that insulin granules are emptied immediately after the fusion pore open while the granule still holds its structure. Actin remodeling was observed by 2-photon microscopy on the site of fusion. Confocal microscopy showed that actin was coated around the fusing granule. Clathrin, Arp2/3, then Dynamin are recruited to the site of fusion immediately after the opening of the fusion pore. This process drives actin polymerization at the site of fusion. Inhibition of Clathrin, Arp2/3 and dynamin with drugs significantly altered the dynamics of granule fusion and affected actin remodeling. Blocking Arp2/3 by CK666 abolished the actin coating and greatly slowed down or paused the progress of granule collapse.

Conclusion: Our data shows that Insulin was released immediately after the pore opened, which indicates decrease in granule volume is not necessary for loss of content. Endocytic machinery recruit to the site of fusion right after the fusion starts. Interference with the endocytic proteins' function significantly altered the granule fusion dynamics. This results indicates that the vesicle components and membrane start to pinch off during the fusion process by endocytosis, which is responsible for the granule collapse.

Does and to what extent insulin decides the fasting glucose levels?

M. Watve, M. Diwekar, S. Kulkarni, A. Ojha;
Biology, Indian Institute of Science Education and Research, Pune, Pune, India.

Background and aims: The fasting steady state level of glucose is assumed to be mainly determined by insulin signaling although other insulin independent neuronal and hormonal mechanisms are known to regulate glucose. This assumption has not been critically evaluated and the relative role of insulin dependent and independent mechanisms in determining fasting glucose remains unknown. We use multiple approaches to examine the role of insulin in determining fasting plasma glucose.
Materials and methods: We examine whether glucose and insulin levels affect each other in a fasting steady state using multiple approaches including (i) a series of mathematical models with classical and alternative assumptions and their steady state solutions (ii) experimental results of tissue specific insulin receptor knock-outs in rodents (ii) insulin suppression and insulin raising experiments in rodents and humans (iv) human population data on glucose and insulin during fasting and glucose tolerance curve in type 2 diabetic and non-diabetic subjects. (v) A network model incorporating insulin dependent and independent mechanisms and their regulators. (vi) Re-examining classical evidence for insulin mediated regulation of fasting glucose.
Results: (i) In mathematical modeling the set of assumptions that allow insulin signaling to determine fasting glucose levels, does not allow an insulin resistant hyperinsulinemic, normoglycemic state. The classical insulin centric model and clinical picture of type 2 diabetes and prediabetes are mutually incompatible. (ii) Muscle, fat, beta cell and liver specific insulin receptor knockouts have failed to give compensatory hyperinsulinemic normoglycemic state and long lasting fasting hyperglycemic state (iii) In all insulin suppression experiments in rodents as well as humans, the apparent insulin sensitivity increased after insulin suppression and fasting glucose remained normal. Disabling insulin degrading enzyme increased fasting insulin levels but did not decrease fasting glucose. (iv) Fasting glucose and insulin are poorly correlated in human data and their relationship is not explained by the classical pathway. (v) Network model reveals that insulin signaling is not central to glucose homeostasis and type 2 diabetic state. Targeting insulin signaling does not result in a stable non-diabetic state. This result is compatible with the failure of reversing diabetes with a focus on insulin signaling. (vi) The classical evidence for insulin mediated regulation of fasting glucose has alternative interpretations that have not been eliminated.
Conclusion: All evidence converges to the conclusion that although alteration in insulin levels or insulin sensitivity alters the glucose tolerance curve, it does not alter the fasting steady state levels of plasma glucose. There is no evidence that the fasting glucose levels are determined by insulin signaling and the classical pathway of glucose homeostasis needs to be re-examined. The fasting glucose level is likely to be mainly determined by insulin independent glucose regulation mechanisms.

Insulin clearance is modulated by insulin sensitivity independently of hypersecretion

R. Bizzotto[1], A. Natali[2], A. Gastaldelli[3], R.A. De Fronzo[4], S. Arslanian[5], E. Ferrannini[3], A. Mari[1];
[1]CNR Institute of Neuroscience, Padova, Italy, [2]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, [3]CNR Institute of Clinical Physiology, Pisa, Italy, [4]Department of Medicine, University of Texas Health Science Center, San Antonio, USA, [5]Division of Weight Management, Children's Hospital of Pittsburgh, University of Pittsburgh Medical Center, Pittsburgh, USA.

Background and aims: The study of the determinants of endogenous insulin clearance (EIC) is complicated by the phenomenon of saturation, which, if neglected, leads to overestimating the associations between reduced insulin clearance and conditions of elevated insulin secretion rates (ISR) such as insulin resistance and obesity. To overcome this problem, we have developed a novel physiologically-based mathematical model of insulin kinetics able to describe EIC over a wide range of insulin concentrations obtained by glucose-stimulated ISR and exogenous insulin infusion.
Materials and methods: To develop the model we used data from multiple studies: a) intravenous glucose infusion with different patterns (7 different studies, $N = 211$ subjects); b) one- or two-step hyper insulinaemic euglycaemic clamp with different insulin infusion rates (3 studies, $N = 1685$); c) hyper glycaemic and euglycaemic clamp tests in the same subject (1 study, $N = 126$). Subjects were non-diabetic (ND, $N = 1519$) or had type 2 diabetes (T2D, $N = 300$), had a wide range of age (10–76 y) and BMI (17–64 kg/m^2) and were multiracial. Insulin kinetics was described by a circulatory model in which fractional insulin extraction from plasma is saturable in the liver whilst is constant in extra-hepatic organs. ISR was estimated from C-peptide by deconvolution. Standardized EIC, i.e. not dependent on the subject's insulin levels, was estimated for ISR equal to 100 and 400 pmol min^{-1} m^{-2} (EIC_{100} and EIC_{400}), aiming at representing both fasting and fed ISR, respectively. In the euglycaemic clamp studies ($N = 1879$), insulin sensitivity was measured as the M/I index.
Results: The model predicted actual plasma insulin concentrations accurately, with homogeneous parameters across the different studies. EIC decreased by 28.0 ± 0.3% when ISR varied from 100 to 400 pmol min^{-1} m^{-2}. In a multiple regression model of EIC_{100} including M/I, T2D, BMI, age, sex, race and study, independent significant predictors were: T2D (standardized $\beta = 0.15$ T2D *vs* NGT), sex ($\beta = 0.04$ males *vs* females), race ($\beta = 0.08$ white *vs* black), and M/I ($\beta = 0.23$) ($r^2 = 0.35$). M/I was the most important predictor of EIC_{100} ($\Delta r^2 = 0.15$). EIC_{100} in the 1st and 3rd M/I quartiles was 0.95 and 1.17 L min^{-1} m^{-2}. Similar results were obtained for EIC_{400}. An increase in ISR from 60 to 100 pmol min^{-1} m^{-2} (representing fasting ISR in insulin-sensitive and insulin-resistant subjects) was due to a 4% EIC reduction caused by saturation and to a 28% reduction produced by insulin resistance. In a subset of ND subjects in whom fasting AST, ALT, GGT, HDL, LDL, cholesterol, triglycerides, and FFA were available ($N = 1053$), additional independent predictors of EIC_{100} were FFA ($\beta = 0.08$), AST ($\beta = -0.11$) and GGT ($\beta = 0.08$), though with an overall modest impact ($\Delta r^2 = 0.02$).
Conclusion: The direct relationship of EIC with insulin sensitivity is primary and not an indirect effect of saturation. Insulin sensitivity is the most important determinant of EIC. T2D, sex, race, FFA, AST and GGT, but not BMI, are correlates of EIC independent of insulin sensitivity, although their quantitative contribution is modest.

Pharmacological characterisation of an ultra-long acting once-weekly insulin-Fc fusion with continuous glucose monitoring

C.D. Church[1], V. Howard[2], S. Oldham[2], R. Gaddipati[2], K. Mather[2], A. Rossi[1], G. Browne[3], L. Liang[1], J. Naylor[1], J. Dhillon[3], D. Hornigold[1], J. Trevaskis[2], D. Baker[1], C.J. Rhodes[2], A. Buchanan[3];
[1]Cardiovascular, renal and metabolism (CVRM), MedImmune, Cambridge, UK, [2]Cardiovascular, renal and metabolism (CVRM), MedImmune LLC, Gaithersburg, USA, [3]Antibody Discovery and Protein Engineering (ADPE), MedImmune, Cambridge, UK.

Background and aims: Basal insulin analogues have been designed and produced to mimic endogenous insulin secretion. Current basal insulin therapy for type 2 diabetes mellitus support daily dosing for patients with a focus on minimising nocturnal hypoglycaemia events. However, daily injections result in poor patient compliance. Therefore, an insulin analogue with a longer action time with less frequent administration could improve patient compliance and thus glycaemic control. Aim: Develop a once-weekly insulin analogue for the control of hyperglycaemia in patients with type 2 diabetes mellitus who require basal insulin.
Materials and methods: To achieve extended insulin action pharmacology, a panel of recombinant native single chain insulin molecules were fused to fragment crystallizable region (Fc) consisting of B chain to A chain-linker variants fused to Fc. Insulin-Fc variants were profiled in human and rodent insulin action assays including insulin receptor signalling, phosphorylated AKT (Ser473) in hepatocytes and glucose uptake in adipocytes *in vitro*. Additionally, blood glucose was monitored over one week in rodent models of obesity and hyperglycaemia (high-fat diet-induced obesity, *db*/*db*and Zucker diabetic fatty ZDF rats) following a single subcutaneous injection of Insulin-Fc variants (10, 30, 60 or 90 nmol/kg). We utilised continuous glucose monitoring (CGM) telemetry to profile the day-night control of blood glucose in ZDF rats dosed with Insulin-Fc variants.
Results: Insulin-Fc variants were designed and produced in CHO cells. A panel of Insulin-Fc variants showed a wide range of potencies for insulin receptor (IR) and insulin-like growth factor 1 receptor (IGF1R) in a luminescence linked reporter assay, as compared to endogenous insulin. Further characterisation of Insulin-Fc variants in primary mouse, rat and human hepatocytes for phosphorylated AKT (Ser473) signalling demonstrated several variants with an EC_{50} potency within 100-fold of endogenous insulin. Glucose uptake in 3T3L1 adipocytes confirmed the potency of Insulin-Fc variants (EC_{50} within 100-fold of endogenous insulin). Two Insulin-Fc molecules were subsequently characterised in *db*/*db* and high-fat diet-induced obesity (DIO) mouse models and this revealed greater than 50% blood glucose lowering (AUC, $P < 0.05$) for 5 days following administration of a single dose of Insulin-Fc. High resolution blood glucose profiling using CGM telemetry in ZDF rats showed enhanced glucose control in both day and night periods (AUC, $P < 0.05$) up to 10 days following a single-dose (90 nmol/kg) of Insulin-Fc. Chronic repeat-dosing of an Insulin-Fc variant every 10 days for 5 weeks demonstrated improved glycaemic control (−22% HbA1c from baseline with 60 nmol/kg, $P < 0.05$).
Conclusion: We report a novel basal insulin analogue with fusion of insulin to Fc that exhibits extended pharmacokinetic and pharmacodynamic profiles in rodent models of hyperglycaemia, consistent with once-weekly administration in humans. High resolution continuous glucose monitoring demonstrates enhanced glycaemic control in ZDF rats during both day and night periods with Insulin-Fc variants.

Association between a metabolic syndrome severity score and all-cause mortality in type 1 diabetes: a 10-year follow-up study

R. Miccoli, M. Garofolo, R. Giannarelli, F. Campi, D. Lucchesi, L. Giusti, V. Sancho Bornez, A. Dardano, G. Daniele, S. Del Prato, G. Penno;
Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy.

Background and aims: The prevalence of distinctive traits of the Metabolic Syndrome (MetS) is increasing among individuals with type 1 diabetes mellitus (T1DM). We have therefore determined in a longitudinal study the association between a "MetS severity score" (MetS score; courtesy of Dr. Mark DeBoer) and all-cause mortality in T1DM.
Materials and methods: We consecutively recruited 774 T1DM individuals (age 40.2 ± 11.7 years; diabetes duration (DD) 19.4 ± 12.2 years; BMI 24.8 ± 3.6 kg/m^2; HbA1c 7.8 ± 1.2%) for whom all-cause mortality was assessed over a 10.6 ± 2.6 year follow-up. MetS score was based on waist circumference (WC), systolic blood pressure (sBP), HDL-cholesterol and triglycerides with exclusion of blood glucose. Hazard ratios (HRs) for MetS score stratified by quartiles and all-cause mortality were determined by unadjusted and adjusted Cox regression.
Results: Mean MetS score was −0.50 ± 0.67 (mean ± SD; median −0.58; IQR −0.96 to −0.15). After stratification by quartiles, compared to Q1, Q2–4 showed a progressive increase of age, BMI, diastolic blood pressure, fasting glucose, HbA1c, total-, LDL- and nonHDL-cholesterol, uric acid and fibrinogen ($p < 0.0001$). WC, sBP and triglycerides, and ACR also increased, while HDL and eGFR (CKD-EPI) decreased ($p = 0.006$). A progressive increase was found in percentage of males ($p = 0.061$), CV events (1.0%, 4.6%, 6.2% and 9.3%; $p = 0.003$), eGFR <60 ml/min/1.73 m^2 ($p = 0.038$), micro- or macroalbuminuria, ($p = 0.007$), and retinopathy ($p = 0.003$) as well as use of BP-lowering agents, RAS-blockers, lipid-lowering and anti-platelet drugs ($p < 0.0001$). A total of 52 deaths occurred during the 8,184 person-years of follow-up (6.7%; 6.36 × 1000 person-years). Death rate increased with MetS score: Q1 2.1%; Q2 5.7% (HR 3.10, 95%CI 0.99–9.75, $p = 0.053$); Q3 5.7% (2.78, 0.88–8.73, $p = 0.080$); Q4 13.5% (7.02, 2.45–20.12, $p < 0.0001$; K-M, Log Rank 21.46, $p < 0.0001$). Adjusting for age (HR 1.08, 95%CI 1.06–1.11, $p < 0.0001$) and sex (M, 1.737, 0.98–3.08, $p = 0.059$), HRs vs Q1 ($p = 0.020$) were: Q2 2.59 (95%CI 0.82–8.15, $p = 0.104$); Q3 1.94 (0.61–6.12, $p = 0.258$); Q4 4.24 (1.46–12.31; $p = 0.008$). Adjusting for age ($p < 0.0001$), sex ($p = 0.022$), DD, BMI, HbA1c, LDL-cholesterol, CVD, retinopathy, eGFR ($p = 0.013$), ACR ($p < 0.001$), and prior CV events, HRs vs Q1 ($p = 0.047$) were: Q2 3.36 (95%CI 1.05–10.76, $p = 0.041$); Q3 2.21 (95%CI 0.69–7.08, $p = 0.352$); Q4 4.05 (95%CI 1.39–11.75; $p = 0.01$). In a fully adjusted model that adds also variables included in the equation (i.e., WC, sBP, triglycerides and HDL), age, sex, eGFR and ACR were independent predictor of death, while HRs of MetS score quartiles ($p = 0.056$) were: Q2 3.18 (95%CI 0.99–10.19, $p = 0.051$); Q3 2.11 (95%CI 0.66–6.75, $p = 0.211$); Q4 3.87 (95%CI 1.33–11.23; $p = 0.013$).
Conclusion: Our results suggest that the MetS score may predict all-cause mortality independent of both other cardiovascular risk factors as well as of the single components of MetS. However, larger studies or meta-analytic approaches combining multiple cohorts will be necessary to confirm this initial observation.

Estimation of glucose disposal rate in type 1 diabetes using clinical and research biomarkers

A.J. Jenkins[1,2], A.S. Januszewski[1,2], N. Sachithanandan[2,3], G. Ward[2,3], C. Karschimkus[2], D.N. O'Neal[1,2];
[1]NHMRC Clinical Trials Centre, University of Sydney, Camperdown, Australia, [2]Department of Medicine, University of Melbourne, Fitzroy VIC, Australia, [3]Department of Endocrinology, St Vincent's Hospital, Fitzroy VIC, Australia.

Background and aims: In Type 1 diabetes Insulin resistance is a novel risk factor for vascular complications. The gold-standard for assessing insulin sensitivity is the glucose disposal rate (GDR) measured by euglycemic hyperinsulinemic clamp, a research tool. Based on clamp studies ($n = 24$), GDR range 3.8–13.4 mg/kg/min, Williams et al developed an equation to estimate GDR (eGDR) based on clinical factors (hypertension, waist/hip ratio and HbA1c), which has been associated with and predictive of complications. **Aim:** To develop a panel of clinical ± research biochemical biomarker equations which correlate with clamp study quantified GDR (and other insulin sensitivity-related measures) in T1D adults.
Materials and methods: An euglycemic, hyperinsulinemic clamp was performed in 28 T1D adults (age (mean ± SD) 43 ± 22 yrs, T1D duration 21 ± 11 yrs, HbA1c 7.7 ± 1.4%; 9 with microvascular complications)

GDR, M/I (mean glucose infusion rate over 60 min from insulin infusion start/mean plasma insulin concentration during the same period) and Log10 M/I, all measured during the last 60 min of the clamp were dependent variables. Thirty-eight biomarkers (demographics, clinical variables (e.g. HbA1c, lipids) and research biomarkers (of inflammation, adipokines, and oxidative stress) were independent variables. Exhaustive search was used to select best performing models with up to 5 variables (based on R^2) and coefficients were calculated using multiple regression. eGDR, eM/I and eLog M/I were calculated using: 1) all variables, 2) only demographics and routine chemistry; 3) only research biomarkers; 4) only research biomarkers and demographics.

Results: GDR, M/I and Log10 M/I mean, range were 7.06 mg/kg/min and 1.87–14.05 mg/kg/min, 0.014 and 0.002–0.037, −1.95 and −2.70–−1.43 respectively. Levels of all three parameters calculated in the last 30, 60 and 90 min of the clamp correlated with each other $r = 0.99$, $p < 0.0001$. The best eLog10 M/I models accounted for up to 68% of Log10 M/I variability. The best eLog10 M/I model derived from demographic and clinical parameters included (standardized beta): gender (0.77), age (0.34), HDL-C (0.77), pulse pressure (−0.39) and waist/hip ratio (−0.27). The best eLog10 M/I model derived from research biomarkers included CRP (−0.39), total adiponectin (0.63), leptin (−0.39) and IL-6 (0.38).

Conclusion: Estimating GDR using simple, routinely available parameters is feasible and provide alternates to assess insulin resistance in T1D in research and potentially clinical settings.

Table 1: R^2 and p values for 4 models predicting GDR, M/I and Log10 M/I

Model	Models estimating measured clamp parameters using 4 or 5 parameters	GDR	M/I	Log10 M/I
1	All variables	0.51, p<0.002	0.59, p<0.0003	0.68, p<0.00002
2	Clinical chemistry + demographics	0.55, p<0.002	0.61, p<0.0005	0.67, p<0.00009
3	Research biomarkers	0.44, p<0.008	0.58, p<0.0003	0.68, p<0.00002
4	Research biomarkers + demographics	0.44, p<0.008	0.55, p<0.0008	0.68, p<0.00002

The higher insulin sensitivity the higher exercise capacity in patients with type 1 diabetes

A. Uruska, P. Niedzwiecki, D. Naskret, O. Rozanska, A. Cieluch, D. Powezki, M. Chudzinski, D. Zozulinska-Ziolkiewicz;
Department of Internal Medicine and Diabetology, Poznan University of Medical Science, Poznan, Poland.

Background and aims: Insulin resistance (IR) is an important clinical problem in type 1 diabetes. Decreased insulin sensitivity is a risk factor for the development of chronic diabetic complications and influences metabolic management. It has a direct effect on the function of the heart and blood vessels in this group of patients. Thus IR could be connected with physical exercise capacity in type 1 diabetes. On the other hand, physical activity has an extremely beneficial influence on the prognosis of patients with type 1 diabetes. This study aimed to evaluate the influence of insulin resistance on physical exercise capacity in patients with type 1 diabetes.

Materials and methods: The study included 42 men with type 1 diabetes, the age was 32 years (IQR 28–36), with a duration of diabetes of 5 years (IQR 2–13), HbA1c 7.6% (IQR 6.5–8.4), daily insulin dose: 0.43 U/kg/day (IQR 0.31–0.57) and BMI 23.5 kg/m^2 (IQR 21.6–26.2). The study excluded patients with hypertension, chronic complications of diabetes, acute inflammation, with episodes of severe hypoglycemia or DKA in one month before the test. Insulin sensitivity was assessed using a normoglycemic-hyperinsulinemic clamp with measurement of glucose disposal rate (GDR). The clamp was performed 48–56 hours before exercise test. During cardiopulmonary exercise test on a cycle ergometer, rate of oxygen consumption was measured and maximal oxygen uptake (VO2max) was assessed.

Results: There was no statistically significant correlation between VO2max (ml/min/kg) with diabetes duration (Rs −0.32, $p = 0.08$), daily insulin dose (Rs −0.22, $p = 0.23$) and HbA1c level (Rs −0.34, $p = 0.07$). VO2max was negatively correlated with BMI (Rs −0.47, $p = 0.008$). Moreover, significant positive correlation of GDR and VO2max was observed (Rs 0.78, $p = 0.01$).

Conclusion: There is a link between insulin resistance and physical exercise capacity in type 1 diabetes. Higher insulin sensitivity is correlated with higherVO2max in patients with type 1 diabetes.

Impaired subcutaneous insulin delivery in type 2 diabetes patients

E. Fryk[1], J. Olausson[2], L. Strindberg[1], B. Becattini[1], K. Mossberg[1], M. Schmelz[3], H. Brogren[1], G. Solinas[1], P.-A. Jansson[1];
[1]Molecular and clinical medicine, Sahlgrenska University Hospital, Göteborg, Sweden, [2]Department of Clinical Microbiology, Sahlgrenska University Hospital, Göteborg, Sweden, [3]Department of Experimental Pain Research Mannheim, Medical Faculty, Heidelberg, Germany.

Background and aims: Previous studies showed a delayed transendothelial transport (TET) of insulin in insulin-resistant participants in agreement with an *endothelial barrier for insulin* in skeletal muscle. We hypothesized that an impaired TET of insulin is also present in adipose tissue and affects kinetics of insulin's antilipolytic effect in a study of lean, obese and type 2 diabetes (T2D) participants.

Materials and methods: Nine T2D patients (Age: 59 ± 4 years, BMI: 34 ± 2 kg/m^2, fP-Glucose: 8.3 ± 1.7 mmol/l, fS-Insulin: 10.3 ± 5.3 mU/l) were matched for age and BMI with 9 obese (Age: 62 ± 5, BMI: 32 ± 2, fP-Glucose: 5.8 ± 0.6, fS-Insulin: 10.1 ± 3.5), and for age with nine lean participants (Age: 61 ± 5, BMI: 23 ± 2, fP-Glucose: 5.3 ± 0.5, fS-Insulin: 3.6 ± 1.2). Participants underwent a 75 g oral glucose tolerance test (OGTT) after fasting overnight and they were sampled for arterialized venous blood (plasma free fatty acids (P-FFA) and subcutaneous interstitial fluid with the microdialysis technique (interstitial (I)-insulin and I-glycerol) for 3 hours. Xenon-clearance was used for assessment of adipose tissue blood flow (ATBF). Insulin appearance and insulin delivery index (IDI) were calculated during the first hour after glucose ingestion and the ratio between interstitial and circulating insulin (I/C-ratio) was calculated 60 min after the OGTT.

Results: Glucose and insulin levels were increased after 60 min (15.6 ± 2.9, 10.8 ± 3.1 and 10.9 ± 1.2; 33.5 ± 12.1, 49.4 ± 33.5 and 34.7 ± 10.9) in T2D, obese and lean subjects, respectively. During the first 60 min insulin delivery was lower in T2D compared with lean ($p < 0.05$) but not obese subjects (p = NS). Subcutaneous insulin appearance correlated with maximum suppression of interstitial glycerol ($r_s = 0.5$, $p < 0.05$, $n = 22$) and P-FFA ($r_s = 0.5$, $p < 0.01$, $n = 27$) during the OGTT. However, ATBF AUC_{180} did not correlate with insulin delivery. The I/C-ratio at 60 min (0.56 ± 0.22, 0.45 ± 0.35 and 0.34 ± 0.08) was lower in T2D than in lean ($p < 0.05$) but not obese subjects (p = NS). Correlations were determined with Spearman rank and comparisons between the groups were assessed with Mann-Whitney *U* test.

Conclusion:: There is a significantly decreased subcutaneous transendothelial delivery of insulin in type 2 diabetes compared with lean but not obese participants.

T63 displays beneficial effects on various tissues in animal models of diabetes via pleiotropic protective actions

V. Chavanelle[1], Y.F. Otero[1], P. Sirvent[1], P.D. Cani[2], S.L. Peltier[1];
[1]Valbiotis, La Rochelle, France, [2]Louvain Drug Research Institute, Louvain, Belgium.

Background and aims: Nowadays, about 60 million people are diagnosed with type 2 diabetes (T2D) in Europe and its prevalence is increasing, mostly due to overweight and obesity. Prediabetes precedes T2D and is reversible although 70% of individuals with prediabetes will eventually develop T2D if no intervention is made. Additional strategies are needed to manage prediabetes. The pathophysiology of prediabetes is complex and involves impairments in many organs. It has been previously shown that T63, an active principle ingredient candidate for managing prediabetes, was effective to prevent glucose homeostasis impairments in rodent models of T2D. In an open phase I/II clinical study, T63 also improved glucose and insulin responses to a carbohydrate challenge in healthy subjects. This study provides new data on 2 different animal models of T2D and prediabetes that show an action of T63 on various organs, suggesting a pleiotropic effect of the candidate and bringing new leads for understanding the mechanisms involved.
Materials and methods: All experiments were carried out along the "Principles of laboratory animal care" (NIH Publication no. 85-23, revised 1985) and approved by the local ethics committee (C2EA-02). Forty db/db mice (aged 5 weeks) were fed for 6 weeks either a control diet or the same diet supplemented with 2.7% T63. Thirty-six male C57BL6 mice (aged 5 weeks) were randomised into 3 groups. Control group was fed a control low-fat diet. High Fat (HF) group was fed a HF diet (36% fat). HF-T63 group was fed a HF diet supplemented with 2.7% T63. Total duration of the HF study was 16 weeks.
Results: In db/db mice, T63 lowered fasting glycaemia and delayed the defect of insulin secretion, one of the hallmarks of T2D. In HF-fed mice, T63 improved an insulin-sensitivity index following an oral glucose test. In the inguinal fat, HF diet impaired the activation of the insulin pathway following an acute injection of insulin. Interestingly, T63 restored the activation of Akt in this tissue (Insulin stimulated phosphorylation ratio 6.14-fold higher than vehicle vs. 1.01-fold in HF group, $p < 0.01$). Additionally, hepatic triglyceride content, known as a powerful inductor of liver insulin resistance, was reduced in HF-T63 group, compared to HF (−40%, $p < 0.001$). T63 administration increased liver gene expression of FGF21, which has been involved in the regulation of many metabolic pathways. T63 also showed preventive effects on HF diet-induced gut microbiota dysbiosis. Specifically, the relative abundance of *Parasutterella* and *Barnesiella*, two bacteria previously linked with obesity and insulin sensitivity, was increased in HF-T63 group compared to HF (1.55% vs. 0.33%, $p < 0.001$ and 9.36% vs. 3.12%, $p < 0.001$).
Conclusion: In conclusion, T63 improved glucose metabolism in 2 mouse models of prediabetes and T2D via actions on various tissues. The evolution of the physiopathology of T2D is complex and involves many organs. The pleiotropic effects of T63 make it a promising intervention strategy to prevent T2D development. The candidate is currently under investigation in an international phase II clinical trial on prediabetic subjects.

Liver-specific nicotinamide N-methyltransferase deficiency protects mice from body weight gain and improves insulin sensitivity under standard diet

S. Brachs[1,2], J. Polack[1,2], M. Brachs[1], R. Elvert[3], F. Bärenz[3], S. Ruf[3], M. Kabiri[3], A. Kannt[3,4], J. Spranger[1,2];
[1]Department of Endocrinology, Diabetes and Nutrition, Charité - Universitätsmedizin Berlin, Berlin, [2]DZHK (German Centre for Cardiovascular Research), partner site Berlin, Berlin, [3]Sanofi Research and Development, Frankfurt am Main, [4]Institute of Experimental and Clinical Pharmacology and Toxicology, Heidelberg University, Mannheim, Germany.

Background and aims: Experimental evidence reveals a correlation between Nicotinamide N-methyltransferase (NNMT) activity and obesity and related metabolic disease. Using a whole-body *Nnmt* knockout (KO) mouse model, we recently investigated the effects of *Nnmt* deletion on energy metabolism and the development of obesity under different diets. In humans, *NNMT* expression is highest in liver followed by adipose tissue (AT). Contrary to mice, *Nnmt* expression is high in liver but appears to be exceeded at least tenfold in AT. Therefore, we generated AT-specific as well as liver-specific *Nnmt* KO mice to investigate and dissect the metabolic role of NNMT.
Materials and methods: A conditional $Nnmt^{fl/fl}$ mouse line was bred to both a FABP-Cre and an Alb-Cre deleter line to generate an AT-specific ($ANNMT^{-/-}$) and a liver-specific NNMT KO ($LNNMT^{-/-}$), respectively. Body composition, metabolic parameters, glucose homeostasis and insulin sensitivity were assessed in $ANNMT^{-/-}$ and $LNNMT^{-/-}$ compared to control mice (WT) feeding either a standard diet (SD) or a high-fat diet (HFD). In all cohorts, we measured 1-methylnicotinamide (MNAM) concentrations, performed ipGTTs and conducted hyperinsulinemic-euglycemic (HE) clamps.
Results: Analyzing $ANNMT^{-/-}$ mice, we did not observe any impact of the AT-specific *Nnmt* deletion on metabolism. $ANNMT^{-/-}$ mice showed similar weight gain, body composition, glucose tolerance and insulin sensitivity, however, had a strongly reduced *Nnmt* expression and MNAM levels in AT. No such differences were found in liver of $ANNMT^{-/-}$ mice. In contrast, $LNNMT^{-/-}$ mice showed virtually no *Nnmt* expression in liver and low hepatic MNAM levels whereas plasma MNAM was similar compared to WT and slightly higher in AT. Regardless of feeding SD or HFD, weight gain and especially body fat content did not increase in $LNNMT^{-/-}$ mice and they, consequently, displayed lower plasma insulin levels. Furthermore, liver weights of $LNNMT^{-/-}$ mice were significantly reduced compared to WT. Despite of their lean phenotype, no improvements of acute glucose handling were revealed performing ipGTTs with mice on SD or HFD. However analyzing insulin sensitivity, $LNNMT^{-/-}$ mice fed a SD exhibit improved glucose infusion rates (GIR) and an enhanced glucose uptake (GU) during a HE clamp. This was not maintained in $LNNMT^{-/-}$ mice on HFD. They showed a low GIR, a suppression of endogenous glucose production about 50% and a reduced GU similar as WT mice.
Conclusion: In summary, we did not reveal a metabolic impact of AT-specific *Nnmt* deletion whereas we observed a strong improvement of body composition in $LNNMT^{-/-}$ mice under SD and HFD showing a reduced fat mass and less body weight gain. Nevertheless, no effect of liver-specific *Nnmt* deletion was found on glucose handling. However, insulin sensitivity was significantly elevated in $LNNMT^{-/-}$ on SD but this effect was not preserved in $LNNMT^{-/-}$ mice fed a HFD.

Renal denervation stimulates hepatic glucose uptake in dogs

L.M. Moore, D.S. Edgerton, E. Allen, B. Farmer, P. Williams, A.D. Cherrington, G. Kraft;
Vanderbilt University, Nashville, USA.

Background and aims: Renal denervation (RDN) has generated considerable interest as a method to treat drug-resistant hypertension. Recent data showed that RDN can improve hepatic insulin sensitivity; however

the mechanism remains unknown. The portal signal, generated during the absorption of glucose into the portal vein, is a major determinant of hepatic glucose uptake (HGU) and it has been shown to result from a decrease in the sympathetic tone to the liver. The objective of this study was to investigate whether renal denervation would reduce hepatic sympathetic tone, thereby preventing the stimulating effect of portal glucose delivery on HGU.

Materials and methods: Dogs underwent bilateral surgical renal sympathetic denervation ($n = 5$). Renal denervation was confirmed after the study by the nearly complete loss of NE content in both kidneys (Table). The study consisted of a 3 hour hyperinsulinemic hyperglycemic pancreatic clamp. In the first 90 mins (Period 1), all glucose was infused into a peripheral vein; during the last 90 mins (Period 2), glucose was also infused intra-portally (4 mg/kg/min) to establish the portal glucose signal, and glucose was still infused into a leg vein in order to equalize the hepatic glucose load in both periods.

Results: Arterial insulin (21 ± 3 and 20 ± 4 μU/mL) and glucagon (24 ± 4 and 23 ± 2 pg/mL) levels were not different in the 2 periods. During Period 1 the glucose concentration was maintained at 221 ± 5 mg/dL while during Period 2 it was 200 ± 4 mg/dL. The liver glucose loads were matched between periods (42 ± 5 and 43 ± 4 mg/kg/min), as designed. As previously reported, RDN surgery was associated with an increased liver glucose uptake (3.6 ± 0.4 mg/kg/min during Period 1 compared to values of ≈2 mg/kg/min under the same conditions in non-RDN animals). Notably, there was no increase in net hepatic glucose uptake from Period 1 to Period 2 (3.5 ± 0.7 mg/kg/min) in the RDN animals. This value was not different from that seen in non-RDN animals exposed to the portal glucose signal. Interestingly renal denervation was associated with a marked decrease in liver NE content (−85%, see table).

Conclusion: Reduced hepatic sympathetic input appears to be the mechanism by which renal denervation increases HGU. The notion that RDN and the hepatic portal vein glucose signal act via the same mechanism is supported by the fact that the latter had no effect on HGU in dogs that had undergone RDN.

Norepinephrine content (ng/g of tissue)	Control (n=6)	Renal denervation (n=5)	% decrease	P value
Right Kidney	914±132	123±90	87	<0.001
Left Kidney	958±157	33±18	97	<0.001
Liver	245±18	36±19	85	<0.001

Table: Norepinephrine content (in ng/g of tissue) in organs of sham operated control (previously presented) and renal denervated animals collected at the end of study. Values are the average of 2 biopsies of the cortex for the kidneys and 2 lobes of the liver

A novel preclinical model to define the window between plasma glucose lowering versus water retention in the gut during SGLT1 inhibition

M. Fritsch Fredin[1], M. Sundqvist[2], H. Peilot Sjögren[3], C. Kankkonen[3], M. Persson[2], M. Strimfors[1], D. Lindén[1], T. Rydén-Bergsten[4], D. Karlsson[1];
[1]Bioscience, AstraZeneca R&D Molndal, Molndal, [2]DMPK, AstraZeneca R&D Molndal, Molndal, [3]Discovery Sciences, AstraZeneca R&D Molndal, Molndal, [4]AstraZeneca R&D Molndal, Molndal, Sweden.

Background and aims: Sodium Glucose co-Transporter 1 (SGLT1) inhibition improves glucose control at the expense of increasing the risk for developing diarrhoea due to glucose-driven gut water accumulation. Since rodents are resistant to SGLT1 inhibition-induced diarrhoea, it has been difficult to develop a preclinical model that predicts the therapeutic window for SGLT1 inhibitors in man. The aim of this work was to first develop a surrogate rat model for diarrhoea based on water retention in the gut. SGLT1 inhibitors with clinical data (LIK066, canagliflozin and sotagliflozin), were used to build the water retention model. The model was then used to explore the therapeutic window for a gut-restricted SGLT1 inhibitor (mizagliflozin).

Materials and methods: Fasted Sprague-Dawley rats were gavaged with 2g/kg glucose and increasing doses of mizagliflozin, LIK066, canagliflozin or sotagliflozin ($n \geq 3$/dose group and $n = 16$ vehicle). One hour later, animals were euthanized and the water content in the small intestine and jejunual mucosal drug exposure were quantified. Another set of fasted rats underwent an oral glucose tolerance test (OGTT) using 2 g/kg glucose containing 7400 Bq/μl [^{14}C(U)]-D-glucose tracer. Blood samples were collected before and up to 240 minutes post gavage for the analyses of plasma ^{14}C-glucose, glucose, insulin and drug exposure ($n = 3$–6). *In vitro* potencies of the SGLT1 inhibitors were assessed by their ability to reduce the transport of the glucose analogue, Methyl α-D-glucopyranoside ([^{14}C]-AMG) in HEK293S cells overexpressing SGLT1. The assay was run at physiological glucose concentration (5mM) and in the absence of serum.

Results: Water retention in the small intestine was dose-dependently increased for all compounds tested. By modelling the free jejunal SGLT1 inhibitor exposure level, water retention occurred at exposure levels 1–3 fold above compound IC_{50}. During the OGTT, mizagliflozin dose-dependently decreased ^{14}C-glucose appearance in the plasma ($AUC_{0\text{-}120min}$ for mizagliflozin; 0.15 μmol/kg AUC = 666 ± 100*, 0.5 μmol/kg AUC = 448 ± 87*, 1.5 μmol/kg AUC = 227 ± 79* *versus* vehicle AUC = 831 ± 77, *$p < 0.05$). Plasma glucose and insulin were dose-dependently decreased (glucose for mizagliflozin; 0.15 μmol/kg AUC = 361 ± 68*, 0.5 μmol/kg AUC = 240 ± 42*, 1.5 μmol/kg AUC = 127 ± 58* *versus* vehicle AUC = 462 ± 57 and insulin for mizagliflozin; 0.15 μmol/kg, AUC = 13669 ± 5282, 0.5 μmol/kg AUC = 7771 ± 1431*, 1.5 μmol/kg AUC = 4147 ± 3013* *versus* vehicle AUC = 22862 ± 6846, *$p < 0.05$). *In vivo* IC_{50} for plasma glucose lowering of mizagliflozin occurred at jejunal concentrations of 1.2 μM (95% CI: 0.9−1.3 μM) while water retention IC_{50} was 2.5 μM (95% CI: 1.8–3.2 μM), thus approximately at 2-fold higher gut exposure compared to the glucose lowering.

Conclusion: We have developed a new rat model that uses water retention in the gut as a surrogate marker for diarrhoea. We demonstrate a 2-fold separation between glucose lowering and water retention for a gut-restricted SGLT1 inhibitor, mizagliflozin. This new water retention model can help to assess the risk for diarrhoea using SGLT1 inhibition before entering clinical trials. Whether the model can be used for other osmotic mechanisms in the gut needs to be explored.

Effect of hyperamylinaemia on expression of genes involved in metabolic hormone signalling in the brain

T. Nie, S. Zhang, G. Vazhoor Amarsingh, H. Liu, G.J.S. Cooper;
School of Biological Sciences, The University of Auckland, Auckland, New Zealand.

Background and aims: Amylin is postulated to be involved in the development of Type 2 diabetes (T2D), as human amylin forms pancreatic amyloid in diabetic patients. Mice expressing human amylin have been developed to study this. But β-cell loss limits the expression of amylin and insulin. Thus, these mice can't be used to investigate chronic hyperamylinaemia nor the insulin resistant stage of T2D. Our group has developed transgenic mice which overexpress a nonamyloidogenic

variant with three proline substitutions at residues 25, 28 and 29, called the Line 44 model. These mice develop obesity, hyperglycaemia, hyperamylinaemia and hyperinsulinaemia. Homozygous (HOM) mice show more severe hyperglycaemia than hemizygous (HEM) mice. We aimed to examine how the expression of genes involved in amylin, insulin and leptin signalling in the brain was affected by hyperamylinaemia in this model at different disease stages.

Materials and methods: Brain samples were taken from HEM, HOM and nontransgenic (NON) mice at 100 days (prediabetic) and diabetic onset (three consecutive blood glucose measurements >11 mmol/l). The brain was split into four parts: the hindbrain, midbrain, left and right cortices. We used molecular probes to measure the expression of 42 genes in HEM and HOM mice and compared this to NON controls. $n = 5$ NON, 3 HEM, 4 HOM (prediabetic), and 6 NON, 6 HEM, 6 HOM (diabetic).

Results: Statistical analysis was performed with the NanoStringDiff package in R. We applied a false discovery rate of 5% and found several genes with significantly altered expression. We examined the fold change (FC, shown as $\log_2$) to determine their likely biological impact.

Notable genes included: *Cart* is an appetite suppressor normally increased by insulin and leptin. We found it decreased in the prediabetic hindbrain (FC = −1.51 in HEM, −0.64 in HOM) and the diabetic cortices (Left: FC = −1.37 in HEM, −0.99 in HOM. Right: FC = −1.06 in HEM, not significant in HOM). *c-fos* is a common marker of amylin signalling. Expression was decreased in the prediabetic hindbrain (FC = −0.96 in HEM, −1.61 in HOM). Interestingly, it was increased in HEM but decreased in HOM in both cortices at diabetic onset (Left: FC = 1.18 in HEM, −0.65 in HOM. Right: FC = 1.12 in HEM, −0.77 in HOM). *Pomc* is another appetite suppressor increased by insulin and leptin signalling. In the hindbrain, expression was reduced at 100 days (FC = −2.08 in HEM, −0.84 in HOM) but increased in HOM when diabetic (FC = 1.87). *Socs3*, a well-known inhibitor of leptin signalling, was significantly differentially expressed in HOM mice only. It was decreased in the prediabetic hindbrain (FC = −1.01). However, *Socs3* was increased in all other regions at both time points (Prediabetic: FC = 2.06 in midbrain, 1.66 in left cortex, 2.00 in right cortex. Diabetic: FC = 1.78 in midbrain, 1.27 in left cortex, 1.16 in right cortex).

Conclusion: Hyperamylinaemia altered the brain expression of a number of genes in the signalling pathways of amylin, insulin and leptin. These changes may have contributed to resistance to these hormones, leading to the obese and diabetic phenotype of the Line 44 model. Reduced hindbrain *c-fos* suggested the presence of amylin resistance before the onset of diabetes. Lowered *Cart* and *Pomc* expression indicated resistance to insulin and/or leptin which may have led to hyperphagia and obesity. Elevated *Socs3* levels in HOM mice suggested downregulation of leptin signalling which may have contributed to the more severe diabetic phenotype seen in HOM mice.

Evaluation of GPR120 regulation of glucose homeostasis and incretin secretion using intestinal cell lines and incretin receptor knockout mice

A.M. McKillop[1], B.M. Moran[2], M.G. Miskelly[1], P.R. Flatt[1];
[1]School of Biomedical Sciences, University of Ulster, Coleraine, UK, [2]Department of Biopharmaceutical and Medical Science, Galway-Mayo Institute of Technology, Galway, Ireland.

Background and aims: GPR120 is a rhodopsin-like GPCR that has a high affinity for long chain saturated C14-18 fatty acids and unsaturated C16-22 fatty acids. Stimulation of GPR120 by free fatty acids results in elevation of [Ca2+]i and activation of the ERK cascade suggesting interactions with the Gαq family of G proteins. The aims of this study were to assess the role of the GPR120 agonist GW-9508 in glucose homeostasis and incretin regulation from enteroendocrine L- and K-cells in diabetic and incretin receptor knockout mice, and determine the cellular localisation of GPR120 in mouse intestinal tissue and clonal GLP-1 and GIP cell lines.

Materials and methods: Cellular localisation of GPR120 was determined by double staining immunohistochemistry in intestinal tissue from NIH Swiss mice, in GLP-1 secreting GLUT-ag cells and GIP secreting pGIP/neo STC-1 cells. Anti-hyperglycaemic, insulinotropic and incretin secreting properties of GW-9508 (0.1 μmol/kg body weight) were explored with oral and intraperitoneal glucose (18 mmol/kg body weight) tolerance tests (GTT) in lean and high fat fed (HFF) diabetic mice. *In vivo* studies were also carried out in age matched GLP-1 receptor knockout, GIP receptor knockout and wild-type C57/BL6 mice.

Results: Compared to intraperitoneal injection, oral administration of GW-9508 (0.1 μmol/kg body weight) together with glucose reduced the glycaemic excursion by 22–31% ($p < 0.05$–$p < 0.01$) and enhanced glucose-induced insulin release by 30% ($p < 0.01$), compared to glucose control. GW-9508 increased total GLP-1 release by 44% ($p < 0.01$) after 15 min and stimulated total GIP release by 47% ($p < 0.001$) after 15 min. In high fat fed diabetic mice, orally administered GW-9508 lowered plasma glucose by 17–27% ($p < 0.05$–$p < 0.01$) and augmented insulin release by 22–39% ($p < 0.05$–$p < 0.001$). GIP (1-42) and GLP-1 (7-36) (25 nmol/kg body weight) administered orally with glucose had no effect in GIP and GLP-1 knockout mice, respectively; the glucose lowering and insulinotropic effects of GW-9508 were abolished. GW-9508 lowered the glycaemic excursion by 14% ($p < 0.05$) and increased insulin release by 24% ($p < 0.01$) in C57/BL6 wild-type mice. GW-9508 increased circulating total GLP-1 release by 39–44% ($p < 0.01$) and total GIP by 37–47% ($p < 0.01$–$p < 0.001$) after 15 and 30 min of GW-9508 administration in wild-type mice. Immunocytochemistry demonstrated co-localisation of GPR120 expression and incretin hormones in mouse enteroendocrine L- and K-cells, GLP-1 secreting GLUTag cells and GIP secreting pGIP/Neo STC-1 cells.

Conclusion: GPR120 is expressed on intestinal L- and K-cells and stimulated GLP-1/GIP secretion plays an integral role in mediating enhanced insulin secretion and improved glucose tolerance, suggesting development of potent and selective GPR120 agonists as a therapeutic approach for diabetes.

Characterisation of a new mouse model for gestational diabetes

K. Grupe, F. Dannehl, M. Planteur, S. Scherneck;
Technical University of Braunschweig, Braunschweig, Germany.

Background and aims: Gestational diabetes (GDM) is a complex metabolic disease in which both environmental factors and a genetic predisposition are involved. Patients show impaired glucose tolerance in pregnancy and have a higher risk to develop type 2 diabetes in later life. However, adequate models to study the pathomechanisms and the interaction of genetic and lifestyle factors are still lacking. Female New Zealand obese (NZO) mice are characterized by a polygenic metabolic disorder showing increased body weight and insulin resistance on the one hand, but do not develop manifest diabetes on the other hand. The aim of this study is to investigate the capability of NZO mice as a model for the human disease.

Materials and methods: In NZO and NMRI (control) mice oral glucose tolerance tests (oGTT; 2 mg glucose/g body weight) were performed both preconceptional and on day 14 of gestation. Blood glucose and insulin levels were measured within a time course between 0 (basal) and 240 minutes after glucose administration. At both aforementioned times (i.e. preconceptional and on day 14 of gestation), pancreata were histologically assessed, particularly the proliferative response of the islets of Langerhans (Ki67-positive islet cells) as a consequence of the increased insulin demand due to pregnancy.

Results: Compared to NMRI control mice the NZO strain showed no hyperglycaemia neither prior to conception (141 vs 126 mg/dl, n.s.) nor at day 14 of gestation (123 vs 114 mg/dl, n.s.). However, the oGTT revealed impaired glucose tolerance within the NZO mouse strain at both times that resulted in an increased AUC of 40%. Preconceptional insulin values were higher in the NZO mice, whereas the levels did not differ between the two strains on day 14 of gestation. The islets of both strains had intact immunoreactivity for insulin and showed no differences in their proliferation prior to conception (Ki67-positive nuclei 3.1% vs 2.4%, n.s.). On day 14 of gestation islet cells of NZO mice showed significantly lower proliferation in comparison to the NMRI control strain (3.7% vs 7.2%, $p < 0.01$).

Conclusion: Having impaired glucose tolerance and a decreased compensatory response of the islets of Langerhans during pregnancy, NZO mice show important characteristics of GDM. In addition, preconceptionally elevated insulin levels and peripheral insulin resistance indicate the occurrence of prediabetes within the NZO strain. In conclusion, the NZO mouse provides a suitable model to study the human disease.

Insights in the role of a fatty acid oxidation enzyme in insulin secretion: rare genetic variants and a new murine model of SCHAD deficiency

K. Velasco[1], J. Lüdeke[1], H. Hovland[1], Å. Ottesen[1], M. Choi[1], L.M. Myklebust[2], K. Fjeld[3], I. Aukrust[3], T. Arnesen[2], P. Njølstad[4], R.N. Kulkarni[5], A. Molven[1];
[1]Department of Clinical Medicine, University of Bergen, Bergen, Norway, [2]Department of Biomedicine, University of Bergen, Bergen, Norway, [3]Department of Medical Genetics, Haukeland University Hospital, Bergen, Norway, [4]Department of Clinical Science, University of Bergen, Bergen, Norway, [5]Joslin Diabetes Center, Boston, USA.

Background and aims: Congenital Hyperinsulinism of Infancy (CHI) is a group of inherited disorders characterized by persistent hypoglycemia and hyperinsulinemia. CHI is caused by mutations in genes that affect regulation of insulin secretion in β-cells. One such gene is *HADH*, which encodes short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD), a ubiquitously expressed mitochondrial enzyme of the fatty acid oxidation pathway. Literature data suggest that SCHAD-CHI is caused by specific deficiency of this protein in β-cells and that rare SCHAD variants may protect against diabetes. This study was undertaken to investigate how SCHAD is involved in regulation of insulin secretion.

Materials and methods: Sixteen rare amino acid substitutions present in human populations were characterized in terms of subcellular localization, protein stability and enzymatic activity by cloning into bacterial/eukaryotic expression vectors. To avoid that endogenous SCHAD protein obscured functional assessment, a SCHAD-negative HEK293 cell line was constructed using CRISPR technology. A β-cell-specific SCHAD knock-out mouse (B-SCHADKO) was constructed by crossing *Hadh*-floxed animals with mice expressing Cre under the regulation of the *Ins1* promoter.

Results: Intracellular targeting to the mitochondria was unaffected for all variants. Four variants (G34R, I184F, P258L, G303S; all previously linked to CHI) exhibited very low protein levels when expressed in eukaryotic cells, most likely due to a posttranslational quality control mechanism as they could be stably expressed in a cell-free system. A one way ANOVA showed that there were significant differences among the enzymatic activity of the variants [$F(11,24) = 194.1$, $p < 0.001$]. A post-hoc Dunnett's test showed that the pathogenic variants H170R, P258L and G303S (respectively 7.33 ± 2.3, 9.7 ± 0.4, 0.8 ± 1.3 μmol/min/mg) have significantly lower enzymatic activity than the WT (180.6 ± 2.9 μmol/min/mg) at $p < 0.001$, while the P215T (211.34 ± 4.6 μmol/min/mg) variant has significantly higher activity than the WT at $p = 0.10$. The remaining variants had similar properties as wild-type SCHAD protein. Both male and female B-SCHADKO mice exhibited significantly reduced plasma glucose in the random fed state (♂ 8.7 ± 0.8 vs. 6.3 ± 1.5 mmol/L, $p = 0.0016$; ♀ 7.9 ± 0.4 vs. 5.3 ± 1.1 mmol/L, $p < 0.0001$) and after overnight fasting (♂ 4.5 ± 0.7 vs. 3.1 ± 0.7 mmol/L, $p < 0.0002$; ♀ 3.4 ± 0.4 vs. 2.3 ± 0.2 mmol/L, $p < 0.0001$). Insulin and tolerance tests showed that GSIS and overall glucose homeostasis were not significantly different in B-SCHADKO and control mice.

Conclusion: Disease-associated SCHAD variants, but not the tested rare population variants showed altered functional properties. The hypoglycemic phenotype of SCHAD deficiency is beta-cell autonomous, but cannot be explained simply by increased insulin secretion.

A new implantable insulin-delivery device designed for extraperitoneal space, an alternative site for insulin delivery

J. Magisson[1], A. Sassi[1], A. Kobalyan[1], C.-T. Burcez[1], R. Bouaoun[1], K. Gouget Kaufmann[1], M. Vix[2], N. Jeandidier[3], S. Sigrist[1];
[1]Defymed S.A.S, Strasbourg, [2]IRCAD, Strasbourg, France, [3]Department of Endocrinology, Diabetes and Metabolic Diseases, Strasbourg, France.

Background and aims: Glycaemic instability and hypoglycaemia are major problems for late stage diabetic patients and are related to non-physiologic subcutaneous (s. c.) administration of insulin. Intraperitoneal (i. p.) delivery with implantable pumps or catheter-based devices enables first hepatic pass of insulin via portal absorption and is clinically relevant. However, it faces limitations such as insulin stability, high infection rate, catheter obstruction. Consequently, a new implantable device, ExOlin®, was developed. It consists in a flat pouch made of porous membranes with a catheter and an s. c. injection port for easy administration of insulin. To avoid peritoneal inflammation and tissue adhesions, this device is placed in the extraperitoneal space located between parietal peritoneum and fascia of abdominal muscles. In this study, kinetics of insulin delivery in extraperitoneal was compared to s. c. and i. p. routes.

Materials and methods: Plasma insulin levels in portal and peripheral veins assessed by ELISA assay were compared in extraperitoneal, s. c. and i. p. 5, 15, 30, 60 min after administration in healthy rats and 5 and 30 min after administration in swine (2U of rapid Human insulin/rat, 40U of rapid Human insulin analog/swine), In swine, injection was performed into ExOlin®. Kinetics of insulin delivery through ExOlin® device was tested in diabetic rats implanted in i.p. or extraperitoneal by measurement of glycaemia during 150 min after injection of 2U of rapid Human insulin.

Results: In rats, portal insulin levels were different between s. c., i. p. and extraperitoneal routes at 5 min post injection (i. p.: 2557 ± 661 mU/L $n = 9$; extraperitoneal: 1577 ± 887 mU/L $n = 10$ vs s. c.: 451 ± 102 mU/L $n = 9$) with higher portal insulin level for i. p. compared to s. c. ($p < 0.01$). Then, a progressive increase was observed for s. c. group showing higher levels of insulin compared to extraperitoneal at 60 min (s. c. 2262 ± 459 mU/L $n = 8$ vs extraperitoneal 695 ± 196 mU/L $n = 9$; $p < 0,05$). In parallel, levels of insulin in caudal vein peaked at 15 min for i. p. and extraperitoneal sites, while it raised rapidly for s. c. group until 30 min post-injection and stabilized at 60 min with levels significantly higher than i. p. or extraperitoneal groups (at 60 min: s. c. 1019 ± 193 mU/L $n = 8$; i. p. 269 ± 58 mU/L $n = 8$ extraperitoneal 463 ± 85 mU/L $n = 10$; $p < 0,01$ s. c. vs i. p. and extraperitoneal). In swine with ExOlin®, higher insulin levels in portal vein compared to ear vein were measured 5 min post-injection (112 ± 37 mU/L in portal $n = 4$; 57 ± 32 mU/L in ear vein $n = 4$). In diabetic rats, injection of Human insulin in ExOlin® in i. p. or extraperitoneal induced a decrease of glycaemia comparable to the one obtained with a direct injection.

Conclusion: In this study, we demonstrated in small and large animal models that extraperitoneal site is promising for insulin delivery due to kinetics and portal absorption comparable to i. p. route. We showed that a membrane-based insulin delivery device does not alter portal absorption kinetics. Combination of both device and delivery site constitutes a potent alternative to i. p. route in brittle and hypoglycaemia prone type 1 diabetes.

Proteomics of secreted glucagon reveals heterogeneous complexes as novel mediators of alpha cell function

F. Asadi[1], S. Dhanvantari[2,3];
[1]Pathology, The University of Western Ontario, London, [2]Pathology and Medical Biophysics, The University of Western Ontario, London, [3]Lawson Health Research Institute, London, Canada.

Background and aims: Targeting glucagon secretion from pancreatic alpha cells has been proposed as a therapeutic strategy for the treatment of diabetes. To identify possible modulators of glucagon secretion, we are using a proteomics approach that targets glucagon within secretory granules and secreted glucagon-immunoreactive complexes. Our ongoing work has identified a novel and dynamic network of proteins associated with glucagon within secretory granules in αTC1-6 cells. The aims of the present study are *i)* to investigate the potential roles of these proteins in modulating glucagon secretion; and *ii)* to investigate if glucagon remains associated with secretory granule proteins after secretion.
Materials and methods: Protein complexes in isolated secretory granule fractions from αTC1-6 cells were pulled down with Fc-glucagon, and proteins were identified using LC-MS/MS. Functional readouts of select proteins were conducted through siRNA-mediated silencing in αTC1-6 cells and measurement of glucagon secretion by ELISA. To investigate the association of secretory granule proteins with glucagon after secretion, cells were cultured in DMEM without glutamine, sodium pyruvate and FBS for 24h. Media were removed and extracted in acid/ethanol (95% ethanol containing 0.18 M HCl) and separated into soluble and insoluble fractions by centrifugation. The acid/ethanol-soluble fraction was used to identify glucagon-immunoreactive complexes by immunoblotting, and to identify associated proteins within these complexes by LC-MS/MS of silver nitrate-stained bands. Values were compared among groups using 1-way ANOVA ($\alpha = 0.05$).
Results: Several novel proteins were identified within secretory granules that interact with glucagon: peroxiredoxin-2, malate dehydrogenase cytoplasmic, aconitate hydratase mitochondrial, 14-3-3 protein zeta/delta, ELKS/Rab6-interacting/CAST family member 1 (ERC1), tubulin alpha-1B, ATP synthase subunit alpha mitochondrial, histone H4, Sodium/potassium-transporting ATPase subunit gamma, protein disulfide-isomerase. Glucagon secretion was increased ($p < 0.001$, $n = 3$) upon siRNA silencing of ERC1. Glucagon secretion was decreased after knock-down of 14-3-3 zeta/delta, malate dehydrogenase cytoplasmic, Sodium/potassium-transporting ATPase subunit gamma, protein disulfide-isomerase ($p < 0.001$, $n = 3$), peroxiredoxin-2, ATP synthase subunit alpha mitochondrial, and histone H4 ($p < 0.01$, $n = 3$) and tubulin alpha-1B ($p < 0.05$, $n = 3$). Immunoblotting of both crude and acid-EtOH-extracted media revealed two glucagon-immunoreactive bands at 10 kDa and 22 kDa. Proteomic analysis of both bands revealed the presence of glucagon and secretory/regulatory proteins, such as chromogranin A, secretogranins and carboxypeptidase E. Most notably, 14-3-3 zeta/delta was associated with the 22 kDa band, and siRNA silencing of 14-3-3 zeta/delta reduced the density of this band ($p < 0.05$, $n = 6$).
Conclusion: We have discovered a novel network of secretory granule proteins that interact with glucagon to regulate its secretion. Our results also indicate that glucagon is secreted as heterogenous complexes of secretory proteins. In particular, 14-3-3zeta/delta is associated with glucagon within secretory granules and after secretion, and may be a novel player in the regulation of glucagon secretion.

Pancreatic alpha cells respond to glucose with a change in the frequency of intracellular calcium oscillations

J.A. Kellard, J.G. Knudsen, L. Briant, P. Rorsman;
Radcliffe Department of Medicine, University of Oxford, Oxford, UK.

Background and aims: Glucagon, secreted from pancreatic α-cells during hypoglycaemia, elevates blood glucose by increasing hepatic glucose output. α-cells exhibit glucose-dependent intracellular Ca^{2+} oscillations, which drive glucagon secretion. Understanding how glucose influences Ca^{2+}oscillations is important, as glucagon secretion becomes defective in diabetes. However, the precise relationship between oscillations in Ca^{2+} and glucose in α-cells remains unknown. Studies have reported that glucose increases, decreases or does not affect Ca^{2+} activity in α-cells. These discrepancies may be due to differences in methodology and/or accuracy of α-cell identification. By applying new, and more reliable, methodology to α-cell identification we aim to increase our understanding of the relationship between glucose and Ca^{2+} oscillations in α-cells under different conditions. Diabetes and obesity are known to be inextricably linked. In order to explore whether this is (in part) due to α-cell dysfunction induced by elevated circulating free fats acids (FFA) we investigated Ca^{2+} responses following prolonged exposure to elevated FFA.
Materials and methods: Mice expressing a genetically-encoded Ca^{2+} indicator (GCaMP) specifically in α-cells (using a Cre-Lox system under control of the glucagon promotor) were generated and validated by staining and FACS followed by quantification of mRNA expression. Ca^{2+} responses to glucose were imaged using confocal microscopy in freshly isolated islets and in islets incubated in elevated (0.72 mM) FFA for 48h.
Results: 76% of $GCaMP^{+}$ cells co-stained for glucagon ($n = 4$ mice). Cells FACS sorted for fluorescent marker expression had 20 fold higher glucagon mRNA content than cells negative cells for the fluorescent marker. Ca^{2+} oscillation frequency in freshly isolated islets was higher at 1 mM glucose (0.97 ± 0.1/min) than at both, 6 mM (0.53 ± 0.08/min; $p = 0.0008$) and 15 mM glucose (0.47 ± 0.06/min; $p < 0.0001$; $n = 144$ cells from 6 mice). Ca^{2+} oscillation amplitude was unaffected by changes in glucose ($p = 0.7774$). In FFA incubated islets, Ca^{2+} oscillation frequency at 6 mM glucose (0.65 ± 0.1/min) was greater than at both, 1 mM (0.33 ± 0.06/min; $p = 0.035$) and 15 mM glucose (0.35 ± 0.08/min; $p = 0.0161$; $n = 21$ cells from 3 mice).
Conclusion: These data validate GCaMP as a reliable tool for α-cell identification and Ca^{2+} monitoring. Glucose influenced the frequency but not amplitude of Ca^{2+} oscillations. This glucose-dependency was altered following high-fat incubation. We will next seek to investigate these findings using Ca^{2+} imaging in a high fat diet fed α-cell GCaMP mice.

Loss of melatonin receptor 1 in mouse pancreatic islets results in dysregulated glucagon secretion in vitro

C.L. Lyons, E. Cowan, D.G. Abellán, C.L.F. Nagorny, H. Mulder, M. Fex;
Unit of Molecular Metabolism, Department of Clinical Sciences, Lund University Diabetes Centre, Lund University, Malmö, Sweden.

Background and aims: Disturbances of circadian rhythm, regulated by the hormone melatonin, is associated with an increased risk of developing type 2 diabetes (T2D). In fact, genome-wide association studies (GWAS) have identified a single nucleotide polymorphism in the melatonin receptor 1B (MTNR1B/Mt2) which results in reduced insulin secretion and future risk of T2D in risk allele carriers. Nevertheless, there is still a lack of knowledge regarding the melatonin receptor 1A (MTNR1A/Mt1) and regulation of glucose homeostasis. Due to its location on the pancreatic alpha cells, this receptor may be involved in regulation of glucagon secretion. Here, the aim was to investigate the islet cell-specific effects of melatonin, with a focus on Mt1, to delineate the missing link between increased melatonin action and impaired islet function.
Materials and methods: Wildtype (WT) and *Mt1* knock out ($Mt1^{-/-}$) mice, on a C3H/He background, were maintained at a 12h light/dark cycle, and fed *ad libitum*. Intravenous glucose tests (IVGTTs) were performed in 12-week-old sedated mice ($n = 10$–16 mice). D-glucose (1 g/kg) was injected intravenously and plasma glucose and insulin levels measured by ELISA. Islets were isolated from collagenase-digested pancreas (12–18 wk), handpicked and incubated with 1 mM, 2.8 mM, 6 mM and 16.7 mM glucose ±100 nm melatonin, or 10 mM arginine for 1 h after a 1 h starvation with buffer containing 2.8 mM glucose ($n = 6$–12 mice). Release of insulin and glucagon *in vitro* was measured by ELISA. The studies were approved by the animal ethics committee at Lund University.
Results: Loss of *Mt1* results in enhanced insulin secretion ($^{**}p < 0.01$) and reduced glucose clearance ($^{**}p < 0.01$) *in vivo*, following a glucose challenge, compared to WT littermates. Male $Mt1^{-/-}$ mice weighed significantly less than WT mice ($^{**}p < 0.01$), but both males and females were used in the IVGTTs. In contrast, when the islets were stimulated *in vitro* with low (2.8 mM) and high glucose (16.7 mM), there was no difference in insulin secretion between the genotypes. Furthermore, stimulation with increasing glucose concentrations reduced glucagon secretion in WT islets but caused a significant increase of glucagon release in $Mt1^{-/-}$ islets at 6mM glucose ($^{*}p < 0.05$) and a 1.7-fold increase at 16.7 mM glucose ($^{**}p < 0.01$). Strikingly, addition of arginine, a depolarizing agent, in combination with high glucose, normalized glucagon secretion in the $Mt1^{-/-}$ islets, suggesting that loss of Mt1 signaling impairs plasma membrane depolarization. Incubation of $Mt1^{-/-}$ islets with melatonin stimulated insulin secretion ($^{*}p < 0.05$) at high glucose but did not affect glucagon secretion.
Conclusion: Loss of functional Mt1 signalling can influence whole body metabolism, and *in vitro* glucagon and insulin secretion. Additional studies will delineate the dose response relationship between melatonin, insulin and glucagon *in vitro*, and utilize fluorescently labelled $Mt1^{-/-}$ alpha cells for *in vivo* analysis, to determine the mechanism of action of melatonin. In summary, melatonin plays a role in metabolic dysfunction and islet cell function. Elucidation of these pathways may aid in the development of therapeutics to combat T2D.

Bone protective effect of a novel long-acting GLP-1/GIP/Glucagon triple agonist (HM15211) in an animal model

S. Lee, Y.-Y. Kim, J. Lee, S.-H. Lee, Y. Kim, I. Choi, S. Kim;
Hanmi Pharmaceutical Co. Ltd, Seoul, Republic of Korea.

Background and aims: Severe weight loss is often associated with reduction of bone mineral density (BMD) and an imbalance between bone formation and reabsorption in obese people. As a consequence, there can be an increased risk of bone fractures with body weight loss. Several studies have proposed that the gut hormones, GIP and GLP-1, might be modulators of bone growth and remodeling. HM15211 is a novel long-acting GLP-1/GIP/Glucagon agonist that is being developed for the treatment of obesity. In this study, we investigated whether treatment with HM15211 prevents bone loss under a severe weight loss condition, and the underlying mechanism of action.
Materials and methods: Diet induced obesity (DIO) osteoporosis rat model was induced by surgical ovariectomy and fed 60% kcal fat diet (cat# D12492, Research diet Inc., USA) to immatured 5 weeks old female sprague dawley (SD) rats for 2 months. Plasma levels of decarboxylated osteocalcin and P1NP (procollagen type 1 pro-peptide) were measured by rat GLU-osteocalcon high sensitive EIA kit and rat P1NP ELISA kit. Bone mineral density (BMD) of femur bones were monitored using a high resolution in vivo micro-CT system. Bone protection related gene

expression was analyzed in mouse osteoblast cell (MC3T3-E1) following chronic treatment of HM15211

Results: *In vitro* study, to elucidate the underlying molecular mechanism, related marker gene expression was investigated using the mouse osteoblast cell. In line with the bone protective effect in vivo, HM15211 led to significant increases in type1 collagen-α1 and carboxylated osteocalcin expression, which were blunted by inhibition of GIPR-mediated signaling. In vivo study, After 4 weeks subcutaneous treatment of HM15211 (120 μg/kg/Q3D), lower levels of serum decarboxylated osteocalcin (42.2 ng/mL) and higher serum P1NP (procollagen type I pro-peptide, 53.2 ng/mL) were observed compared with those of vehicle- (156.4 ng/mL for osteocalcin, 28.6 ng/mL for PINP) and liraglutide-treated groups (94 μg/kg/BID, 120.6 ng/mL for osteocalcin, 29.4 ng/mL for PINP). Furthermore, HM15211 showed comparable BMD of femur bones and lumbar spine with vehicle group while weight loss was greater (−26.0% vs. vehicle) compared to liraglutide (−11.5% vs. vehicle).

Conclusion: These results of animal study suggest that treatment with HM15211 effectively prevents bone loss even after potent body weight loss in high fat dieted ovariectomized obese rats. In conclusion, these results suggest that HM15211 might provide potent weight loss without the otherwise inevitable bone loss.

Separate effects of glucagon like peptide-2 (GLP-2) and glucose-dependent insulinotropic polypeptide (GIP) on bone remodelling

K. Skov-Jeppesen[1,2], M. Svane[3,2], C. Martinussen[3], M. Gabe[1], L. Gasbjerg[1,2], S. Madsbad[3], J. Holst[1,2], M. Rosenkilde[1,2], B. Hartmann[1,2]; [1]Department of Biomedical Sciences, University of Copenhagen, Copenhagen, [2]Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, [3]Department of Endocrinology, Hvidovre Hospital, Hvidovre, Denmark.

Background and aims: Glucagon like peptide-2 (GLP-2) and glucose-dependent insulinotropic polypeptide (GIP) both reduce bone resorption in humans. The GIP receptor (GIPR) is expressed on osteoclasts, osteoblasts, and osteocytes indicating a direct effect of GIP on bone remodelling. The GLP-2 receptor (GLP-2R), on the other hand, has not been identified on bone cells and the mechanism underlying the antiresorptive effect of GLP-2 remains unknown. Based on unpublished *in vitro* studies showing that GLP-2 acts as an agonist on the GIPR, we speculated whether the effect of GLP-2 on bone remodelling is mediated through the GIPR. We investigated this by antagonizing the GIPR using our newly developed selective GIPR-antagonist GIP(3-30)NH_2.

Materials and methods: The study was a randomized, placebo-controlled, single-blinded, crossover study with four study days each consisting of a continuous intravenous infusion from time = −20 min to time = 240 min (GIP(3-30)NH_2 800 pmol/kg/min or saline) and a subcutaneous injection at time = 0 min (GLP-2 (800 ug), GIP(1-42) (200 ug), or saline) in the following combinations: GIP(3-30)NH_2+GLP-2; GLP-2 alone; GIP(1-42) alone; and placebo (saline). Our main outcome was C-telopeptide of type 1 collagen (CTX) as a marker of bone resorption and N-terminal propeptide of type 1 collagen (P1NP) as a marker of bone formation.

Results: Eight healthy, non-smoking, caucasian men with a median age of 27 years (range 20–34 years) and a median body mass index of 22.6 kg/m^2 (range 21.1–23.9 kg/m^2) were included in the study. CTX significantly decreased for both GIP(1-42) and GLP-2 injections reaching a nadir of 55.3 ± 6.3% (mean ± SEM) of baseline (time = 90 min) for GIP(1-42) and 60.5 ± 5.0% (time = 180 min) for GLP-2 compared with 85.4 ± 4.2% (time = 180) for placebo. Co-administration of GLP-2 with GIP(3-30)NH_2 did not significant change the effect of GLP-2 as a nadir of 63.2 ± 3.1% was reached after 180 min ($p = 0.95$). GIP(1-42) increased P1NP to 115.1 ± 2.2% of baseline (time = 30 min), significantly more than placebo. This increase was not observed for GLP-2 alone or in combination with GIP(3-30)NH_2, as both situations significantly decreased P1NP compared with placebo, but did not differ from each other (91.3 ± 1.1% and 88.1 ± 3.0%, $p = 0.50$).

Conclusion: We found that the GLP-2 induced reduction in bone resorption (CTX) was not antagonized by our selective GIPR antagonist, GIP(3-30)NH_2, and we conclude that the antiresorptive effect of GLP-2 is independent of the GIPR in humans. Importantly, we found that subcutaneous injected GIP(1-42) reduced bone resorption (CTX) and also, in contrast to GLP-2, increased bone formation (P1NP) in healthy people indicating an uncoupling effect of GIP.

Direct effects of glucagon on human adipose tissue metabolism

M.J. Pereira, G.J. Boersma, P.G. Kamble, P. Lundkvist, K. Almby, J.W. Eriksson;
Uppsala University, Uppsala, Sweden.

Background and aims: Glucagon acts as a counter-regulatory hormone to insulin and is therefore essential for glucose regulation. The main physiological role of glucagon is to stimulate hepatic glucose output, for example during hypoglycemia. In type 2 diabetes, fasting blood glucagon levels are elevated and contribute to hyperglycemia. In *in vitro* experiments, glucagon has been shown to increase lipolysis in human adipose tissue, however, *in vivo* experiments using glucagon infusion does not give consistent results. In addition, discordant data exist regarding the impact of glucagon on adipocyte glucose metabolism. Therefore, we aimed to study the action of glucagon on human adipocyte glucose and lipid metabolism.

Materials and methods: Abdominal subcutaneous adipose tissue was obtained with needle biopsies from healthy volunteers (6M/7F, 22–56 yrs, BMI: 22.0–34.4 kg/m^2). Adipocytes were isolated with collagenase and pre-incubated without (control) or with glucagon (0.01–100 nM) and w/wo insulin for 10–15 min. Then, 14C-glucose uptake was measured during 45 min and lipolysis was assessed with or without the beta-adrenergic agonist, isoproterenol, by measuring the glycerol release into the medium during 2 h.

Results: Glucagon dose-dependently (0.01–100 nM) increased basal and insulin-stimulated (25 and 1000 μM) glucose uptake in adipocytes by about 2-fold and 1.7-fold ($p < 0.05$), respectively, with the maximum effect observed at 10 nM (a supraphysiological level). The increase in both basal and insulin-stimulated glucose uptake was already significant with a pathophysiological concentration of glucagon: 0.1 nM and 1.3-fold increase ($p < 0.05$), compared with basal. When adipocytes were treated with glucagon 10 nM and insulin (25 or 1000 μU/mL) together, the rise in glucose uptake was additive ($p < 0.05$), suggesting independent mechanisms of

action. In addition, treatment with glucagon did not modify the adipocyte sensitivity to insulin on glucose uptake. Treatment of adipocytes with glucagon dose-dependently increased basal and isoproterenol-stimulated lipolysis up to 3.7- and 2.0-fold ($p < 0.05$) at 1 nM, respectively, compared to control. However, treatment of adipocytes with glucagon did not affect the ability of insulin to inhibit isoproterenol-stimulated lipolysis.

Conclusion: Glucagon at high concentrations can paradoxically increase glucose uptake in human adipocytes, which would promote lowering of circulating glucose. Conversely, lipolysis was increased. Potentially, these specific actions of glucagon in adipose tissue may favor fatty acid over glucose availability as energy substrates in other tissues like muscle and liver.

Postprandial effects of individual and combined GIP and GLP-1 receptor antagonism in healthy subjects

L.S. Gasbjerg[1,2], M.M. Helsted[3,2], A.H. Sparre-Ulrich[1], A.R. Lanng[2], S. Stensen[2], M.H. Jakobsen[3], B. Hartmann[1], M.B. Christensen[4,5], J.J. Holst[1], T. Vilsbøll[2,4], M.M. Rosenkilde[1], F.K. Knop[2,6];
[1]Department of Biomedical Sciences and Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, [2]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Hellerup, [3]Department of Biomedical Sciences, University of Copenhagen, Copenhagen, [4]Department of Clinical Medicine, University of Copenhagen, Copenhagen, [5]Department of Clinical Pharmacology, Bispebjerg Hospital, Copenhagen, [6]Department of Clinical Medicine and Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark.

Background and aims: The gut-derived incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1) are known for insulinotropic and glucose-lowering effects. However, their individual roles in postprandial glucose homeostasis are unknown. In this study, we infused the novel, selective GIP receptor antagonist GIP(3-30)NH_2 and the GLP-1 receptor antagonist exendin(9-39) during a meal to determine the roles of endogenous GIP and GLP-1 on postprandial glucose metabolism.

Materials and methods: On four separate days, 12 healthy men (age 19–65 years, body mass index 20–25 kg/m^2) underwent a 270-minute liquid mixed meal test (1894 kJ: 49.3% carbohydrates, 5.9% protein, 34.8% fat) with randomised and double-blinded infusions (from −20 to 270 min) of GIP(3-30)NH_2 (800 pmol/kg/min) + exendin(9-39) (20 min of 1000 pmol/kg/min, thereafter 450 pmol/kg/min) (A), GIP(3-30)NH_2 (B), exendin(9-39) (C) and saline (D). The antagonist infusion rates were chosen based on their inhibitory potencies in vitro.

Results: On Day A, B and C, glucose excursions were significantly increased by 85 ± 29%, 55 ± 20% and 15 ± 16% (mean ± SEM), respectively, compared to D. Day A and B excursions were significantly higher than C (Fig. 1). Glucagon levels at 60 min differed between Day A and B (11.5 ± 1.2 vs. 7.5 ± 0.6 pmol/l (mean ± SEM), $P = 0.01$), and Day B and C (7.5 ± 0.6 vs. 12.9 ± 1.5 pmol/l, $P = 0.008$). GLP-1 was higher on Day A ($P = 0.01$) and C ($P = 0.02$) than D. No significant effects on insulin, C-peptide, gastric emptying (paracetamol absorption test) or GIP were observed.

Conclusion: Following a liquid mixed meal, endogenous GIP affects postprandial plasma glucose excursions more than GLP-1, and GIP and GLP-1 additively lower plasma glucose. Furthermore, opposite effects of GIP and GLP-1 on postprandial glucagon concentrations were observed.

Individual and combined glucose-lowering effects of glucagon receptor antagonism and dipeptidyl peptidase-4 inhibition

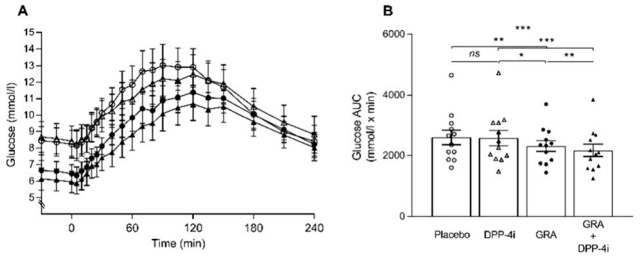
H. Maagensen[1], S. Haedersdal[1], A. Lund[1], E. Nielsen-Hannerup[1], J. Holst[2], F. Knop[1,2], T. Vilsbøll[3,4];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, Hellerup, [2]Novo Nordisk Foundation Center for Basic Metabolic Research, Copenhagen, [3]Steno Diabetes Center Copenhagen, Gentofte, [4]Department of Clinical Medicine, Faculty of of Health and Medical Sciences, Copenhagen University, Copenhagen, Denmark.

Background and aims: Type 2 diabetes is characterised by absolute or relative hypoinsulinaemia and hyperglucagonaemia. Dipeptidyl peptidase 4 inhibitors (DPP-4i) augment insulin secretion and decrease glucagon secretion, but if glucagon is removed from the metabolic equation, the effect of DPP-4i is unknown.

Materials and methods: In a randomised, placebo-controlled, double-dummy, double-blinded, cross-over study, patients with type 2 diabetes ($n = 12$, age [mean (SD)]: 60.9 (7.8) years, BMI 34.6 (7.1) kg/m^2; HbA1c 50.3 (10.5) mmol/mol) underwent four 4-hour liquid mixed meal tests preceded by single-dose administration of 1) placebo, 2) DPP-4i (5 mg linagliptin) 2 hours before the meal, 3) glucagon receptor antagonist (GRA) (300 mg LY2409021) 10 hours before the meal, and 4) GRA + DPP-4i. Indirect calorimetry, plasma glucose, C-peptide, glucagon and paracetamol (paracetamol absorption test) was measured. Stable isotopes were infused for glucose and glycerol turnover and endogenous glucose production.

Results: Compared to placebo, fasting plasma glucose was lowered by GRA but not DPP-4i. Adding DPP-4i to GRA did not lower fasting plasma glucose further. Compared to placebo, DPP-4i increased insulin responses to the meal (C-peptide AUC) ($p < 0.01$), but did not result in a difference in plasma glucose excursions (Figure). GRA alone lowered glucose AUC, and the combination of GRA and DPP4i lowered glucose AUC further.

Conclusion: The combination of DPP-4i and GRA has additive effects on postprandial glucose excursions. This seems to be driven by the efficient reduction in fasting plasma glucose by GRA combined with additional reduction in postprandial glucose excursions by DPP-4i.



Plasma glucose excursions (A) and AUC (B) following a mixed meal tolerance test preceded by single doses of 1) placebo (open circles), 2) dipeptidyl peptidase 4 inhibitor (DPP-4i) (open triangles), 3) glucagon receptor antagonist (GRA) (filled circles) and 4) GRA+DPP-4i (filled triangles). Data are mean ± SEM. *** $p < 0.001$ ** $p < 0.01$, * $p < 0.05$, ns $p > 0.05$.

The initial rise in GIP secretion during OGTT correlates with the initial suppression of glucagon secretion in adolescents with obesity and type 2 diabetes

H. Kristinsson[1], H. Manell[1], M. Dahlbom[2], J. Presto[3], C. Gäredal[3], H. Ritzén[3], M. Vilhelmsson[3], E. Kilstedt[3], F. Johnson[3], H. Stenberg[3], A. Forslund[2], P. Bergsten[1];
[1]Uppsala University, Uppsala, [2]Akademiska Sjukhuset, Uppsala, [3]Mercodia, Uppsala, Sweden.

Background and aims: We have previously reported that glucagon levels at fasting and during OGTT are increased in obese adolescents as glucose intolerance develops. Specifically, we observed that initial suppression of glucagon during OGTT is absent in obese children with prediabetes or overt T2DM. Obese adults have increased incretin GIP levels, which are further elevated in subjects with T2DM. These observations have been interpreted as increased GIP levels may be the reason behind increased glucagon secretion in obese adults. We hypothesized that elevated glucagon levels at fasting and during OGTT in obese adolescents with or without T2DM were associated with increased levels of GIP.
Materials and methods: GIP and glucagon in plasma samples from adolescents with obesity and normal glucose tolerance (NGT = 12), impaired glucose tolerance (IGT = 19) or type 2 diabetes mellitus (T2DM = 4) and lean (n = 17) 10–17 year old adolescents were measured from plasma samples collected at fasting and during OGTT at −5, 5, 10, 15, 30, 60, 90 and 120 minutes by ELISA (Mercodia AB, Uppsala, Sweden). The GIP ELISA measures total GIP levels (GIP 1–42 and the inactivated part GIP 3–42). Ethical approval was obtained from the Uppsala Ethical Review Board.
Results: Fasting GIP levels (mean ± SEM) were similar between lean adolescents (4.7 ± 0.6 pM) and obese with NGT (5.4 ± 1.0 pM), IGT (4.9 ± 0.8 pM) or T2DM (3.9 ± 1.7 pM). In contrast, corresponding fasting glucagon concentrations varied greatly between the groups and were lowest for lean adolescents (7.8 ± 0.5 pM) followed by obese NGT (11.1 ± 1.0 pM), IGT (13.8 ± 1.1 pM) and highest for T2DM (18.4 ± 1.5 pM). During OGTT the initial rise in GIP secretion, (AUC_{10}), was highest in obese NGT (177 pmol/L*min) followed by lean controls (161 pmol/L*min), obese IGT (115 pmol/L*min) and T2DM (114 pmol/L*min) (Fig 1). The initial suppression in glucagon secretion was most accentuated in lean with AUC_{10} of −3.3 pmol/L*min followed by −1.1 pmol/L*min in obese NGT while in obese IGT and obese T2DM there was a rise in glucagon secretion of 3.9 and 30.6 pmol/L*min, respectively. GIP secretion throughout the OGTT was highest in lean adolescents with AUC_{120} of 5812 pmol/L*min, followed by obese NGT (4683 pmol/L*min), IGT (4586 pmol/L*min) and obese T2DM adolescents (3128 pmol/L*min). Lean adolescents had the lowest amount of glucagon secreted during the OGTT and T2DM the highest.
Conclusion: In lean and obese adolescents there is no correlation between plasma GIP and glucagon levels at fasting. In contrast, during OGTT reduced initial GIP secretion response is associated with lack of glucagon suppression. We conclude that, firstly, fasting hyperglucagonemia in obese adolescents developing T2DM does not seem to be driven by GIP secretion and, secondly, that accentuated initial GIP secretion during OGTT may reduce glucagon levels.

Glucagon and gastrointestinal hormones changes after Roux-en-Y gastric bypass: an IMI DIRECT study

J. Gassenhuber[1], F. Frau[1], V. Raverdy[2], F. Baerenz[1], M. Gebauer[1], F. Pattou[2];
[1]Sanofi, Frankfurt, Germany, [2]CHU Lille, University of Lille, Inserm U1190, Lille, France.

Background and aims: Type 2 diabetes (T2D) and associated obesity have reached epidemic proportions worldwide. The most effective weight loss treatment for obesity is bariatric surgery and has been proven superior to medical treatments. The mechanisms behind long lasting weight reduction and T2D remission after surgery are still unclear. It has been hypothesized that changes of circulating levels of gut hormones, in particular GLP1, are essential for this outcome. Several studies have already measured hormone levels after Roux-en-Y Gastric Bypass (RYGB), but often with a small sample size and, therefore, uncertainty on the changes still exist.
Materials and methods: We analyzed the changes of active/total GLP-1, GIP, PYY, Ghrelin and Glucagon in 39 obese subjects, from the IMI-DIRECT consortium, before (M0) and 3 months (M3) after RYGB. Mixed meal tolerance tests (MMTT) were performed after an overnight fast. Blood samples were taken at fasting and 15, 30, 60, 90, 120 and 180 minutes after ingestion of a standardized meal. In addition, pre- and post-prandial amino acid serum levels were quantified for 9 patients at fasting (T0) and 15 minutes (T15) after the mixed meal.
Results: We detected strong postprandial changes in several incretin hormones after gastric bypass. In particular, we showed a high increase in glucagon levels during the MMTT. Before surgery, the increase was 29 pg/ml (T0 = 53 ± 25 pg/ml to T15 = 82 ± 54 pg/ml), but after surgery we saw an increase of 208 pg/ml (T0 = 32 ± 17 pg/ml to T15 = 240 ± 104 pg/ml). The difference in the AUC for Glucagon for the MMTT was highly significant $p = 1.32E-06$. The sum of all amino acids in serum was similar before and after surgery at baseline, but the increase of serum amino acids at T15 was ~3 times higher after surgery. For instance the increase in serum Arginine during MMTT at T15 before surgery was 17 μmol, (M0T0 = 64 ± 15 μmol ≥ M0T15 = 81 ± 20 μmol) but after RYGB it increased to ~58 μmol (M3T0 = 77 ± 37 μmol ≥ M3T15 = 135 ± 54 μmol).
Conclusion: This result might be the missing piece for the explanation of mechanism behind diabetes remission and huge weight loss after surgery. In fact, the known glucagon effect of reducing appetite and increasing energy expenditure should be synergistic to the well described GLP1 effects. The strong increase of serum amino acids might be the driver of increased glucagon secretion after RYGB.

Increased GLP-1 levels after bariatric surgery are not explainable by adaptations to enteroendocrine cells or the intestinal peptidome

P. Larraufie, A.K. McGavigan, R.G. Kay, F. Reimann, F.M. Gribble;
Institute of Metabolic Science, Cambridge, UK.

Background and aims: Bariatric surgery is a treatment of choice for obesity due to its long term effectiveness and association with diabetes remission. Post-prandial plasma levels of glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) are dramatically increased after surgery, and likely contribute to the beneficial metabolic effects due to their multiple actions including enhanced insulin secretion and reduced food intake. The aim of this study was to investigate whether transcriptomic changes in enteroendocrine cells (EECs) or alterations in the intestinal tissue peptidome contribute to the post-surgical changes in plasma gut hormone profiles.
Materials and methods: Vertical Sleeve Gastrectomy (VSG) was performed on lean NeuroD1-Cre/YFP mice expressing a fluorescent reporter in EECs. Glucose gavage was performed 6 weeks after surgery on VSG-operated, weight-matched and sham operated mice, for plasma hormone and glucose measurements. EECs were purified by flow cytometry from the upper and lower small intestine and colon, and analysed by RNA sequencing. Mucosal extracts from sequential 5cm segments along the length of the gastrointestinal tract of fasted mice were analysed by mass-spectrometry (LC-MS/MS) to identify and quantify peptide hormones.
Results: VSG-operated mice lost more weight than sham controls during the first week after surgery. Mirroring the changes seen after bariatric surgery in humans, the VSG group had increased plasma GLP-1 and insulin levels after an oral glucose challenge, and more rapid glucose clearance. LC-MS/MS analysis identified and quantified a full range of processed gut hormones in tissue extracts, including GIP, GLP-1/2, oxyntomodulin, PYY, neurotensin, SST14/28 and secretin. The tissue peptide profile of the longitudinal gut axis was not different after VSG compared with sham or weight-matched controls. RNAseq analysis of purified EECs demonstrated representation of a range of EEC types, including cells producing GLP-1, CCK, GIP, PYY or serotonin. Principal component analysis revealed strong clustering of the EEC samples based on their tissue of origin, but no differences attributable to the surgery group. Only a few genes were differently expressed between the different surgical conditions, with a significant overrepresentation of genes involved in metabolite and small molecule transport and metabolism.
Conclusion: VSG did not alter the EEC transcriptome or tissue peptidome from different regions of the intestinal tract, leading us to conclude that adaptations to EEC identity or local intestinal hormone biosynthesis do not underlie altered gut hormone levels after surgery. Instead, the dramatically increased post-prandial plasma GLP-1 and PYY profiles observed after bariatric surgery are likely explained by other physiological modifications such as differences in intestinal nutrient delivery, digestion and absorption.

The effect of Roux-en-Y gastric bypass surgery on the gut mucosal gene expression profile and circulating gut hormones

M.M. Christensen[1], T. Jorsal[1], B. Mortensen[1], E. Wandall[2], E. Langholz[2], S. Friis[2], D. Worm[3], R.K. Støving[4], A. Aldries[5], C.B. Juhl[5], J. Rehfeld[6], N. Vrang[7], J. Jelsing[7], T. Vilsbøll[1], F.K. Knop[1];
[1]Clinical Metabolic Physiology, Steno Diabetes Center Copenhagen, University of Copenhagen, Copenhagen, Denmark, [2]Endoscopic Unit, Herlev-Gentofte Hospital, University of Copenhagen, Copenhagen, Denmark, [3]Department of Medicine, Amager Hospital, University of Copenhagen, Copenhagen, Denmark, [4]Elite Research Center for Medical Endocrinology & Center for Eating Disorders, Odense University Hospital, Odense, Denmark, [5]Surgical Unit, Sydvestjysk Sygehus, Esbjerg, Denmark, [6]Department of Clinical Chemistry, Centre of Diagnostic Investigations, Rigshospitalet, Copenhagen, Denmark, [7]Gubra, Hørsholm, Denmark.

Background and aims: The weight loss and improved glucose homeostasis observed after Roux-en-Y gastric bypass (RYGB) surgery is associated with changes in circulating concentrations of gastrointestinal peptide hormones such as glucagon-like peptide-1 (GLP-1), peptide YY (PYY) and ghrelin. In order to potentially discover unrecognized RYGB-induced alterations in the expression of gut hormones, we aimed to investigate the entire mRNA gene expression profile encoding signalling peptides in small intestinal biopsies obtained before and after surgery.

Materials and methods: Twenty morbidly obese individuals referred to RYGB (sex: 5/15 (male/female); glycaemic status: 3/17 (type 2 diabetes/ normal glucose tolerance); age [median (ranges)]: 47 (29;56) years; body weight 123.1 (100.9;173.0) kg; BMI: 43.4 (35.5;52.2) kg/m^2) underwent upper enteroscopy with mucosal biopsy retrieval and liquid mixed meal tolerance tests before and after surgery. Next-generation full mRNA sequencing of biopsies was performed. Available assays for measurements of circulating peptide hormones corresponding to the differentially regulated genes were applied.

Results: Global gene expression analysis of mucosal biopsies identified sixteen robustly expressed genes (reads per kilobase million >1) encoding enteroendocrine and neuroendocrine peptide hormones (*ADM*, *ADM2*, *CCK*, *EDN2*, *EDN3*, *GCG*, *GHRL*, *GIP*, *GUCA2A*, *GUCA2B*, *MLN*, *NPY*, *NTS*,*OXT*, *PYY* and *SST*) with significantly altered mRNA expression after RYGB (false discovery rate adjusted-p value <0.1). Corresponding changes in postprandial plasma hormone responses were seen for GLP-1, glucagon, neurotensin and ghrelin.

Conclusion: These findings show that RYGB surgery affects the transcription of a range of genes encoding signalling peptides in the small intestine, indicating that the beneficial metabolic effects of RYGB rely on a complex modulation of enteroendocrine and neuroendocrine factors in the gut.

Post-prandial hypoglycaemia after Roux en-Y gastric bypass: Could Neuromedin U play a role in the pathogenesis?

D. Bottazzo[1], D. Tricò[1], D. Guarino[2], S. Baldi[2], M. Anselmino[3], S. Taddei[1], E. Ferrannini[4], M. Nannipieri[1];
[1]Clinical and Experimental Medicine, University of Pisa, Pisa, [2]Clinical and Experimental Medicine, CNR Institute of Clinical Physiology and University of Pisa, Pisa, [3]Bariatric Surgery Unit, Azienda Ospedaliera Universitaria Pisana, Pisa, [4]CNR Institute of Clinical Physiology, Pisa, Italy.

Background and aims: Neuromedin U (NMU), a multifunctional neuropeptide, is produced in the human foregut and suppresses insulin secretion from pancreatic beta cells, suggesting that NMU may play a role in regulating glucose metabolism. Post-prandial hypoglycaemia (PPHG), a well-recognised complication of bariatric surgery, is induced by an early inappropriate insulin secretion, in part dependent on a lack of inhibition of insulin secretion. We evaluated the role of NMU in the pathogenesis of PPHG in subjects treated by Roux en-Y gastric bypass (RYGB).

Materials and methods: Nineteen morbidly obese, non-diabetic subjects, treated by RYGB, who developed typical hypoglycaemic symptoms in the post-prandial state under everyday life conditions, received a 5-hr OGTT 18–24 months after surgery. PPHG was defined as a plasma glucose ≤3.3 mmol/L during the OGTT in the presence of typical hypoglycaemic symptoms. A group of 15 subjects treated by RYGB 24 months previously but negative for hypoglycaemic symptoms, served as control group. Insulin sensitivity was assessed by the OGIS index and beta cell function by modelling analysis of the C-peptide response to the OGTT. Plasma NMU concentrations were measured by an ELISA method at fasting and during the OGTT time corresponding to the individual glucose nadir.

Results: After surgery, BMI was lower in PPHG than No-PPHG (29.2 ± 4.0 *vs* 32.8 ± 5.7 kg/m^2, $p = 0.045$). Fasting and mean plasma glucose and fasting insulin concentrations and secretion rates were similar in both groups. As expected, the glucose nadir was significantly lower in PPHG subjects (2.7 ± 0.5 *vs* 4.0 ± 0.3 mmol/L, $p < 0.0001$). Mean insulin concentrations and insulin secretion rates during OGTT were higher in PPHG than in No-PPHG ($p = 0.05$). The area under the insulin curve in the 1st hour was higher in PPHG than in No-PPHG (58.1 ± 28.2 *vs* 40.3 ± 20.1 pmol L^{-1}·min, $p = 0.05$). Peripheral insulin sensitivity was similar in both groups, whereas beta cell glucose sensitivity was higher in PPHG than No-PPHG (125 ± 64 *vs* 74 ± 49 pmol min^{-1} m^{-2} mM^{-1}, $p = 0.02$). Fasting plasma NMU concentrations were similar in PPHG and No-PPHG (686 ± 304 *vs* 538 ± 309 pg/ml), whereas NMU concentrations at the time of glucose nadir were lower in PPHG compared to No-PPHG (620 ± 369 *vs* 929 ± 453 pg/ml, $p = 0.03$). There was a strong positive correlation between fasting and NMU nadir concentrations ($r = 0.85$, $p < 0.0001$), while NMU at glucose nadir was inversely correlated with Ins AUC-60 ($r = 0.31$, $p = 0.04$).

Conclusion: Individuals with spontaneous post-prandial hypoglycaemia after RYGB have lower NMU concentrations at the glucose nadir during an OGTT. The inverse relation of NMU at glucose nadir and 1st-hour insulin secretion is compatible with a defective response of NMU to suppress glucose-stimulated insulin secretion and to prevent hypoglycaemia.

Different nutrient handling and gut hormone response after gastric bypass and sleeve gastrectomy

M.S. Svane[1,2], K.N. Bojsen-Møller[1,2], C. Martinussen[1,2], C. Dirksen[1], S. Reitelseder[3], L. Holm[3,4], V.B. Kristiansen[5], J.J. Holst[2], S. Madsbad[1,2];
[1]Dept. of Endocrinology, Hvidovre Hospital, Hvidovre, Denmark, [2]NNF Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark, [3]Institute of Sports Medicine, Bispebjerg Hospital, Copenhagen, Denmark, [4]School of Sport, Exercise and Rehabilitation Sciences, University of Birmingham, Birmingham, UK, [5]Dept. of Surgical Gastroenterology, Hvidovre Hospital, Hvidovre, Denmark.

Background and aims: Sleeve gastrectomy (SG) and Roux-en-Y gastric bypass (RYGB) induce comparable weight loss and improvements in glycemic control despite marked differences in postoperative gastrointestinal rearrangements. Accelerated transit of nutrients to the small intestine and exaggerated secretion of GLP-1 are important for the beneficial effects of RYGB, whereas the responsible mechanisms behind SG are less investigated. We hypothesized that absorption of glucose and protein is accelerated after both SG and RYGB compared with unoperated controls (C) and compared absorption of nutrients and gastro-entero-pancreatic hormone profiles between groups.

Materials and methods: 12 SG and 12 RYGB operated and 12 C matched on age, sex, BMI, and post-operative weight loss were investigated. Absorption rates of ingested glucose and phenylalanine (phe) originating from ingested casein protein and protein metabolism were determined via double tracer technique with primed-continuous iv infusions of [6,6-D_2]glucose, L-[ring-D_5]phe, L-[ring-3,5-D_2]tyrosine and [$^{15}N_2$]urea combined with a 6 hour liquid mixed meal test (400 kcal, 50E% carb, 35E% fat, 15E% prot) containing [$^{13}C_6$] glucose and intrinsically [^{15}N] phe labelled casein.

Results: Peak rate of appearance (R_a) of oral glucose was higher after RYGB and SG compared with C (RYGB: 36 ± 1 μmol/kg FFM/min, SG: 27 ± 1, C 22 ± 1; $p < 0.05$ for all comparisons) and peak R_a of phe was higher after RYGB, but similar in SG and C (RYGB 0.37 ± 0.04, SG 0.23 ± 0.02, C 0.17 ± 0.01, $p < 0.01$ for RYGB vs SG and C, $p = 0.22$ for SG vs C). In addition, initial oral recovery of ingested phe was greatly accelerated after RYGB vs SG and C (60 min oral recovery: RYGB: 30 ± 2%, SG: 13 ± 3, C: 4 ± 0.5, $p < 0.01$ for all comparisons), but the total 6 hour oral recovery did not differ (RYGB: 67% ± 3, SG: 70 ± 4, C: 67 ± 4, $p = 0.6$). Likewise, net protein synthesis was more enhanced within the first postprandial hour after RYGB ($p < 0.01$ vs. SG and C), whereas total 6 hours net protein balance and urea turnover did not differ between groups. The rapid absorption of glucose and protein after RYGB was associated with higher but more transient excursions of plasma glucose

and amino acids followed by increased secretion of glugacon-like peptide 1 (GLP-1), insulin and peptide YY (PYY) exclusively after RYGB. In contrast, ghrelin concentration was lower and glucose-dependent insulinotropic polypeptide (GIP) was higher after SG compared with RYGB.

Conclusion: Postprandial nutrient absorption and gastro-entero-pancreatic hormone secretions differed after RYGB and SG. RYGB was characterized by accelerated glucose and protein absorption, followed by exaggerated glucose excursions and early stimulation of whole-body protein synthesis. In contrast, glucose absorption and protein turnover after SG was modestly accelerated and largely resembled that of controls. GLP-1 and PYY were increased especially after RYGB, whereas ghrelin was lower after SG. Hence, different mechanisms may underlie improved glycemic control and weight loss after these two surgical procedures.

The different mechanisms of action of GIP and GLP-1 explain their different efficacy as therapeutic agents in type 2 diabetes

E. Grespan[1], T. Giorgino[1], A. Natali[2], E. Ferrannini[3], A. Mari[1];
[1]CNR Institute of Neuroscience, Padua, [2]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, [3]CNR Institute of Clinical Physiology, Pisa, Italy.

Background and aims: The reduced incretin effect in type 2 diabetes (T2D) represents an important cause of postprandial hyperglycaemia, but the different pharmacologic efficacy of its major players, GLP-1 and GIP, remains unexplained. At cellular level the mechanisms activated by the two hormones and the defects of T2D are still poorly understood. In this study, we have extended a recently developed mathematical model of the β-cell to 1) investigate the role of incretins at the cellular level on Ca^{2+} signalling and on the glucose mediated amplifying pathway (AP); 2) characterise incretin action *in vivo* in subjects with normal glucose tolerance (NGT) or T2D; 4) provide an explanation for the different insulinotropic activity of GIP and GLP-1 in T2D subjects.

Materials and methods: We used *in vivo* data from: A) two studies with constant infusions of GIP or GLP-1 at basal glucose; B) four hyperglycaemic clamp studies with boluses or constant infusion of GIP or GLP-1; C) a graded glucose infusion test with constant infusion of GLP-1; D) two OGTT or isoglycaemic intravenous glucose infusion studies with GIP or GLP-1 infusion. In the β-cell model, we hypothesize that GIP and GLP-1 increase insulin secretion rate (ISR) by a transient increase in Ca^{2+} levels (the first 10–20 min after the incretin stimulus) and by potentiating the AP; the $Ca^{2+}$and glucose-dependent refilling function representing the AP is multiplied by a time-dependent factor (K_{incr}); $K_{incr} = 1$ without and $K_{incr} > 1$ with incretin stimulation.

Results: A transient Ca^{2+} increase is necessary to reproduce the transient ISR increase observed with GIP infusion at basal glucose in NGT subjects (Study A). This mechanism also accounts for the increase in early ISR during the OGTT (Study D). The amplification of the refilling function through the factor K_{incr} accounts for the sustained ISR potentiation in all studies. The estimated effect on transient Ca^{2+} increase was similar for GIP and GLP-1 and was preserved in T2D compared to NGT. In contrast, the effects of GIP and GLP-1 on K_{incr} had markedly different patterns: K_{incr}increased linearly with GLP-1 over a wide dose range, while with GIP K_{incr} reached a plateau already at low GIP concentrations (Figure). K_{incr} sensitivity to GLP-1 was reduced by ~30% in T2D subjects compared to NGT, while for GIP the maximal K_{incr} was reduced by ~50%.

Conclusion: By modelling a variety of *in vivo* protocols, the following cellular mechanisms of incretins emerge: 1) a transient rise in intracellular Ca^{2+}, which underlies the early effects of incretins; and 2) a potentiation of the AP, which mediates the sustained ISR. Our analysis suggests that in T2D the incretin effect on Ca^{2+} is preserved while the amplification of the AP is impaired, though not abolished. Finally, we found that saturation of GIP effects, more than impaired sensitivity, underlies the lack of insulinotropic activity of pharmacological doses of GIP in T2D.

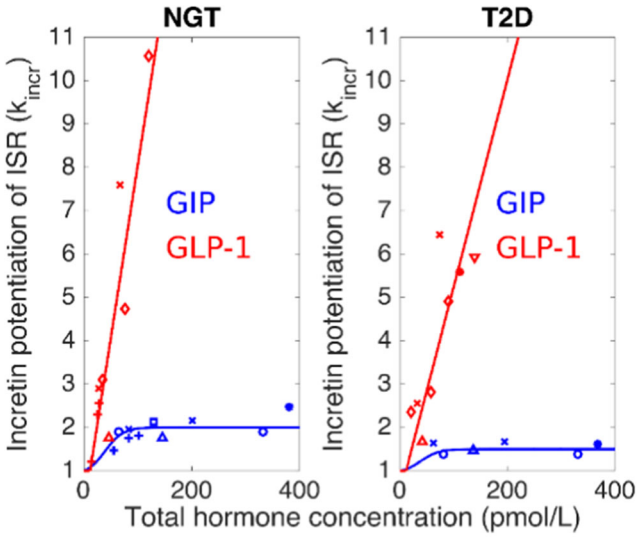

Figure: Relationship between K_{incr} and total GIP (blue lines) or GLP-1 (red lines) concentration. The analysis reveals saturation of the effect of GIP but not of GLP-1. Markers represent the different studies.

Remission of type 2 diabetes: underlying mechanisms revealed by the Diabetes Remission Clinical Trial (DiRECT)

R. Taylor[1], A. Al-Mrabeh[1], S. Zhyzhneuskaya[1], C. Peters[1], A.C. Barnes[2], B.S. Aribisala[3], K.G. Hollingsworth[1], N. Sattar[4], M.E.J. Lean[5];
[1]Magnetic Resonance Center, Newcastle upon Tyne, [2]Human Nutrition Research Group, Newcastle University, Newcastle upon Tyne, [3]Magnetic Resonance Center, Newcastle University, Newcastle upon Tyne, [4]Institute of Cardiovascular and Medical Science, University of Glasgow, Glasgow, [5]Human Nutrition, School of Medicine, University of Glasgow, Glasgow, UK.

Background and aims: DiRECT is a prospective, randomised study of type 2 diabetes (<6 years duration) which demonstrated 46% of participants had normal glucose control off all medication at 12 months. It is important to understand the mechanisms underlying this reversal.

Materials and methods: Weight loss was induced using a liquid diet replacement (825–853 kcal/day) for 3–5 months with withdrawal of all anti-diabetic drugs on day 1. Liver and pancreas fat was quantified by 3-point Dixon MRI. Hepatic very low density lipoprotein triglyceride (VLDL1-TG) metabolism and first phase insulin secretion, were measured before and after weight loss. Those with HbA1c <48 mmol/mol (<6.5%) and fasting plasma glucose <7.0 mmol/l after weight loss (n = 40; responders) were compared with non-responders (n = 18).

Results: At baseline, the two groups were similar in age (53.0 ± 1.2 vs. 53.3 ± 1.9 years) and BMI (34.9 ± 0.7 vs. 35.7 ± 1.2 kg/m^2) but not duration of diabetes (2.7 ± 0.3 vs. 3.8 ± 0.4 years, p = 0.04). HbA1c was 57.5 ± 1.7 vs. 62.5 ± 2.1 mmol/mol respectively; p < 0.07). During the weight loss phase, weight decreased in responders (100.6 ± 2.6 to 84.4 ± 2.1 kg;

$p < 0.0001$; $n = 40$) and in non-responders (102.1 ± 4.4 to 88.7 ± 4.4 kg; $p < 0.0001$; $n = 18$. Responders had a non-significantly lower fasting plasma glucose than non-responders (8.3 ± 0.4 vs. 9.3 ± 0.7 mmol/l; $p = 0.18$). Decreases occurred in liver fat in both responders and non-responders (16.7 ± 1.5 to 3.3 ± 0.7%, $p < 0.0001$; and 14.5 ± 2.6 to 2.6 ± 0.5%; $p < 0.0001$). In responders, VLDL1-TG production decreased after weight loss (560.7 ± 30.9 to 413.6 ± 25.8 mg/kg/day, $p < 0.0001$). In non-responders, there was a non-significant fall (581.1 ± 52.1 to 521.8 ± 41.9 mg/kg/day; $p = 0.28$) although the difference was not significantly different between responders and non-responders (−147.2 ± 33.8 vs. −59.2 ± 52.7; $p = 0.17$). Total plasma triglyceride (largely chylomicrons plus VLDL1-TG) fell similarly in responders and non-responders after intervention (1.84 ± 0.13 to 1.30 ± 0.13 mmol/l, $p < 0.0001$ and 1.91 ± 0.25 to 1.24 ± 0.14 mmol/l respectively, $p = 0.002$). Pancreas fat content fell similarly in responders and non-responders (8.7 ± 0.4 to 7.8 ± 0.4%; $p < 0.0001$ vs. 7.9 ± 0.6 to 7.1 ± 0.4%; $p = 0.004$; $p = 0.25$). First phase insulin secretion increased in responders after weight loss from 0.04[−0.05–0.32] to 0.11 [0.0005–0.51] nmol/min/m^2 ($p < 0.0001$), whereas no change was observed in the non-responders (0.02[−0.07–0.13] to 0.01[−0.04–0.05] nmol/min/m^2; $p = 0.59$).

Conclusion: Failure of restoration of first phase insulin secretion, but not differential lipid or hepatic responses, characterises non-responders. De-differentiation of beta cells in early type 2 diabetes is not reversible in all, despite removal of the metabolic stress. Such individuals are characterised by longer duration of diabetes even in the first 6 years of type 2 diabetes.

Ethnic differences in hepatic and adipose tissue insulin sensitivity in normal glucose tolerant black west African and white European men

O. Bello[1], M. Ladwa[1], C.S. Marathe[1], F. Shojee-Moradie[2], N. Jackson[2], J.L. Peacock[3], A.M. Umpleby[2], S.A. Amiel[1], L.M. Goff[1];
[1]Division of Diabetes & Nutritional Sciences, King's College London, London, [2]Diabetes and Metabolic Medicine, University of Surrey, Guildford, [3]School of Population Health and Environmental Sciences, King's College London, London, UK.

Background and aims: There is a disproportionately high prevalence of type 2 diabetes (T2D) in populations of black ethnicity; greater insulin resistance has been extensively reported however little is known about distinctions in tissue-specific insulin sensitivity. We aimed to explore ethnic differences in insulin sensitivity of peripheral glucose disposal, hepatic glucose output and adipose tissue lipolysis using tracer techniques, in healthy black west African (BWA) and white European (WE) men.

Materials and methods: Twenty-one BWA and 19 WE normal glucose tolerant men underwent a 2-step hyperinsulinemic-euglycemic clamp (insulin dose 10 mU/m^2 BSA/min and 40 mU/m^2 BSA/min) with stable [6,6 $^2H_2$]-glucose and [$^2H_5$]-glycerol isotope infusions. We assessed peripheral glucose disposal as peripheral insulin sensitivity (IS_{PERI}) using the percentage change in rate of glucose disappearance in the high dose insulin infusion, hepatic glucose output as hepatic insulin sensitivity (IS_{HEP}) and adipose tissue lipolysis as adipose tissue insulin sensitivity (IS_{ADI}) using percentage suppression of glucose and glycerol appearance in the low dose insulin infusion, respectively. Participant characteristics and clamp derived measures were assessed for normality and compared using independent samples t-test and Mann Whitney *U* test; data are presented as mean ± SD, geometric mean (95% CI) or median (interquartile range).

Results: Participants were matched for age (BWA 25 (18) *vs* WE 28 (30) years, $p = 0.49$) and BMI (BWA 26.8 ± 3.6 *vs* WE 25.5 ± 4.0 kg/m^2, $p = 0.29$). There were no ethnic differences in waist circumference (BWA 87.5 (83.4, 91.8) *vs* WE 89.3 (84.1, 94.9) cm, $p = 0.57$), body fat percentage (BWA 20.7 ± 6.2 *vs* WE 19.4 ± 6.2%, $p = 0.52$), cholesterol (BWA 4.26 (3.85, 4.73) *vs* WE 4.53 (4.05, 5.05) mmol/l, $p = 0.41$) or fasting glucose (BWA 5.12 ± 0.46 *vs* 5.19 ± 0.41 mmol/l, $p = 0.62$), however fasting triglycerides were significantly lower in BWA men (BWA 0.67 (0.59, 0.77) *vs* WE 0.88 (0.73, 1.05) mmol/l, $p = 0.02$). We observed no ethnic differences in peripheral insulin sensitivity (IS_{PERI}; BWA 324.4 ± 121.6 *vs* WE 350.7 ± 105.3%, $p = 0.56$). However, BWA exhibited significantly lower hepatic (IS_{HEP}; BWA 65.3 (14.0) *vs* WE 75.7 (9.2) %, $p < 0.01$) and adipose tissue insulin sensitivity (IS_{ADI}; BWA 20.4 ± 20.4 *vs* WE 63.7 ± 12.8%, $p < 0.01$) compared to WE.

Conclusion: In this preliminary analysis comparing normal glucose tolerant men of BWA and WE ethnicity, matched for age and whole body adiposity, we have observed ethnic differences in insulin sensitivity of hepatic glucose output and adipose tissue lipolysis despite similar peripheral glucose disposal. Our findings suggest there may be ethnic distinctions in health which may contribute to the pathophysiology of type 2 diabetes by which the BWA population experience greater insulin resistance of the liver and adipose tissue.

PS 032 Novel biomarkers

514

Metabolomics reveal changes in plasma concentrations of 3-hydroxybutyric acid, citric acid, oleic acid and proline in gestational diabetes

N.J. Johansen[1], M. Demant[1], T. Suvitaival[1], K. Trost[1], L. Ahonen[1], L. Bonde[1], J.A. Svare[2], C.L. Quigley[1], T. Vilsbøll[1,3], F.K. Knop[1,3];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]2Department of Gynecology and Obstetrics, Herlev Hospital, [3]Department of Clinical Medicine, University of Copenhagen, Denmark.

Background and aims: The reversible nature of gestational diabetes mellitus (GDM) provides a unique possibility to describe diabetic *vs* normal glucose homeostasis in the same subject. With a target-discovery focus, we applied comprehensive metabolomics to provide a detailed here-and-now fingerprint of the overall metabolic state in pregnant third trimester (TT) women with GDM and normal glucose tolerance (NGT), respectively, and again post-partum (PP).
Materials and methods: Fasting and postprandial (75 minutes from ingestion of a standardised mixed meal) plasma samples obtained from 9 women with GDM (age: 31 ± 6 years; BMI: 31.6 ± 6.4 kg/m^2) and 6 pregnant women with NGT (age: 28 ± 3 years; BMI: 29.7 ± 5.4 kg/m^2) during TT and 3–4 months PP (at which point all women with GDM had re-established NGT) were analysed using two-dimensional gas chromatography with time-of-flight mass spectrometry.
Results: During TT, fasting 3-hydroxybutyric acid and citric acid were elevated in the GDM *vs* NGT group ($p \leq 0.0060$) with normalisation of both metabolites in the GDM group after birth and no between-group differences during PP ($p \geq 0.77$). Fasting malic acid and oleic acid decreased significantly in the GDM group following delivery ($p < 0.010$), but no between-group differences were observed during TT or PP. In the GDM group, postprandial malic acid levels increased PP *vs* TT ($p = 0.030$). We observed a trending higher fasting proline in the GDM group *vs* the NGT group and significant increases in fasting proline in both groups following delivery ($p \leq 0.014$).
Conclusion: Our results provide insights into the effect of pregnancy and GDM on plasma metabolites and suggest that 3-hydroxybutyric acid, citric acid, malic acid, oleic acid and proline may play hitherto underestimated roles in the pathophysiology of GDM.
Disclosure: **N.J. Johansen:** None.

A targeted proteomic profile of prevalent diabetes in a population-based sample

K. Beijer[1], J. Sundström[1], J. Ärnlöv[2], T. Fall[1], E. Ingelsson[3], L. Lind[1];
[1]Medical Sciences, Uppsala University, Uppsala, Sweden, [2]Karolinska Institute, Stockholm, Sweden, [3]Stanford University, Palo Alto, USA.

Background and aims: In genome-wide association studies (GWAS), a great number of genes linked to diabetes have been identified. The aim of the present study, was to investigate if circulating levels of a large number of preselected proteins were associated with diabetes.
Materials and methods: In 2,467 subjects in the population-based EpiHealth study (ages 45–75 years, 50% females), 249 proteins were analyzed by the proximity extension assay (PEA) technique. Diabetes was defined as taking antidiabetic treatment or having a fasting glucose of >7.0 mmol/l. Two thirds of the cohort was used for the discovery analysis, and the rest of the sample was used for validation.
Results: Following adjustment for age, sex, BMI, education, physical activity, smoking and alcohol intake, 68 proteins were significantly related to prevalent diabetes in the discovery analysis using a false discover rate (FDR) of <5%. Twenty-nine of those proteins, could be validated (FDR <5%). The ten top findings were (in descending order); Cathepsin D ($p < 9.56*10^{-6}$), Retinal dehydrogenase 1, Alpha-L-iduronidase, Hydroxyacid oxidase 1, Galectin-4, Growth/differentiation factor 15, Lipoprotein lipase, Interleukin-1 receptor antagonist protein, Cathepsin O, Sialic acid-binding Ig-like lectin 7 ($p = 0.0011$). The 29 proteins represent several physiological pathways.
Conclusion: Using a discovery/validation approach within a population-based sample, 29 proteins were identified as being linked to prevalent diabetes in the cross-sectional setting. These proteins are involved in several physiological pathways. Future prospective studies are needed to investigate the importance of these findings.

516

Linagliptin treatment is associated with improved cobalamin (vitamin B_{12}) storage in mice and potentially in humans

H. Tammen[1], M. Kömhoff[2], M. Mark[3], B. Hocher[4], D. Delic[3], R. Hess[1], M. von Eynatten[5], T. Klein[3];
[1]PXBioVisioN GmbH, Hannover, [2]Department of Pediatrics, University Marburg, Marburg, [3]Boehringer Ingelheim GmbH & Co. KG, Biberach, [4]Institute of Nutritional Sciences, University of Potsdam, Potsdam, [5]Boehringer Ingelheim International GmbH, Ingelheim, Germany.

Background and aims: Linagliptin (LINA) is a dipeptidyl peptidase 4 inhibitor indicated for the treatment of type 2 diabetes (T2D). We utilized specimens from an experimental animal model (5/6 nephrectomized mice) to explain nephron- and cardio-protective effects of LINA. Kidney, heart and liver samples were analyzed using multiplex mass spectrometry methods. The results were validated in human plasma and urine specimens using ELISA assays.
Materials and methods: Analysis of mice tissue samples (kidney $n = 38$, liver $n = 12$, heart $n = 38$) was performed by reversed-phase liquid chromatography coupled with matrix-assisted laser desorption ionisation mass spectrometry. Assessments of methylmalonic acid (MMA), as a marker of cobalamin homeostasis, were performed in human urine and plasma samples using a commercially available competitive ELISA assay.
Results: As expected, LINA was associated with changes in expression and/or lytic processing of proteins and peptides. Surprisingly, LINA treatment resulted in a significant increase in intracellular levels of cobalamin (approx. 5-fold [heart, liver], up to 20-fold [kidney]; all $p < 0.001$, ANOVA). To determine if increased cobalamin storage with LINA treatment may also occur in humans, we measured MMA in patients' plasma ($n = 301$; 150 placebo and 151 LINA) and urine ($n = 245$; 125 placebo and 120 LINA) samples at two timepoints (V3 and V7; 6 months apart) from the previously completed MARLINA-T2D trial (24 weeks' treatment with LINA or placebo in T2D patients with early stage kidney disease). MMA is regarded as a surrogate marker of cobalamin supply and elevated MMA levels are indicative of a functional cobalamin deficit. MMA levels are primarily determined by cobalamin supply, i.e. an intervention with LINA cannot improve the cobalamin status if an insufficient supply is present. In contrast to the standard diet in the animal model applied, cobalamin supply is more prone to variations in humans. Consequently, analysis of measured MMA levels from the clinical study focused on the outcome with LINA at V7 in patients with good cobalamin supply at baseline (i.e. low MMA plasma levels at V3). Our results show: 1) Applying a threshold of 140 nmol/L at V3 (baseline), LINA treatment for 24 weeks was associated with a significant reduction in MMA levels at V7 ($p = 0.02$, $n = 94$, Kruskal-Wallis). 2) In this patient subset we found a strong correlation (Pearson's $r = 0.95$) between MMA levels at V3 and reduced levels of MMA at V7 with LINA. This correlation was evident both in plasma and urine.
Conclusion: Our observations suggest that, in humans, a mechanism congruent to the one in mice potentially exists, indicating that LINA treatment might improve cobalamin homeostasis. This novel treatment effect of LINA could be of particular clinical relevance in patient populations with a higher prevalence of cobalamin deficiency, such as older

patients, Asian patients or patients on metformin. Validation of our findings in larger cohorts over longer treatment periods, alongside assessments of additional biomarkers of the cobalamin status (e.g. transcobalamin II), and quantification of the potential clinical implications, merit further research.

Insulin-like Growth Factor-1 (IGF-1) regulates the levels of serum uric acid through the urate transporters

A. Fuoco, G.C. Mannino, R. Spiga, C. Di Fatta, E. Mancuso, C. Averta, F. Andreozzi, G. Sesti;
Department of Medical and Surgical Sciences, University Magna Graecia of Catanzaro, Catanzaro, Italy.

Background and aims: Increasing evidence suggests that low plasma IGF-1 levels are associated with reduced insulin-sensitivity, obesity, metabolic syndrome, and predict development of both Type2 Diabetes Mellitus and cardiovascular diseases. We have recently demonstrated a significant inverse correlation between plasma levels of IGF-1 and uric acid (UA). Previous studies have reported an association between the polymorphism rs35767G/A, located in the promoter of *IGF-1* gene, and the circulating concentrations of this hormone. In this study, we assessed the association of rs35767 G/A with UA concentration in serum and urine, in a cohort of adult Whites. We also investigated IGF-1 ability to modulate the expression of transporters involved in reabsorption and secretion of UA in the kidney.

Materials and methods: The study group comprised 2794 adult Whites. 24-hour urinary uric acid concentration was available for 229 subjects. rs35767 polymorphism was screened using TaqMan genotyping assays. HEK293 (human embryonic kidney-293) cell line was treated with IGF-1 (1, 5, 10, 50 nM) for 24-hours, and differences in the expression of urate transporters were evaluated via Western Blot and real time rtPCR.

Results: Individuals carrying the IGF-1-raising allele (rs35767T) exhibited significantly lower levels of serum urate according to both additive and recessive models, after correction for gender, age, BMI, glucose tolerance, glomerular filtration rate, and anti-hypertensive treatment. TT genotype carriers displayed higher uricosuria as compared with C allele carriers, after adjusting for confounders. Exposure of HEK293 cells to IGF-1 resulted in a dose-dependent increase ($p < 0.01$) of UA transporters deputed to UA excretion (MRP4, NPT1 and BCRP), and reduction of GLUT9 expression, the major mediator of UA reabsorption, both at mRNA and protein level ($p < 0.05$).

Conclusion: We observed a significant association between the functional polymorphism rs35767 near *IGF-1* with serum urate concentrations and we provide a mechanistic explanation supporting a causal role for IGF-1 in the regulation of UA homeostasis.

Genetic regulation of pigment epithelium-derived factor (PEDF), a multifunctional anti-tumour factor: an exome-chip association analysis in subjects with type 2 diabetes

C.Y.Y. Cheung, P.C.H. Lee, C.S. Tang, A. Xu, C.H.Y. Fong, K.K.K. Ng, K.H.M. Kwok, W.-S. Chow, Y.-C. Woo, M.M.A. Yuen, K.K.B. Tan, T.-H. Lam, H.-F. Tse, P.-C. Sham, K.S.L. Lam;
The University of Hong Kong, Hong Kong, Hong Kong.

Background and aims: Diabetes is associated with an increased risk of cancers. The anti-tumour effects of pigment epithelium-derived factor (PEDF) have been extensively reported. However, the association of circulating PEDF level with cancer remains controversial and little is known of its genetic regulation. No genome-wide or exome-wide association studies on circulating PEDF level have been published to date. This study aimed to identify the genetic determinants influencing circulating PEDF level and evaluate the relationship between circulating PEDF level and cancer in subjects with type 2 diabetes (T2DM).

Materials and methods: An exome-chip association study evaluating the genetic determinants of circulating PEDF level was conducted in 5385 Chinese subjects with T2DM. The discovery stage involved 2936 subjects, followed by a replication analysis in 2449 independent subjects with T2DM who had not been genotyped with the exome-chip. A case-control study was then conducted to examine the relationship between serum PEDF level and history of cancer in 421 cases and 4964 controls within the same cohort.

Results: All genome-wide significant association signals were detected at chromosome 17p13.3, a region which has been implicated in multiple human cancers. The strongest association with circulating PEDF level was detected at a missense variant of *SERPINF1*, the gene which encodes the PEDF protein ($P_{combined} = 2.06 \times 10^{-57}$; β[SE]: −0.33[0.02]). Two missense variants of *SMYD4* ($P_{combined} = 7.56 \times 10^{-25}$; β[SE]: 0.21[0.02]) and *SERPINF2* ($P_{combined} = 8.22 \times 10^{-10}$; β[SE]: −0.15[0.02]) showed novel associations at genome-wide significance. Elevated serum PEDF level was found to be independently associated with history of cancer ($P = 1.35 \times 10^{-3}$; OR[95%CI]: 1.92[1.29–2.87] per ug/ml), after adjustment for age, gender, body mass index and duration of diabetes.

Conclusion: We identified three missense variants of *SERPINF1*, *SMYD4* and *SERPINF2* significantly associated with circulating PEDF level in an exome-chip association study. The observed elevated circulating level of PEDF in T2DM subjects with a history of cancer might represent a counter-regulatory response, or a compensatory mechanism. Our data provided novel insight into the genetic regulation of PEDF. The findings from this study may stimulate further prospective investigations into the use of circulating PEDF level and its associated genetic variants as potential biomarkers for cancer progression and development, especially in individuals with T2DM.

Expression of lymphocytes phenotypic markers in patients with diabetic foot syndrome and healing rate of ulcerative defects

M. Mashkova[1], T. Mokhort[1], V. Goranov[1], L. Chvatova[1], O. Symantovich[1], I. Pukita[2], E. Yurenya[2], A. Shyshko[1];
[1]Belarusian State Medical University, Minsk, [2]City Endocrinology Center, Minsk, Belarus.

Background and aims: to study the relationship between lymphocytes phenotypic markers expression in patients with diabetic foot syndrome (DFS) with a healing rate of ulcerative defect.

Materials and methods: 13 patients with DFS (DFS group) and 13 diabetic patients without foot ulcers (control group) (both groups comparable in age and other clinical and general laboratory characteristics, ongoing treatment, offloading mode) were invoved in the study. All DFS patients had chronic non-infected foot ulcers Wagner 2. Ulcer area was calculated at the first visit and in 8 weeks. Peripheral blood lymphocytes phenotyping was performed in both groups.

Results: Patients with diabetic foot ulcers,in comparison with diabetic controls, had significantly higher percentages of B lymphocytes (CD19+) ($p < 0.05$) and CD4+ T cells ($p < 0.05$), but no significant difference for

CD8+ T cells. Percentage of CD 95+ cells was significantly reduced in DFS group ($p < 0.05$) in comparison with control group (table 1). In correlation analysis significant positive correlation was revealed between CD95+ marker expression and wound healing rate in DFS group ($r = 0.5112$, $p < 0.05$).

Conclusion: Our study shows that the alteration of reparative processes in diabetic ulcers is accompanied by a change in the receptor sensitivity of lymphocytes (CD95), and hence their ability to Fas-mediated apoptosis.

Table 1. – Lymphocyte markers in control DFS and control groups

CD marker	Control group*	DFS group*
CD3+,%	56,2 [55,1-57,8]	74,2 [68,3-80,1]**

PS 033 Inflammation, adipose tissue and obesity: human studies

520

A lower level of intestinal inflammation markers is associated with a higher insulin resistance in patients with morbid obesity

A. Ho Plágaro[1], C. Gutiérrez Repiso[1], C. Santiago Fernández[1], S. García Serrano[2], L. Garrido Sánchez[1], S. Valdés[2], M. Gonzalo[2], G. Alcaín Martínez[1], F. Martín Reyes[1], A. Rodríguez Cañete[2], F. Moreno Ruiz[2], C. Montiel Casado[2], E. García Fuentes[1];
[1]Hospital Universitario Virgen de la Victoria/Instituto de Investigación Biomédica de Málaga (IBIMA), Málaga, [2]Hospital Regional Universitario/Instituto de Investigación Biomédica de Málaga (IBIMA), Málaga, Spain.

Background and aims: Inflammation in different tissues, such as adipose tissue, has been typically associated with the development of metabolic diseases such as obesity and insulin resistance. However little is known about the inflammation at intestinal level. The aim of this study is to evaluate the expression of different inflammatory proteins in duodenal biopsies from morbidly obese subjects and its relationships with insulin resistance.

Materials and methods: The study was undertaken in 40 morbidly obese subjects and in 12 non-obese non-diabetic control subjects. Morbidly obese subjects were classified in subjects with low homeostasis model assessment of insulin resistance (HOMA-IR) value (MO-low-IR), subjects with high HOMA-IR value (MO-high-IR) (both groups without treatment for T2D) and subjects with T2D who were only receiving metformin treatment (MO-metf-T2D). A duodenum biopsy was collected by endoscopy in both morbidly obese subjects and control subjects, and inflammatory protein levels were analyzed by ProcartaPlex Immunoassays.

Results: In the control group we found a lower level of IL-2, IL-4, IL-6, IL-9, IL-13, IL-18 and IL-27 with respect to MO-low-IR group ($p < 0.05$, respectively), a lower level of IL-4 and IL-9 with respect to MO-high-IR group ($p < 0.05$, respectively), and a lower level of IL-4, IL-9 and IL-18 with respect to MO-metf-T2D group ($p < 0.05$, respectively). In the MO-low-IR group we found a higher level of IL-4, IL-6, IL-13 and IL-27 with respect to MO-high-IR group ($p < 0.05$, respectively), and a higher level of IL-13 with respect to MO-metf-T2D group ($p < 0.05$). No significant differences were found between MO-high-IR and MO-metf-T2D group.

Conclusion: Morbidly obese subjects have higher levels of pro/anti-inflammatory cytokines than control subjects. MO-high-IR group has lower levels of cytokines related to Th1 and Th2 responses than MO-low-IR.

Omentin-induced secretion of proteins by primary human adipocytes and stimulation of the innate immune system

C. Niersmann[1,2], S.M. Hauck[2,3], J.M. Kannenberg[1,2], K. Röhrig[1,2], C. von Toerne[3], M. Roden[1,4], C. Herder[1,2], M. Carstensen-Kirberg[1,2];
[1]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University Düsseldorf, Düsseldorf, [2]German Center for Diabetes Research, München-Neuherberg, [3]Research Unit Protein Science, Helmoltz Zentrum München, German Research Center for Environmental Health, München-Neuherberg, [4]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University Düsseldorf, Düsseldorf, Germany.

Background and aims: Omentin was initially identified as anti-inflammatory adipokine with insulin-sensitizing and atheroprotective

properties. In contrast, we recently found that omentin induces the release of 29 pro-inflammatory chemokines and cytokines in primary human adipocytes which might be mediated by the activation of the inflammatory NFκB, p38 and ERK pathways. However, details on the underlying mechanism of omentin are currently unclear. Therefore, the proposed project aimed to investigate the impact of omentin on the secretion of proteins by primary human adipocytes and based on these results to identify the signaling pathways in which the omentin-regulated proteins are overrepresented.

Materials and methods: Primary human adipocytes from five non-diabetic donors were treated without or with 500 ng/ml or 2000 ng/ml omentin for 24h. The secretome of adipocytes was analyzed using LC-MSMS-based proteomics analysis. Differences in protein secretion between omentin-treated and untreated human adipocytes were assessed using the paired t-test. In addition, we analyzed the overrepresentation of proteins that were regulated by 2000 ng/ml omentin in canonical pathways using the Ingenuity Pathway Analysis software.

Results: In the supernatants of the adipocytes 3493 proteins were detectable. Of these proteins, 140 proteins were differentially regulated by both omentin concentrations compared to untreated adipocytes ($p < 0.05$). Omentin-regulated proteins were overrepresented in seven canonical pathways ($p < 0.05$). These signaling pathways include the complement system (e.g. C3: +215%, C1R: +70%), the inhibition of matrix metalloproteases (e.g. MMP2: +78%, TIMP1: +166%) and the acute phase response signaling (e.g. CFB: +3423%, SERPINA3 + 140%) ($p < 0.001$). Most of the potential upstream regulators are pro-inflammatory cytokines (e.g. IL-1β, TNF, IFNγ) (all $p < 0.05$) that are involved in various immune responses and inflammatory processes. Another group of potential activators are complexes of inflammatory pathways (e.g. NFκB) ($p < 0.001$). TNFAIP6 is the most regulated protein (+13940%) ($p < 0.01$) and is known as negative regulator of inflammatory processes.

Conclusion: Our findings suggest that omentin regulates the release of proteins by human adipocytes via processes that are involved in the innate immune system. Thereby, our data give evidence for the activation of the inflammatory NFκB signaling pathway. The upregulation of TNFAIP6 might represent an endogenous counterregulation of the pro-inflammatory effects of omentin in human adipocytes.

The impact of inflammation on alternative splicing at PPARG locus in hypertrophic obesity

S. Cataldi[1], M. Aprile[1], P. Italiani[2], A. Ciccodicola[1], V. Costa[1];
[1]Institute of Genetics and Biophysics "A. Buzzati-Traverso" (IGB-CNR), National Research Council, Naples, [2]Institute of Protein Biochemistry (IBP-CNR), National Research Council, Naples, Italy.

Background and aims: PPARγ is the master transcription factor controlling the adipocyte differentiation. Moreover, it regulates the expression of genes responsible of lipid metabolism, glucose and insulin homeostasis. During hypertrophic obesity, characterized by chronic inflammation, the overall expression and activity of PPARγ is compromised in adipose tissue determining defective adipogenesis and insulin resistance. Interestingly, our group identified dominant negative PPARγ isoforms (DNIs), highly expressed in human and mouse adipose tissue and able to affect PPARγ target genes involved in lipid and glucose homeostasis. Here we aim to analyze the impact of inflammation and the expression of PPARγ canonical and DNIs in hypetrophic adipocytes *in vitro* model.

Materials and methods: h*TERT*-immortalized adipose-derived mesenchymal stem cells (AdMSCs) were used as *in vitro* model of adipocyte differentiation. AdMSCs were treated with two differentiation mix containing insulin, rosiglitazone and other adipogenic *stimuli* for 20 days. Then, different experimental conditions (e.g. prolonged differentiation time and free fatty acid mix) were used to induce hypertrophy in mature adipocytes. Lipid accumulation was evaluated by Oil red O staining and densitometric measurement. Undifferentiated AdMSCs were treated for 24hrs with conditioned media of human monocyte-derived macrophages (LPS-stimulated), hypertrophic adipocytes, human cancer cell lines (including MCF7 and MDA) and human recombinant proteins of proinflammatory cytokines and chemokines. Expression analyses were performed by qPCRs and data were reported as mean values of at least three biological replicates and analyzed by paired Student t test. *P* value <0.05 was considered statistically significant.

Results: Human hypertrophic adipocytes generated *in vitro* from AdMSCs showed a significant increase of lipid droplet size and lipid accumulation compared to terminally differentiated mature adipocytes. The expression of PPARγ-target genes, including *GLUT4*, *IRS2* and *ADIPOQ*, was significantly impaired in hypertrophic cells *vs* mature adipocytes. Notably, these cells showed an increased expression ratio of DNIs/canonical isoforms compared to mature ones. Furthermore, we assessed the effects of several pro-inflammatory *stimuli* on undifferentiated AdMSCs - including conditioned media of human macrophages, hypertrophic adipocytes and cancer cell lines, as well as human recombinant cytokines and chemokines (e.g. IL8, TNFα, IL1β, IL6) - detecting an increased ratio of DNIs/canonical isoforms, similarly to hypertrophic adipocytes. These results suggest that inflammatory *milieu* in hypertrophic adipose tissue could alter the relative expression of canonical and dominant negative PPARγ isoforms, in turn compromising adipocyte differentiation and insulin-sensitivity.

Conclusion: For the first time we report the expression of PPARγ DNIs in hypertrophic adipocytes. Our data reveal a significant shift of DNIs/canonical PPARγ levels in these cells and a concomitant reduced expression of PPARγ-target genes, in line with the global impairment of PPARγ activity in the obese state. Additionally, our data suggest that this alteration is due to pro-inflammatory *stimuli* and cells which are hallmark of insulin-resistant adipose tissue in hypertrophic obesity.

Disclosure: **S. Cataldi:** None.

Resistin inhibits neuronal autophagy through Toll Like Receptor (TLR) 4

Y. Benomar, J. Miao, S. Al Rifai, G. Poizat, L. Riffault, D. Crepin, M. Taouis;
Molecular Neuroendocrinology of food intake, Paris-Saclay Institute of Neuroscience UMR9197, University Paris Sud, Orsay, France.

Background and aims: Autophagy is known to play a crucial role in the maintenance of cellular energy homeostasis and was identified as a non-selective degradation pathway induced when cells are energy-deprived. Autophagy also occurs in non-starved cells by participating in cellular inflammatory responses through mainly eliminating injured and aged mitochondria that constitute an important source of reactive oxygen species implicated in cellular inflammation. We have previously reported that resistin, through the activation of hypothalamic TLR4 receptor, induces whole body insulin resistance and promotes neuronal inflammation, but however, whether a link exists between resistin and autophagy in neurons is unknown. In the present study, we hypothesized that resistin-induced neuroinflammation could be attributed, at least partially, to a defect or deregulation of autophagy process in neuronal cells.

Materials and methods: Using human neuroblastoma cell line SH-SY5Y cells, we analysed the impact of serum deprivation and resistin treatment, for different period of times, on key cellular markers of autophagy, including ATG7, Beclin1, LC3I/II and p62, this was assessed by immunohistochemistry, western blotting and RTqPCR analyses. The role of TLR4 on neuronal autophagy induced by resistin, was also assessed in TLR4-depleted SH-SY5Y cells. Additionally, resistin-dependent neuronal autophagy was evaluated in vivo, in the hypothalami of wild type and TLR4 knockout mice treated with or without resistin through ICV route.

Results: As expected, we show that serum-starvation increases autophagy in human SH-SY5Y neuroblastoma cell line as evidenced by increased expression of LC31/II and ATG7 and downregulation of p62 considered as key autophagy markers. Interestingly, we report that resistin inhibits starvation-induced neuronal autophagy, and this effect is exacerbated in the presence of NH4Cl, an inhibitor of autosomal degradation. Using siTLR4 approach, we also demonstrate that resistin impairs autophagy through TLR4. Furthermore, we decipher the signaling pathways involved in resistin action and demonstrate that resistin inhibits AMPK phosphorylation and increases Akt/mTOR phosphorylation contrasting with autophagy impact on these signalling pathways. Finally, we validated the impact of resistin in mice and showed, in the hypothalamus, that the inhibitory effect of resistin towards autophagy markers is completely abolished in TLR4 knockout mice.
Conclusion: Altogether, these findings reveal resisitn/TLR4 as a new regulatory pathway of neuronal autophagy and contribute to the understanding of the underlying mechanisms involved in the impairment of neuronal autophagy.

Obesity is associated with a more inflammatory phenotype of macrophages in human pancreatic islets

W. He, K. Maedler;
University of Bremen, Bremen, Germany.

Background and aims: Obesity is a major risk factor for the development of type 2 diabetes (T2D). A chronic, low-grade, sterile inflammation is present in obesity; tissue macrophages contribute to such inflammation, leading to persistent insulin resistance and β-cell failure. Changes in macrophage polarization are tightly associated to macrophage function and are involved in many diseases. In this current research, we aimed to characterize potential obesity-related changes in macrophage polarization markers in human pancreatic islets.
Materials and methods: To establish the relationship between obesity and islet macrophage markers, expression of macrophage polarization markers *ITGAX (CD11c)*, *NOS2 (iNOS)* and *IL1b* as M1 macrophage-associated genes, *CD163*, *IL10* and *TGFb* as M2 macrophage-associated genes and *CD68* as general macrophage marker was analyzed by qRT-PCR in isolated human pancreatic islets from obese (BMI >30) and non-obese (BMI <30) donors as well as in human islets following depletion of islet resident macrophages by treatment of clodronate liposomes.
Results: Islets from obese donors expressed significantly more *NOS2* (2.7-fold) than from non-obese donors, while general macrophage marker *CD68* and M2 macrophage markers *CD163* and *IL10* were not significantly changed between obese and non-obese donors. After depletion of islet resident macrophages by clodronate treatment, expression of *ITGAX*, *IL1b*, *IL10* and *CD163* was mostly deprived in human islets, indicating macrophage-dependency of these genes. In contrast, *TGFb* expression was unchanged, suggesting a macrophage-independent source in human islets. *NOS2*expression was not affected by clodronate treatment in islets from non-obese donors, but reduced in islets from obese donors, which suggests an obesity-induced iNOS expression in macrophages of human islets.
Conclusion: Our results indicate that CD11c, IL-1β, IL-10 and CD163 in human islets are associated with islet macrophages. The increased islet macrophage *NOS2* expression in obese individuals suggests that obesity is associated with a switch to an M1-like inflammatory phenotype in islet macrophages, which may further contribute to obesity-induced islet inflammation and finally β-cell failure.

Human obesity alters circadian clock function through NF-κB activation

E. Maury[1], L. Noel[1], B. Navez[2], S.M. Brichard[1];
[1]Endocrinology, Diabetes and Nutrition Unit, Institute of Experimental and Clinical Research, Faculty of Medicine, Catholic University of Louvain, Brussels, [2]Digestive Surgery Unit, Medical Sector, Catholic University of Louvain, Brussels, Belgium.

Background and aims: Nutritional environment affects the transcription-translation feedback oscillators of the circadian clock that maintain metabolic homeostasis. These loops are composed of activators (BMAL1 and CLOCK) that induce the transcription of repressors, the most important being PERIOD 2 (PER2). PER2 inhibits the forward limb and this process generates a rhythm of ~24 hr. Experimental genetic models have provided evidence that many complications of obesity are mediated through metabolic inflammation induced by activation of the transcription factor NF-κB. Here, we investigated the link between clock disruption and NF-κB mediated inflammation in human obesity.
Materials and methods: Human omental adipose tissue was obtained from 5 obese and 5 non-obese age-matched patients (body mass index: ~50 *vs.* 25 kg/m^2) undergoing abdominal surgery. Using fluorescence-activated cell sorting analysis, omental preadipocytes obtained from the stromal vascular fractions were identified as PDGFRα$^+$, CD31$^-$, CD45$^-$ cells. Preadipocytes were infected with *Per2-dLuciferase*-expressing lentivirus (a rapidly-degradable form of luciferase driven by the *Per2* gene promoter), synchronized and bioluminescence was recorded continuously for 5–7 days. Binding of the p65 subunit of NF-κB and BMAL1 to *PER2* promoter was measured by chromatin immunoprecipitation (ChIP). ChIP of RNA polymerase II was also performed to explore the rhythms in nascent transcription. Additionally, ChIP were conducted on *CCL2*, a chemokine involved in the pathogenesis of type 2 diabetes. In some experiments, NF-κB inhibition was achieved either by pharmacological or gene silencing approaches, restoring NF-κB activity of obese subjects to a non-obese state.
Results: By measuring *Per2-dLuciferase* bioluminescence, we described endogenous cell-autonomous human adipose tissue oscillators, independently of food intake and nutrient signals. We found a period lengthening of *Per2-dLuciferase* oscillations in obese preadipocytes (23.33 ± 0.11 hr *vs.* 22.53 ± 0.27 hr, $p < 0.05$), reflecting an altered function of the molecular clock. ChIP assays revealed that p65 binding to *PER2* is enhanced by almost 10 times in obese preadipocytes ($p < 0.05$) while binding of BMAL1 and RNA polymerase II are significantly decreased ($p < 0.05$) consistently with the reduced *PER2* expression observed. Increased NF-κB activity was also associated with altered BMAL1 occupancy on *CCL2* promoter and a ~10 fold increased recruitment of RNA polymerase II ($p < 0.05$), consistently with increased CCL2 expression and secretion. NF-κB inhibition in obese preadipocytes restored BMAL1 binding and clock function to a non-obese level.
Conclusion: Collectively, our findings demonstrate that obesity alters clock function through NF-κB signaling in human omental adipose tissue. Our results suggest that the disruption of these oscillators in obesity leads to abnormal chemokine production and may contribute to metabolic disorders.

Complement C3 and C4, but not their regulators or activated products, are associated with metabolic syndrome: the CODAM study

Y. Xin, E. Hertle, C.J.H. van der Kallen, C.G. Schalkwijk, C.D.A. Stehouwer, M.M.J. van Greevenbroek;
Internal Medicine, Maastricht University Medical Centre and CARIM School for Cardiovascular Diseases, Maastricht, Netherlands.

Background and aims: Metabolic syndrome is identified as a precursor for advanced metabolic diseases, such as type 2 diabetes and cardiovascular disease. Obesity is one of the initial events in the pathological processes that define metabolic syndrome. Plasma complement concentrations are higher in people with obesity and may contribute to adipose tissue dysfunction and development of the metabolic syndrome. We investigated the associations of components of the alternative (C3, C3a, Bb, factor D [FD], factor H [FH], properdin], and the classical complement pathways (C4, C1q, C1-inhibitor [C1-INH]) with prevalent and incident metabolic syndrome in a cohort with moderately increased risk of cardiometabolic disease.
Materials and methods: The study cohort comprised 574 participants (61% men, age 59.6 ± 7.0 years) at baseline and 489 participants after 7-year follow-up. Linear regression models were used to evaluate the associations between complement concentrations and metabolic syndrome components (i.e. triglycerides, HDL-cholesterol, glucose, systolic and diastolic blood pressure, waist circumference) at baseline. Multiple logistic regression analyses were used to investigate associations of baseline plasma complement concentrations (standardized values) with (1) prevalent metabolic syndrome, and (2) incident metabolic syndrome in those without metabolic syndrome at baseline (n = 189). Additional analyses were done to investigate the possible driver(s) and underlying mechanisms of the prospective associations.
Results: In linear regression analyses, all complement factors, except for factor Bb, were significantly, and in an adverse direction, associated with one or more individual components of metabolic syndrome. In logistic regression analyses, C3 was higher in those with metabolic syndrome compared to those without (odds ratio (OR) = 3.60 [95% confidence interval: 2.73; 4.75]). Similar associations were observed for C3a (OR = 1.25 [1.03; 1.52]), FH (OR = 2.93 [2.24; 3.83]), properdin (OR = 1.88 [1.50; 2.34]), and C4 (OR = 1.39 [1.13; 1.69]), but not for Bb, C1q or C1-INH. Only C3 (OR = 1.48 [1.02; 2.14]) and C4 (OR = 1.95 [1.32; 2.88]) were associated with incident metabolic syndrome (n = 40 cases). After additional adjustment for baseline levels of components of the metabolic syndrome, this prospective association was substantially attenuated for C3, but not for C4.
Conclusion: Our results show significant cross-sectional associations of several complement components with the prevalence of metabolic syndrome. Among those, only C3 and C4 were found to be involved in the development of metabolic syndrome, potentially via different underlying mechanisms. Further studies are needed to better understand the etiological pathways that underlie the relationship between complement and the metabolic syndrome.

Circulating WISP1/CCN4 is associated with body fat distribution and adipose tissue dysfunction in subjects with type 2 diabetes

V.V. Klimontov[1], D.M. Bulumbaeva[1], A.P. Lykov[1], O.N. Fazullina[1], N.P. Bgatova[1], A.F.H. Pfeiffer[2,3], O. Pivovarova[2,4], N. Rudovich[2,5];
[1]Research Institute of Clinical and Experimental Lymphology – Branch of the Institute of Cytology and Genetics, Novosibirsk, Russian Federation, [2]German Center for Diabetes Research (ZDZ), Muenchen-Neuherberg, Germany, [3]Charité University Medicine, Berlin, Germany, [4]German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, Germany, [5]Spital Bülach, Bülach, Switzerland.

Background and aims: Wnt1-inducible signaling pathway protein 1 (WISP1), also known as CCN4, is a member of the CCN family of secreted, extracellular matrix associated signaling proteins. Recently WISP1 was validated as a novel adipokine that may play a role in linking obesity to inflammation and insulin resistance. The data on WISP1 in diabetes are scarce. The aim of our study was to assess the relationships between the circulating WISP1 and the levels of other adipokines, inflammatory markers, fat mass and body fat distribution, and parameters of glycemic control in type 2 diabetic subjects.
Materials and methods: We observed 156 patients, 45 M/111 F, from 41 to 80 years of age (median 61 years), including 102 subjects with obesity. Twenty four non-obese non-diabetic subjects, matched by age and sex, were acted as control. The levels of WISP1, high-sensitivity C-reactive protein (hsCRP), alpha1-acid glycoprotein, and macrophage inflammatory protein 1alpha (MIP-1alpha) were measured in the fasting serum by ELISA. Serum concentrations of leptin, resistin, visfatin, adipsin, adiponectin, IL-6, IL-8, IL-18 and TNF-alpha were determined by Multiplex analysis. The fat mass and distribution was assessed by DEXA. Glucose variability (GV) parameters: Mean Amplitude of Glucose Excursions, Continuous Overlapping Net Glycemic Action, High Blood Glucose Index, and Low Blood Glucose Index were derived from continuous glucose monitoring. The mean diameter of adipocytes was estimated in the samples of subcutaneous adipose tissue in 25 patients.
Results: Patients with diabetes, as compared to control, had significantly higher levels of WISP1 (p = 0.02), leptin (p = 0.005), resistin (p < 0.0001), adipsin (p < 0.0001), visfatin (p = 0.0003), hsCRP (p < 0.0001), AGP (p < 0.0001), MIP-1alpha (p = 0.006) and IL-6 (p = 0.01). Other investigated molecules did not shown significant differences. Serum WISP1 levels demonstrated positive correlation with percentage of fat mass in central abdominal area (r = 0.46, p < 0.001). No associations with BMI, total fat mass and mean adipocyte diameter were found. The concentrations of WISP1 demonstrated positive correlations with resistin, visfatin and MIP-1alpha levels (r = 0.36, r = 0.28 and r = 0.47 respectively, all p < 0.01), but it did not correlated with other inflammatory markers, HbA1c and estimated GV parameters. In a multiple regression analysis percentage of fat mass in central abdominal area was the only reliable predictor of serum WISP1 levels (beta = 0.393, p = 0.04).
Conclusion: In subjects with type 2 diabetes serum levels of circulating WISP1 are associated with body fat distribution and adipose tissue dysfunction. The relationships between WISP1 and inflammation need further investigations.

Genetic deletion of RAGE in db/db mice interferes in the liver with other AGE-receptors and AGE-detoxifying systems sustaining lipogenesis and inflammation

R. Mastrocola[1,2], A.S. Cento[1], D. Collotta[3], F. Chiazza[3], F. Barutta[4], J. Scheijen[2], M. Aragno[1], K. Gaens[2,5], M. Collino[3], C.G. Schalkwijk[2,5], K. Wouters[2];
[1]Dept. of Clinical and Biological Sciences, University of Turin, Turin, Italy, [2]Dept. of Internal Medicine, University of Maastricht, Maastricht, Netherlands, [3]Dept. of Drug Science and Technology, University of Turin, Turin, Italy, [4]Dept. of Medical Sciences, University of Turin, Turin, Italy, [5]CARIM School for Cardiovascular Diseases, University of Maastricht, Maastricht, Netherlands.

Background and aims: Advanced glycation end products (AGEs) are toxic compounds involved in the onset of insulin resistance in obesity. In particular, AGEs are preferentially trapped by adipose tissue through the binding with the AGE-receptor RAGE, leading to the activation of proinflammatory signalling in adipocytes that can interfere with peripheral insulin sensitivity. The genetically-induced deletion of RAGE in leptin receptor deleted (db/db) mice, a model of type 2 diabetes/obesity, is reported to prevent AGEs trapping in adipocytes, paralleled by increased circulating levels of AGEs, and reduced adipose tissue inflammation and insulin resistance. Since this might increase the exposition to AGEs of highly perfused organs, such as the liver, we aimed to analyze whether the deletion of RAGE affected hepatic AGEs accumulation and detoxification in the liver of obese/diabetic animals.
Materials and methods: At 13 weeks of age, wild-type C57, db/db and db/db RAGE-/- mice were sacrificed, plasma was collected and liver was removed. Gene and protein expression of AGEs receptors and detoxifying systems were analyzed in parallel to hepatic AGEs content, activation of lipogenesis, and markers of inflammation.
Results: The deletion of RAGE in the liver of db/db mice was associated with decreased expression of AGE-receptor-1 ($P < 0.05$ vs. db/db) and reduced expression and activity of glyoxalase-1 ($P < 0.01$ vs. db/db), two major AGEs detoxifying systems, and increased galectin-3 expression ($P < 0.05$ vs. db/db), another AGEs-receptor. The latter may be a compensatory response to remove plasma AGEs. Thus, despite the lacking of RAGE, high levels of intrahepatic AGEs were maintained in db/db RAGE-/- mice, due to either the trapping exerted by galectin-3 and/or the reduced potential of detoxifying systems. These alterations were also associated to persistent activation of the SREBP1c lipogenic pathway ($P < 0.001$ vs. C57), and the proinflammatory NLRP3 signaling pathway ($P < 0.05$ vs. C57), that were not prevented by RAGE deletion compared to db/db mice.
Conclusion: RAGE deletion in the liver of an animal model of type 2 diabetes influences other AGE-receptors and AGE-detoxifying systems. In particular, the increase in galectin-3 in db/db RAGE-/- mice liver might be responsible for the sustained hepatosteatosis and inflammation. This complex mechanism of control should be taken into account when investigating on the pathogenic contribution of AGEs to hepatic obesity/diabetes complications.

Constitutive Androstane Receptor deficiency leads to sexually dimorphic metabolic disorders in aging

C. Lukowicz[1], M. Régnier[1], F. Lasserre[1], A. Polizzi[1], A. Montagner[2], S. Smati[1], Y. Lippi[1], F. Lenfant[1], V. Theodorou[1], L. Gamet-Payrastre[1], S. Ellero-Simatos[1], P. Gourdy[2], N. Loiseau[1], H. Guillou[1], L. Mselli-Lakhal[1];
[1]INRA ToxAlim, Toulouse, [2]INSERM I2MC, Toulouse, France.

Background and aims: The Constitutive Androstane Receptor (CAR or NR1I3) is a key transcription factor regulating the expression of xenobiotic metabolizing enzymes. It is highly active in the liver and plays an important role in the protection of the organism against exogenous but also endogenous toxic molecules such as bile acid and bilirubin. It is also involved in the catabolism of thyroid and steroid hormones. Therefore CAR contributes both to detoxication and to the energy homeostasis. Its contribution to the regulation of metabolism remains misunderstood and has been mostly studied in males. However many aspects of liver function are gender-dependent. In this work, we aimed at investigating whether sex-steroid hormones may influence CAR-dependent signaling.
Materials and methods: We followed male and female C57BL6/J (WT) or CAR knockout mice (CAR-/-) fed with a standard chow diet for 16 months and assessed different metabolic parameters such as body weight, glucose and insulin tolerance over 1 year. We collected the livers and other tissue samples and analyzed them through biochemical, histological, and transcriptomic approaches.
Results: CAR-/- males become obese in aging (body weight gain +11.02 g compared to WT). This obesity is associated with a glucose and insulin intolerance as well as hyperglycemia and hyperinsulinemia. CAR-/- males also develop a dyslipidemia and an important steatosis, with significant hepatocyte cytolysis. CAR -/- females show a different metabolic profile with a slight overweight, a better glucose tolerance and no dyslipidemia and no steatosis. Liver transcriptomic analyzes performed in both gender revealed a sexually dimorphic profile of CAR-dependent functions with distinct regulation of gene involved in steroid hormone catabolism between male and female CAR-/- (*Cyp17a1*, *Cyp21a1*, *Srd5a1*, *Srd5a3*). Ovariectomy of female CAR-/- mice led them to develop the same metabolic disorders as observed in males, namely obesity, glucose intolerance, fasted hyperglycemia and hepatic steatosis.
Conclusion: This study highlights a gender-dependent impact of CAR on metabolism. The absence of CAR promotes metabolic disorders in males, potentially due to high levels of corticosterone. In contrast, females are protected from these diseases through a process requiring sexual steroid hormones. This protective mechanism offers interesting possibilities for the treatment of metabolic syndrome.

Inhibition of MG53 E3 ligase activity as a possible new target in the treatment of type 2 diabetes

J. Reinke[1], T. Sadowski[2], K. Breitschopf[3];
[1]R&D Diabetes Division, GI Endocrinology & Obesity, Sanofi-Aventis Deutschland GmbH, Frankfurt, [2]R&D Diabetes Division, Comorbidities and Complications, Sanofi-Aventis Deutschland GmbH, Frankfurt, [3]Global Research Project Management, Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany.

Background and aims: Mitsugumin 53 (MG53) belongs to the muscle-specific tripartite motif-containing (TRIM) family and is also known as TRIM72. In mice MG53 is expressed in skeletal muscle and heart, and plays a dual role as an E3 ligase and as a cellular membrane repair protein. The E3 ligase function of MG53 was proposed to target both insulin receptor (IR) and insulin receptor substrate 1 (IRS1) for ubiquitin-dependent degradation. MG53 deficiency protects mice against high fat diet (HFD)-induced metabolic syndrome, but also leads to progressive skeletal myopathy. The aim of this study were to develop a better understanding of the MG53 ligase function in the setting of T2D, and to demonstrate that selectively inhibiting the ligase activity of MG53 is appropriate for developing insulin sensitizing anti-diabetic drugs.

Materials and methods: To address our aims, we generated a transgenic mouse carrying a C14S substitution in the MG53 gene (MG53-KI mouse). This mutation has been described to specifically inactivate the E3 ligase function, while all other functions of MG53 are maintained. Investigation and characterization of the MG53-KI mice compared to their littermate-control wildtype mice (WT) under chow (ND) and high fat diet (HFD) conditions, including gene and protein expression (qRT-PCR, western blot), ipGTT and insulin signaling pathway analysis, were performed.
Results: Mice specifically lacking MG53 ligase function (MG53-KI) and WT mice showed the same *TRIM72* mRNA expression level in skeletal muscle. However, MG53 relative protein expression was, independent of the diet, reduced by more than 95% (ND: WT ($n = 5$) vs. MG53-KI ($n = 6$), $p < 0.001$; HFD: WT ($n = 6$) vs. MG53-KI ($n = 7$), $p < 0.001$) in MG53-KI mice compared to WT mice. Body weight and body composition analysis performed after MG53-KI and WT mice were placed for 22 weeks on ND or HFD exhibited no differences. An ipGTT performed in WT or MG53-KI mice placed on HFD for 10 weeks revealed a slightly decreased glucose tolerance in MG53-KI animals (Glucose AUC: WT ($n = 6$) vs. MG53-KI ($n = 7$), $p < 0.05$). Insulin signaling pathway activity in skeletal muscle was not altered as shown by similar AKT and GSK-3 α/β phosphorylation.
Conclusion: The newly generated MG53-KI mouse showed normal *TRIM72* mRNA expression level, but resembled the MG53 KO mouse in respect to MG53 protein expression. However, published data demonstrating that MG53 deficiency protects mice against HFD-induced metabolic syndrome was not reproduced. Our data does not support a role for MG53 on metabolic parameters in the setting of T2D. The reason for reduced MG53 protein levels in the MG53-KI mouse is currently unknown and requires further study.

Interindividual susceptibility to type 2 diabetes in mice: hepatic transcriptome and DNA methylome profiling

S. Saussenthaler[1,2], M. Ouni[1,2], M. Jähnert[1,2], P. Huypens[2,3], J. Beckers[2,3], A. Schürmann[1,2];
[1]German Institute of Human Nutrition (DIfE), Potsdam-Rehbrücke, [2]German Center for Diabetes Research (DZD), Neuherberg, [3]Helmholtz Center Munich (HMGU), Neuherberg, Germany.

Background and aims: The development of type 2 diabetes (T2D) is driven by genetic as well as life style factors. However, genetically identical mice maintained on a high-fat diet exhibit a broad variation in T2D onset. The aim of this study was to identify perturbations in the hepatic transcriptome and DNA methylome prior to the onset of T2D and to examine whether these DNA methylation differences are sufficient for the prediction of the disease.
Materials and methods: Female New Zealand Obese mice were classified into diabetes-resistant (DR) and diabetes-prone (DP) cohorts based on their liver fat content combined with early blood glucose concentrations at 10 weeks of age. This prediction allowed the isolation of metabolically relevant tissues, including the liver, several weeks before T2D onset. Liver transcriptome and DNA methylome were analyzed using RNA sequencing and whole genome bisulfite sequencing, respectively ($n = 6$ per group). Pathway enrichment analysis was conducted with DAVID 6.7 in order to determine biological processes and signaling pathways that are dysregulated prior to the manifestation of T2D.
Results: Liver transcriptome analysis uncovered 1372 differentially expressed transcripts ($p < 0.05$; FPKM >1) between DR and DP mice. These transcripts were enriched in metabolic processes, such as fatty acid metabolism and citrate cycle. Additionally, whole genome bisulfite sequencing led to the identification of 455,782 differentially methylated CpG sites between both groups ($p < 0.05$; minimal 24 read counts per group). The integration of both datasets as well as implementation of stringent filtering criteria including significant Pearson correlation of CpG methylation and corresponding mRNA expression ($p < 0.05$) led to the identification of 151 CpG sites that are highly conserved between mouse and human and related to 112 transcripts. Identified transcripts showed significant enrichment in insulin, VEGF and mTOR signaling as the most relevant hepatic alterations preceding T2D.
Conclusion: In the liver, several genes involved in insulin, VEGF and mTOR signaling are affected by DNA methylation. Additionally, the most promising candidates will be analyzed in blood cells in order to evaluate them as T2D biomarker in humans.

Two immune-related GTPases prevent from hepatic fat accumulation by inducing autophagy

K. Schwerbel[1,2], A. Kamitz[1,2], M. Jähnert[1,2], P. Gottmann[1,2], F. Schumacher[3], B. Kleuser[3], T. Haltenhof[4], F. Heyd[4], M. Roden[5,2], A. Chadt[5,2], H. Al-Hasani[5,2], W. Jonas[1,2], H. Vogel[1,2], A. Schürmann[1,2];
[1]German Institute of Human Nutrition (DIfE), Potsdam-Rehbrücke, [2]German Center for Diabetes Research (DZD), Neuherberg, [3]University of Potsdam, Potsdam, [4]Freie Universität Berlin, Berlin, [5]German Diabetes Center (DDZ), Düsseldorf, Germany.

Background and aims: The cause of non-alcoholic fatty liver disease (NAFLD) is multifactorial including genetic and environmental factors. However, the genetic basis of this disease still remains incompletely defined. In a backcross population of New Zealand obese (NZO) and C57BL/6J (B6) mice, a major quantitative trait locus (QTL) designated *Ltg/NZO* for increased liver triglycerides was identified on chromosome 18. Two genes coding for immune-related GTPases appear to be the most likely genes responsible for the effect of *Ltg/NZO*. The aim of the study was to characterize the role and function of both GTPases.
Materials and methods: Recombinant congenic mice carrying 5.3 Mbp of *Ltg/NZO* were fed a high-fat diet and metabolically characterized in respect to their hepatic insulin sensitivity, autophagic capacity and lipid profile. Bioinformatics analysis and Electrophoretic Mobility Shift Assay (EMSA) were performed to elucidate the genetic cause for the differential expression pattern.
Results: NZO-allele carriers ($Ltg/NZO^{N/N}$) showed 2-fold higher liver triglyceride concentration than B6-allele carriers ($Ltg/NZO^{N/B}$) due to a reduced induction of autophagy in the liver. Furthermore, $Ltg/NZO^{N/N}$ revealed impaired hepatic insulin sensitivity in line with higher diacylglycerol levels. Haplotype mapping and expression studies identified two immune-related GTPases, *Ifgga2 and Ifgga4*, as most likely candidates of *Ltg/NZO*. Expression of *Ifgga2* and *Ifgga4* was lower in livers of $Ltg/NZO^{N/N}$ compared to $Ltg/NZO^{N/B}$ mice by 5.6-fold and 16.4-fold, respectively. An active enhancer element which harbors a FOXO1-binding motif is located upstream of both genes. $Ltg/NZO^{N/N}$ mice carry a one base pair deletion next to the FOXO1-binding motif. EMSA analysis indicates that this deletion is responsible for the reduced expression of both GTPases. Moreover, the human orthologue *IRGM* was significantly lower expressed in the liver of NAFLD patients compared to that of lean subjects.
Conclusion: A sufficient expression of *IRGM* and its orthologous, *Ifgga2* and *Ifgga4*, prevent from the hepatic accumulation of triglycerides in humans and mice.

Impact of different mtDNA mutations on glucose homeostasis and fat accumulation in liver in aging mice

C. Johne, S. Schröder, M. Tiedge, S. Baltrusch;
Institute of Medical Biochemistry and Molecular Biology, Rostock University, Rostock, Germany.

Background and aims: Mutations of the mitochondrial encoded subunits of the respiratory chain lead to mitochondrial dysfunction and an impaired metabolism, two risk factors that have been discussed to promote the pathogenesis of type 2 diabetes mellitus. In a comparison of 3 different conplastic mouse strains we investigated the effects of various mtDNA point mutations on the blood glucose level and fat distribution during aging.
Materials and methods: At the age of 3, 6, 9, and 12 month mice from the following strains were examined: C57BL/6NTac (control) and the conplastic mouse strains C57BL/6NTac-mt$^{BPL/1J}$ (NADH dehydrogenase mutation und cytochrome c oxidase mutation, mtBPL), C57BL/6NTac-mt$^{NOD/LtJ}$(cytochrome c oxidase and t-RNA-Arg mutation, mtNOD) and C57BL/6NTac-mt$^{A/J}$ (t-RNA-Arg mutation). Blood glucose, serum insulin and triglycerides were measured from blood samples and fat distribution was subsequently analyzed after removal of the organs.
Results: Fasten blood glucose level at 3 month old control mice were elevated (5 mmol/l) compared to mice from all three conplastic strains (3.6–4 mmol/l). Low blood glucose level in 9 month old mtNOD mice correlated with increased serum insulin at that age. Such correlation was also found with mtBPL mice. These animals showed an increase in blood glucose level up to the age of 9 month (up to 5 mmol/l) but a decline at 12 month (4.4 mmol/l). Both control and mtNOD mice showed higher triglyceride level in serum at the age of 3 month. At later time points no differences between all 4 strains were observed. In contrast, the level of liver triglycerides increased with age in all mice, but was significantly higher in 12 month old mtBPL mice.
Conclusion: Aged 12 month old mice from the two conplastic strains mtNOD and mtBPL, which only differ in two point mutations in the mitochondrial genome, display clear differences in insulin controlled blood glucose homeostasis, fat redistribution and lipid accumulation in liver. The rate of mtDNA mutations increases with age due to missing repair mechanisms in mitochondria. Thus, mtDNA mutations could accelerate the aging process in a type of vicious circle and thereby facilitate the pathogenesis of type 2 diabetes mellitus.

The experiment study of effects of multi-electrode renal denervation on insulin sensitivity and glucose metabolism

T. Pan[1], Y. Qian[2], G.-J. Teng[3];
[1]Southeast University, Nanjing, [2]Department of Anesthesiology, Nanjing Drum Tower Hospital, Nanjing, [3]Zhongda Hospital, Southeast University, Nanjing, China.

Background and aims: Renal denervation (RDN) may have some impact on insulin resistance and type 2 diabetes mellitus (T2DM), but the efficacy is still in controversy, and the effects and pathophysiology of multi-electrode RDN to treat T2DM are largely unknown. We sought to observe the effects of multi-electrode catheter-based RDN on insulin sensitivity and glucose metabolism in a canine model of T2DM.
Materials and methods: Thirty-three canines were divided equally into three groups: bilateral renal denervation (BRDN) group, left renal denervation (LRDN) group and sham operation (SHAM) group. Body weight and blood biochemistry were determined at baseline, 20-week and 32-week, and renal arterial angiography and computerized tomographic angiography (CTA) were determined before, 1-month, 2-month and 3-month after surgery. In addition, western blot was performed to identify the activities of gluconeogenic enzymes and insulin signaling proteins.
Results: High-fat diet feeding and streptozotocin injection succeeded leading to canine models of T2DM at 20-week. Compared with SHAM group, fasting plasma glucose, fasting insulin, homeostasis model assessment-insulin resistance, noradrenaline and angiotensin II in RDN groups had significantly decreased at 3-month follow-up. CTA and histopathological analyses did not show any dissection, aneurysm, thrombus or rupture of all the renal arteries. Western blot analyses showed that RDN modulated insulin action via the activation of insulin receptors-AKT signaling cascade in the liver, giving rise to the suppression of the gluconeogenetic genes.
Conclusion: These findings identified that multi-electrode catheter-based RDN could effectively decrease gluconeogenesis and glycogenolysis, resulting in improvements in insulin sensitivity and glucose metabolism in canines with T2DM.

Next generation of spontaneous diabetic model of ZDSD rats with intact leptin signalling develop cardiac dysfunction and compromised cardiac dysfunction

G. Sun, G. Zhang, V. Jackson, J. Wang;
Crown Bioscience, San Diego, USA.

Background and aims: Cardiomyopathy is the leading cause of morbidity and mortality among all complications of type 2 diabetic (T2D) and obese patients. Diabetic cardiomyopathy (DC) is characterized by an initial cardiac hypertrophy followed by thinning of the cardiac walls with declines in both systolic and diastolic functions, which ultimately leads to heart failure. No rodent models fully captured phenotypes of DC. The ZDSD rat, a new generation of T2D rat model with intact leptin signaling features with slow onset of diabetes, obesity and dyslipidemia, which closely mimics the development of the disease in patients. Here we sought to evaluate the cardiac function and reserve during the development of metabolic syndromes in ZDSD rats.
Materials and methods: 12 male ZDSD rats and age-matched SD controls were monitored for blood pressure, glucose, and cardiac function using echocardiography. Animals were also challenged with 1 mg/kg dobutamine for the assessment of cardiac reserve.
Results: ZDSD rats developed hypertension from age of 18 weeks with both systolic and diastolic blood pressure significantly higher than controls. Their left ventricular (LV) functions were compromised along with changes in cardiac morphology. At resting state, ZDSD rats showed LV hypertrophy from age of 18 to 22 weeks after which cardiac walls became thinner with larger LV volume. Concomitantly, both ejection fraction (EF) and transmitral E/A ratio of LV declined at 34 weeks old. Upon treatment with dobutamine for 5 minutes, SD rats reached almost 98% EF and 80% fractional shortening (FS), while the values of ZDSD were 91% and 60% respectively after 30 weeks old, suggesting the loss of contractility and cardiac reserve of the animals.
Conclusion: ZDSD rats which carry multiple dysmetabolic phenotypes are spontaneously hypertensive with reduction in LV function and cardiac reserve which resembles ultrasonic symptoms of diabetic cardiomyopathy patients. Therefore, ZDSD rats may serve as a suitable preclinical model to study potential therapeutic approaches to treat cardiomyopathy with presence of metabolic syndromes.

Aged New Zealand Obese (NZO) mice are protected against diet-induced loss of beta cells

R. Kehm[1,2], O. Kluth[1,2], A. Schürmann[1,2], T. Grune[1,2], A. Höhn[1,2];
[1]German Institute of Human Nutrition (DIfE), Potsdam-Rehbrücke, [2]German Center for Diabetes Research (DZD), München-Neuherberg, Germany.

Background and aims: Insulin-producing, pancreatic beta-cells are key regulators of blood glucose levels responsible for the maintenance of glucose homeostasis. In aging, their secretory capacity decreases

accompanied by impaired insulin action in peripheral tissues. Additionally, these effects are deteriorated by diet-induced obesity and low physical activity. Combined with limited regeneration capacities of beta cells, this contributes to a decline in functional mass and the onset of type 2 diabetes. In the adipose and diabetes-prone New Zealand Obese (NZO) mouse strain, peripheral insulin resistance and beta cell defects occur under a specific diet regimen. NZO mice were used to investigate the effects of aging on pancreatic beta-cell integrity and functionality under glucolipotoxic conditions.

Materials and methods: Starting at the age of 7 weeks, NZO mice were fed initially without carbohydrates for 11 (young) or 32 (aged) weeks. This was followed by a carbohydrate intervention for up to 21 days to induce hyperglycemia.

Results: As previously shown, a rapid and continuous increase in plasma blood glucose levels and a visible loss of beta-cells occurred in carbohydrate-fed, young NZO mice accompanied by a decrease in plasma insulin and proinsulin levels after 4 days. GLUT-2 immunostaining indicated a carbohydrate-induced loss of beta cell glucose-transporters. In contrast, aged NZO mice on carbohydrates revealed lower plasma blood glucose levels as well as increasing plasma insulin and proinsulin levels together with higher amounts of GLUT-2. Interestingly, compared to the young mice, an extended beta-cell mass and area was observed in aged NZO mice at the end of the intervention. Immunostaining of Ki-67 as a cellular proliferation marker, revealed no difference between young and aged NZO mice, but a reduced number of PDX-1^{+}-beta cells was found in young NZOs. Furthermore, preliminary analysis of microarray-based transcriptomics of isolated islets indicated that transcription factors essential for beta-cell development and insulin gene expression are downregulated in young, carbohydrate-fed NZO mice, whereas cell cycle regulators were upregulated in aged animals.

Conclusion: These findings suggest a less harmful effect of carbohydrates in aged NZO mice, presumably mediated via improved beta-cell maturation.

PS 035 Inflammation in type 2 diabetes: human studies

537

Association of serum Sestrin2 level with metabolic risk factors in newly diagnosed drug-naive type 2 diabetes

Y. Lee[1], J. Kim[1], E. Roh[1], S. Hong[1], N. Kim[2], J. Seo[2], S. Kim[2], N. Kim[2], K. Choi[1], S. Baik[1], H. Yoo[1];
[1]Korea university guro hospital, Seoul, [2]Korea university hospital, Seoul, Republic of Korea.

Background and aims: The prevalence of diabetes is continuously increasing, accelerating the morbidity and mortality of cardiovascular disease (CVD) worldwide. A novel therapeutic strategy targeting the disease-specific underlying mechanism is essential to block the vicious cycle between diabetes and CVD. Sestrin2 is a newly discovered antioxidative molecule. Sesn2 functions as a stress-inducible metabolic regulator by inhibiting oxidative stress and pro-inflammatory signaling, mainly via mechanisms dependent on AMP-dependent protein kinase (AMPK) and mammalian target of rapamycin complex 1 (mTORC1). Previous in-vitro and in-vivo experimental studies have shown that Sestrin2 attenuates oxidative stress and the pro-inflammatory pathway, resulting in improving metabolic homeostasis. However, the relationship between circulating Sestrin2 concentration and cardiometabolic risks in humans has not been explored.

Materials and methods: 240 subjects (46 without diabetes and 194 with diabetes) were included from the Korea Guro Diabetes Program. Sestrin2 concentration was measured using a commercially available enzyme-linked mmunosorbent assay (ELISA). We used carotid intima media thickness, brachial ankle pulse wave velocity and whole body dual-energy X-ray absorptiometry to evaluate the various cardiometabolic risk factors including body composition, insulin resistance, and atherosclerosis.

Results: Sestrin2 concentration showed a trend of increasing in subjects with metabolic syndrome. After adjustment for age and gender, Sestrin2 level had a positive relationship with serum triglyceride, alanine aminotransferase (ALT), and creatinine levels, but no association with carotid atherosclerosis. Especially, in subjects with type 2 diabetes Sestrin2 concentration exhibited a significant positive correlation with body mass index ($P = 0.015$), waist circumference ($P = 0.020$), high-sensitivity C reactive protein ($P = 0.008$), Homeostatic Model Assessment of Insulin Resistance (HOMA-IR) ($P = 0.041$), percentage body fat ($P = 0.001$), and truncal fat mass ($P = 0.005$) after adjusting age and gender. Multiple stepwise regression analysis identified age, serum ALT and creatinine levels, and percentage body fat as independent determining factors for Sestrin2 concentration in patients with type 2 diabetes ($R^2 = 0.173$).

Conclusion: This study is the first to demonstrate a trend for increased Sestrin2 level in subjects with metabolic syndrome. In particular, in subjects with type 2 diabetes, Sestrin2 was significantly related to insulin resistance and percentage body fat, suggesting its potential as a novel modulatory factor for metabolic disorders in humans.

Antagonistic functions of WNT5A and SFRP5 in hepatic glucose metabolism and inflammation

M. Carstensen-Kirberg[1,2], C. Niersmann[1,2], K. Röhrig[1,2], M. Roden[1,3], C. Herder[1,2];
[1]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, [2]German Center for Diabetes Research (DZD), München-Neuherberg, [3]Division of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Düsseldorf, Germany.

Background and aims: In mice, the pro-inflammatory wingless-related MMTV integration site (WNT)5A reduces insulin sensitivity and is

antagonised by the secreted frizzled-related protein 5 (SFRP5). In humans, the interplay between WNT5A and SFRP5 in the pathogenesis of type 2 diabetes is less well studied. This study aimed to characterise the interaction of WNT5A and SFRP5 in glucose metabolism and inflammation in human hepatocytes.

Materials and methods: The human HepaRG cell line was treated without or with (i) 5 ng/ml WNT5A, (ii) 5000 ng/ml SFRP5 as well as (iii) 5 ng/ml WNT5A and 5000 ng/ml SFRP5 for 24 h. mRNA levels of key enzymes of the gluconeogenesis were assessed using real-time PCR. Inflammatory proteins in the supernatant were analysed using a primer extension technology-based assay for 92 biomarkers. Total and phosphorylated protein content of components of inflammatory pathways was measured using Western blotting.

Results: WNT5A increased mRNA levels of phosphoenolpyruvate carboxykinase (PCK)2 and glucose-6-phosphatase catalytic subunit (G6PC) by 50% and 196% compared to control ($p < 0.05$). The co-treatment with SFRP5 in addition to WNT5A decreased PCK2 and G6PC mRNA by 36% and 48% compared to control ($p < 0.05$). Furthermore, WNT5A reduced the secretion of protein levels of 23 pro-inflammatory proteins in the supernatant on average by 56% compared to control ($p < 0.05$). Most of these proteins were chemokines (C-C motif chemokine (CCL) 2, 8, 20 and C-X-C motif chemokine (CXCL) 1, 5, 6, 8, 10, 11) and pro-inflammatory cytokines (interleukin (IL)-6, IL-18, leukemia inhibitory factor). WNT5A also decreased the phosphorylation level of NF-κB by 36% ($p < 0.01$). The co-treatment with SFRP5 led to a secretion profile similar to control.

Conclusion: In contrast to mouse models, WNT5A has anti-inflammatory effects on human hepatocytes which might be mediated by the partial inactivation of the NF-κB signalling pathway. However, WNT5A unfavourably affects the expression of gluconeogenic enzymes. Its antagonist SFRP5 counterregulates both beneficial and harmful hepatic effects of WNT5A.

Relationship of complement parameters in type 2 diabetic patients with non-alcoholic fatty liver disease

E. Sipter, L.J. Barkai, D. Csuka, Z. Prohaszka, N. Hosszufalusi;
3rd Department of Internal Medicine, Semmelweis University, Budapest, Hungary.

Background and aims: Inflammation has been identified as a component in pathomechanism of type 2 diabetes mellitus (T2DM) and non-alcoholic fatty liver disease. The fatty liver index (FLI) is a noninvasive method for the estimation of fatty liver, which increases the cardiovascular risk and mortality. The complement cascade is a complex system, which plays an important role in inflammatory response. The aim of our study was to compare the activity of complement pathway members in T2DM patients with and without non-alcoholic fatty liver disease.

Materials and methods: In our prospective study 100 subjects with type 2 diabetes mellitus were investigated. The fatty liver index was calculated using BMI, waist circumference, γ-glutamyltransferase and triglycerides levels. FLI higher than 60 rules in fatty liver disease. Medical history, clinical data and blood samples were collected from patients. Functional activity of the lectin complement pathway member ficolin-3, activity of mannose-binding lectin (MBL), and C3 and C4 concentrations were measured from blood samples using in-house sandwich ELISA methods. For statistical analysis we used GraphPad Prism 5.

Results: 63 patients have increased FLI and 37 patients have FLI less than 60. Regarding the routine clinical laboratory parameters no significant difference was found in HbA1c levels of patients (6.4% vs 6.85%). Significantly higher ($p < 0.05$) C3 concentration and ficolin-3 activity were found in the T2DM with fatty liver disease compared to patients with low FLI. (1.95 [1.75–2.21] μg/l vs 1.76 [1.52–1.96] μg/l and 90.82 [46.18–134.3] % vs 54.18 [23.28–99.07] %). Significantly lower ($p < 0.05$) MBL activity was found in the fatty liver disease group. (76.05 [5.65–102.0] % vs 100.7 [33.24–115.5] %). There was also significant difference between the BMI of the patients (22.19 vs 31.84 kg/m^2). In the case of C4 complement component no significant difference was found.

Conclusion: Lower activity of MBL, and higher concentration of C3 and ficolin-3 activity were found in T2DM patients with high fatty liver index. Our study suggested that complement alternative and lectin pathway can be upregulated in non-alcoholic fatty liver disease among patients with type 2 diabetes mellitus. The difference between the phenotype of the patients can direct the treatment and give the possibility to decrease the inflammation and the cardiovascular risk.

Intra-acinar fat in the pancreas of non-diabetic and type 2 diabetic subjects

M. Suleiman, C. De Luca, M. Bugliani, S. Mossuto, F. Grano, P. Marchetti, L. Marselli;
University of Pisa, Pisa, Italy.

Background and aims: Little information is available on intra-acinar fat (IF) features in humans. In the present study we performed morphometric analysis of IF from overweight/obese non-diabetic (ND) and matched type 2 diabetic (T2D) organ donors.

Materials and methods: We studied 13 ND (age: 69 ± 4 years; 5M/8F; BMI: 31.3 ± 0.4 Kg/m^2, data expressed as mean ± SEM) and 15 T2D (age: 71 ± 2 years; 9M/6F; BMI: 29.8 ± 0.7 Kg/m^2) organ donors. Morphometric assessments of adipocytes, insulin (Abcam Ab) and glucagon (Sigma Ab) were performed with pancreatic tissue sections using a DM5500 Leica microscope and the MetaMorph v 1.8.0 software. Macrophages were identified by immunohistochemistry using anti-CD68 (Dako) and anti-CD163 (Thermo Scientific) antibodies. Insulin secretion was assessed from isolated islets in response to acute glucose stimulation.

Results: Adipocyte number tended to be higher in T2D (8.1 ± 1.3/mm^2) than ND (7.0 ± 1.7/mm^2) and their size was greater in T2D (8,890 ± 934 μm^2) than ND (5,439 ± 557 μm^2, $p < 0.01$). Overall, the proportion of IF area in relation to acinar tissue area trended higher (+46%, $p = 0.06$) in T2D (6.8 ± 1.2%) than ND (3.7 ± 1.0%). Insulin positive area (T2D: 0.47 ± 0.05%; ND: 0.55 ± 0.06%) as well as glucagon positive area (T2D: 0.24 ± 0.03%; ND: 0.32 ± 0.06%) did not differ significantly in the two groups. The number of adipocytes with adjacent ≥2 CD68$^+$ cells counted in 4 mm^2 of pancreatic tissue was higher in T2D than ND (6.8 ± 1.8 vs 2.7 ± 0.7%, $p = 0.05$), whereas no significant difference was seen in CD163$^+$ cells. Glucose-stimulated insulin secretion index was lower in T2D (2.1 ± 0.2) than ND (3.7 ± 0.4, $p < 0.01$). A positive correlation (Pearson analysis) was found between adipocyte size and insulin area in ND ($r = 0.68$, $p = 0.01$). No significant correlation was seen between IF features and ex-vivo insulin release.

Conclusion: At our experimental conditions, adipocyte size was higher in T2D pancreatic samples, that also showed a higher infiltration by CD68$^+$ cells. If and how these differences can affect beta cell amount and function remain to be assessed.

Extracellular nicotinamide phosphoribosyltransferase (eNAMPT) induces beta cell dysfunction via p38 and STAT3 signalling

P.W. Caton[1], R. Beavil[2], D.J. Hodson[3], G.G. Lavery[4], S. Sayers[1];
[1]Diabetes Research Group, King's College London, London, [2]King's College London, London, [3]Institute of Metabolism and Systems

Research, University of Birmingham, Birmingham, [4]Institute of Metabolism and Systems Research, University of Birmingham, London, UK.

Background and aims: Elevated serum extracellular nicotinamide phosphoribosyltransferase (eNAMPT; visfatin/PBEF) levels are associated with beta-cell failure in Type 2 diabetes (T2D). Despite this, the effects of eNAMPT on beta-cell function are poorly elucidated. Understanding the effects of eNAMPT on beta-cells requires consideration of concentration and structure-function relationships. In non-diabetic serum, eNAMPT circulates at <1 ng/ml, rising to >5 ng/ml in T2D. Moreover, eNAMPT predominantly exists as a dimer, which is essential for the NAD biosynthetic capacity of eNAMPT. However, we have also reported selective elevation of a monomeric eNAMPT in mouse models of T2D. Here we examined the effects of eNAMPT-dimer and -monomer on pancreatic islets at physiological (<1 ng/ml) and pathophysiological (>5 ng/ml) concentrations.
Materials and methods: Isolated mouse and human islets were treated with monomeric or dimeric eNAMPT (24–48 h; 1 or 5 ng/ml). We assessed islet glucose-stimulated insulin secretion (GSIS; static and dynamic); calcium flux ($[Ca^{2+}]_{cyt}$; Fura-2 confocal imaging); apoptosis (Caspase-Glo 3/7 activity); islet gene expression (qPCR) and islet NAD (colourimetric assay).
Results: We identified distinct concentration- and structure-dependent effects of eNAMPT on islets. Exposure of islets to physiological levels of eNAMPT-dimer (1 ng/ml) significantly increased static and dynamic GSIS ($n = 10$, 5 size matched islets/well) and intracellular $[Ca^{2+}]_{cyt}$ (16 islets, $n = 3$ mice/treatment) ($P < 0.05$, $P < 0.01$, respectively). Moreover, gene expression markers of beta-cell identity (*PDX1*, *NKX2.2*, *INS*) were increased. These effects were associated with increases in islet NAD levels. In contrast, treatment of islets with pathophysiological concentrations of eNAMPT-dimer (5 ng/ml) or with eNAMPT-monomer (1 and 5 ng/ml) led to reduced GSIS ($P < 0.05$), calcium flux, and *PDX1*, *NKX2.2* and *INS* mRNA. Correspondingly, apoptosis ($n = 8$, 6 size matched islets/well, $P < 0.05$) and inflammatory gene expression (*CCL2*: $P < 0.01$, *Il1B*: $P < 0.05$) were enhanced following exposure to eNAMPT-dimer (5 ng/ml) or eNAMPT-monomer (1 and 5 ng/ml). These effects of eNAMPT appear to be NAD-independent. The deleterious effects of eNAMPT-dimer and -monomer were blocked when islets were co-treated with inhibitors of p38 (SB203580; 1υM) or STAT3 (NCS74859; 25 υM).
Conclusion: We report distinct dose- and structure-dependent effects of eNAMPT on pancreatic islets. 1 ng/ml eNAMPT-dimer - similar to the serum structure-concentration combination observed in non-diabetic individuals - enhanced beta-cell function and increased markers of beta-cell identity. In contrast, exposure to eNAMPT at levels/structures seen in T2D led to impaired beta-cell function, through inflammatory mechanisms involving p38 and STAT3 signalling. Together, these data suggest that at physiological levels, eNAMPT plays a key role in maintaining beta-cell function and identity, likely via NAD-dependent effects. In contrast, pathophysiological levels of eNAMPT contribute to development of T2D by through impaired beta-cell function and identity, in part via NAD-independent effects. Therefore, eNAMPT represents a novel therapeutic approach for treating T2D.

Anti-inflammatory and immune-mediated effects of metformin therapy in patients with type 2 diabetes

M.D. Tron'ko, O.V. Furmanova, V.V. Popova, Y.A. Sayenko, V.L. Orlenko, K.Y. Ivaskiva, K.M. Tron'ko, K.P. Zak;
V.P. Komisarenko Institute of Endocrinology and Metabolism of Natl. Acad. Med. Sci. Ukraine, Kyiv, Ukraine.

Background and aims: Metformin is one of the most prescribed drugs for treatment of type 2 diabetes (T2D). It is recently shown, that metformin has not only hypoglycemic properties but also beneficial effect on other important functions of the body. However, the mechanism of the pluripotent effect of metformin is not clear. Especially, the role of inflammation and the immune system is insufficiently studied, although T2D and its complications are referred to inflammatory diseases. Aim is to study some indices of immunity and inflammation in newly diagnosed patients with T2D, after their treatment with metformin.
Materials and methods: There were examined 35 patients with newly diagnosed T2D. Of these, 20 clinically homogeneous patients were selected with following administration of metformin therapy (2000 mg/day for 3 months). The control group consisted of 32 healthy individuals. The total number of leukocytes and leukocyte composition was determined by the hematological analyzer and simultaneously visually in blood smears. The index of inflammation (NLR) is calculated from the ratio of neutrophils to lymphocytes. Immunophenotype of lymphocytes (CD3+ T, CD4+ T, CD8+ T, CD20+, CD56+cells) was determined by FACS analyses and the level of cytokines (IL-1β, IL-2, IL-4, IL-6, IL-10, TNFα) and chemokynes (IL-8, IL-16) - with immunosorbent ELISA assay.
Results: In 90 days after metformin administration there was a decrease of leukocytosis (7.17 ± 0.29 vs 5.93 ± 0.22 10^9/l, $p < 0{,}01$), NLR index (3.19 ± 0.26 vs 2.06 ± 0.19, $p < 0.01$), monocyte number ($0.77 \pm 0{,}06$ vs 0.33 ± 0.06 10^9/l, $p < 0.01$) and CD4+T-cells (0.66 ± 0.07 vs 0.45 ± 0.07 10^9/l, $p < 0{,}05$) in most patients with T2D. At the same time there is a marked decrease of proinflammatory cytokine level and, in particular, IL-1β (2.4 ± 0.42 vs 0.36 ± 0.11, pg/ml, $p < 0.01$), and TNFα (2.63 ± 0.64 vs 0.46 ± 0.24 pg/ml, $p < 0.01$), and chemokine IL-16 (89.6 ± 9.3 vs 130.5 ± 11.2 pg/ml, $p < 0{,}05$), which correlated well with a decrease in % HbA1c and an improvement in the clinical status of patients.
Conclusion: An immuno-mediated anti-inflammatory effect also plays an important role in the mechanism of the curative effect of metformin in T2D.

Vitamin-D improves glycaemic outcome in prediabetes through reduced fetuin-A and systemic inflammation

M. Kumar[1], D. Dutta[2], S.A. Mondal[3], S. Mukhopadhyay[4];
[1]Department of Endocrinology, Centre for Endocrinology, Diabetes And Research (CEDAR), Patiala, [2]Department of Endocrinology, Venkateshwar Hospitals, Delhi, [3]Department of Biochemistry, IPGMER and SSKM Hospital, Kolkata, [4]Department of Endocrinology, IPGMER and SSKM Hospital, Kolkata, India.

Background and aims: The study aimed to evaluate the impact of VitD supplementation on FetA and systemic inflammation [interleukin (IL) 6,

IL1β, tumor necrosis factor (TNF) α, soluble TNF receptor (sTNFR)1, sTNFR2] in IPD, and their relation with long-term glycemic outcomes
Materials and methods: From an initially screened 2245 individuals, 207 IPD with persistent IFG and/or IGT over 2 successive OGTTs with vitD <30 ng/ml were randomized into intervention group (Group-I) (cholecalciferol 60,000 U once weekly for 8 weeks and then monthly with 1250 mg of calcium carbonate/day for study duration), and control groups [Group-C1 (Calcium Control Group: 1250 mg of calcium carbonate/day); and Group-C2 (Placebo Control Group: placebo tablet similar to calcium tablet). All received therapeutic lifestyle modification. Glucose tolerance, insulin, 25OHD, lipids, IL6, TNF-α and hsCRP were done baseline and annually. Data from IPD with at least 1-year follow up were analyzed.
Results: Data from 192 IPD (males: females = 122:70) with at least 1-year follow-up were analyzed (mean follow-up: 27.68 ± 9.72 months. At end of study, IPD in intervention group had greatest reduction in FBG, 2hPGBG, HbA1c, fetuin-A, total cholesterol, IL6, sTNFR1, sTNFR2, which was statistically significant. Group-I IPD also had greatest increase in 25OHD (Δ25OHD: 22.96 [11.54–40.30] ng/ml; $P < 0.001$). Quantum of decrease in serum triglycerides, LDL-C and HDL-C was greatest in Group-I. Placebo control group (Group-C2) had greatest increase in hip circumference and IL1β. Analysis based on glycemic outcomes revealed IPD who reverted to normoglycemia had highest baseline 25OHD, sTNFR2, along with greatest reduction (Δ change) in FetA, sTNFR1 and sTNFR2. 42.7% (41/96) IPD in intervention group reversed back to normoglycemia, in contrast to 22.92% (22/96) in control groups ($P = 0.003$). With regards to progression to T2DM, it was 10.41% (10/96) in intervention group and 17.70% (17/96) in control groups ($P = 0.144$). Cox regression revealed that FBG, 25OHD, fetuin-A, HOMA-IR, sTNFR1 and Group-I independently predicted prediabetes reversal to normoglycemia. Only FetA was an independent predictor of prediabetes progression to T2DM. Every 1 mg/dl increase in blood glucose was associated with 3.7% decreased reversal to normoglycemia. Every 1 ng/ml increase in serum 25OHD was associated with 3% increased reversal to normoglycemia. Every 1 mcg/ml increase in FetA was associated with 0.4% decreased reversal to normoglycemia and 0.6% increased progression to T2DM. Kaplan Meier analysis also showed significantly higher rates of prediabetes reversal to normoglycemia in intervention group ($P = 0.033$; log rank test [Mantel-Cox]). 42.7% IPD in intervention group reversed back to normoglycemia in contrast to 22.92% in the control groups.This evaluation achieved power of 83.7%, keeping α (Type I error) at 0.05.
Conclusion: VitD supplementation in prediabetes was associated with improved glycemic outcomes, significant reduction in serum FetA, decreased IR and systemic inflammation.

Role of O-GlcNAc glycosylation in the inflammatory effect of LPS in macrophage

H. Al-Mukh, L. Baudoin, M. Khair, L. Francese, F. Niedergang, T. Issad; Institut Cochin, INSERM U1016, CNRS UMR8104, University Paris Descartes, Paris, France.

Background and aims: O-GlcNAc glycosylation (O-GlcNAcylation) is a reversible post translational modification catalysed by O-GlcNAc transferase (OGT). O-GlcNAcylation regulates the activity of cytosolic and nuclear proteins according to glucose availability. This modification, Which corresponds to the addition of N-Acetylglucosamine (GlcNAc) on serine and threonine residues of proteins, participates in several hyperglycemia-associated complications. An important feature of metabolic diseases such as diabetes and obesity is the presence of a low-grade chronic inflammation that causes numerous complications. Chronic hyperglycemia is known to play a role in this inflammation. However, the relationships between O-GlcNAcylation and inflammatory processes remain poorly explored. The aim of this work was to evaluate potential involvement of O-GlcNAcylation in proinflammatory signalling in macrophages.
Materials and methods: The study was performed using the RAW264.7 murine macrophage cell line, peritoneal or bone marrow derived macrophages from wt or OGT-KO mice as well as macrophages differentiated from human monocytes. O-GlcNAcylation of proteins was evaluated using a BRET-based biosensor targeted to different cell compartments, or by western blot using anti-O-GlcNAc antibody.
Results: Using Thiamet G, a specific inhibitor of OGA (the enzyme that removes O-GlcNAc from proteins), we observed that increasing O-GlcNAcylation in murine macrophages potentiates the effect of LPS (lipopolysaccharide) on the expression of pro-inflammatory cytokines. Moreover, using a BRET-based biosensor, we observed that activation of Toll-like receptor 4 (TLR4) by LPS increased BRET signal at the plasma membrane, in the cytosol and in the nucleus of RAW264.7 macrophages. Similar results were observed in these cells when O-GlcNAcylation was evaluated by western-blotting with an anti-O-GlcNAc antibody. These effects were also confirmed in primary bone marrow-derived and peritoneal mouse macrophages, as well as in human monocyte derived macrophage. Precipitation of O-GlcNAcylated proteins using Wheat-germ lectin sepharose beads revealed that LPS induced O-GlcNAcylation of NFκB in macrophages. We then evaluated the consequences of OGT deletion on the expression of pro-inflammatory genes. Peritoneal-derived macrophages were prepared from OGT Lox/lox-LysM-Cre mice. We observed that whereas OGT deletion had no effect on LPS-induced NOS2 and TNFα mRNA expression, it resulted in an inhibition of LPS-induced IL1β mRNA expression by 94 ± 4% ($p < 0.001$) and that of IL6 by 78% ± 11% ($p < 0.001$). This suggest that some but not all of the pro-inflammatory effects of LPS involve the O-GlcNAcylation signaling pathway.
Conclusion: Our results indicate that activation of the O-GlcNAcylation pathway may be an integral part of the TLR4- induced signal, and suggest that this pathway is crucial to some of the pro-inflammatory effect of LPS in macrophages.

Protective role of SIRT1 against the deleterious effect of inflammation in insulin sensitivity and thermogenesis in brown adipocytes

C. Escalona[1,2], P. Vázquez[1,2], E. García-Casarrubios[1], M. Obregón[1], Á.M. Valverde[1,2];
[1]Instituto de Investigaciones Biomédicas "Alberto Sols" (IIB, CSIC-UAM), Madrid, [2]CIBER de Diabetes y Enfermedades Metabólicas (CIBERDEM), ISCIII., Madrid, Spain.

Background and aims: Activation of brown adipose tissue (BAT) by modulation of SIRT1 activity is a promising approach to combat obesity or type 2 diabetes mellitus (T2DM). These conditions are associated with a chronic low-grade systemic inflammation, which is considered a critical underlying factor in the development of insulin resistance. Our aim was to identify the mechanisms implicated in the potential therapeutic benefit of targeting SIRT1 in BAT to ameliorate inflammation-mediated insulin resistance and defective thermogenesis.
Materials and methods: The impact of SIRT1 in BAT inflammation was studied by acute treatment of wild-type or SIRT1-Tg mice with bacterial lipopolysaccharide (LPS). We also studied the effect of resveratrol, a SIRT1 activator, in BAT from db/db mice treated for 8 weeks. Proinflammatory-mediated signaling cascades, insulin signaling and thermogenic mediators were analyzed by western blot and RT-PCR. As an in vitro model we used immortalized brown adipocytes from wild-type differentiated in the absence or presence of resveratrol or from SIRT1-Tg mice. These cells were stimulated with conditioned medium (CM) from Raw 267.4 macrophages treated or not with LPS and proinflammatory signaling, insulin signaling and noradrenaline-mediated UCP1 was assayed.
Results: Proinflammatory signalling cascades mediated by JNK, p38 MAPK, JAK-STAT3 and NFκB were enhanced in BAT from db/db mice compared to db+ lean controls. Conversely, insulin-mediated signaling was decreased. This insulin resistance was accompanied by a change in the pattern of IR isoforms showing a robust presence of IRA only in BAT from db/db mice. Treatment of db/db mice with resveratrol increased Ucp1 ($p = 0.057$), Dio2 ($p = 0.0571$) and Fgf21 ($^*p < 0.05$) mRNA levels in BAT. In a model of acute administration of LPS in lean mice a similar proinflammatory signalling in BAT was found, assessing BAT sensitivity to the proinflammatory environment. Interestingly, moderate SIRT1 overexpression decreased Il6 mRNA levels and STAT3 phosphorylation in LPS-injected mice. Differentiated brown adipocytes stimulated with CM from LPS-stimulated Raw 264.7 macrophages showed a rapid activation of inflammatory signaling and subsequently insulin resistance manifested by reduced Akt phosphorylation and glucose uptake as well as decreased response to noradrenaline in the induction of UCP1. These responses were attenuated by differentiating brown adipocytes in the presence of resveratrol or alternatively by moderate overexpression of SIRT1.
Conclusion: Our results suggest that activation of SIRT1 in brown adipocytes might play a major and beneficial role against insulin resistance and defective thermogenesis associated to inflammation.

Leukotriene B4 induces mitochondrial dysfunction in skeletal muscle by mediating oxidative stress and inflammation

M. Abu Bakar;
Bioprocess Technology Division, School of Industrial Technology, Universiti Sains Malaysia, Penang, Malaysia.

Background and aims: Mitochondrial dysfunction and oxidative stress in skeletal muscle are among the detrimental events in development of type 2 diabetes (T2D). Leukotriene B4 (LTB4) is a potent leukocyte chemoattractant regulated by 5-lipoxygenase (5-LO) and leukotriene A4 hydrolase activities in the event of chronic inflammatory conditions, including T2D. However, little is known about the metabolic role of LTB4 on mitochondrial oxidative stress. Therefore in the current study, we focused on the metabolic effects of LTB4 on mitochondrial functions in skeletal muscle.
Materials and methods: The molecular mechanism underlying the roles of LTB4 on skeletal muscle was investigated *in vitro* and *in vivo* using immunoblotting, real-time RT-PCR and flow cytometry analyses.
Results: LTB4 treatment in a dose-dependent manner augmented the degree of mitochondrial superoxide generation in myotubes. Such impairments in mitochondrial integrity and dynamics by increased dynamin-related protein-1 (Drp1) and fission-1 (Fis1) protein expression but, reduced mitofusin (Mfn)-1 protein expression were noticed. Furthermore, LTB4 considerably augmented the expression of Cytochrome C and Bax, but diminished the expression of Bcl-2, thus promoting myotubes apoptosis and inflammation. Additionally, LTB4 treatment resulted in the suppression of phosphatidyl inositol 3- kinase (PI3K)/Akt signaling. Finally, impaired insulin sensitivity with severe oxidative damage and mitochondrial impairments in skeletal muscle of transgenic mice expressing human LTB4 (LTB4-Tg) mice were observed compared to wild-type C57BL/6J mice.
Conclusion: Overall, the current investigation uncovers a novel mechanism through which LTB4 leads to oxidative damage and mitochondrial dysfunction in the progression of T2D.

Role of resistin/TLR4 signalling pathway in HFD induced hypothalamic inflammation and gliosis

S. Al-Rifai, D. Crepin, L. Riffault, C. Alexandre, G. Poizat, M. Taouis, Y. Benomar;
Molecular Neuroendocrinology of food intake, Paris-Saclay Institute of Neuroscience UMR9197, University Paris Sud, Orsay, France.

Background and aims: Obesity is linked to several metabolic disorders including low grade inflammation and insulin resistance, which constitutes a principal risk factor for type 2 diabetes (T2D). Increasing evidence indicates that changes in adipose-secreted factors in obesity, dramatically affect insulin sensitivity. Among these adipokines, resistin is described as a causal factor for obesity-mediated peripheral inflammation and insulin resistance. Several studies reported that resistin is also expressed in the hypothalamus, however, little is known about the molecular mechanisms mediating its effects at the neuronal level. Recently, we have shown that central resistin acts by way of hypothalamic TLR4 receptors promoting whole-body insulin resistance. Here we aim to investigate the involvement of resistin/TLR4 pathways on the onset of hypothalamic inflammation and gliosis. This study also aims to characterize the hypothalamic nuclei and neural cells expressing resistin and to establish the temporal regulation of hypothalamic resistin expression by High Fat Diet (HFD) feeding.
Materials and methods: To reach our objective, male C57BL/6 mice were fed with standard chow diet or HFD for 3 days, 8 days and 8 weeks, in addition C57BL6 TLR4$^{-/-}$ mice and their control littermates were treated for 3 days with or without resistin through ICV route. At the end of the experimental period we analyzed the impact of HFD and ICV resistin treatment on hypothalamic resistin expression, inflammation and reactive gliosis. This was assessed by combined in situ hybridization, immunohistochemistry and RTqPCR analyses.
Results: As expected, we show that HFD feeding induces hypothalamic inflammation, and reactive gliosis in the medio-basal hypothalamus (MBH). Interestingly, we report for the first time, that both long-term

and short-term HFD-induced hypothalamic inflammation is associated with a significant increase of resistin expression in tanycytes and neurons throughout the MBH, suggesting the potential involvement of resistin in the early-onset of hypothalamic inflammation. Next, we investigated whether central resistin/TLR4 pathways could directly contribute to hypothalamic inflammation; we show that central resistin infusion for 3 days markedly increases inflammatory markers in the hypothalamic arcuate nucleus and adjacent median eminence in association with reactive gliosis involving recruitment of both microglia and astrocytes. Interestingly, we report that the knockdown of TLR4 almost completely abolished resistin-dependent both hypothalamic inflammation and reactive gliosis.

Conclusion: Altogether, our findings demonstrate that Resistin/TLR4 signaling pathway constitute a crucial/key pathway promoting the onset of hypothalamic inflammation. Targeting this signaling pathway may constitute a significant breakthrough to overcome obesity-induced hypothalamic inflammation and related metabolic dysfunctions.

Impaired PPAR gamma signalling but not endoplasmic reticulum stress promotes inflammation in white adipose tissue of hormone-sensitive lipase deficient mice

P. Kotzbeck[1,2], C. Haudum[1], I. Foessl[1], B. Boulgaropoulos[1,3], K. Bounab[1], T.O. Eichmann[2,4], B. Obermayer-Pietsch[1], G. Haemmerle[2], S. Cinti[5], T.R. Pieber[1,3], R. Zechner[2,6];

[1]Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria, [2]Institute of Molecular Biosciences, University of Graz, Graz, Austria, [3]Institute for Biomedicine and Health Sciences, Joanneum Research Forschungsgesellschaft mbH HEALTH, Graz, Austria, [4]Center for Explorative Lipidomics, BioTechMed-Graz, Graz, Austria, [5]Department of Experimental and Clinical Medicine, Center of Obesity, University of Ancona (Politecnica delle Marche), Ancona, Italy, [6]BioTechMed-Graz, Graz, Austria.

Background and aims: Hormone-sensitive lipase (HSL) plays a crucial role in intracellular lipolysis. Mutation or loss of HSL leads to diacylglycerol accumulation, reduced fatty acid mobilization, and impaired peroxisome proliferator-activated receptor (PPAR) gamma signaling. Diacylglycerol accumulation contributes to lipotoxicity and may induce endoplasmic reticulum (ER) stress which is able to initiate inflammatory processes. Impaired PPAR gamma signaling is also associated with inflammatory responses in adipose tissue. Previous studies have shown that HSL knock out mice exhibit macrophage infiltration and adipose tissue inflammation, but the mechanisms leading to such adipose tissue inflammation have not been studied so far. Therefore, we aimed to investigate whether impaired PPAR gamma signaling or ER stress in white adipose tissue of HSL knock out mice is causal for adipose tissue inflammation.

Materials and methods: Markers of adipose tissue inflammation (F4/80 expression, Mac-2 staining and crown-like structures quantification), adipose tissue function (adiponectin, perilipin expression) and ER stress (Chop expression, peIF2 alpha/eIF2 alpha ratio) were analyzed in different adipose tissue depots of adult, lean HSL knock out and control mice under basal conditions and after chronic treatment with the PPAR gamma agonist rosiglitazone. Additionally, diacylglycerol and ceramide concentrations were measured in white adipose tissue of HSL knock out and control mice under basal conditions and after chronic rosiglitazone treatment.

Results: HSL knock out mice exhibited 23% decreased epididymal adipose tissue mass, moderate adipocyte hypertrophy and marked macrophage infiltration represented by increased CLS count and 2.8-fold increased F4/80 mRNA expression ($p < 0.01$). Phosphorylation of eIF2 alpha was 1.9-fold ($p < 0.001$) and Chop mRNA expression 7.7-fold increased ($p < 0.01$) in white adipose tissue of HSL knock out mice. Ultrastructural analysis showed markedly dilated ER in white adipocytes of HSL knock out mice. Rosiglitazone treatment abrogated macrophage infiltration and thereby ameliorated adipose tissue inflammation. ER stress markers in contrast remained unchanged and were still elevated by 16-fold ($p < 0.01$) in white adipose tissue of rosiglitazone treated HSL knock out mice compared to the respective control mice. Lipidomic profiling of white adipose tissue showed that diacylglycerol accumulation in HSL knock out mice remained unaffected by rosiglitazone treatment and might be causal for ER stress but not inflammation.

Conclusion: Our data clearly show that impaired PPAR gamma signaling but not ER stress contributes to white adipose tissue inflammation of HSL knock out mice.

The role of TLR4 interactor with leucine-rich repeats (TRIL) in hypothalamic inflammation

A. Moura-Assis[1], J. de Lima Junior[1], J. Gaspar[2], R. Gaspar[1], E. R. Ropelle[3], L.A. Velloso[1];

[1]Internal Medicine, University of Campinas - Faculty of Medical Sciences, Campinas, [2]Department of Biochemistry, Federal University of Santa Catarina, Santa Catarina, [3]Internal Medicine, University of Campinas - Faculty of Applied Sciences, Limeira, Brazil.

Background and aims: The neural control of whole body energy homeostasis is controlled by key brain nuclei. In particular, the hypothalamus integrates short-term signals from the gut and long-term signals from adipose tissue to ensure correct meal initiation/termination and glucose/lipid homeostasis. In this sense, AgRP-expressing neurons and POMC-expressing neurons become more or less active in a calorically deficient state, respectively.In face of dietary excess, the obesity-associated activation of inflammatory pathways in the hypothalamus promotes caloric overconsumption and weight gain in mice. This process occurs partially via activation of TLR4 by saturated fatty acids. In other contexts, TLR4 signaling in the brain is mediated by the TLR4 interactor with leucine-rich repeats (TRIL). Our main purpose was to determine the putative involvement of TRIL in diet-induced hypothalamic inflammation. We performed bioinformatics analysis from RNA-seq database of hypothalamic neurons, using inflammatory markers, to identify genes with large negative or positive correlation with TRIL. We also knocked down the expression of TRIL in the arcuate nucleus to evaluate changes in food intake and body weight.

Materials and methods: We employed male, 6 week-old Swiss and C57BL/6J mice, fed on chow or high-fat diet for 1, 2, 4 or 8 weeks. The transcript levels in the hypothalamus were measured by RT-PCR, western blot analyses was used for determination of protein content of inflammatory markers and immunofluorescence microscopy for evaluate the distribution of TRIL in neuronal and non-neuronal cells in arcuate nucleus of hypothalamus. The bioinformatics analysis from RNA-seq database focused on the magnitude of the correlation between TRIL and inflammatory genes. Finally, we used lentiviral particles to knock-down TRIL expression in arcuate nucleus through intracerebroventricular infusion.

Results: TRIL colocalized with ACTH (POMC neurons) and a marker of activated microglia (Iba1); in addition we also found colocalization with astrocyte markers (GFAP). The expression of TRIL mRNA increased significantly after 1 and 2 weeks on high fat consumption and was back to baseline after 4 weeks, a similar expression pattern was observed for TLR4. The increased mRNA expression of TRIL and TLR4 was accompanied of increased IKK phosphorylation. The bioinformatics analysis indicated positive correlation between TRIL and inflammatory genes such as *il18*(indicative of inflammasome activation), *p2ry1* (indicative of microglial activation), *tnfrsf19* (member of the TNF-receptor

superfamily), among others. Finally, the knocked down of TRIL in mice fed on chow did not change the body and epididymal weight and food intake.
Conclusion: Collectively our results suggest that TRIL is involved in the TLR4-mediated early response to dietary fats. The expression of TRIL in neuronal and non-neuronal hypothalamic cells provides evidence that the immunologic responses to dietary excess might be mediated by TRIL. The role of TRIL inhibition in high fat-fed mice and its effect on food intake, energy expenditure and hypothalamic inflammation will be addressed in the next experiments.

Cystatin C alleviates obesity-associated tissue inflammation and insulin resistance

M.A. Dedual[1,2], S. Wueest[1,2], T.R.J. Aeppli[1,2], T.D. Challa[1,2], D. Konrad[1,2];
[1]Division of Pediatric Endocrinology and Diabetology, University Children's Hospital, Zurich, [2]Children's Research Center, University Children's Hospital, Zurich, Switzerland.

Background and aims: We recently demonstrated that removal of one kidney (uninephrectomy) in mice reduced high fat-diet (HFD)-induced adipose tissue inflammation and improved hepatic insulin sensitivity. Moreover, uninephrectomized mice revealed increased plasma levels of cystatin C, a circulating factor with suggested anti-inflammatory properties. We, thus, hypothesized that cystatin C alleviate obesity-associated adipose tissue inflammation.
Materials and methods: 6-week-old C57BL/6J wild type (WT) and cystatin-C-deficient mice (CysC KO) were fed a regular chow or HFD (~60% kcal fat) for 20 weeks. Glucose metabolism was assessed by intraperitoneal glucose tolerance tests (ipGTT) and by hyperinsulinaemic-euglycaemic clamp studies. After scarification, liver and fat depots were analyzed applying Western blotting, rtPCR and histological staining.
Results: HFD-induced aggravation in glucose tolerance was significantly elevated in CysC KO compared to WT mice (ΔAUC ipGTT 348 ± 85 mmol/l*min in WT vs. 803 ± 106 mmol/l*min in CysC KO, $p < 0.01$). Moreover, hyperinsulinaemic-euglycaemic clamps in HFD-fed mice revealed a significantly lower insulin-mediated inhibition of endogenous glucose production (EGP) in CysC KO compared to WT mice (24.2 ± 3.3 mg/kg*min in WT vs. 44.6 ± 3.7 mg/kg*min in CysC KO, $p < 0.05$), indicating exacerbated hepatic insulin resistance in CysC KO mice. In addition, glucose uptake into inguinal adipose tissue during clamps was ~50% reduced in CysC KO mice, paralleled by significantly reduced serine^{473} phosphorylation of Akt (1.0 ± 0.2 in WT vs. 0.3 ± 0.0 in CysC KO, $p < 0.05$). mRNA levels of the pro-inflammatory factor IL-6 (1.0 ± 0.2 in WT vs. 2.8 ± 0.6 in CysC KO, $p < 0.05$) and the pro-fibrotic factor Tgfβ1 (1.0 ± 0.2 in WT vs. 2.2 ± 0.5 in CysC KO, $p < 0.05$) were increased in epididymal fat of HFD-fed CysC KO mice. Similarly, mRNA levels of pro-inflammatory cytokines IL-6 (1.0 ± 0.1 in WT vs. 3.5 ± 0.4 in CysC KO, $p < 0.05$) and IL-1β (1.0 ± 0.1 in WT vs. 1.8 ± 0.2 in CysC KO, $p < 0.05$) were increased in livers of HFD-fed CysC KO mice, paralleled by signs of hepatocellular injury in histological sections of such mice. Moreover, *in vitro* treatment of fat explants harvested from HFD-fed WT mice with recombinant cystatin C reduced expression of pro-inflammatory cytokines.
Conclusion: Our data indicate a beneficial role of cystatin C in obesity-associated (adipose tissue) inflammation and (hepatic) insulin resistance.

Mouse strain-specific immunometabolic response in white adipose tissue during cold exposure

K. Adamcova[1], K. Bardova[1], P. Janovska[1], O. Horakova[1], P. Flachs[1], M. Svobodova[1], M. Rossmeisl[1], L. Madsen[2,3], K. Kristiansen[3], J. Kopecky[1];
[1]Department of Adipose Tissue Biology, Institute of Physiology of the Czech Academy of Sciences, Prague, Czech Republic, [2]National Institute of Nutrition and Seafood Research, Bergen, Norway, [3]Department of Biology, Laboratory of Genomics and Molecular Biomedicine, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Cold exposure (CE) was shown to activate lipid metabolism in epididymal white adipose tissue (eWAT), with a stronger effect in obesity-resistant A/J as compared with obesity-prone C57BL/6J (B6) mice. The ability of WAT to serve as a whole-body buffer for lipids depends in part on presence of adipocytes with high lipolytic/re-esterification capacity, and possibly on the extent of WAT remodelling under the conditions of changing energy demands. Since WAT metabolism is interconnected with tissue immune responses, we investigated whether the effect of CE on eWAT metabolism was mirrored by the content and polarization of WAT macrophages.
Materials and methods: Two-month-old male A/J and B6 mice fed chow diet were maintained at thermoneutral temperature (30°C) or exposed to cold (6°C for 48 hours). eWAT was analyzed immunohistochemically and/or using quantitative PCR (qPCR); macrophages were characterized using flow cytometry. Statistical analysis was performed by SigmaStat using TwoWay ANOVA.
Results: CE decreased weight of eWAT with a more pronounced effect in A/J mice. The occurrence of UCP1-negative and ATGL- and DGAT1-positive paucilocular adipocytes was induced by CE in both strains, with a stronger induction in A/J mice. Our results document both strain-specific difference and influence of CE on eWAT abundance of macrophages. In response to CE, tissue content of M1 ($CD11c^+$, $CD206^-$) macrophages decreased in A/J, but not in B6 mice (cells/mg tissue: B6 vs. A/J; at thermoneutrality: 31 ± 8 vs. 16 ± 5; in cold: 49 ± 13 vs. 7 ± 2;). Tissue content of M2 ($CD11c^-$, $CD206^+$) macrophages was not influenced by CE in either strain of mice (cells/mg tissue: B6 vs. A/J; at thermoneutrality: 228 ± 56 vs. 89 ± 18; in cold: 211 ± 25 vs. 77 ± 22). Overall the M2/M1 ratio was increased in AJ mice by cold exposure.
Conclusion: These results suggest a causal link between the reduced content of M1 macrophages and relatively strong activation of lipid metabolism in response to CE in obesity resistant A/J mice in comparison with obesity prone B6 mice.

Microbiome inhibition of IRAK-4 by trimethylamine mediates metabolic and immune benefits in high fat diet-induced insulin resistance

M.-E. Dumas[1], J. Chilloux[1], A. Myridakis[1], L. Hoyles[1,2], A. Everard[2], H. Plovier[2], P. Cani[2,3], F. Brial[3], D. Gauguier[3,4], D. Smyth[4], L. Zhang[4], P. Liu[4];
[1]Dept of Surgery and Cancer, Div. Integrative Systems Medicine, Imperial College London, London, UK, [2]Universite catholique de Louvain, Brussels, Belgium, [3]Universite Pierre and Marie Curie, Paris, France, [4]Ottawa Heart Centre, Ottawa, Canada.

Background and aims: The interaction between high-fat diet (HFD) feeding and the gut microbiome has a strong impact on the onset of insulin resistance (IR). In particular, bacterial lipopolysaccharides (LPS) and dietary fats trigger low-grade inflammation through activation of *Toll*-like receptor 4 (TLR4), a process called metabolic endotoxemia. However, little is known about how the microbiome can mitigate this process. Here, we investigate longitudinal physiological and metabotypical responses of C57BL/6 mice to HFD feeding.

Materials and methods: We performed a series of *in vivo* experiments in High Fat Diet contexts with i) modulating choline content, ii) blocking trimethylamine (TMA) production, iii) administering TMAiv) deleting Irak4 by KO, v) inhibiting Irak4 by a chemical inhibitor.Samples were analysed by transcriptomics (liver), metabolomics (1H NMR and UPLC-MS/MS for serum and urine).We also performed in vitro kinome screens, followed by Kd and IC50 curves. We treated immortalised murine Kupffer cells (KUP5) with palmitate and TMA to assess cytokine production. These experiments were complemented by molecular dynamics simulations to model interactions between TMA and the IRAK-4 protein.
Results: We demonstrate that this microbiome-associated metabolite decouples inflammation and IR from obesity in HFD. Through *in vitro* kinome screens and *in silico* molecular dynamics studies, we reveal TMA specifically inhibits Interleukin-1 Receptor-associated Kinase 4 (IRAK-4), a central kinase integrating signals from various TLRs and cytokine receptors. Consistent with this, genetic ablation and chemical inhibition of IRAK-4 result in similar metabolic and immune improvements in HFD.
Conclusion: In conclusion, TMA is a key microbial effector inhibiting IRAK-4 and mediating metabolic and immune effects with benefits upon HFD. Thereby we highlight the critical contribution of the microbial signalling metabolome in homeostatic regulation of host disease and the emerging role of the kinome in microbial-mammalian chemical crosstalk.

AGEs induce alterations of sphingolipids metabolism in the liver of genetically- and diet-induced diabetic mice

A.S. Cento[1], K. Gaens[2,3], D. Collotta[4], F. Chiazza[4], F. Barutta[5], J. Scheijen[2], M. Aragno[1], M. Collino[4], K. Wouters[2], C.G. Schalkwijk[2,3], R. Mastrocola[1,2];
[1]Dept. of Clinical and Biological Sciences, University of Turin, Turin, Italy, [2]Dept. of Internal Medicine, University of Maastricht, Maastricht, Netherlands, [3]CARIM School for Cardiovascular Diseases, University of Maastricht, Maastricht, Netherlands, [4]Dept. of Drug Science and Technology, University of Turin, Turin, Italy, [5]Dept. of Medical Sciences, University of Turin, Turin, Italy.

Background and aims: High plasma levels of the sphingolipid metabolism intermediates ceramide (Cer) and sphingosine-1-phosphate (S1P) have been found in obese and type 2 diabetic patients. Cer and S1P are reported to induce the inflammatory response leading to impaired insulin signaling in peripheral tissues. Emerging evidence suggests that accumulating Advanced Glycation End-products (AGEs) can alter the sphingolipids metabolism equilibrium, possibly contributing to the onset of insulin-resistance. We, thus, investigated whether AGEs accumulation can affect the sphingolipids metabolism in animal models of insulin resistance.
Materials and methods: To study the direct contribution of AGEs to sphingolipids metabolism and the putative role of the AGE-receptor RAGE therein, HepG2 cells were incubated with 0.5 μM control-albumin and modified N^{ε}-(carboxymethyl)lysine (CML)-albumin, pre-incubated or not with RAGE antibody. To study the role of AGEs on *in vivo* sphingolipid metabolism, C57Bl/6J (WT), and LeptrDb-/- (DbDb) mice were fed a standard diet (SD), while a group of C57Bl/6J was fed a 60% high trans-fat diet (HFD). In addition, two subgroups of SD and HFD fed mice were supplemented with the anti-AGEs compound pyridoxamine. AGEs levels were evaluated in the liver by LC-MSMS and western blotting. Cer and S1P were measured by GC-MS. The expressions of RAGE and of the enzymes involved in sphingolipid metabolism were assessed by RT-PCR and western blotting.
Results: High levels of AGEs and RAGE were detected in the liver of both DbDb and HFD mice in comparison to WT controls. Moreover, the expression of sphingolipid metabolism enzymes was altered in these mice, accompanied by increased levels of Cer and S1P. Specifically, the levels of ceramide synthase 2 and 5 and sphingosine kinase 1 were increased, while those of neutral ceramidase and S1P phosphatase were reduced. In addition, pyridoxamine supplementation to HFD mice diminished hepatic AGEs accumulation and prevented sphingolipids metabolism alterations and insulin resistance development. In line, CML administration to HepG2 cells evoked alterations similar to those observed *in vivo*, and blocking antibodies against RAGE reverted some of the altered enzyme expressions.
Conclusion: The sphingolipid metabolism is affected in different models of diabetes. The modulation of the enzymes responsible for maintenance of the sphingolipid metabolism equilibrium in CML-incubated HepG2 cells indicates the direct involvement of AGEs and their receptor RAGE in these alterations. The role of AGEs was confirmed by the *in vivo* action of pyridoxamine. These results suggest that the modulation of sphingolipids metabolism through the prevention of AGEs accumulation may reduce insulin resistance development.

Metabolic and hormonal alterations after orchiectomy in the rat: effect of testosterone substitution

N.L. Katsilambros[1], I.P. Doulamis[1], P. Konstantopoulos[1], A. Tzani[1], A. Daskalopoulou[1], T. Spinos[2], E. Bletsa[2], D. Mitsopoulou[2], M. Spinou[2], M. Brinia[2], K. Palaiopanos[2], L. Korou[1], D.N. Perrea[1];

[1]Laboratory for Experimental Surgery and Surgical Research, National and Kapodistrian University of Athens, Greece, Athens, [2]Student of the National and Kapodistrian University of Athens, Greece, Athens, Greece.

Background and aims: Hypogonadism is considered a risk factor for diabetes and metabolic syndrome. The association between low testosterone (T) and its underlying causes remain unclear and controversial. The present experiments aimed to possibly clarify some aspects of this subject.
Materials and methods: Twenty-nine male Wistar rats aged 11–12 weeks, were randomly divided in 3 groups: Controls (C, $n = 10$): Sham operation; Orchiectomy (ORCH, $n = 9$) and Orchiectomy+T substitution (ORCH+T, $n = 10$). Blood samples were obtained for glucose, total-, HDL-, LDL- cholesterol (T-chol, HDL-chol, LDL-chol) and triglycerides (TG) measurements at day 1 (operation), after 10 days (im injection 100 μg/100 g b.w. of testosterone enanthate), 25d (second T injection) and 40d (sacrifice). In addition, in a subgroup of the animals ($n = 6$ in each main category) insulin, irisin and resistin were measured by rat specific ELISA tests at d1, d10 and d40 time intervals. Values for biochemical and hormonal measurements are expressed as mean ± SD and median ± IQR, respectively. Parametric and non-parametric tests were applied as indicated.
Results: No significant changes in glucose, TG, HDL-chol and body weight were observed. As shown in the table T-chol and LDL-chol were higher in the ORCH group as compared to C ($p < 0.05$). In opposite, both T-chol and LDL-chol were lower in comparison to C in the ORCH+T rats. As it concerns hormonal data, orchiectomy was associated with increased levels of insulin at d10 (median ± IQR: 3.67 ± 1.40 ng/mL vs 0.85 ± 1.42 ng/mL, $p = 0.032$, for d10 and d1, respectively). Hormonal replacement significantly attenuated the negative effect of orchiectomy in insulin resistance as indicated by the observed fall both in insulin levels (median ± IQR: 4.10 ± 2.47 ng/mL vs 1.78 ± 0.68 ng/mL, $p = 0.015$, for d10 and d40, respectively) and HOMA-IR index (median ± IQR: 3.68 ± 1.87 vs 1.74 ± 0.69, $p = 0.026$, for d10 and d40, respectively). Irisin's levels followed the same pattern as the aforementioned markers in the ORCH+T group, peaking 10 days after orchiectomy and returning to its initial levels at d40 (median ± IQR: 0.27 ± 0.11 ng/mL vs 0.85 ± 0.54 ng/mL vs 0.02 ± 0.07 ng/mL, $p = 0.002$ in both cases, for d1, d10 and d40, respectively).
Conclusion: Experimental hypogonadism results in an unfavorable (atherogenic) lipid profile, which is not observed when the ORCH animals are substituted for T. In addition, the observed hormonal changes, if further confirmed, suggest the existence of post-orchiectomy insulin resistance which is improved by T administration.

A short bout of HFD desynchronises feeding behaviour in mice thereby affecting glucose and lipid metabolism

S. Wueest[1], M.A. Dedual[1,2], D. Konrad[1,2];
[1]Children's Hospital and Children's Research Center, University Children's Hospital, Zurich, [2]Zurich Center for Integrative Human Physiology, University of Zurich, Zurich, Switzerland.

Background and aims: A short bout of HFD impairs glucose tolerance and induces hepatic steatosis in mice. While prolonged HFD-induced metabolic complications are partly mediated by increased food intake during the light (inactive) phase, such link has not yet been established in short-term HFD-fed mice. Herein, we hypothesised that a short bout of HFD desynchronizes feeding behaviour thereby contributing to glucose intolerance and hepatic steatosis.
Materials and methods: 12-week-old C57BL/6J mice were fed a regular chow or high fat diet (HFD, ~60% kcal fat) for 4 days. Food intake was determined in metabolic cages and glucose metabolism was assessed by performing intraperitoneal glucose tolerance tests. Upon scarification, liver and fat depot weights were measured and tissue was collected for analysis. Western blots, rtPCR and a colorimetric assay for the assessment of liver triglyceride levels were performed.
Results: Changing diet from regular chow to HFD led to an immediate increase in food intake already during the 1st light phase (0.5 ± 0.2 g in chow-fed vs. 1.0 ± 0.1 g in HFD-fed, $p < 0.05$), suggesting that HFD desynchronizes feeding behaviour instantly. As expected, 4 days of ad libitum HFD-feeding significantly impaired glucose tolerance (AUC 1639 ± 76 mmol/l*min before HFD vs. 1827 ± 96 mmol/l*min after HFD, $p < 0.05$). Such effect was prevented in mice receiving intermittent HFD-feeding for 4 days (i.e. mice that had no access to food during the light phase) (AUC 1546 ± 41 mmol/l*min before HFD vs. 1690 ± 92 mmol/l*min after HFD, $p = 0.25$), indicating that desynchronized feeding behaviour contributes to short-term HFD-induced glucose intolerance. Of note, food intake was similar between the groups (2.8 ± 0.1 g/mouse*day in ad libitum HFD-fed vs. 2.5 ± 0.1 g/mouse*day in intermittent HFD-fed, $p = 0.2$), as was body weight (31.4 ± 1.0 g in ad libitum HFD-fed vs. 31.5 ± 0.5 g in intermittent HFD-fed, $p = 0.9$). However, intermittent HFD-fed mice revealed higher inguinal fat depot weights (275 ± 30 mg in ad libitum HFD-fed vs. 347 ± 22 mg in intermittent HFD-fed, $p = 0.08$), whereas liver weight was significantly lower in intermittent fed mice (1462 ± 58 mg in ad libitum HFD-fed vs. 1272 ± 59 mg in intermittent HFD-fed, $p < 0.05$). Phosphorylation of hormone sensitivity lipase (HSL) was significantly elevated in inguinal fat depots of intermittent HFD-fed mice (1.0 ± 0.1 in ad libitum HFD-fed vs. 1.5 ± 0.1 in intermittent HFD-fed, $p < 0.01$), indicating increased lipolysis. In support of increased FFA flux to the liver, hepatic PPARα mRNA expression was significantly elevated in intermittent HFD-fed mice (1.0 ± 0.2 in ad libitum HFD-fed vs. 1.8 ± 0.2 in intermittent HFD-fed, $p < 0.05$). In agreement, liver triglyceride levels were significantly increased in intermitted HFD-fed mice (20.5 ± 2.5 μmol/g liver in ad libitum HFD-fed vs. 39.1 ± 5.6 μmol/g liver in intermittent HFD-fed, $p < 0.05$).
Conclusion: Desynchronized feeding behaviour induced by a short bout of HFD impairs glucose tolerance and impacts on liver lipid metabolism.

Unsaturated fatty acids rescue GLP-1 secreting cells from a ceramide induced increase in ROS following long term exposure to saturated fatty acids

S. Ntika[1,2], K. Thombare[1], M. Aryapoor[1], C. Krizhanovskii[1,2];
[1]Cardiometabolic research, Södertälje Hospital, Södertälje, [2]Molecular Medicine and Surgery, Karolinska Institute, Stockholm, Sweden.

Background and aims: Studies of the effects of fatty acids (FAs) on the function of GLP-1-secreting cells show that FAs, and especially monounsaturated FAs stimulate GLP-1 release, while long term exposure to elevated levels of the saturated FA palmitate is indicated to induce lipotoxicity *in vivo* and *in vitro*. *In vitro* studies further support that cosupplementation with unsaturated FAs confers lipoprotection. Indeed,

numerous studies in various cell types demonstrate that the extent and nature of the effects induced by FAs are dependent on the molecular species of FA and the length of exposure. The present study was designed to further elucidate the mechanisms underlying the effects of saturated/unsaturated FAs on GLP-1-producing cells in terms of lipotoxicity/lipoprotection and GLP-1 secretion.
Materials and methods: GLP-1-secreting GLUTag cells were cultured in the presence/absence of saturated (16:0) and unsaturated (18:1) fatty acids (0.125 mmol/L) in different time points, followed by analyses of viability, apoptosis, GLP-1 secretion, as well as involvement of fatty acid oxidation, ROS production and ceramide kinase assay. In addition, effects on the expression of superoxide dismutase (SOD), catalase or glutathione peroxidase (GPx) were determined.
Results: Our results demonstrate that generation of intracellular ceramide and mitochondrial FA oxidation contributes to increased ROS production following long term exposure to saturated FAs in GLP-1-secreting cells. Cosupplementation with unsaturated reduces ceramide synthesis, increase the expression of ceramide kinase and attenuate ROS production, caspase-3 activity and DNA fragmentation.
Conclusion: Unsaturated FAs (18:1) reduce ceramide content - thereby attenuating the main source of the lipotoxic ROS production in response to long term exposure to elevated levels of saturated FA (16:0). Findings may be of value for nutritional interventions, as well as for identification of novel targets, to help preserve L-cell mass and potentiate GLP-1 secretion in diabesity.

Intracellular lipid mobilisation in INS-1E beta cells is required for sustained glucose-stimulated insulin secretion

L. Oberhauser, T. Brun, P. Maechler;
Department of Cell Physiology and Metabolism, University of Geneva Medical Center, Geneva, Switzerland.

Background and aims: Chronic exposure to elevated glucose levels impairs beta-cell function and eventually leads to cell death. This effect, referred to as glucotoxicity, has been described to be worsened by chronic free fatty acids (glucolipotoxicity). However, the associated turnover of the stored lipids and the consequences on glucose-stimulated insulin secretion remains a matter of debate. The aim of this study was to determine the contribution of the turnover of *de novo* lipid synthesis versus exogenous saturated and unsaturated fatty acids on the function of INS-1E beta-cells.
Materials and methods: INS-1E beta-cells were cultured for 3 days at standard 11.1 mM (control) and high 25 mM glucose in the presence or absence of BSA-complexed 0.4 mM palmitate or oleate, or a mix of both (2 × 0.2 mM) fatty acids. Lipid accumulation and mobilization were assessed by quantifying Bodipy probe fluorescent signal after the 3 days of treatment along a 12h time course at low 5.5 mM glucose. Maximal lipid storage capacity was determined by co-incubating cells with the lipase inhibitor Orlistat during the 3 days of treatment. INS-1E beta-cell function was assessed by 96-well online kinetic measurements of insulin secretion (using luciferase-based C-peptide substitution) upon glucose stimulation with or without Orlistat or insulin pre-treatment.
Results: Chronic treatment with high glucose increased cellular lipids 1.5-fold compared to control (*de novo* lipid synthesis). This effect was markedly potentiated by the addition of oleate in the medium as it increased lipid accumulation by 25-fold compared to control ($p < 0.0001$). Palmitate did so to a much lesser extent (7-fold), while the mix of both fatty acids showed an intermediary lipid accumulation profile (15-fold, $p < 0.01$). The inhibition of cell lipases by Orlistat indicated a maximal lipid accumulation capacity of 40-fold the control ($p < 0.0001$), revealing a substantial lipid turnover in INS-1E beta-cells. However, the blockade of beta-oxidation by Etomoxir during the 3 days of treatment did not further increase lipid accumulation. Once incubated at low glucose, intracellular lipids were differently mobilized according to the previous culture conditions. Over the 12h at low glucose, lipid pool from *de novo* synthesis remained constant, whereas more than 80% of the lipids stored by the cells previously treated with high glucose plus palmitate were mobilized within 3h. Concomitantly, about 75% of the lipid pool in cells treated with high glucose plus the mix of palmitate and oleate was mobilized versus only 30% for the cells treated with high glucose plus oleate. Preventing the cells from mobilizing their stored lipids using Orlistat blunted glucose-stimulated insulin secretion in all conditions. Interestingly, insulin treatment also reduced both lipid mobilization and the secretory response.
Conclusion: INS-1E beta-cells chronically exposed to free fatty acids massively store neutral lipids that can be rapidly mobilized. This turnover depends on the chemical identity of the fatty acids, the saturated palmitate being mobilized much faster than the unsaturated oleate. The mobilized lipids are preferentially required for insulin secretion rather than being used as an energy source. Moreover, insulin seems to act as a negative feedback on glucose-stimulated insulin secretion by lowering fatty-acid mobilization in INS-1E beta-cells.

The protective effect of SFC on high fat diet induced NAFLD in C57BL/6J mice

S. Hong[1,2], Y. Kang[1,2];
[1]The Graduate School Ajou University, Suwon, Gyunggi-do, [2]Department of Physiology, Ajou University School of Medicine, Suwon, Gyunggi-do, Republic of Korea.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a fatty liver disease ranging from simple steatosis to non-alcoholic steatohepatitis (NASH). High fat diet (HFD) generally leads to NAFLD accompanying with obesity. Augmented mobilization of large amount of fatty acids from adipose tissues to the liver is thought to be a cause for development of HFD-induced NAFLD. Thus, inhibition of fatty acid uptake into hepatocyte would be a maneuver for protection of HFD-induced NAFLD. This study was initiated to whether sodium fluorcitrate (SFC) known as a fatty acid uptake inhibitor prevents HFD-induced NAFLD in C57BL/6J mice.
Materials and methods: In hepG2 cells, we treated SFC 0.2mM for 1 hours, followed by palmitate (100uM) conjugated BODIPY-C16 fluroscence uptake for another 3 hours and detected fluorescence.
Results: Initially, we investigated the protective effect of SFC on saturated fatty acid- nduced lipotoxicity in HepG2 hepatocytes. SFC reduced BODIPY-C16 uptake into HepG2 cells and prevented fatty acid- induced lipid accumulation. In addition, SFC treatment was protective against palmitate-induced stress/inflammatory and insulin resistance signals. SFC reduced levels of palmitate-induced p-JNK, p-NFkB, CHOP and restored levels of palmitate-induced p-AKT and p-GSK. C57BL/6J mice with HFD feeding for 16 weeks showed most characteristics occurring in NAFLD. HFD increased TG content in liver and activated stress/inflammatory signals such as p-JNK and p-NFkB. HFD enhanced expression of inflammatory genes such as IL-1b, TNF-a, and MCP. Hepatic injury was also observed by increased level of plasm levels of AST and ALT in HFD-fed mice. Simultaneous treatment with SFC (10 mg/kg, 16 weeks) in HFD-fed mice reduced all markers of HFD-induced NAFLD. SFC reduced hepatic TG level and stress/inflammatory signals in HFD-fed mice. SFC restored HFD-induced insulin resistance signal and hepatic injury. SFC also prevented HFD-induced hyperglycemia and insulin resistance.
Conclusion: In conclusion, inhibition of fatty acid uptake into hepatocytes through SFC treatment can be a strategy to prevent HFD-induced NAFLD.

Linking of bioenergetic function of mitochondria to tissue-specific molecular fingerprints in mice and humans

L. Kappler[1], M. Hoene[1], J. Li[2], C. Hu[2], C. von Törne[3], L. Kollipara[4], C. Hoffmann[1], A. Böhm[5,6], S. Hauck[3], G. Xu[2], H.-U. Häring[1,6], A. Peter[1,6], A. Sickmann[4,7], C. Weigert[1,6], R. Lehmann[1,6];
[1]Department of Diagnostic Laboratory Medicine, Clinical Chemistry Central Laboratory, Tuebingen, Germany, [2]Key Laboratory of Separation Science for Analytical Chemistry, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China, [3]Research Unit Protein Science, Helmholtz Zentrum, Muenchen, Germany, [4]Leibniz-Institut für Analytische Wissenschaften - ISAS - e.V., Dortmund, Germany, [5]Internal Medicine 4, Tuebingen, Germany, [6]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Zentrum Muenchen at the University of Tuebingen, Tuebingen, Germany, [7]Department of Chemistry, College of Physical Sciences, Aberdeen, UK.

Background and aims: Mitochondria are the major sites for energy production in most tissues, thus are molecularly tailored to meet tissue-specific demands. Unravelling the link of mitochondrial protein and lipid molecular fingerprints between tissues and their impact on mitochondrial function provides an important tool for the disentangling of tissue-specificities upon mitochondrial alterations facing external stimuli such as excess substrate flux by diet causing insulin resistance (IR) and diabetes.
Materials and methods: Mitochondrial function was investigated by respirometry (Oxygraph 2k) in mice and human tissue samples. LC-MS/MS-based proteomic/lipidomic analyses of ultracentrifugation-isolated mitochondria from skeletal muscle and liver of a pre-diabetic mouse model (6 weeks of control (10 kJ% fat/20 kJ% protein/70 kJ% carbohydrates) vs high-energy diet (HED; 45 kJ% fat/20 kJ% protein/35 kJ% carbohydrates) were performed ($n = 8$ each). Mitochondrial proteome was covered by non-targeted data-independent acquisition (DIA).
Results: Lipidomics revealed distinctly different lipid profiles (~280 species/50 µg mitochondrial protein) between tissues. This was specifically reflected in the acyl chain composition of phospholipids including the mitochondrial signature lipid cardiolipin (28 species) and phosphatidylethanolamine (57 species), both key regulators of oxidative phosphorylation. Despite this tissue-specificity of mitochondria, their response to HED was comparable on lipid level. However, functional analysis of isolated mitochondria from mice and human revealed that muscle oxidised more of the complex 1 substrate pyruvate (when already respiring on a fatty acid) whereas liver increased respiration more after addition of the complex 2-associated substrate succinate, indicating a routing of pyruvate towards carboxylation. Both tissues showed a higher fat oxidation capacity in the IR state. DIA identified ~2000 proteins in liver and ~900 in muscle mitochondria showing diet associated clustering by principle component analysis.
Conclusion: We linked the mitochondrial molecular composition with tissue-specific mitochondrial (dys)function generating a novel tool for elucidating mitochondrial adaptions to e.g. diet-induced IR.

Chronic treatment with acylated analogues of apelin-13 improves glycaemic control and lipid profiles in diet induced obese diabetic mice

F.P.M. O'Harte, V. Parthsarathy, C. Hogg, P.R. Flatt;
School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: Apelin-13 is an adipokine which has promising metabolic effects but is rapidly degraded in plasma. Previous studies have shown that modified apelin analogues exhibited enzyme resistance in plasma and improved circulating half-life compared to apelin-13. This study investigated the antidiabetic effects of chronic administration of stable long acting fatty acid modified apelin analogues, namely, (Lys^{8}GluPAL)apelin-13 amide and pGlu(Lys^{8}GluPAL)apelin-13 amide, in diet induced obese-diabetic mice.
Materials and methods: Male NIH Swiss mice (groups $n = 8$) were maintained either on a high-fat diet (45% fat) from 8 to 28 weeks old, or control mice were fed a normal diet (10% fat). When diet induced obesity-diabetes was established after high-fat feeding, mice were injected i.p. once daily with apelin analogues, liraglutide (25 nmol/kg) or saline (controls).
Results: Administration of (Lys^{8}GluPAL)apelin-13 amide and pGlu(Lys^{8}GluPAL)apelin-13 amide for 28 days significantly reduced food intake and decreased body weight. Non-fasting glucose was reduced ($p < 0.01$ to $p < 0.001$) and circulating insulin concentrations elevated ($p < 0.01$ to $p < 0.001$). This was accompanied by enhanced insulin responses ($p < 0.01$ to $p < 0.001$) and significant reductions in glucose excursion after both oral ($p < 0.01$) or i.p. ($p < 0.01$) glucose challenges and feeding. Apelin analogues also significantly improved HbA_{1c} ($p < 0.01$), enhanced insulin sensitivity ($p < 0.01$), reduced triglycerides ($p < 0.001$), increased HDL-cholesterol ($p < 0.01$) and decreased LDL-cholesterol ($p < 0.01$), compared to saline treated diet induced obese mice. Cholesterol levels were decreased ($p < 0.01$) by pGlu(Lys^{8}GluPAL)apelin-13 amide and both apelin treated groups showed improved bone mineral content, reduced fat deposits and increased plasma GLP-1 concentrations. Daily treatment with liraglutide mirrored many of these changes (not on bone or adipose tissue), but unlike apelin analogues increased plasma amylase. Consumption of O_2, production of CO_2, respiratory exchange ratio and energy expenditure were improved by apelin analogues. These results indicate that long-term treatment with acylated analogues (Lys^{8}GluPAL)apelin-13 amide and particularly pGlu(Lys^{8}GluPAL)apelin-13 amide resulted in similar or enhanced therapeutic responses compared to liraglutide in high-fat fed mice.
Conclusion: Stable fatty acid modified apelin analogues represent a new and exciting development in the treatment of obesity-diabetes.

Weight loss reduces postprandial dicarbonyl stress but not AGEs in abdominally obese men

M.D.G. Van den Eynde[1,2], Y.H.A. Kusters[1,2], J.L.J. Scheijen[1], A.J.H. Houben[1], P.J. Joris[2,3], J. Plat[3], R.P. Mensink[2,3], C.D.A. Stehouwer[1], C.G. Schalkwijk[1,2];
[1]Department of Internal Medicine, School for Cardiovascular Diseases (CARIM), Maastricht University Medical Center, Maastricht, [2]Top Institute of Food and Nutrition (TIFN), Wageningen, [3]Department of Human Biology, School of Nutrition and Translational Research in Metabolism (NUTRIM), Maastricht University Medical Center, Maastricht, Netherlands.

Background and aims: Dicarbonyl compounds are highly reactive byproducts of glycolysis and are a major contributor to the formation of advanced glycation endproducts (AGEs) and the development of insulin resistance and vascular complications. We recently demonstrated that increased α-dicarbonyls in the postprandial phase in patients with impaired glucose metabolism and type 2 diabetes were reduced by weight loss. However, data of α-dicarbonyls and AGEs in abdominally obese individuals are lacking. Therefore, we aim to examine fasting and postprandial levels of α-dicarbonyls and AGEs in lean and abdominally obese men and we evaluate whether a weight loss intervention reduces α-dicarbonyl stress and AGEs.
Materials and methods: Plasma samples were collected from lean ($n = 25$) and abdominally obese men ($n = 52$) in the fasting state, and in the postprandial phase during a mixed meal test. Abdominally obese men were randomized to either an 8-week dietary weight loss intervention program or their habitual diet; after 8 weeks a second mixed meal test was performed. The α-dicarbonyls, methylglyoxal (MGO), glyoxal (GO) and 3-deoxyglucosone (3-DG) and AGEs were measured by UPLC-MS/MS. In the fasting state, skin autofluorescence (SAF) was measured using the AGE-reader. An independent samples t-test was used for the cross-sectional data, one-factor analysis of covariance with the baseline value as a covariate was used to detect differences between groups over time.
Results: Fasting MGO, GO, and 3-DG did not differ significantly between lean and abdominally obese men (MGO: 293 ± 52 nM vs 297 ± 54 nM, GO: 755 ± 195 nM vs 686 ± 139 nM, 3-DG: 958 ± 74 nM vs 993 ± 117 nM). In accordance, also AGEs and SAF did not show any difference between lean and obese individuals. However, postprandial α-dicarbonyl concentrations were significantly higher in obese men as compared to lean men (iAUC difference between lean and obese: MGO $p < 0.01$, GO $p = 0.06$, 3-DG $p < 0.01$). After an 8-week dietary weight loss intervention (−10% body weight on average), fasting α-dicarbonyls tended to decrease (MGO: from 291 ± 52 nM to 275 ± 52 nM; GO: from 674 ± 152 nM to 607 ± 136 nM; 3-DG: from 950 ± 105 nM to 938 ± 86 nM), while the weight stable group did not show such differences. AGEs and SAF measurements did not change significantly. Postprandial α-dicarbonyl levels in the weight reduction group were reduced (iAUC: MGO −75%, GO −50%, 3-DG −68%) as compared to the weight stable group (MGO $p < 0.05$, GO $p < 0.05$, 3-DG $p < 0.01$).
Conclusion: This study shows that abdominal obesity is characterized by increased postprandial α-dicarbonyl stress. While AGE and SAF levels were largely unaltered, postprandial α-dicarbonyl stress can be significantly reduced by weight reduction in abdominally obese individuals.

High number of responders with pharmacotherapy-induced weight loss ≥15% in a placebo-controlled dose-ranging study of semaglutide in subjects with obesity

A.L. Birkenfeld[1], J. Wilding[2], B. McGowan[3], O. Mosenzon[4], S.D. Pedersen[5], S. Wharton[6], L. Endahl[7], C.E. Heerdegen-Jepsen[7], P.M. O'Neil[8];
[1]University Hospital and Faculty of Medicine, TU Dresden, Germany, [2]University of Liverpool, Liverpool, UK, [3]Guy's and St Thomas NHS Foundation Trust, London, UK, [4]Hadassah Hebrew University Hospital, Jerusalem, Israel, [5]C-ENDO Diabetes & Endocrinology Clinic, Calgary, Canada, [6]York University, Toronto, ON, Canada, [7]Novo Nordisk, Søborg, Denmark, [8]Medical University of South Carolina, Charleston, USA.

Background and aims: Semaglutide (SEMA) is a glucagon-like peptide 1 receptor agonist recently approved to treat type 2 diabetes and currently under investigation at higher doses for weight management. A recent phase 2 trial showed significant, dose-dependent weight loss vs placebo for once-daily SEMA at doses of 0.05–0.4 mg. In this *post-hoc* analysis, the proportion of subjects achieving ≥15% or ≥20% weight loss in this trial was assessed by assigned treatment and by whether treatment was completed.
Materials and methods: This was a randomised, double-blinded, placebo-controlled phase 2 trial of SEMA with dietary and exercise counselling in adults with obesity without diabetes. SEMA (0.05, 0.1, 0.2, 0.3 or 0.4 mg) or matching placebo was given by once-daily s.c. self-injection; starting at 0.05 mg, and escalated to the next dose level every 4 weeks until the target dose was reached. Total treatment duration (including an escalation phase ≤16 weeks) was 52 weeks. Subjects who discontinued treatment for any reason ceased subsequent visits but were encouraged to return at week 52 for off-treatment assessment. The proportions with weight loss ≥15% or ≥20% of baseline were assessed at week 52 for those with data on or off treatment with SEMA or placebo.
Results: 649 subjects (35% male) were randomised on the above schedule. Mean age was 44–48 years across dosing groups (overall range 18–77); mean weight was 111–114 kg (73–244), and mean BMI 39–40 kg/m^2 (30–80). Week 52 data were available for 600 subjects (92%); 525 on treatment, 75 off treatment. Response was dose-related and the proportion of responders in both weight-loss categories was high at doses of 0.2–0.4 mg/day; overall 32–42% of subjects lost ≥15% of baseline weight and 14–29% lost ≥20%, vs 6% and 2%, respectively, on placebo. Almost all responders in both categories at these SEMA doses were still on treatment at week 52 (97–100% across dosing arms). Among subjects who completed the full 52-week treatment period, 33–50% receiving 0.2–0.4 mg/day SEMA had a weight loss ≥15%, and 15–35% had a loss ≥20% (Figure).
Conclusion: A high proportion of subjects in this phase 2 study who completed SEMA treatment at doses of 0.2–0.4 mg/day over 52 weeks lost at least 15% of baseline body weight. For those who received 0.4 mg/day, half lost ≥15% and 35% lost ≥20% of their baseline weight.

The effects of acarbose, sitagliptin, verapamil, liraglutide and pasireotide on hypoglycaemia and glycaemic variability in Roux-en-Y gastric bypass operated subjects

C.C. Øhrstrøm[1], D.L. Hansen[2], U.L. Kielgast[1], J.J. Holst[3], D. Worm[4]; [1]Zealand University Hospital, Køge, [2]Steno Diabetes Center, Gentofte, [3]University of Copenhagen, Copenhagen, [4]Amager Hospital, Copenhagen, Denmark.

Background and aims: Hypoglycemia is a severe complication after Roux-en-Y gastric bypass (RYGB), with no effective treatment options. We investigated the glucose stabilizing effects of five therapeutic agents in RYGB operated subjects with hypoglycemia.

Materials and methods: In a randomized crossover study, 11 RYGB operated subjects with documented hypoglycemia (blood glucose <3.9 mmol/L) underwent six separate meal tolerance tests (MTT) preceded by either: no treatment, acarbose 50 mg × 6 daily for 1 week, sitagliptin 100 mg for 1 week, verapamil 120 mg for 1 week, liraglutide 1.2 mg for 3 weeks or pasireotide 300 μg as a single dose. Blood samples were drawn at fixed time intervals from −20 to 180 min. Hormonal responses were calculated as the incremental area under the curve (iAUC), and the glucose response was further specified as the area above (+iAUC) and below (−iAUC) baseline values. Furthermore, the treatment effect was evaluated in everyday life by 6 days of continuous glucose monitoring (CGM) during treatment with acarbose, sitagliptin, verapamil, liraglutide, and compared to a baseline recording with no treatment. Data were analyzed by use of linear mixed models.

Results: (See table 1) During the MTT, treatment with acarbose and pasireotide significantly increased nadir glucose, whereas treatment with sitagliptin decreased nadir glucose. Acarbose, liraglutide and pasireotide significantly reduced $-iAUC_{glucose}$, while only acarbose reduced $+iAUC_{glucose}$ and pasireotide increased this area. Time spent in hypoglycemia (<3.9 mmol/L) decreased with both acarbose and pasireotide, whereas time in hyperglycemia (>7.9 mmol/L) decreased with acarbose but increased with pasireotide. Treatment with acarbose and pasireotide significantly reduced $iAUC_{insulin}$. During the CGM recordings, treatment with liraglutide increased minimum interstitial fluid glucose (IG) and both liraglutide and acarbose reduced the standard deviation of the IG measurements. Treatment with acarbose, sitagliptin and liraglutide reduced percentage of time spent in hyperglycemia, whereas none of the treatments had any impact on time spent in hypoglycemia.

Conclusion: In response to a standardized meal, treatment with acarbose reduced both hypoglycemia and hyperglycemia, whereas pasireotide completely resolved hypoglycemia but at the cost of increased hyperglycemia. In everyday life, both acarbose and liraglutide decreased glycemic variability and reduced hyperglycemia, but had little effect on hypoglycemia. Acarbose, pasireotide and perhaps liraglutide can be considered in the treatment of hypoglycemia following RYGB.

A randomised, phase 2, placebo- and active-controlled dose-ranging study of semaglutide for treatment of obesity in subjects without diabetes

J. Wilding[1], A.L. Birkenfeld[2], B. McGowan[3], O. Mosenzon[4], S.D. Pedersen[5], S. Wharton[6], M. Kabisch[7], C.G. Carson[7], P.M. O'Neil[8]; [1]University of Liverpool, Liverpool, UK, [2]University Hospital and Faculty of Medicine, TU Dresden, Germany, [3]Guy's and St Thomas' NHS Foundation Trust, London, UK, [4]Hadassah Hebrew University Hospital, Jerusalem, Israel, [5]C-ENDO Diabetes & Endocrinology Clinic, Calgary, Canada, [6]York University, Toronto, Canada, [7]Novo Nordisk, Søborg, Denmark, [8]Medical University of South Carolina, Charleston, USA.

Background and aims: The global rise in the prevalence of obesity and its comorbidities is a major public health challenge. The incretin glucagon-like peptide-1 (GLP-1) regulates both insulin secretion and appetite, and significant weight loss has been observed among subjects treated with the GLP-1 receptor agonists liraglutide (LIRA) and semaglutide (SEMA). The use of SEMA for treatment of obesity without diabetes was evaluated in a Phase 2 clinical trial.

Materials and methods: This was a multinational, randomised, double-blinded, dose-ranging study of SEMA versus placebo (PBO) and an active LIRA control (3 mg), each with dietary and physical activity counselling. Eligible subjects were adults with obesity (BMI ≥30 kg/m^2) without diabetes and with at least one previous non-surgical attempt at weight loss. Participants were randomised to receive PBO or active treatment with either once-daily subcutaneous SEMA at doses of 0.05, 0.1, 0.2, 0.3, or 0.4 mg (starting at 0.05 mg and escalating every 4 weeks to target dose) or with once-daily subcutaneous LIRA 3 mg (weekly escalation from 0.6 mg), in a 6:1 active:PBO ratio. Each active group had a PBO counterpart of matching injection volume and escalation schedule; all PBO groups were pooled for analysis. Two additional faster-escalation SEMA groups are not presented here. The primary endpoint was change in body weight (%) from baseline (BL) to week 52 (analysis of covariance model; treatment, region, sex, and BL body weight as covariates).

Results: A total of 957 subjects (35% male) were randomised and treated (102–103 per active arm; 136 pooled PBO). Mean (range) BL characteristics were: age 47 (18–86) years, weight 111 (70–244) kg, and BMI 39 (30–80) kg/m^2. Overall, 93% (892/957) had body weight data at Week 52 (81% on drug, 12% discontinued). Estimated mean weight losses from BL to Week 52 were −2.3% (PBO) and −7.8% (LIRA 3 mg), vs −6.0% (0.05 mg; $P = 0.001$ vs PBO), −8.6% (0.1 mg), −11.6% (0.2 mg), −11.2% (0.3 mg) and −13.8% (0.4 mg; $P < 0.0001$ vs PBO for 0.1–0.4 mg). All comparisons remained significant after adjustment for multiple testing. Mean weight loss for 0.2–0.4 mg were all $P < 0.01$ (unadjusted) vs LIRA 3 mg. Weight loss ≥5% occurred in an estimated 23% (PBO) and 66% (LIRA 3 mg) vs 54% (0.05 mg), 67% (0.1 mg), 75% (0.2 mg), 81% (0.3 mg), and 83% (0.4 mg) of subjects (all $P < 0.0001$ vs PBO). Weight loss ≥10% occurred in an estimated 10% (PBO) and 34% (LIRA 3 mg) vs 19% (SEMA 0.05 mg; P=NS vs PBO), 37% (0.1 mg), 56% (0.2 mg), 58% (0.3 mg), and 65% (0.4 mg) of subjects ($P < 0.0001$ vs PBO for 0.1–0.4 mg). All SEMA doses were generally tolerated; there were no new safety concerns observed. The most common adverse events on SEMA were dose-related gastrointestinal events as seen previously with GLP-1 receptor agonists.

Conclusion: In combination with dietary and physical activity counselling, all SEMA doses from 0.05 to 0.4 mg daily were tolerated and resulted in dose-related reductions in body weight that were superior to PBO among people with obesity without diabetes.

Serum acid uric levels as an indicator for metabolically unhealthy obesity in youth: results from a population-based cohort in Germany

E.A.A. Rocha[1], M. Vogel[2], J. Stanik[2], A. Körner[3], W. Kiess[1];
[1]University of Leipzig, Hospital for Children and Adolescents, University of Leipzig, Leipzig, [2]University of Leipzig, Centre of Paediatric Research (CPL), University of Leipzig, Leipzig, [3]Hospital for Children and Adolescents, Department of Women and Child Health, University Hospitals, University of Leipzig, Leipzig, Germany.

Background and aims: Obesity during the childhood and adolescence increases the risk of several other chronic diseases and, because of its epidemic proportions, has become a major public health problem worldwide. Increasing evidence shows, paradoxically, that some obese individuals, reported as having "metabolically healthy obesity (MHO)", seem to be protected from developing type 2 diabetes mellitus and a cardiovascular disease, in contrast to those with metabolically unhealthy obesity (MUO). The aim of this study was to improve the understanding of potential clinical and metabolic indicators that may help to distinguish between MHO from MUO phenotype. The specific aim of this study was to explore the relationship between serum uric acid levels and metabolic health in overweight and obese children and adolescents.
Materials and methods: The study involved 246 overweight/obese (ov/ob) and 212 normal weight individuals enrolled in the LIFE-Child study, aged between 6 and 18 years. LIFE-Child is a longitudinal study to evaluate how environmental, metabolic and genetic factors affect development and health from fetal life to adulthood.
Results: Among the 246 ov/ob individuals, 173 (70%) can be regarded as MHO and 73 (30%) can be regarded as MUO. Overweight/obese individuals who were completely free of metabolic cardiovascular risk, i.e., fasting serum lipids, blood pressure and glucose were classified as MHO. Individuals meeting one or more criteria of cardiovascular risk factors were classified as metabolically unhealthy obesity (MUO). The MHO individuals were younger, more likely to be male, had lower BMI-SDS and had lower levels of uric acid and C-peptide and liver enzymes. In addition, glucose metabolism was altered in MUO as indicated by increased insulin levels and reduced WBISI with normal glycemia compared to the MHO group. In logistic regression models, UA SDS, waist circumference, and C-peptide, were significant indicators of MUO after adjusting for age, sex, pubertal status, and BMI-SDS.
Conclusion: Our results show that nearly one-sixth of the individuals are already identified as MUO. Findings suggest that higher levels of uric acid are an indicator of MUO in German overweight and obese children and adolescent.

Beta cells in diabetes remission and hypoglycaemia after Roux-en-Y gastric bypass surgery, visualised by 68Ga-exendin-4 PET/CT

M. Boss[1,2], L.N. Deden[2,3], H. de Boer[3], E.O. Aarts[2], E. Hazebroek[2], M. Brom[1], F.J. Berends[2], M. Gotthardt[1];
[1]Nuclear medicine, Radboudumc, Nijmegen, [2]Surgery, Rijnstate hospital, Arnhem, [3]Internal Medicine, Rijnstate hospital, Arnhem, Netherlands.

Background and aims: Roux-en-Y gastric bypass surgery (RYGB) is performed in patients with morbid obesity to achieve weight loss. In addition, remission of type 2 diabetes (T2D) occurs in >60% of patients. In rare cases, hyperinsulinaemic hypoglycaemia develops. Mechanisms underlying these responses are incompletely understood, but a role for beta cell activity (BCA) and beta cell mass (BCM) is hypothesized. Studying BCM *in vivo* is possible using radiolabeled Exendin-4, a stable analogue of glucagon-like peptide-1, that specifically accumulates in beta cells. In this study, the role of beta cell mass in differences in metabolic responses to RYGB was examined by ^{68}Ga-exendin-4 PET/CT.
Materials and methods: BCA and BCM were compared between patients with differences in glycaemic control after RYGB. Five patients with complete T2D remission (responders), five without complete T2D remission (non-responders) and five with hypoglycaemia were included. BCA was measured by arginine stimulation. BCM was studied by ^{68}Ga-exendin-4 PET/CT. Total pancreatic uptake of ^{68}Ga-exendin-4 was measured as a marker for BCM.
Results: Patient characteristics and weight loss were comparable between the groups. BCA was lower in non-responders compared to responders, (acute C-peptide responses: 0.4 ± 0.2 and 0.9 ± 0.3 nmol/l, $p = 0.02$). Pancreatic 68Ga-exendin-4 uptake was 26% lower in non-responders (83 ± 58 kBq) compared to responders (111 ± 55 kBq), although not statistically significant ($p = 0.088$). BCA and BCM did not correlate. In hypoglycaemia, mean BCM was higher than in responders (191 ± 63 kBq, $p = 0.032$).
Conclusion: This data suggests that BCM is higher in T2D responders compared to non- responders and higher in hypoglycaemia compared responders. In conclusion, BCM may play an important role patient response to RYGB. ^{68}Ga-exendin-4 PET/CT is a feasible technique to measure BCM *in vivo* and study its role in pathophysiological mechanisms underlying diabetes.

Morbid obesity does not attenuate ethnic differences in regionalisation of body fat

M.B. Whyte[1,2], P. Chitongo[2], L.N. Roberts[2], R. Arya[2], S.J.B. Aylwin[2];
[1]Clinical & Experimental Medicine, University of Surrey, Guildford, [2]Medicine, King's College Hospital NHS Foundation Trust, London, UK.

Background and aims: Body mass index (BMI) is a risk factor for mortality but this relationship is weaker for black African origin than Caucasians and may relate to racial differences in body fat distribution. However, studies have primarily been made in those with a BMI of <40 kg/m^2. We examined whether racial differences in central-to-peripheral body fat distribution are present in those with morbid obesity. Due to gender differences in body composition, females only were analysed. As women increase central fat deposition during menopausal transition, we compared women of 'premenopausal' (<52 years) to 'postmenopausal' (≥52 years) age.
Materials and methods: Patients were recruited from a bariatric obesity clinic. Inclusion criteria: females, BMI ≥40 kg/m^2, age ≥18 years. Exclusion criteria: known diabetes, active cancer, history of myocardial infarction, cerebrovascular disease, bariatric surgery. Visceral adipose tissue (VAT) evaluated by single-slice computed tomography (CT) at midpoint of L4 vertebral body. Semi-automated assessment of VAT and subcutaneous adipose tissue (SAT) compartments were performed using Analyze direct 10 software (AnalyzeDirect, Kansas, USA). Adipose tissue area was determined by a Hounsfield unit range between −190 and −30. Fasting samples were collected for glucose, insulin and lipid profile. Insulin resistance was calculated using Homeostasis Model Assessment 2 (HOMA2-IR). BMI and VAT quintile, ethnicity, age category were used in a General Linear Model (GLM) for HOMA2-IR. Comparisons

between (self-reported) ethnicity groups using Kruskal-Wallis (non-parametric) and ANOVA (parametric) data. Data are mean(SD) except triglycerides: median (interquartile range).

Results: A total of $n = 71$ (Caucasian $n = 40$, black African origin (BAO) $n = 14$, Asian $n = 17$) were studied ('premenopausal' $n = 51$). There was no difference in BMI (Table 1) or age: Caucasian 45.1(9.5), BAO 49.3(11.7), Asian 42.1(11.0) years; $P = 0.158$ between ethnicities. BAO and Asians had lower triglycerides and VAT than Caucasians. There were no differences in SAT area between ethnicity, however the VAT/SAT ratio was higher in Caucasians than BAO or Asians (Table 1). HOMA2-IR was lower in BAO than Asians and Caucasians. There was no difference in VAT or SAT between age categories (Table 1). In the GLM, BAO predicted lower HOMA2-IR than Caucasians (β −0.902, 95% CI −1.671 to −0.133; $P = 0.022$). Compared to largest VAT quintile (VAT5), lowest VAT (VAT1) predicted lower HOMA2-IR (β −1.205; $P = 0.043$), as did VAT2 (β −1.485; $P = 0.009$), VAT3 (β −1.171; $P = 0.031$) and VAT4 (β −1.293; $P = 0.013$). No relationship of age or BMI category to HOMA2-IR.

Conclusion: Even in morbid obesity, differences remain in the regionalisation of body fat between ethnicities. There is greater visceral adiposity in morbidly obese Caucasian females. This might partially explain the closer relationship of BMI to mortality risk in Caucasian females than in other ethnicities.

Table 1.

	Ethnicity			Age	
	Caucasian	Black African Origin	Asian	<52 years	≥52 years

Aberrant functional connectivity of the anterior insula with reward and inhibitory control circuits and its association with plasma levels of leptin in obese individuals

A. Ferrulli[1], F. Devoto[2], L. Zapparoli[3], R. Bonandrini[2], L.M. Sconfienza[3], G. Banfi[3], L. Luzi[4], E. Paulesu[2];
[1]IRCCS Policlinico San Donato, San Donato Milanese (MI), [2]University of Milano-Bicocca, Milan, [3]IRCCS Galeazzi, Milan, Italy, [4]University of Milan, Milan, Italy.

Background and aims: There is growing evidence for the role of the insular cortex in the integration of information coming from either sensory and somatosensory cortices and from higher-order areas. However, its role in the regulation of food intake and its interaction with hormones implied in meal termination is still poorly understood. Here, we used resting-state functional brain connectivity (FBC) to explore system-level dysfunctions in the brain of obese (OB) individuals and their correlations with the plasma levels of leptin.

Materials and methods: We started with a quantitative meta-analysis of previous fMRI data on obesity and identified the left anterior insula and the overlying frontal operculum (AI/fO) as a region with convergent hyper-activation in OB individuals exposed to food-related stimuli. This cluster was then used as a seed for a seed-based FBC analysis in 10 OB and 11 normal weight controls matched for sex, age and education. The analysis implied the calculation of the functional correlations of each and every brain voxel with the seed along the resting state fMRI time series.

Results: OB individuals, compared with the control group, showed hyper-connectivity between the left AI/fO and key regions of the reward system, such as the left medial orbitofrontal cortex (OFC), in addition to the bilateral parahippocampal gyri and the posterior cingulate gyrus; conversely, they exhibited hypo-connectivity between the seed and the left dorsolateral prefrontal cortex (DLPFC), which is a key region involved in inhibitory control (all Ps <0.05 corrected for multiple comparisons). Finally, we found a substantial trend for a negative correlation between AI/fO-OFC hyper-connectivity and plasma levels of leptin ($\rho = -0.612$, $p = 0.06$).

Conclusion: Our results provide evidence for an imbalance between reward and inhibitory control systems in OB individuals, which might be worsened by an altered response to food intake regulatory hormones (e.g., leptin), thus driving the overeating behaviour. In sum, our results suggest that the AI/fO is a privileged anatomical location capable to integrate information from both reward and inhibitory control brain regions, and might be a suitable candidate for neuro-modulatory treatments aimed at recalibrating its connectivity profile.

PS 039 Obesity and lipid metabolism: studies in human-derived cells

569

Integral lipidomic analysis of human skeletal muscle and visceral adipose tissue biopsy samples from lean, obese and type 2 diabetic individuals

U. Loizides-Mangold[1], S. Chanon[2], M. Robert[3], E. Lefai[2], C. Dibner[1];
[1]Department of Internal Medicine Specialties, University of Geneva, Geneva, Switzerland, [2]CarMeN Laboratory, INSERM U1060, INRA 1397, University Lyon 1, Oullins, France, [3]Department of Digestive and Bariatric Surgery, Edouard Herriot Hospital, Lyon, France.

Background and aims: Type 2 diabetes is characterized by impaired insulin secretion and insulin resistance. Upon obesity, adipocyte storage capacity is eventually exceeded and lipids are released into the plasma. Chronically increased plasma lipids further promote insulin resistance as excessive accumulation of lipids and their intermediate products causes lipotoxicity in peripheral organs including pancreatic islets, liver, and muscle. In particular, lipid-induced ER stress leads to excessive UPR activation in the ER, with substantial impact on calcium homeostasis and insulin secretion. We therefore aimed to investigate the skeletal muscle and visceral adipose tissue lipidomic signatures of obesity and T2D in humans.
Materials and methods: Human tissue biopsy samples were obtained from lean, obese and obese/type 2 diabetic (T2D) human skeletal muscle ($N = 67$) and visceral adipose tissue donors ($N = 37$). Adipose biopsy samples were taken from the same individuals that were also subjected to muscle biopsy, and compared across subjects in each group, and among the groups. Lipid extracts were prepared using a modified MTBE extraction protocol on tissue biopsies with the addition of internal lipid standard. MRM based tandem mass spectrometry was performed for the identification and quantification of phospho- and sphingolipid lipid species by direct infusion on a TSQ Vantage mass spectrometer equipped with a robotic nanoflow ion source (Nanomate).
Results: Our results show that the ratio of phosphatidylcholine to phosphatidylethanolamine (PC/PE) is increased upon obesity and T2D in human skeletal muscle biopsy samples (lean vs obese, $p = 0.03$; lean vs T2D $p = 0.008$), potentially affecting ER homeostasis. Furthermore, levels of the mitochondria-specific lipid cardiolipin were decreased, reflecting the more sedentary lifestyle of obese/T2D donors (lean vs T2D $p = 0.022$). Sphingolipids were also affected in human skeletal muscle and visceral adipose tissue upon obesity and T2D. Moreover, obesity and T2D had a profound effect on the fatty acid composition of membrane lipids. Almost all major phospholipids were composed of significantly higher levels of saturated fatty acids (SFAs) and mono-unsaturated fatty acids (MUFAs) with potential impact on membrane fluidity and ER homeostasis.
Conclusion: This comparative analysis between lipid profiles from muscle and adipose tissue biopsies allows for novel and important information on tissue specific lipidomic profiles upon obesity and T2D. Data from our ongoing lipidomic analyses on human skeletal muscle tissue and visceral adipose tissue derived from lean, obese and T2D donors support the hypothesis that lipid metabolic changes occur upon these pathologies.

Long-chain ceramides are lipotoxicity-induced cell non-autonomous endoplasmic reticulum stress-activating secretory signals released from skeletal myocytes

L.D. Roberts[1], B.D. McNally[2], S.A. Murfitt[2], F. Sanders[2], J. Garnham[1], M. Vacca[3], K. Witte[1], A.J. Murray[4], J.L. Griffin[2];
[1]Leeds Institute of Cardiovascular & Metabolic Medicine, University of Leeds, Leeds, [2]Department of Biochemistry, University of Cambridge, Cambridge, [3]Institute of Metabolic Science, University of Cambridge, Cambridge, [4]Physiology, Development & Neuroscience, University of Cambridge, Cambridge, UK.

Background and aims: Mammalian tissues have developed responsive pathways to counter cellular stress. In type 2 diabetes (T2D), obesity and dyslipidaemia, tissues are exposed to multiple stressors including free fatty acids (FFA), which lead to lipotoxicity. The Endoplasmic Reticulum (ER) has a key role in the folding and packaging of secretory proteins, and in lipid biosynthesis. Upon the detection of stress stimuli in the ER, the unfolded protein response (UPR) is activated through three distinct branches; regulated by the proteins PERK, IRE1 and ATF6. Chronic ER stress has deleterious effects and has emerged as an underlying mechanism of FFA-induced insulin resistance in skeletal muscle. Tissue-localized ER UPRs were recently observed to activate systemic UPR activation, suggesting an, as yet unknown, ER stress-propagating cell non-autonomous intra- and inter-organ signal. Determining the mechanisms of this stress communication across tissues is crucial to understanding the role of ER stress in T2D aetiology. This work aims to identify lipotoxicity-induced signals released from myocytes and skeletal muscle which function to propagate the ER stress response.
Materials and methods: Human and mouse C2C12 myoblasts were differentiated into myotubes and treated with palmitate (100 and 200 μM) throughout. RT-qPCR analysis of ER stress markers in the myoblasts was performed (EDEM1, ATF4, ATF3, HSPA5). Exosomes were isolated from conditioned myocyte media. *Pectoralis major* muscle biopsies and plasma were obtained from 80 patient volunteers with Body Mass Indices (BMI) ranging from 17.8–40.8. Gastrocnemius muscle and plasma was harvested from C57BL6 mice fed either a western or 60% High fat diet for 12 weeks. Lipidomic analysis of cell media and exosomes, mouse and human skeletal muscle and plasma was performed using Liquid Chromatography-Mass Spectrometry (LC-MS).
Results: Lipotoxicity and ER stress were induced in murine C2C12 and human primary skeletal myotubes using the FFA, palmitate. Conditioned media from these myotubes induced the expression of the UPR genes in naïve myotubes (EDEM1 2-fold t-test $P < 0.01$, ATF4 3.5-fold t-test $P < 0.001$, HSPA5 1.3-fold, $P < 0.05$). The ER stress-inducing ability of the conditioned media was retained in boiled media (protein denaturation), in the isolated media lipid fraction, and in exosomes isolated from the media, suggesting a lipid signal secreted within exosomes. Using lipidomics, long-chain ceramides (Cer 34:1, Cer 40:1, Cer 40:2 and Cer 42:1) were found to be enriched in exosomes from the media of FFA-treated myotubes, via a PERK-dependent ER stress pathway. Ceramide 40:1 and 42:1 induced ER stress in human and murine myocytes (Cer 40:1 ATF4 2-fold t-test $P < 0.05$, HSPA5 1.5-fold, $P < 0.05$, Cer 42:1 ATF4 3-fold $P < 0.01$, HSPA5 1.5-fold $P < 0.05$) and were enriched in the skeletal muscle of both diet induced mouse models of diabetes, and in obese humans.
Conclusion: These data suggest long-chain ceramides may be a novel skeletal myocyte non-autonomous intra-organ signal propagating ER stress resultant from FFA-induced lipotoxicity.

Structure-toxicity relationships of different saturated and unsaturated free fatty acids with respect to mechanisms of toxic action in human EndoC-βH1 beta cells

T. Plötz[1], B. Krümmel[1], I. Mehmeti[2], S. Lenzen[1];
[1]Institute of Experimental Diabetes Research, Hannover Medical School, Hannover, [2]Institute of Clinical Biochemistry, Hannover Medical School, Hannover, Germany.

Background and aims: Type 2 diabetes is associated with chronically increased plasma concentrations of free fatty acids (FFAs), which trigger β-cell dysfunction and apoptosis, also referred to as lipotoxicity. This lipotoxicity has been linked to an excessive beta-oxidation of FFAs within the mitochondria and peroxisomes, thereby leading to oxidative stress due to increased production of toxic reactive oxygen species. Moreover, ER-stress and formation of lipid droplets are considered as further mechanisms involved in lipotoxicity. However, the underlying mechanism of FFA-mediated β-cell apoptosis has not yet been fully elucidated. Therefore, the aim of this study was to gain a deeper insight into the mechanism of lipotoxicity with structure-toxicity relationships using various long-chain (LC) and very long-chain (VLC) saturated, mono- and poly-unsaturated FFAs in the human EndoC-βH1 β-cell line.
Materials and methods: EndoC-βH1 tissue culture β-cells were incubated with various LC and VLC saturated and unsaturated FFAs. Toxicity was determined by using caspase-3 assay. The formation of β-cell-toxic hydrogen peroxide (H_2O_2) by FFAs was analyzed by expression of the H_2O_2-sensitive fluorescence protein HyPer in mitochondria and peroxisomes. Lipid droplets within EndoC-βH1 β-cells were determined by fluorescence microscopy after fixation and staining with *Oil Red O*. The respective ER-stress genes were quantified after FFA incubation by RT-qPCR using specific primers.
Results: Only LC and VLC saturated and mono-unsaturated FFAs (≥16 carbon atoms) were toxic to human insulin-producing EndoC-βH1 β-cells as documented by caspase-3 activation. The toxicity increased with increasing chain length. However, we observed in EndoC-βH1 β-cells a decrease in toxicity as the number of double bonds in FFAs increased and, in addition, as the double bond approached the carboxyl group. Hence, the position and the number of double bonds affected the toxicity. Generally, the toxicity correlated with the metabolism of LC and VLC FFAs in the peroxisomal beta-oxidation, in which the toxic H_2O_2 is generated. Interestingly, there was a difference between effects of saturated and mono-unsaturated FFAs upon the ER, where only saturated VLC FFAs were able to induce ER-stress genes in human EndoC-βH1 β-cells. Neither unsaturated VLC FFAs nor LC FFAs had an effect on the gene expression of any of the analyzed ER-stress genes. In contrast to the induction of ER-stress, saturated VLC FFAs did not form lipid droplets, whereas all other analyzed LC and VLC FFAs generated lipid droplets in human EndoC-βH1 β-cells.
Conclusion: Only LC (C16-C18) and even more so VLC (C20-C22) saturated and mono-unsaturated FFAs were toxic to human EndoC-βH1 β-cells. This chain length dependent toxicity correlated with the metabolic preference for their metabolism in the peroxisomal beta-oxidation, where toxic H_2O_2 is generated, which could be proved by experiments with the H_2O_2-sensitive protein HyPer. In contrast poly-unsaturated FFAs showed a decrease in toxicity in human EndoC-βH1 β-cells. When comparing lipid droplet formation and ER stress gene induction an inverse correlation could be documented, even though there was no difference in the toxicity of FFAs irrespective of their chemical structure.

The importance of adipocyte H2S-synthesising enzymes in human adipose tissue adipogenesis and systemic insulin action

J. Moreno-Navarrete[1], F. Comas[1], J. Latorre[1], M. Arnoriaga-Rodríguez[1], F. Ortega[1], M. Kern[2], O. Cusso[3], M. Sabater[1], W. Ricart[1], X. Ribas[3], M. Costas[3], M. Blüher[2], J. Fernández-Real[1];
[1]Institut d'Investigació Biomèdica de Girona (IdIBGi), Girona, [2]University of Leipzig, Leipzig, Germany, [3]Institut de Química Computational i Catàlisi (IQCC), Girona, Spain.

Background and aims: Recent studies in 3T3-L1 cells and mice suggest a possible role of H_2S biosynthesis in adipogenesis. Here, we aimed to investigate the possible role of H_2S-synthesising enzymes [cystathionine γ-lyase (CTH), cystathionine β-synthase (CBS), mercaptopyruvate sulfurtransferase (MPST)] in human adipose tissue (AT) adipogenesis and systemic insulin action.
Materials and methods: Both visceral (VAT) and subcutaneous (SAT) *CTH*, *CBS* and *MPST* mRNA and protein levels were measured in five independent (2 cross-sectional and 3 longitudinal) cohorts. Hydrogen sulfide levels were measured by fluorescent probe. *Ex vivo* cysteine and piridoxal phosphate coadministration (H_2S-synthesising enzyme activators) was performed in AT explants ($n = 16$) according to systemic insulin sensitivity (hyperinsulinemic-euglycemic clamp). *In vitro* experiments using lentiviral-induced specific gene knockdown and chemical inhibitors during human adipocyte differentiation were also performed.
Results: Both VAT and SAT *CTH*, *CBS* and *MPST* mRNA and protein levels were significantly decreased in participants with obesity and type 2 diabetes, highly expressed in adipocyte fraction, and positively correlated with expression of adipogenic- and insulin signaling-related genes, while in inverse proportion to genes linked to adipose tissue dysfunction (inflammation and senescence) in two independent cohorts. Concordantly, *CTH* in subcutaneous adipose tissue was positively correlated with insulin sensitivity, while the improvement in insulin action induced by bariatric surgery, physical activity and diet -induced weight loss, all resulted in increased expression of H_2S-synthesising enzymes in parallel to *ADIPOQ*. *Ex vivo* experiments demonstrated that the activation of H_2S biosynthesis resulted in increased adipogenesis, which was enhanced in those participants with increased insulin sensitivity. *In vitro* experiments revealed that *CTH*, *CBS* and *MPST* gene knockdown or the CTH inhibitor DL-propargylglycine inhibited adipocyte differentiation, insulin action and H_2S biosynthesis, whereas GYY4137 (an H_2S donor) exerted opposite effects.
Conclusion: These data demonstrated that transsulfuration pathway is required for human adipogenesis and exerts an important role in the relationship between adipose tissue physiology and systemic insulin action.

Effects of glycated insulin on adipogenic differentiation

A. Piccoli[1], T. Bisogno[1,2], M. Maccarrone[1,3], P. Pozzilli[1,4], N. Napoli[1,5], R. Strollo[1];
[1]Universita Campus Bio-Medico di Roma, Rome, Italy, [2]National Research Council, Pozzuoli, Italy, [3]European Center for Brain Research (CERC)/Santa Lucia Foundation IRCCS, Rome, Italy, [4]Queen Mary, University of London, London, UK, [5]Washington University in St Louis, St Louis, USA.

Background and aims: Hyperglycaemia and chronic low-grade inflammation associated with obesity and diabetes are a main source of reactive oxidants (ROS). High levels of ROS may generate oxidative post-translational modification (oxPTMs) that may impair proteins biological functions. We have shown that insulin could also be a target of these modifications that include glycation, oxidation and chlorination. Adipose tissue is a primary target of this hormone and a key player in insulin resistance (IR): evidence from animal studies show that the glycation of insulin or other proteins result in a significant impairment of biological function of adipose tissue, affecting adipokines expression and insulin sensitivity. However, how oxPTMs such as glycation interfere with insulin function and their involvement in IR and type 2 diabetes (T2D) is still unknown. We hypothesize that insulin glycation may be involved in IR and in the pathogenesis of T2D. Therefore, the aim of this study was to assess the possible effects of glycated vs. native insulin on adipocyte differentiation.
Materials and methods: Human recombinant insulin was glycated *in vitro* following our established protocol. Insulin glycation was monitored through PAGE. Human preadipocytes (HPAd), a primary cell line from

subcutaneous adipose tissue, and adipose-derived stem cells (ASCs), isolated from tissues of lean and obese subjects (BMI <25 and BMI >30), were differentiated with standard adipogenic medium in presence of native or glycated insulin. Cellular differentiation was assessed by gene and protein expression analyses of adipogenic markers (adiponectin, peroxisome proliferator-activated receptor gamma -*Pparγ*-, fatty acid binding protein 4 -*Fabp4*-, glucose transporter 4 -*Glut4*-) and of receptors for adiponectin (*AdipoR1*) and for insulin (*InsR*), through real time RT-PCR and immunoblot respectively.

Results: Our preliminary results showed that preadipocytes (both HPAd and ASCs) exposed to glycated insulin had impaired differentiation capacities: Oil Red O-staining showed that glycated insulin reduced adipocyte differentiation. Considering gene expression, we observed an overall downregulation of adipogenic markers, with a significant decrease of adiponectin both in leans- and in obese-derived cells ($p = 0.007$ and $p = 0.017$ respectively), lower levels of *Glut4* and a significant lower expression of *Fabp4* ($p = 0.002$) in cells from leans differentiated with glycated insulin. Moreover, we also observed a strong increased of *Pparγ* in normal weight subjects, with a significance of $p = 0.013$, and raised levels of *AdipoR1* ($p = 0.005$) in obese-derived cells, treated with modified insulin. Unlike gene expression analysis, protein levels of INSR presented a significant down regulation in cells treated with glycated insulin, with a p value of 0.0266 in leans and of 0.011 in obese subjects.

Conclusion: In conclusion, our data highlight for the first time that glycated insulin affect human adipocytes differentiation and impair insulin receptor expression, suggesting to deeper investigate of its role as a possible mediator in the pathogenesis of T2D.

MicroRNAs regulate expression of uncoupling protein 2 gene (UCP-2) in visceral adipose tissues of obese individuals

A. Kurylowicz[1], M. Owczarz[1], J. Polosak[1], M. Jonas[1], M. Jonas[2], W. Lisik[2], M. Puzianowska-Kuznicka[1];
[1]Department of Human Epigenetics, Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, [2]Department of General and Transplantation Surgery, Medical University of Warsaw, Warsaw, Poland.

Background and aims: Impaired thermogenesis may contribute to the positive energy balance and therefore promote obesity. Indeed, adipose tissues of obese individuals are characterized by the lower expression of the key genes involved in thermogenesis, e.g. a gene encoding uncoupling protein 2 (*UCP-2*). However, mechanisms underlying this phenomenon are unknown. In recent years there has been great progress in the understanding of the role of microRNA (miRNA) in the regulation of expression of various genes, including those related to adipocyte differentiation and function. The aim of the study was to examine if *UCP-2* mRNA levels in adipose tissues of obese individuals correlate with the expression of the relevant miRNAs, potentially interfering with *UCP-2* mRNA 5′UTR sequence.

Materials and methods: We used *in silico* analysis with the TargetScanHuman, miRanda-mirSVR and the Pictar programs to identify miRNA potentially interfering with *UCP-2* mRNA 5′UTR sequence. Next generation sequencing (NGS) was applied as a screening analysis to measure expression of the selected miRNA in 37 samples of visceral (VAT) and subcutaneous (SAT) adipose tissues from normal-weight (N) and obese (O) individuals. Subsequently, miRNAs expression was validated by the *real-time* PCR method in 164 samples of VAT and SAT (from 55 obese and 27 normal weight patients) and correlated with the expression of the *UCP-2* on the mRNA level.

Results: *UCP-2* mRNA levels were significantly lower in VAT and SAT of obese subjects compared to the normal-weight individuals ($P = 0.002$ and $P = 0.009$, respectively). Based on the *in silico* analysis 6 miRNAs potentially interfering with *UCP-2* mRNA were selected (namely: hsa-miR-15a-5p, hsa-miR-15b-5p, hsa-miR-16-5p, hsa-miR-185-5p, hsa-miR-214-5p and hsa-miR-424-5p). Screening analysis by NGS only in case of hsa-miR-214-5p and hsa-miR-424-5p confirmed significant differences in their expression between the investigated tissues. These results were verified by the *real-time* PCR and correlated with *UCP-2* mRNA levels. Significant negative correlations between hsa-miR-214-5p as well as hsa-miR-424-5p expression levels and *UCP-2* mRNA were found in VAT of obese individuals ($P = 0.001$, $r_s = -0.457$ and $P = 0.008$, $r_s = -0.347$, respectively; Figure 1).

Conclusion: Decreased expression of the *UCP-2* mRNA in VAT of obese individuals may result from the interference with hsa-miR-214-5p and hsa-miR-424-5p. The mechanisms responsible for the lower expression of *UCP-2* in SAT of obese subjects remain unknown.

Comparative and functional analysis of plasma membrane-derived extracellular vesicles from obese vs nonobese women

J. Latorre[1,2], F. Santamaria-Martos[3], I. Benítez[3], J. Moreno-Navarrete[1,2], M. Sabater[1,2], W. Ricart[1,2], M. Sanchez de la Torre[3,4], S. Mora[5], J. Fernández-Real[1,2], F. Ortega[1,2];
[1]Diabetes, Endocrinology and Nutrition, Institut d'Investigació Biomèdica de Girona Dr. Josep Trueta, Salt, Spain, [2]Centro de Investigación Biomédica en Red de la Fisiopatología de la Obesidad y la Nutrición (CIBEROBN), Instituto de Salud Carlos III (ISCIII), Madrid, Spain, [3]Group of Translational Research in Respiratory Medicine, Hospital Universitari Arnau de Vilanova i Santa Maria, IRB Lleida, Lleida, Spain, [4]Centro de Investigación Biomédica en Red de Enfermedades Respiratorias (CIBERES), Instituto de Salud Carlos III (ISCIII), Madrid, Spain, [5]Department of Molecular and Cellular Physiology, Institute of Translational Medicine (ITM), University of Liverpool, Liverpool, UK.

Background and aims: Since the discovery of plasma membrane-derived extracellular vesicles (EVs) as vehicles for exchange of regulatory microRNAs (miRNAs), RNA-based cell-to-cell communication through circulating EVs has attracted many studies endorsing the concept that EVs and their cargo are of most relevance in physiology and physiopathology. Today we know that EVs are released to the circulation by cells found in adipose tissue, namely mature adipocytes, transferring miRNAs that may mediate the adaptive response of recipient cells. This study investigated plasma EVs from obese vs. nonobese women and their functional impact in adipocytes.

Materials and methods: Plasma EVs were isolated by ultracentrifugation. Concentration and size were examined by nanoparticle tracking analysis (NanoSight). Functional analyses were performed in human adipocytes using isolated plasma EVs from obese and nonobese women. RNA was purified from plasma and plasma EVs of 45 women (47 ± 12 years, 58% of obesity), and profiles of mature miRNAs were assessed.

Results: Smaller plasma EVs were found in obese when compared to nonobese women. Positive associations were identified between circulating EVs number and parameters of impaired glucose tolerance. Treatments with EVs from obese subjects led to a significant reduction of genes involved in lipid biosynthesis, while increasing the expression of IRS1 (12.3%, $p = 0.002$) in human adipocytes. Almost 40% of plasma cell-free miRNAs were also recovered from isolated plasma EVs (defined as Ct values<37 in ≥75% of samples). BMI together with parameters of insulin resistance were major contributors to EVs-incorporated miRNA patterns.
Conclusion: Size, concentration, and the miRNA cargo of plasma EVs are independently and significantly associated with obesity and parameters of insulin resistance, and may mediate intercellular communication relevant to metabolism in fully-differentiated adipocytes.

CEBP-beta regulates RAP1 expression in visceral adipose tissue of obese patients

C. Formichi[1,2], G. Sebastiani[1,2], N. Brusco[2], S. Cantara[1], G.E. Grieco[2], C. Maccora[1], A. Tirone[3], G. Vuolo[3], C. Ciuoli[1], F. Dotta[1,2];
[1]University of Siena, Siena, [2]Umberto Di Mario Foundation, Toscana Life Science, Siena, [3]Le Scotte Hospital, Siena, Italy.

Background and aims: The prevalence of obesity and its associated comorbidities has dramatically increased in the last decades. However, factors involved in the development of metabolic complications of obesity are still to be fully elucidated. Previous studies demonstrated that RAP1 protein - a component of shelterin complex, which binds and protects mammalian *telomeres* - has a role in regulation of metabolism and that RAP1 whole-body knockout mouse show adult-onset obesity and metabolic impairment. Our aim was to evaluate RAP1 expression and regulation in different human adipose depots.
Materials and methods: We performed real time PCR to measure RAP1 expression in visceral (VAT) and subcutaneous (ScAT) adipose tissue of 49 obese patients and 14 metabolically healthy normal-weight subjects. To elucidate the cause of differential RAP1 expression in VAT, we searched for predicted transcription factors, using predictive algorithms, and selected the adipogenic transcription factor CEBPβ. CEBPβ mRNA can be translated into different protein isoforms: the activating isoform LAP (*liver-enriched transcriptional activating protein*) and the inhibiting isoform LIP (*liver-enriched transcriptional inhibitory protein*). Indeed, previous studies demonstrated that the ratio between these two isoforms is critical for CEBPβ-mediated gene expression. We performed Western Blot analysis to evaluate CEBPβ expression in VAT of 10 obese patients and 4 controls. In addition, we performed ChIP analysis on chromatin samples from cultured visceral preadipocytes.
Results: RAP1 mRNA expression was significantly reduced in VAT of obese patients with metabolic syndrome ($n = 37$) compared to metabolically healthy obese ($n = 12$) and controls (respectively, $p = 0.042$ e $p < 0.0001$); no difference was found in RAP1 expression in ScAT between obese and controls ($p = 0.246$). Next, we analyzed CEBPβ expression in VAT: obese patients showed an inhibitory expression pattern of CEBPβ, with higher LIP/LAP ratio compared to controls ($p = 0.024$). Of note, obese patients with higher LIP/LAP ratio showed a higher body weight, total cholesterol and triglycerides levels and lower HDL levels ($p = 0.0095$, $p = 0.042$, $p = 0.038$ and $p = 0.014$, respectively) compared to obese patients with lower LIP/LAP ratio. ChIP analysis confirmed that CEBPβ binds RAP1 promoter.
Conclusion: In conclusion, our data highlight the role of an altered expression pattern of transcription factor CEBPβ in RAP1 reduced expression in VAT; this mechanism could be involved in the development of obesity-related metabolic complications. Interestingly, we showed that the differential expression of CEBPβ isoforms can identify subsets of obese patients with a different metabolic profile.

Glucagon-like peptide 2 (GLP-2): an underestimated signal in metabolic control

J.J. Vendrell[1], M. Ejarque[1], D. Beiroa[2], E. Calvo[1], N. Keiran[1], C. Nuñez Roa[1], R. Nogueiras[3], S. Fernandez-Veledo[1];
[1]Endocrinology, Institut d'Investigacio Sanitaria Pere Virgili (IISPV), Tarragona, [2]Department of Physiology, University of Santiago de Compostela-Instituto de Investigación Sanitaria, Santiago de Compostela, [3]Department of Physiology, CIMUS, University of Santiago de Compostela-Instituto de Investigación Sanitaria, Santiago de Compostela, Spain.

Background and aims: Glucagon-like peptide-2 (GLP-2) is a gastrointestinal hormone released in response to dietary nutrients as GLP-1, which acts through a specific receptor, the GLP-2 receptor (GLP-2R). To date, GLP-2R expression has been mainly located in gut, where it exerts potent trophic effects, and in brain, where it acts as an anorexigenic hormone. Nonetheless, some in vivo observations suggest a wider expression profile than expected. This work aims to gain insight into the molecular function of GLP-2/GLP-2R axis on energetic metabolism, focusing on its potential modulatory function on adipose tissue (AT).
Materials and methods: SGBS cell line was used as an *in vitro* model of human subcutaneous pre-adipocytes. Gene and protein expression studies were performed. *Animal studies.* Chow and high-fat diet (HFD) mice were treated once a day with GLP-2 analogue (Teduglutide) for 4 weeks, and different metabolic studies were performed
Results: In agreement with previous data, short-term GLP-2 agonist centrally-treated mice showed a decreased food intake and weight gain. Surprisingly, these effects were not maintained in a chronic treatment of 14 days. Chronic modulation of central GLP-2R of diet-induced obesity (DIO) mice did not affect metabolism either. Conversely, chronic activation of peripheral GLP-2R provided body weight-independent glucose tolerance. Interestingly, Teduglutide shown an anti-inflammatory effect on visceral AT meanwhile it had lipogenic effects on subcutaneous AT, suggesting that GLP-2 agonism may have a direct effect on AT. Remarkably, our results demonstrate that GLP-2R is also expressed in AT, mainly in adipocyte fraction. Different from what is seen in intestine, i*n vitro* studies revealed no effects of GLP2 on adipocytes proliferation. However, and consistent with in vivo data, GLP-2 treatment produced an increase on lipids accumulation with an up-regulation of lipogenic genes in subcutaneous adipocytes.
Conclusion: Overall, our data identify AT as a new target for GLP-2 activity. Understanding the role of GLP-2 in the metabolic events that take place in AT may help to define new GLP-2 receptor analogs as potential indications of clinical usefulness in obesity.

Evaluation of active brown adipose tissue by the use of hyperpolarised [1-13C] pyruvate MRI in mice

M. Riis-Vestergaard[1], P. Breining[1], S. Pedersen[1], C. Laustsen[2], H. Stødkilde-Jørgensen[2], P. Borghammer[3], N. Jessen[4], B. Richelsen[1];
[1]Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus C, [2]MR Research Center, Aarhus University, Skejby, [3]Nucelar Medicine and PET Centre, Aarhus University Hospital, Aarhus C, [4]Clinical Pharmacology, Aarhus University Hospital, Aarhus C, Denmark.

Background and aims: Since evidence of persisting brown adipose tissue (BAT) in adults humans emerged in the late 2000's, BAT has been of great interest as a putative pharmacological target for treatment of

metabolic disorders such as obesity, insulin resistance and metabolic syndrome. Activated BAT has the capacity to dissipate energy as heat through uncoupling of the inner mitochondrial membrane and thereby increase energy expenditure. Currently, assessment of the potential of BAT activation in humans is mainly provided by FDG PET scans but in order to expand and supplement these investigations introduction of radiation-free methods are warranted. Thus, the aim is to determine if hyperpolarized [1-^{13}C] pyruvate MRI (HP-MRI) which is a radiation-free method is able to determine BAT activity in mice following chronic cold exposure.

Materials and methods: Long-term cold (6 C) and thermo-neutral (30 C) acclimated mice were scanned with HP-MRI for assessment of the interscapular BAT (iBAT) activity. Likewise, another group of acclimated mice were scanned with the conventional method FDG PET/MRI. Finally, the mice were sacrificed, iBAT was removed and evaluated for gene expression and protein levels of the specific thermogenic marker UCP1.

Results: Cold exposure as compared with thermo-neutrality was found to increase the activity of iBAT by 4–13 fold assessed by the HP-MRI method dependent of the pyruvate metabolite examined ([1-^{13}C]bicarbonate, [1-^{13}C]lactate or [1-^{13}C]alanine). This was in agreement with the findings of a 5-fold increment in FDG uptake ($p < 0.05$) after cold exposure using FDG PET/MRI. Finally, by direct investigation of iBAT, cold exposure resulted in both increased UCP1 mRNA expression and UCP1 protein levels by 3–4 fold ($p < 0.05$).

Conclusion: We found that iBAT activity in mice could be detected using the hyperpolarized [1-^{13}C] pyruvate MRI method revealing changes in metabolites downstream from pyruvate. Besides detection of iBAT this new imaging modality also introduces the potential of detection of changes in intracellular metabolism and may therefore add useful information to the conventional FDG PET studies. HP-MRI may also be a promising radiation-free tool for repetitive BAT studies in humans.

Absence of Interleukin-1 Receptor (IL-1RI) alters adipogenesis and adipokine secretion in high-fat diet-induced obesity

K.A.J. Mitchelson[1], J.C. Ralston[1], C.R. Strain[2], Y.M. Lenighan[1], E.B. Kennedy[1], G.M. Lynch[1], F.C. McGillicuddy[1], P.W. O'Toole[3], H.M. Roche[1];
[1]University College Dublin, Dublin, [2]Teagasc Food Research Centre, Fermoy, [3]University College Cork, Cork, Ireland.

Background and aims: IL1 is a cytokine family involved in immune regulatory and inflammatory response. Lack of IL-1 Receptor (IL-1RI-/-) protects against high-fat diet (HFD)-induced insulin resistance after 3 months (mo) HFD, but this protection was lost after 6 mo HFD. After 6 mo HFD IL-1RI-/- mice were more glucose intolerant and insulin resistant, compared to wildtype (WT) mice. IL-1RI-/- mice displayed loss of adipose functionality, increased adipocyte hypertrophy and reduced TNFα and IL-6 secretion from stromal vascular fraction (SVF). However it was unknown if/how lack of IL-1RI impeded pre-adipocyte differentiation. It has been suggested that microbiome transfer can affect weight gain and phenotype in mice with inflammation-induced disease. The primary aim of this study was to determine how the lack of IL-1RI affected adipogenetic potential and inflammation in adipose tissue

Materials and methods: IL-1R-/- mice on C57BL/6 background breeding pairs were bred to obtain male WT and IL-1R-/- offspring. Mice were fed a HFD for 6 mo (45% kcal) and weight and feed intake was monitored weekly. WT and IL-1R-/- mice were cohoused in a subset of cages to determine whether microbiome transfer can affect phenotype. Glucose tolerance (1.5 g/kg) and insulin tolerance (0.5 U/kg) were examined. We investigated the gene expression of PPAR-γ and FASN and lipogenesis in preadipocytes and differentiated adipocytes. Also IL-6 secretion in adipose tissue organ culture (ATOC) in WT versus IL-1RI-/-. Pre-adipocytes were isolated, differentiated, and expression of adipogenic markers was measured by real time PCR. Triacylglycerol (TAG) accumulation was quantified by Oil Red O absorbance. IL-6 secretion from ATOC following IL-1β/TNFα stimulation was measured by ELISA. Statistical analysis was completed by two-way repeated measures ANOVA for GTT/ ITT, one-way ANOVA for PCR and unpaired t-test for TAG accumulation.

Results: IL-1RI-/- mice gained more body weight than WT mice ($P \leq 0.05$) and increased in adipose tissue (AT) weight. IL-1RI-/- and WT mice displayed similar glucose tolerance. Insulin resistance was greater in IL-1RI-/-, though not statistically significant. When IL-1RI-/- and WT mice were cohoused together, both groups showed higher glucose tolerance. Adipogenesis analysis showed *Ppar-γ* expression was 37- fold higher in differentiated adipocytes from WT mice compared to IL-1RI-/- mice. *Fasn* expression was 11- fold higher in differentiated adipocytes from IL-1RI-/- mice compared to WT mice. TAG accumulation was 50% higher in differentiated adipocytes from WT mice compared to IL-1RI-/- mice. IL-6 secretion from WT ATOC was higher than IL-1RI-/- after stimulation with TNFα and/or IL-1β. The impact of the microbiome was determined and will be presented.

Conclusion: While IL-1RI-/- mice show an increase in AT weight, our results show 6 mo HFD impairs adipocyte differentiation and reduces IL-6 secretion. This indicates that although AT is increased in IL-1R-/-, the amount of mature adipocytes and related adipose inflammation present may be lower, which may provide protection from HFD induced inflammation. The microbiome transfer in co-housed mice was reflected in total weight gain which suggests a mechanism for reduction in total adipose tissue while maintaining the beneficial decrease in inflammation

Characterisation of the exosomal proteins and their potential as regulators of systemic metabolism

R. Garcia Martin, E. Altindis, B.B. Brandao, C. Kahn;
Joslin Diabetes Center and Harvard Medical School, Boston, USA.

Background and aims: Intercellular communication is essential for metabolic processes. Our lab recently showed that tissues can communicate *in vivo* through secretion of exosomal miRNAs which induce changes in gene expression and metabolic adaptation in other tissues. In addition to miRNAs, exosomes are loaded with proteins. However, little is known about how these vary depending on tissue source or their role in the physiological regulation of metabolism. In this study, we aimed to identify both common and unique proteins in exosomes secreted by white/brown adipocytes, hepatocytes, muscle and endothelial cells, and identify the pathways that might be regulated by these proteins

Materials and methods: Murine brown and white adipocytes, AML12 hepatocytes, C2C12 muscle cells and vascular endothelial cells were grown in culture, and exosomes released into the media isolated by ultracentrifugation and filtration. Protein cargo was identified by using tandem mass tag (TMT)-labeling and liquid chromatography-tandem mass spectrometry (LC-MS/MS). Results were confirmed by immunoblotting and compared to cellular content to identify enrichment in exosome versus cell pellet.

Results: By comparing the exosomal proteome released by different cell types, we identified general and cell type-specific exosomal proteins. Thus, adiponectin and LPL were only present in white adipocyte exosomes, whereas SPARC and IGFBP5 were only in myotube exosomes. Similarly, EGF receptor, myosin-9 and thrombospondin-5 were uniquely found in exosomes of hepatocytes, endothelial cells and brown adipocytes, respectively. Several exosomal proteins secreted by hepatocytes were also secreted by muscle cells, including members of the Serpin family, some complement factors and proteins involved in iron/copper metabolism. In contrast, white and brown adipocyte- and

endothelial cell-secreted proteins that were similar included proteins of carbohydrate metabolism (PGK1 and UGP2) and proteosomal proteins. When compared to the relative abundance of these proteins in cells, it was clear that loading of proteins into exosomes was selective, and that some proteins were enriched in different cell types and not in others despite similar abundance in the cell pellets. Several exosomal proteins identified here have been linked to the development of diseases such as obesity and diabetes including SPARC and LGALS3BP, which raises the possibility that these factors present in the exosomal compartments might contribute to the pathology of these metabolic diseases.

Conclusion: Exosomes contain novel and cell type-specific proteins that could be involved in tissue communication in healthy and disease
