BACKGROUND: There are significant disparities in reproductive health care in the U.S. by race, ethnicity, socioeconomic status, and age. The Affordable Care Act (ACA), effective late 2012, reduced racial, ethnic, and economic disparities in insurance coverage and health care utilization, but its impact on reproductive health disparities is unknown. Recent studies showing that (1) adolescent and minority women are more likely to choose effective contraception when cost is not a barrier, and (2) the ACA has reduced cost-sharing and out-of-pocket expenses for long-acting reversible contraceptives (LARCs) and oral contraceptive pills, suggest that the ACA may help to reduce disparities in reproductive health care. This study aims to assess trends in insurance coverage and contraceptive use among reproductive-age women in the U.S., pre- and post-ACA, with a focus on racial, ethnic, and income disparities over time.

METHODS: This study is based on the National Survey of Family Growth (NSFG), a nationally representative survey of reproductive-age men and women in the U.S., using results from survey years 2002, 2006–2008, 2008–2010, 2011–2013 (pre-ACA) and 2013–2015 (post-ACA). Types of insurance coverage and contraceptive use were compared between racial, ethnic, and income groups over time.

RESULTS: The sample comprised 31,222 women from 2002 to 2015, of whom 23,384 were eligible for contraception and included in the analysis. The major demographic shifts over time were a rising proportion of Hispanic women, increasing rates of poverty, and increasing rates of urban residence. Public insurance coverage increased across the years in all racial/ethnic groups and the lowest income group. The share of the population with only single-service (e.g. dental or vision) or no insurance dropped post-ACA, mostly in higher income groups. The percent covered by private insurance was steady across the years. Rates of any contraceptive use were high (88%) and stable, but types of contraception varied over time. Short-acting hormonal contraceptive use decreased steadily from 2002 to 2015 in all racial/ethnic, income, and insurance groups, and sterilization declined from 2011 among non-Hispanic White and high-income women. LARC use increased steadily from 2008 in all racial/ethnic, income, and insurance groups, most prominently for non-Hispanic Black women among whom rates increased from 1% in 2002 to 10% in 2015.

CONCLUSIONS: Use of LARCs is rising in the U.S., especially among Black women, a trend that predates the insurance coverage gains associated with the ACA. Meanwhile sterilization and short-acting hormonal contraceptives are declining in popularity. Further study using interrupted time-series analysis will be conducted to determine the early impact of the ACA on women's contraceptive choices in population groups who have experienced disparities.

TRENDS IN OUTPATIENT PREVENTIVE HEALTH EXAMINATIONS AMONG ASYMPTOMATIC ADULTS Aarti Rao; Minal Kale. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2706184)

BACKGROUND: The preventative health exam (PHE) and its role in primary care have been debated for several decades. At present, while a majority of physicians are proponents of the exam, others believe that it is an inefficient use of health care resources. A 2012 Cochrane review concluded that the PHE does not reduce morbidity and mortality. However, this review mainly drew from studies published prior to 1973, making it difficult to generalize these findings in an evolving healthcare landscape. The objective of this study is to describe trends in visit content in adult PHE visits.

METHODS: We performed a cross-sectional analysis using data from the 2001–2003, and 2011–2013 National Ambulatory Medical Survey (NAMCS). NAMCS is a nationally representative survey conducted annually by the CDC. We focused on ambulatory visits to physicians by adults aged ≥ 18 years. We identified a visit as a PHE if the major visit reason was a general medical examination, or if the visit diagnosis code was a general medical examination. We identified a provider as a PCP if the physician self-identified as the patient's primary care provider. We used the χ^2 test to compare the differences in the weighted proportions of PHE visits over the 10-year interval.

RESULTS: 135,709,770 adults received a PHE from a PCP in 2001–2003 (45.5%; 95% CI, 41.5–49.7%), and 175,094,483 million adults received a PHE from a PCP in 2011–2013 (44.6%; 95% CI, 43.5–49.7%). In the 10-year interval under consideration, PCPs provided significantly less diet and nutrition counseling (26.6 to 17.4%; $P < 0.001$), stress management counseling (4.4 to 1.8%; $P < 0.01$), exercise counseling (20.4 to 14.5%; $P < 0.01$), and tobacco cessation counseling (6.05 to 3.8%; $P < 0.05$), ECG (10.6 to 6.1%; $P < 0.05$), urinalysis (29.9 to 15.5%; $P < 0.001$), PAP smear (16.6 to 8.6%; $P < 0.001$), PSA screening (9.5 to 5.3%; $P < 0.001$), and mammogram (8.9 to 5.9%; $P < 0.01$). In 2011–2013, PCPs provided more preventive services than non-PCPs. PCPs provided significantly more diet and nutrition counseling (17.4 to 10.1%; $P < 0.001$), tobacco cessation counseling (3.8 to 1.9%; $P < 0.01$), weight reduction counseling (5.9 to 2.9%; $P < 0.001$), ECG (6.1 to 1.6%; $P < 0.001$), CBC (24.9 to 6.6%; $P < 0.001$), PSA screening (5.3 to 1.3%; $P < 0.001$), lipid profile (27.8 to 3.7%; $P < 0.001$), HbA1c screening (11.5 to 2.2%; $P < 0.001$), chlamydia screening (1.5 to 0.4%; $P < 0.02$), and depression screening (3.6 to 1.9%; $P < 0.05$). We did not find differences for the following measures: asthma education, stress management, echocardiogram, bone density imaging, urinalysis, mental health counseling, and psychotherapy ($p > 0.05$).

CONCLUSIONS: Overall PCPs provide more preventative and counseling services in comparison to non-PCP providers during the PHE visit. However, the decrease in counseling services provided by PCPs is concerning, and while it may have been driven by an emphasis on quality metrics and a lack of time to devote to patient education, it requires further investigation.

TRENDS IN OUTPATIENT UTILIZATION OF ANTIBIOTICS IN THE UNITED STATES (2005–2015) Mallika Mundkur[4]; Joan Landon[5]; Aaron Kesselheim[2]; Michael Fischer[1]; Jessica M. Franklin[3]; Krista Huybrechts[3]; Elisabetta Patorno[3]. [1]Brigham & Women's Hospital, Boston, MA; [2]Brigham and Women, Boston, MA; [3]Brigham and Women's Hospital, Boston, MA; [4]Brigham and Women's Hospital, Lexington, MA; [5]Brigham and Womens, Boston, MA. (Control ID #2705735)

BACKGROUND: Antibiotic overuse appears to be a persistent public health problem, although the most recent assessments do not include data from the past five years. The main objectives were to describe general trends in utilization of outpatient use of oral antibiotics over the period 2005–2015 and to identify specific time points associated with changes in use.

METHODS: We included individuals from the Optum Research Database (2005–2015), who were at least 18 years old at the start of the calendar year, were enrolled continuously throughout each year of interest, and had at least 6 months of continuous enrollment at baseline. For each yearly and quarterly interval, we assessed the number of filled oral antibiotic prescriptions per 1000 enrollees. We evaluated trends in antibiotic use over the entire time period, stratifying our analysis by age (65 and above vs. under 65). We evaluated antibiotic use overall, and use of major antibiotic classes (i.e. macrolides, penicillins, quinolones). We implemented a computer algorithm within *R* to

automatically identify potential change points for each antibiotic class; we compared the AIC of the resulting piecewise model to simple linear representation of trend to select only clinically meaningful changes. Finally, for the year 2015, we also assessed a number of ICD9-based covariates such as indications, patient characteristics and recent healthcare encounters (e.g. outpatient vs. emergency room).

RESULTS: We assessed over 75 million person-years of data for antibiotic use. Over the period 2005 through 2015, overall use of oral antibiotics declined significantly among adults under 65, from 879 to 806 prescriptions/1000 enrollees/year ($p < .0001$), while for adults 65 and older, rates of use increased non-significantly from 929 to 943 prescriptions/1000 enrollees/year ($p = 0.4312$). During the year 2015, penicillins were the most frequently prescribed antibiotic in adults of both age groups and respiratory conditions remained most common indication associated with antibiotic use (35.8% of fills). While most fills were preceded by an office or emergency room visit (70.1%), nearly one-third of prescriptions could not be associated with any visit. Use of penicillins and quinolones respectively increased and decreased in 2008 ($p < .01$), while use of macrolides decreased following the second quarter of 2013 ($p < .0003$).

CONCLUSIONS: Our study provides the most current view of antibiotic utilization trends among adults, revealing distinct trends among older and younger adults. We have identified two time points at which use of major antibiotics classes have changed significantly for all adults, and are temporally associated with black-box warnings for quinolones (2008) and a safety communication for azithromycin (2013). These findings suggest that clinicians and patients are sensitive to risks of antibiotics when deciding between treatment options.

TRENDS IN PRESSURE ULCERS FOLLOWING MEDICARE'S VALUE-BASED PURCHASING PROGRAMS INVOLVING HOSPITAL-ACQUIRED CONDITIONS: EVIDENCE FROM FLORIDA, WASHINGTON AND NEW YORK, 2009–2014 Shawna N. Smith; Heidi Reichert; Ashley M. Snyder; Laurence F. McMahon; Jennifer Meddings. University of Michigan, Ann Arbor, MI. (Control ID #2705268)

BACKGROUND: Two value-based purchasing policies aiming to reduce hospital-acquired complications (HAC) target pressure ulcers (PUs). The 2008 Hospital-Acquired Conditions Initiative (HACI) denies payment for advanced-stage, hospital acquired PUs and removes lower-stage pressure ulcers as payable comorbidities, when listed as diagnoses in administrative discharge data. CMS' HAC Reduction Program (HACRP) penalizes hospitals for several HACs, including hospital-acquired advanced-stage PUs from administrative data as measured by AHRQ's Patient Safety Indicator (PSI-3). Unlike the HACI PU measures, the PSI-3 applies several exclusions, including higher risks conditions like paralysis. Recent federal reports on PUs using chart review indicate a 23% reduction since 2010; it is unclear if the administrative data used for implementing CMS' value-based purchasing programs support this improvement. This study examines trends in hospital-acquired (HA) and present-on-admission (POA) PU rates, 2009–2014, from administrative data in Florida, New York and Washington. The principle question is, do the current measures using administrative data provide a valid "value signal" as part of CMS transition to value-based payment?

METHODS: We used administrative data from the Healthcare Cost and Utilization Project (HCUP) State Inpatient Databases for Florida, New York and Washington to generate annual PU rates 2009–2014 as a percentage of discharges, by stage and status on admission (used for HACI, without comorbidity exclusions) to compare with the more restrictive PSI-3 rates used for HACRP. Annual data included >4 million adult discharges from >562 acute-care hospitals.

RESULTS: Among all discharges, 94% of PUs were POA rather than HA. Early-stage HA PUs saw the largest relative decline (53%) from 2009–2014, followed by early-stage POA (24%). Advanced HA PUs saw a relative decline of 20%, or a decline in incidence from 0.035 to 0.028%. PSI-3 rates saw a similar relative decline of 25%; however given its more extensive exclusion criteria yielding only ¼ of total discharges eligible for measurement, this yielded only 232 fewer PSI-3 PUs in 2014 than 2009, from >4 million patients. Hospital-level correlation between HA PUs without exclusions and PSI-3 PU rates was also low ($r = 0.19$).

CONCLUSIONS: Both HACI and HACRP policies target PUs as preventable HACs, but use different definitions and measures of PUs. PSI-3's more extensive exclusions for defining preventable PUs result in a much smaller eligible patient population with seemingly substantial relative declines yielding only a few hundred fewer PUs amongst >4 million patients. CMS' policy focus on advanced stage PUs ignores the vast majority of PU incidence and risks interpreting a handful of PU cases as valid "value signal" rather than noise. Further, different definitions of eligible patient populations raise questions as to which PUs are considered preventable and for whom, undermining potential for value-based policy to inform evidence-based practice.

TRENDS IN RACIAL/ETHNIC/NATIVITY DISPARITIES IN CARDIOVASCULAR HEALTH AMONG ADULTS WITHOUT PREVALENT CARDIOVASCULAR DISEASE IN THE UNITED STATES, 1988–2010 Arleen F. Brown[1]; Li-Jung Liang[1]; Stefanie D. Vassar[1]; Jose J. Escarce[1]; Sharon S. Merkin[1]; Eric M. Cheng[1]; Adam K. Richards[1]; Teresa Seeman[1]; W.T. Longstreth[2]. [1]UCLA, Los Angeles, CA; [2]University of Washington, Seattle, WA. (Control ID #2707106)

BACKGROUND: Trends in cardiovascular health disparities are poorly understood, even as diversity in the United States increases. This study examined changes in racial/ethnic/nativity disparities in cardiovascular health by age group, adjusting for sex, education, and poverty.

METHODS: We analyzed data from the National Health and Nutrition Examination Survey (NHANES), cross-sectional, multistage, stratified, clustered probability samples of the non-institutionalized US population, for 1988–1994, 1999–2004, and 2005–2010, excluding persons who reported prior stroke, myocardial infarction, heart failure, or angina. Analyses included 17,552 White, 8,445 African-American, 3,587 US-born Mexican-American, and 4,832 Non-US-born Mexican-American adults ages 25 years and older. We examined racial/ethnic/nativity and period differences in Life's Simple Seven (LS7) health factors and behaviors (blood pressure, cholesterol, hemoglobin A1c [A1c], body mass index [BMI], physical activity, diet, and smoking) and a summed composite measure of "optimal" cardiovascular health, representing the top tertile of the total LS7 score.

RESULTS: We observed declines in control of A1c and BMI and in levels of physical activity and healthy eating, but improvements in cholesterol control and smoking. Disparities in LS7 components and composite scores varied by race/ethnicity/nativity group and period. Relative to whites, African Americans and Non-US-born Mexican Americans had lower optimal cardiovascular health in all age groups and periods. In 1988–1994, cardiovascular health among African Americans was lower by 21.1% (95% CI: 16.5%,25.8%) in 25–44 year

olds and by 13.2% (9.6%,16.5%) in those 65 years and older; by 2005–2010, the differences fell to 14% (10.4%,17.6%) and 7.8% (5.3%,10.7%), respectively. For Non-US-born Mexican Americans in 1988–1994, these differences were 10.7% (4.7%,17.2%) in the 25–44 year olds and 14.9% (10.7%,18.8%) in those 65 years and older; by 2005–2010, these differences fell to 6.4% (1.5%,11.2%) and 8.3% (4.6%,11.5%), respectively. Fewer significant differences existed between whites and US-born Mexican Americans. Many disparities decreased over time because whites had the largest, most consistent absolute reductions in optimal cardiovascular health: between 1988–1994 and 2005–2010, the declines ranged from 11.6% (6.0%,16.7%) for 25–44 year olds to 6.8% (3.2%,10.4%) in those 65 years and older.

CONCLUSIONS: Between 1988 and 2010, the cardiovascular health of the nation declined, and although inequities persisted, several racial/ethnic/nativity disparities decreased due to worsening cardiovascular health among whites rather than gains among African Americans and Mexican Americans.

TRENDS IN SHARED DECISION MAKING AMONG ADULTS IN THE UNITED STATES, 2002–2014

David M. Levine[2]; Bruce E. Landon[3]; Jeffrey A. Linder[1]. [1]Brigham and Women's Hospital, Boston, MA; [2]Brigham and Women's Hospital and Harvard Medical School, Boston, MA; [3]Harvard Medical School, Boston, MA. (Control ID #2704250)

BACKGROUND: Shared decision-making (SDM) occurs when clinician and patient are both involved in decision-making, share information, build consensus, and agree on treatment. SDM's benefits may include improved patient knowledge, reduced uncertainty, and reduced overuse of unnecessary services. Despite significant efforts to optimize SDM, little data exist on SDM nationally over time.

METHODS: The Medical Expenditure Panel Survey is an annual, nationally-representative survey of the US population (annual response range: 53–65%). We restricted our analyses to the adult population aged 18 and older (n = 21,915-26,509/year). To assess SDM, we used 7 questions. Six questions used a never/sometimes/usually/always scale: how often did your clinician (1) ask you to help decide; (2) show respect for alternative treatments; (3) listen carefully to you; (4) explain things so they were easy to understand; (5) show respect for you; and (6) spend enough time with you. The final yes/no question asked if your clinician presented all the options to you. A participant's "SDM composite" was the total number of "always" or "yes" responses. To assess change over time, we compared the mean SDM composite in 2002 and 2014 using the chi-squared test. To evaluate variables associated with SDM, we used multivariable linear regression adjusting for calendar year, age, gender, race/ethnicity, having a usual source of care (USC), having a same-race/ethnicity USC, perceived health, and 14 other variables. Interaction terms with year had minimal effects so were not included.

RESULTS: From 2002 to 2014, participants aged (mean age 45 to 47 years-old), were less White (71 to 64%), more Hispanic (12 to 15%), less privately insured (74 to 68%), and less often had a USC (77 to 75%; all $p < 0.05$). The mean SDM composite increased gradually from 4.4 in 2002 to 5.0 in 2014 ($p < 0.05$). The proportion responding "Always" or "Yes" between 2002 and 2014 increased from 52 to 63% for "help decide," from 65 to 72% for "respect alternatives," from 55 to 66% for "listened to you," from 58 to 67% for "explained to you," from 59 to 71% for "showed respect," from 46 to 57% for "spent enough time," and from 93 to 96% for "presented all options" (all $p < 0.05$). In multivariable analyses, characteristics associated with higher SDM scores included calendar year (0.04 composite points/year), Black vs White race/ethnicity (+0.33 composite points), having a USC (+0.42), and having a same-race/ethnicity USC (+0.23; all $p < 0.05$). Characteristics associated with lower SDM scores included Asian vs White race/ethnicity (−0.28 composite points), being uninsured (−0.17), and worse perceived health (−0.41; all $p < 0.05$).

CONCLUSIONS: Among adult Americans, SDM increased significantly from 2002 to 2014, despite sociodemographic disparities and poor performance for specific SDM questions. Beyond increasing insurance coverage and availability of a USC, efforts to improve SDM should target Americans without a same-race/ethnicity USC and with poor perceived health.

TRENDS OF MODIFIABLE HEALTH BEHAVIORS AND HEALTH OUTCOMES IN AN URBAN COUNTY FROM 2011–2016

Ashela Bean; Mirela Feurdean. Rutgers NJMS, Newark, NJ. (Control ID #2686577)

BACKGROUND: Essex County, NJ ranks number 20th of 21 counties in New Jersey in regards to health outcomes per County Health Rankings. Along with genetics, healthcare and social determinants of health, health behaviors directly influence health outcomes.

METHODS: We used County Health Rankings and Roadmaps registries for data collection. For health outcomes, we searched for premature death using years of potential life lost before age 75, prevalence of diabetes and HIV. For health behaviors, we searched for prevalence of tobacco smoking, obesity, sexually transmitted infections, teen births, and physical inactivity. We compared data from Essex County with the state of New Jersey.

RESULTS: The percentage of adults who smoked in Essex County remained stable (17% in 2016 and 2011), while in the state of New Jersey it decreased by 12% (17% in 2011 to 15% in 2016). The percentage of obese adults in Essex County increased by 3.9% (26% in 2011 to 27% in 2016), and by 4.2% in New Jersey (24% in 2011 to 25% in 2016). The number of newly diagnosed Chlamydia cases (per 100,000 persons) in Essex County increased by 2.9% (644 in 2011 to 662.8 in 2016), and by 23.9% in New Jersey (258 in 2011 to 319.6 in 2016). The number of births per 1,000 females ages 15–19 in Essex County decreased by 22% (41 in 2011 to 32 in 2016), and by 23% in New Jersey (26 in 2011 to 20 in 2016). The percentage of adults aged 20 and over reporting no leisure-time or physical activity in Essex County decreased by 3.6% (28% in 2011 to 27% in 2016), and by 4% in New Jersey (25% in 2011 to 24% in 2016). The HIV prevalence (per 100,000 persons) in Essex County increased by 12% (1428 in 2011 to 1600 in 2016), while it remained stable in New Jersey (513 in 2016 and 2012). No HIV prevalence data for 2011 in New Jersey State was found. The percentage of adults aged 20 and above with diabetes in Essex County increased by 20% (10% in 2011 to 12% in 2016), and by 11% in New Jersey (9% in 2011 to 10% in 2016). The years of potential life lost before age 75 (per 100,000) in Essex County decreased by 19% (8866 in 2011 to 7200 in 2016), and by 11% in New Jersey (6170 in 2011 to 5500 in 2016).

CONCLUSIONS: Since 2011, premature deaths, teen births and physical inactivity have declined in Essex County and New Jersey State. The decline in premature death could be attributed to many factors other than health behaviors. Upward trends were noted with regard to sexually transmitted infections and obesity, prevalence of HIV and diabetes. There was no change in the prevalence of smokers in Essex County, while there was a decline in the state of New Jersey. There are many opportunities for intervention, especially with regards to smoking, obesity and sexually transmitted infections.

TRIPLE SMOKING CESSATION THERAPY WITH VARENICLINE, NICOTINE PATCH AND NICOTINE LOZENGE: A PILOT STUDY TO ASSESS TOLERABILITY

Kristin M. Berg[2, 1]; Douglas E. Jorenby[1]; Michael Fiore[1]; Timothy Baker[1]. [1]University of Wisconsin - Madison, Madison, WI; [2]University of Wisconsin School of Medicine and Public Health, Madison, WI. (Control ID #2695603)

BACKGROUND: For both primary care providers and their patients who smoke, the difficulty of quitting and the lack of new evidence-based treatment options result in frustration and impede cessation success. Innovative combinations of existing cessation medications are one potential mechanism to rapidly advance cessation success. Researchers have examined nicotine patch + varenicline, but studies have yielded conflicting results. In this pilot study, we examined the tolerability of “triple therapy” (nicotine patch + nicotine lozenge + varenicline).

METHODS: This observational pilot study examined triple therapy in 36 smokers trying to quit. Participants were recruited via Facebook (goal = 40), and had to be > 17 years old, smoking at least 5 cigarettes daily, not using bupropion or varenicline, and free of medical or psychological contraindications. The primary outcome was tolerability, measured via adverse events (insomnia, dreams, nausea, mood changes, dizziness, rash, sweating, dyspnea, vomiting, chest tightness, angina) specifically elicited at each contact. Secondary outcomes were satisfaction rates, medication changes, and self-reported point-prevalence abstinence at week 12. Smokers received 9 calls over 12 weeks after their initial in-person visit for nicotine withdrawal, medication-related adverse events (AEs), satisfaction with medications (10-point Likert scales), and smoking status assessments.

RESULTS: Enrolled participants averaged 44 years old (SD = 12.8), were 50% women, and 6% non-white. 35 of 36 participants reported at least one AE; insomnia ($n = 27$, 75%), vivid dreams ($n = 26$, 72%) and nausea ($n = 23$, 64%) were most commonly reported. Most AEs (84%) were reported as mild to moderate in severity. No deaths, hospitalizations, cardiovascular events, or suicidality were reported. Six participants (17%) decreased at least one medication (all AE-related), 5 (14%) decreased then discontinued at least one medication (all AE-related) and 13 participants (36%) discontinued at least one medication (6 AE-related, and 7 AE-unrelated). AE-unrelated reasons for discontinuing medications included relapse, running out, or not feeling the need. Participants were highly satisfied with the medications’ abilities to control their withdrawal symptoms (M = 9.1/10, SD = 1.2) and were equally satisfied with the medications’ abilities to help them quit smoking (M = 9.2/10, SD = 1.4). Self-reported 7-day point-prevalence abstinence at week 12 was 58%, assuming that withdrawn participants ($n = 1$) or participants with missing data ($n = 9$) had relapsed.

CONCLUSIONS: Despite high rates of commonly reported AEs (e.g., nausea, insomnia), and over half the sample altering their medication regimens, triple therapy yielded a high satisfaction rate and high abstinence rate at 12 weeks with no serious events reported. While additional data on safety, tolerability, and efficacy are needed, triple therapy may be a promising new treatment option for smoking cessation.

TRUST: A CRITICAL COMPONENT FOR PHYSICIAN PARTICIPATION IN TEAM-BASED QUALITY IMPROVEMENT INITIATIVES

Partha Das[1]; Thomas H. Lee[2, 3]; Sara Singer[1]. [1]Harvard TH Chan School of Public Health, Boston, MA; [2]Press Ganey, Boston, MA; [3]Brigham and Women’s Hospital, Boston, MA. (Control ID #2705564)

BACKGROUND: Quality improvement (QI) is a priority for organisations striving to achieve the Triple Aim. Implementing QI projects typically involves teaming, which may constitute a new group of individuals brought together to work on a project or an established, stable, and bounded team that manages multiple projects. Teams also may include individuals from one or more disciplines. Research shows that the outcomes of QI projects tend to plateau or are subject to attrition over time. We used mixed methods to investigate whether physicians’ motivation to participate within teams influences the success of QI projects.

METHODS: We searched and iteratively reviewed the academic published and grey literature to form a conceptual model of themes that might influence physician participation in QI activities. We developed interview questions to explore these themes, which included personal experience with QI projects, perceived mediators of success/failure, attitudes of peers and health systems, impact of teaming on personal learning and general clinical duties and the role of junior physicians. We conducted focus groups with hospital-based physicians from a range of specialties (eight participants per group). Participants were a self-selected, convenience sample of attendees at a local leadership course.

RESULTS: Trust was consistently described as critical to the success of QI projects. Analysis revealed three distinct trust domains: 1. Trust that the project has a worthwhile purpose, 2. Trust that the project has a chance of being successful, and 3. Trust that the QI team will be effective in accomplishing project objectives. Participants emphasised that trust needed to be engendered early in the project timeline, preferably prior to commencement. Resource availability (funding or time) and non-financial incentives (the opportunity for publication of results or peer recognition) were considered important motivators. Contrary to most research, support from management was viewed as helpful but not vital for success. Participants felt involving residents and fellows was beneficial for both success and trainees’ education. Participants emphasised the importance of information feedback regarding progress against predefined metrics to team members throughout a project.

CONCLUSIONS: This study highlights the importance to physicians of three domains of trust as necessary preconditions to success in QI initiatives. This finding aligns with organisational behaviour literature, which suggests that teams should have a clear, shared, compelling purpose to motivate members. The lesser importance attributed by physicians to support from senior managers indicates physicians view trust as a greater mediator of success. Alternatively, this could reflect a lack of awareness of what managers do in support of QI. We suggest that prior to launching any team-based QI project, steps should be taken to promote trust in each domain. It may also be advisable for managers to interact more with physicians around QI activities.

UNDERREPRESENTED MINORITY (URM) MEDICAL STUDENT PERSPECTIVES ON RETENTION AND ADVANCEMENT

Ashley J. Smith; Leo Morales; Cam Solomon. University of Washington School of Medicine, Seattle, WA. (Control ID #2701304)

BACKGROUND: Underrepresented minority (URM) medical students have lower retention rates compared with majority medical students. Research identifying effective support or evidence-based interventions for the retention and advancement of URM students is limited. The purpose of this study is to investigate URM medical student perspectives on retention and advancement.

METHODS: An online survey was administered to garner the perspectives of URM medical school graduates between 2011 and 2015. Respondents ($N = 57$)

were recruited by email through URM student networks and referrals. The survey consisted of 4 domains including demographic and social characteristics, medical school characteristics, facilitators of success, and self-assessed success in medical school. Facilitators of success were divided into 6 categories including mentorship, academic support, financial support, peer support, mental health counseling and career counseling. Respondents rated the importance of each facilitator category on an ordinal scale of 0–5, with 0 being "not at all important" and 5 being "extremely important".

RESULTS: Respondents rated faculty mentoring (mean 4.47, SD 1.01) and financial support (mean 4.52 SD 0.80) as the most important factors to retention of URM students in medical school. When asked about desired mentor characteristics, respondents rated having a mentor with the same career interest as them highest (mean 3.88, SD 1.38) followed by someone who was of the same race/ethnicity as them (mean 3.19, SD 1.38). Peer support was also ranked highly (mean 4.17, SD = 1.09). Membership in URM student affinity groups had the greatest positive effect on students psychosocial wellbeing (mean 4.29, SD 1.15, $n = 41$). Membership in URM student affinity groups also had positive effects on professional development (mean 4.00, SD 1.22, $n = 41$) and academic performance (mean 3.54, SD 1.27, $n = 41$).

CONCLUSIONS: Participants reported that mentorship, financial support, and peer support were the most important facilitators associated with retention and success in medical school. This report suggests that medical schools seeking to retain and advance the careers of URM students should focus on providing effective mentorship, adequate financial support, and support for student affinity groups. Racial/ethnicity concordance between students and their faculty mentors was also highly valued by survey respondents, pointing to the importance of minority faculty in medical schools.

UNDERSTANDING AND PURSUING INCLUSION WITHIN HEALTH CARE ORGANIZATIONS Jaya Aysola; Ana Bonilla Martinez; Matthew Kearney; Carlos Carmona; Kareha Agesa; Fran Barg; Eve Higginbotham. University of Pennsylvania, Philadelphia, PA. (Control ID #2707275)

BACKGROUND: We lack knowledge on how organizations can promote inclusion in their efforts to retain a diverse health care workforce. Our objective was to understand the sources of feelings of inclusion and exclusion among faculty, staff, and students at University of Pennsylvania Health Sciences affiliated schools and hospitals.

METHODS: We designed this qualitative analysis to evaluate why a prior survey conducted in the same population revealed significant differences in perceptions of organizational inclusivity. We solicited narratives from employees, faculty, and students across all Penn affiliated health care organizations and asked them to respond anonymously via REDCap to two open-ended questions about their experiences at work or school with inclusion or lack there-of, followed by a series of demographic questions. All data were entered into NVivo 11 for coding and analysis. We conducted a narrative analysis of all fully completed responses ($n = 315$). A randomly selected subset ($n = 30$) of narratives were analyzed by the team to create a codebook. The remainder ($n = 285$) were coded with 20% of the sample triple coded for interrater reliability (mean Kappa score is .93). Any discrepancies in coding were resolved with consensus.

RESULTS: Of the 315 participants, 61% self-identified as female, 48% as a racial/ethnic minority, 17% as LGBT. Narratives overwhelming highlighted opportunities for change at the organizational level and describe a systematic lack of recognition. Narratives reflected the need to feel recognized, especially from more influential members within an organization. The majority of participants referenced a system-level culture that allows for unwritten rules to govern individual acts of discrimination or nepotism. Participants consistently reported the failure of formal channels, such as going to human resources, leadership, or an ombudsman, to address such acts. This often resulted in self-accommodating actions taken by the individual as the ultimate solution, with many describing negative effects on their well-being. Despite reassurances of anonymity, some responded that they could not share their story, while others often sandwiched their negative experiences with positive statements. Some stories revealed feelings of exclusion from those that are not in minority cultures and/or presumptions about what group/s the words "diversity" or "inclusion" refer to, despite the generalizability of those terms. Participants proposed strategies to improve organizational culture, such as implicit bias training, increasing diversity in leadership positions, and creating a culture and a structure that supports advocacy from those that witness discrimination.

CONCLUSIONS: Our study reveals key insights to measure and promote inclusion within organizations and highlights the need for broad-based strategies designed to combat existing presumptions about organizational "inclusion" efforts that may serve to alienate some.

UNDERSTANDING OF HEALTHCARE QUALITY AND ITS EFFECT OF PATIENT DECISION MAKING- A CROSS-SECTIONAL SURVEY Michael Cantor[2]; Barbara Porter[1]. [1]NYU SOM, New York, NY; [2]NYU Schoo of Medicine, NY, NY. (Control ID #2687450)

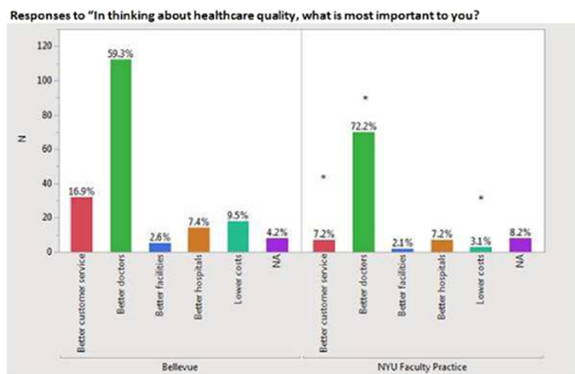
BACKGROUND: Though information on quality is more accessible, little is known about how health care consumers actually use this data in their decision making when choosing a doctor or healthcare institution. Often the important constituents of healthcare quality as perceived by patients are different than those measured or reported by healthcare providers.

METHODS: We developed a 14-question survey to evaluate the role data quality played in patients' healthcare-related decisions. We distributed the paper surveys, in either English or Spanish, in two different practice settings- in the waiting area for the medical clinics at Bellevue Hospital (BHC), which is part of New York City's public hospital system, and in the waiting area of the NYU Faculty Practice's internal medicine office (NYU).At Bellevue, we had a bilingual research assistant actively approach patients, offer them the survey in either English or Spanish, and collect the surveys afterward. At the NYU Faculty Practice, registration staff offered patients the surveys and collected them in English only.

RESULTS: We collected 189 surveys from Bellevue and 97 from NYU. At both sites, most patients were familiar with healthcare quality and also confident in their understanding of the concept. We also did not find any significant difference in this category when we compared groups based on level of education or on type of insurance. Quality was also an important factor for most patients in choosing their doctors or clinics. There was a wide range of responses regarding the meaning of quality to patients (see Figure), with the majority at both sites answering "better doctors." Few patients in either setting were familiar with quality rating sites such as Hospital Compare.

CONCLUSIONS: Healthcare quality is important to patients in their decision making, but the meaning of and measures that go into evaluating quality may differ between patients and providers. Government-sponsored quality rating

sites may need to be re-evaluated to become tools that are more useful to patients.



UNDERSTANDING PHYSICIAN TREATMENT DECISIONS FOR THE MANAGEMENT OF UPPER RESPIRATORY TRACT INFECTIONS Aditi Patel[1, 2]; Alexander Chaitoff[3]; Michael B. Rothberg[1, 2]; Bo Hu[2]; Mahesh Manne[1]; Elizabeth Pfoh[2]; Anita D. Misra-Hebert[1, 2]. [1]Cleveland Clinic, Cleveland Heights, OH; [2]Cleveland Clinic, Cleveland, OH; [3]Cleveland Clinic Lerner College of Medicine, Cleveland, OH. (Control ID #2706350)

BACKGROUND: Inappropriate antibiotic use for upper respiratory tract infections (URI) is a problem. There is extreme variation in the prescribing practices that is unexplained by patient factors. It is important to know how physician beliefs may contribute to inappropriate prescribing. We performed a qualitative study of high and low prescribers to understand the factors which influenced their decision making in the management of URI.

METHODS: Primary care physicians whose rate of antibiotic prescribing above (i.e. high prescribers) or below the mean (i.e. low prescribers) were identified in a previous study using electronic health record data. We created an interview guide to understand the decision making process for antibiotic prescribing for URI including clinical and non-clinical factors (patient satisfaction, time pressure, and comparison to peers) Between August 2015 and April 2016 physicians were contacted via email and invited to participate in a 15–20 min semi-structured interview. Interviews were conducted by 2 study team members (AC, AP) who were blinded to the physicians' prescribing rates. Interviews were audiorecorded and transcribed. Using an inductive qualitative content analysis approach, two team members (AMH and AP) concurrently analyzed 5 transcripts adding descriptive codes and discussed results. Once consensus was reached one team member (AP) analyzed the remainder of the transcripts until thematic saturation was achieved. Codes were then revised and sorted into pertinent themes.

RESULTS: Physicians were interviewed and 20 transcripts were coded including 10 high and 10 low prescribers. Physicians reported that clinical factors (e.g. patient age and comorbidities, duration and severity of symptom), desire to follow evidence based practice, and concern about adverse effects of antibiotics influenced prescribing patterns. Non-clinical factors identified included 1) physician-patient relationship, 2) concern for patient satisfaction being adversely affected, 3) patient expectation and preferences, and 4) patient convenience. High and low prescribers expressed variability in the above themes. When asked "Do you believe you prescribe antibiotics more, less or about the same as your colleagues?" The majority of low prescribers correctly identified themselves as prescribing less vs high prescribers who most often thought they prescribed the same as their colleagues. Low prescriber often cited evidence-based medicine, while high prescribers often expressed concerns about meeting patient expectations.

CONCLUSIONS: Physicians report that non-clinical factors frequently influence their decision to prescribe antibiotics for URI. High prescribers were concerned about patient satisfaction or expectation and appeared to be unaware that they differed from peers. Comparative reports and education about patient satisfaction might be effective for reducing antibiotic prescribing.

UNDERSTANDING SPONSORSHIP IN ACADEMIC MEDICINE: CHARACTERISTICS OF EFFECTIVE SPONSORS AND PROTéGéS AND SUCCESSFUL SPONSORSHIP RELATIONSHIPS AT ONE ACADEMIC HEALTH CENTER Manasa Ayyala; Kimberly Skarupski; Joann Bodurtha; Marlis Gonzalez Fernandez; Lisa Ishii; Barbara Fivush; Rachel Levine. Johns Hopkins University School of Medicine, Baltimore, MD. (Control ID #2705742)

BACKGROUND: In business, sponsorship is critical to advancing high potential employees into leadership. In academic medicine (AM), little is known about how sponsorship functions. Our goal in this qualitative study was to discover in AM who gets sponsored, who does the sponsoring and what makes for a successful sponsorship relationship.

METHODS: We conducted 23 in-depth semi-structured interviews with Johns Hopkins School of Medicine (SOM) faculty in 2016. Faculty were identified as either 'sponsors' or 'protégés.' Sponsors were identified ($N=12$) due to positions of power as department chairs; protégés ($N=11$) based on participation in a SOM executive leadership development program. Two investigators coded transcripts for thematic content using editing style analysis. A coding framework was created through an iterative process involving all study team members. Final themes were derived from this framework.

RESULTS: The following themes were identified: 1) *Mentorship is not enough*: *Sponsorship is episodic and focused on procuring specific opportunities*; 2) *Effective sponsor*: *A well-connected talent scout*; 3) *Effective protégé*: *Rises to the task and remains loyal*; 4) *We are in this together*: *trust and respect are key to successful sponsorship relationships*. Informants described sponsorship as distinct from mentorship. Mentorship is longitudinal; focused on general career development. Sponsorship is characterized as episodic; focused on specific "stretch" opportunities that position protégés for advancement. Sponsors and protégés portrayed an effective sponsor as well-connected and able to recognize talent. They agreed that a sponsor should be well-established and not threatened by the protégé. Sponsors valued humility and focusing on the "bigger picture," when promoting others. Protégés said an effective sponsor must have "your back." Sponsors viewed success as joy from promoting others and ensuring a legacy. Both characterized effective protégés as hard working, team players. Sponsors focused on the protégé's ability to make the most of a "stretch" opportunity and being self-aware of strengths and weaknesses. They described seeing their former selves in a protégé, or seeing traits they admire. Protégés focused on loyalty to the sponsor and understanding that their performance would reflect on their sponsor. The successful sponsorship relationship is based on trust and respect with a clear understanding of mutual benefit. This allows a sponsor to provide candid and constructive feedback to which the protégé is receptive. The protégé trusts that the sponsor will advocate and go out on a limb for them. The sponsor trusts that the protégé feels accountable to their actions as the sponsor's credibility and reputation are on the line.

CONCLUSIONS: Our findings support the importance of sponsorship in advancing in AM. Informants' insights on the attributes of effective sponsors

and protégés and on a successful sponsorship relationship will be helpful for faculty working to achieve academic advancement.

UNDERSTANDING THE IMPACT OF MEDICAL SCRIBES ON PRIMARY CARE PRACTICE Ryan E. Anderson; Evan Tschirhart. Brigham and Women's Hospital, Boston, MA. (Control ID #2706601)

BACKGROUND: While electronic health records hold potential to improve patient care, in practice their use has also produced negative effects on patient-doctor communication and physician professional satisfaction, an impact felt keenly in primary care. Medical scribing represents a promising innovation to reduce burnout and free provider time for direct patient care. However, research on the effects of medical scribing in primary care is limited, and the impact of scribes can be difficult to quantify. Our analysis seeks to understand the effect of medical scribing on patient-doctor communication, patient and clinician satisfaction, and care quality, and to identify barriers and recognize best practices in use.
METHODS: Semi-structured 45-min interviews were conducted with 23 informants engaged in a scribe pilot at a large provider organization. Informants included organization leaders, site administrators, primary care clinicians using scribes and medical scribes themselves across three pilot practices. A code structure of common themes was developed using a consensus-based procedure at regular meetings of the research team. Full interview transcripts were then coded using the constant comparative method to collate recurrent responses, expressed in language similar to that used by informants, in order to illustrate the impacts of scribe use as well as the insights and challenges faced in the implementation experience.
RESULTS: Pilot participants overwhelmingly described the impact of scribes on improving patient communication (91% of informants coded), particularly in perceived listening skills, time spent with patient, and degree of transparency. Perceived patient concerns included loss of privacy (35%), restriction of autonomy (30%), and treatment of the physical exam (26%). Provider responses described reduced emotional exhaustion (93%), reduced time spent on low-value work (87%), greater professional competence (67%), and enjoyment of mentorship role with scribe (47%). Providers cited challenges including scribe turnover, variability in scribe readiness, and required investment in training the scribe. Organization outcomes included improved clinical quality (61%), improved clinical documentation (57%), improved access (39%) and improved team-based care (35%). Impressions of the financial impact of scribe use were mixed and varied by informant. A number of best practices emerged during the pilot which helped to minimize challenges and maximize the benefits of scribe use.
CONCLUSIONS: The use of medical scribes in primary care can improve patient-doctor communication and significantly impact physician joy in practice. Patients approved of scribe use if key concerns could be ameliorated by implementing best practices. Given increasing demands placed on primary care by modern EHRs, growing access concerns for an aging population, and high rates of reported burnout in the field, medical scribing represents an important practice innovation with potential to transform primary care.

UNDERSTANDING THE RELATIONSHIP OF TEAM-BASED CARE AND CONTINUITY OF CARE WITH HIGH-COST UTILIZATION: EVIDENCE FROM THE PATIENT-CENTERED MEDICAL HOME IN THE VETERANS HEALTH ADMINISTRATION. Ashok Reddy[5]; Edwin Wong[3]; Karin M. Nelson[3, 5]; Stephan D. Fihn[4, 5]; Anne Canamucio[1]; Rachel M. Werner[2, 1]. [1]Philadelphia VA Medical Center, Philadelphia, PA; [2]University of Pennsylvania and Philadelphia VA, Philadelphia, PA; [3]VA Puget Sound, Seattle, WA; [4]Department of Veterans Affairs, Seattle, WA; [5]University of Washington, Seattle, WA. (Control ID #2702409)

BACKGROUND: While the patient-centered medical home shifts focus from individual provider-based care to a team-based care model, it remains unknown if team-based care can provide an alternative to continuity with primary care provider (PCP) in reducing healthcare utilization. Our main objective was to assess whether availability of high-quality team-based care and continuity of care with a PCP is associated with utilization of high-cost services. Additionally, we assessed whether the association between care continuity and utilization differed by quality of team-based care.
METHODS: This retrospective cohort study examined 1.1 million patients dually eligible for both VA and Medicare services in 2012. We restricted our sample to patients with at least 2 primary care visits in 2012 and had an assigned VA PCP in 2013. A 50% random sample was used in our analysis. Continuity was measured using the Usual Provider of Care (UPC) score, which indicates the proportion of a patient's visits with the assigned provider from 0 (lowest) to 1 (highest). To measure team-based care for a clinic site, we used the relevant domain of the PACT implementation progress index (PI^2), scoring clinics as −1 (low performing), 0 (medium), or 1 (high). Our primary outcomes were the number of ED visits, any ACSC hospitalization, and number of hospitalizations in 2013. We constructed mixed effects negative binomial and logistic regression models to estimate a patient-level outcome of interest as a function of UPC and team-based care, adjusting for covariates including age, race/ethnicity, sex, income, marital status, co-morbidity, number of PCPs in county, number of hospital beds in county, co-payment, and distance to VA.
RESULTS: The final sample included 551,385 Veterans. During 2013, average ED visit was 1.0, all-cause hospitalizations 0.4, and 5% of Veterans required an ACSC hospitalization. The mean UPC score was .59 (SD .36). In our analysis, a 10% point increase in continuity of care was associated with 1% point decrease in all-cause hospitalization ($p < 0.001$), 3% lower odds of an ACSC hospitalizations ($p < 0.001$), and 0.7% point increase in ER visits ($p < 0.001$). In addition, we found that hospitalization rates in high-quality team-based care clinics were 45% lower than those in low-quality clinics. However, we found no significant association between patient ER visits or ACSC hospitalization and team-based care. In a stratified analysis by team-based care, we found that continuity was more protective in high-performing clinics than in low-performing clinics with regard to hospitalizations, likelihood of having an ACSC hospitalization, and ER visits.
CONCLUSIONS: Our findings suggest that higher continuity of care is associated with lower patient hospitalizations, decreased likelihood of ACSC hospitalization, and higher ED visits. Moreover, while high-quality team-based care cannot substitute for poor continuity on patient outcomes, it can reinforce the impact of continuity on reducing high-cost utilization.

USE OF A REGISTRY AND EDUCATION TO ADDRESS UNCONTROLLED HYPERTENSION FOR LOW INCOME HISPANICS WITH DIABETES: RESULTS FROM FIVE YEARS OF A MEDICAID WAIVER IN TWO RESIDENCY CLINICS Barbara J. Turner[2, 2]; Yuanyuan Liang[1, 2]; Shruthi Vale[2]; Ramin Poursani[3]; David F. Montemayor[2]; Julie Parish Johnson[2]. [1]University of Maryland School of Medicine, Baltimore, MD; [2]University of Texas Health Science Center at San Antonio, San Antonio, TX; [3]University of Texas Health Science Center at San Anotino, San Antonio, TX. (Control ID #2706028)

BACKGROUND: Hispanics are greatly affected by diabetes mellitus (DM) which is often complicated by uncontrolled hypertension (HTN). In a Medicaid Waiver starting in 2013 in 2 residency clinics serving primarily low income Hispanics, we aimed to improve HTN control by developing a DM registry to offer daily summaries of HTN, DM, and lipid control and biannual reports to clinics on quality of care. We educated faculty, residents, and staff about measuring blood pressure, HTN treatment guidelines, adherence supports such as reducing multiple daily doses (BID+), and more affordable drugs. Case managers also educated patients.

METHODS: From the 5-year DM registry, eligible subjects were age 18 to 75 and had >1 systolic blood pressure (SBP) >140 mmHg on treatment in a baseline year with a last SPB >12 months later in the next year. We created four cohorts of patients treated in consecutive years: 2012–13, 2013–14, 2014–15, and 2015–16. The outcome was SPB control (<140 mmHg) in the 2nd year for each cohort. At first high SBP, study variables were: demographics, SBP level, Elixhauser comorbidity score, hemoglobin A1c, # prescribed HTN drug classes, intensity of all HTN drug doses, and any prescribed BID+ drug. Variables at last SBP were: clinic type, # visits, visit adherence (%), change in # of HTN drug classes, change in drug intensity, and any prescribed BID+ drug. In mixed effects logistic regression accounting for subjects in multiple cohorts, we examined predictors for controlled last SBP.

RESULTS: Among 2,349 subjects: 58.0% were women, 80.0% Hispanic, and mean age 56.8 yrs (SD = 9.6). For all subjects, mean baseline SBP was 153.2 (SD = 14.2), mean # baseline drug classes was 1.61 (SD = 1.1) and mean follow-up 551.4 days (SD = 96.8). Last SPB control improved over time ($p < 0.001$): 2012–13 (58.4%); 2013–14 (58.0%), 2014–15 (61.8%), 2015–16 (68.5%). After full adjustment, adjusted odds ratio (AOR) for SBP control in 2015–16 was 1.60 [CI: 1.26-2.05, $p < 0.001$) vs 2012–13. Versus no prescribed BID+ drugs, AOR for SPB control for any BID+ drugs was 0.77 (CI: 0.64-0.91, $p = 0.003$). Odds of SBP control were 16% lower ($p < 0.001$) per HTN drug class prescribed at baseline and 11% lower ($p = 0.007$) per drug added by last SBP. Analysis of HTN drug intensity showed similar effects. Secular changes showed 47.1% of subjects were prescribed BID+ drugs at last SBP in 2012–13 versus 26.6% in 2015–16 while fewer HTN drugs were prescribed both at baseline and added at last SBP in 2015–16 versus earlier years (all $p < 0.001$). At last SPB in 2012–13, 42.0% of subjects were prescribed beta-blockers declining to only 29.2% in 2015–16 ($p < 0.001$).

CONCLUSIONS: In these residency clinics, the challenge of HTN control for complex low income patients with DM and uncontrolled HTN was ameliorated by a registry, education, and adherence support. Improved SPB control was achieved with fewer HTN drugs by focusing on prescribing simpler, more affordable, and more effective regimens.

USE OF CHRONIC CARE MANAGEMENT CODES FOR MEDICARE BENEFICIARIES: A MISSED OPPORTUNITY? Rebekah Gardner[2, 1]; Blake Morphis[1]; Kimberly Pelland[1]; Emily Cooper[1]; Alyssa DaCunha[1]; Rouba Youssef[1]. [1]Healthcentric Advisors, Providence, RI; [2]Alpert Medical School of Brown University, Providence, RI. (Control ID #2697980)

BACKGROUND: Physicians spend significant time outside of office visits caring for complex patients. This work is important but time consuming and historically has not been compensated. In 2015, Medicare introduced a Chronic Care Management (CCM) code to allow billing for non-face-to-face care coordination for beneficiaries with multiple chronic conditions. Little is known about how the new CCM code is used. The objective of this study is to characterize the use of the CCM code among Fee-for-Service (FFS) Medicare beneficiaries in New England in 2015.

METHODS: This retrospective observational analysis includes all FFS Medicare beneficiaries in New England continuously enrolled in Parts A and B in 2015. Using 2013–2015 Medicare claims and enrollment data, we created an eligible pool of beneficiaries who could potentially have received CCM services because they had two or more chronic conditions and a qualifying outpatient claim. We then stratified the pool by CCM status (with or without claims). Our primary outcome is the number of beneficiaries with a CCM claim per 1,000 eligible beneficiaries. Secondary outcomes include the total number of CCM claims, the total reimbursement for those claims, and differences between eligible beneficiaries with and without claims. Descriptive statistics and logistic regression were used, with beneficiary-level characteristics, such as age, sex, and race.

RESULTS: Of the more than 2 million FFS Medicare beneficiaries in New England in 2015, 11,629 (0.54%) had any CCM claim. Massachusetts beneficiaries had the highest penetration of CCM use (8.53 per 1,000 eligible beneficiaries); Vermont the lowest (0.51 per 1,000 eligible beneficiaries). Among those receiving CCM services, the mean number of claims for the year per beneficiary was 1.26. Compared to those who were eligible but did not have a CCM claim, those with a CCM claim were more like to be 65 years or older, white, dually-eligible for Medicare and Medicaid, have five or more chronic conditions, and see fewer specialists. These remained significant after adjustment. The total reimbursement for CCM claims in New England was $422,251 in 2015, with more than half of that going to clinicians in Massachusetts. The mean reimbursement per clinician in Massachusetts was $2,289 for the year, where the average number of claims per clinician was 3.64, compared to New Hampshire at $101 mean reimbursement, where the average number of claims per clinician was 1.41.

CONCLUSIONS: Few FFS Medicare beneficiaries in New England had CCM claims for management of chronic conditions, despite a large pool of eligible beneficiaries. Our findings suggest that the CCM codes, as currently implemented, are not achieving their intended effect. Medicare recently simplified the CCM code requirements, and future analyses can compare whether the changes result in greater uptake. We hope these results can inform implementation of similar initiatives, so Medicare can better support practices in their management of complex patients.

USE OF CT PULMONARY ANGIOGRAPHY TO DIAGNOSE PULMONARY EMBOLISM IN THE EMERGENCY DEPARTMENT OF A COMMUNITY TEACHING HOSPITAL Suresh K. Subedi; Jahangir Khan; Mohammed Osman; Azza Ahmed; Thair Dawood; Carlos Rios-Bedoya. Hurley Medical Center, Grand Blanc, MI. (Control ID #2706507)

BACKGROUND: CT pulmonary angiography (CTPA) in patients at low risk for pulmonary embolism adds to the cost and leads to unnecessary radiation and contrast exposure. Guidelines recommend using pretest probability scores and high sensitivity d-dimer test to identify low risk patients who can safely forego CTPA. Modified wells score is commonly used to categorize suspected pulmonary embolism patients into high probability or low probability. The aim of our study was to investigate the inappropriate use of CTPA in the emergency department and adherence to the guidelines.

METHODS: We conducted a retrospective chart review of adult patients who underwent CTPA for suspected PE in the emergency department from January

1, 2015 to December 31, 2015. Pregnant and trauma patients were excluded. CTPA was considered appropriate if modified wells score (MWS) was greater than 4 or any score with high sensitivity d-dimer greater than 500. CTPA was considered inappropriate if MWS was less than or equal to 4 and d-dimer was either not ordered or value was less than 500.

RESULTS: A total of 295 encounters fulfilled the inclusion criteria. 203 (68.81%) were females and 92 (31.18%) were male patients. Only 16 (5.42%) cases of pulmonary embolism were diagnosed. 122 (41.35%) CTPA were inappropriately performed. D-dimer was not performed in 99% of patients with inappropriately performed CTPA.

CONCLUSIONS: Adherence to published guidelines to diagnose pulmonary embolism is low. Application of modified wells score and d-dimer at initial presentation in the emergency department can avoid excessive ordering of CTPA and eventually decrease costs as well as lower harm to patients in form of contrast and radiation exposure.

USING A DECISION-SUPPORT TOOL TO DECREASE THE USE OF UNNECESSARY TELEMETRY AND URINARY CATHETERS

Charlie M. Wray[2, 3]; John Fahrenbach[4]; Nikhil Bassi[4]; Poushali Bhattacharjee[5]; Matthew Modes[6]; Michael Howell[4]; Vineet M. Arora[1]. [1]University of Chicago Medical Center, Chicago, IL; [2]San Francisco VA Medical Center, San Francisco, CA; [3]University of California, San Francisco, San Francisco, CA; [4]University of Chicago, Chicago, IL; [5]John H. Stroger Hospital, Chicago, IL; [6]University of Washington, Seattle, WA. (Control ID #2699335)

BACKGROUND: The Society of Hospital Medicine's Choosing Wisely guidelines recommend regular assessment of inpatients' need for urinary catheters and telemetry monitoring. Since studies suggest clinicians are not aware which patients have an indwelling catheter or are on telemetry, we aimed to use the electronic patient list to improve cognitive awareness of unnecessary urinary catheters and telemetry utilization.

METHODS: As part of an institutional challenge to promote Choosing Wisely projects, we inserted a passive indicator that signaled an active telemetry or urinary catheter order for each patient in the Epic electronic health record (EHR). Clicking on the indicator, a green check mark located on the electronic patient list, enabled the provider to cancel the order. During the 6-month intervention, monthly e-mail education about the new feature and the Choosing Wisely recommendations were sent to residents and attendings at the start of their general medicine rotation. We utilized an interrupted time-series analysis to estimate changes in utilization. The pre-intervention period was defined as 9 months prior to the intervention. In order to focus on low risk patient populations, we excluded patients with hospital stays >14 days, had an ICU stay, or a catheter on admission. Utilization rates were obtained through the EHR and analyzed with R, v3.3.2.

RESULTS: In total, 1,213 and 7,901 patients with a catheter and telemetry were assessed, respectively. Assuming pre-intervention trends, 29% fewer catheters were ordered (8.5% vs. 6.0%; $p < 0.05$), though no change in catheter duration was found (41.5 vs. 35.8 hrs; $p > 0.05$). While no absolute difference in the percentage of patients who received telemetry orders was seen, a significant decrease in the ordering trend for telemetry ($p < 0.01$) was noted after implementation. Additionally, patients receiving telemetry orders spent 18% less time on telemetry (42.5 vs. 34.9 hrs; $p < 0.01$). The average monthly case mix index (CMI), which reflects the clinical complexity of the patient population, increased from 1.64 to 1.88 ($p < 0.05$) and 1.25 to 1.40 ($p > 0.05$) for patients who received a catheter or telemetry order, respectively.

CONCLUSIONS: Following implementation of this tool, we demonstrated a trend toward less telemetry use, less time spent on telemetry, and fewer catheters ordered. Additionally, the intervention led to more selective utilization of catheters in sicker patients, as observed by the increasing CMI within this cohort. While it remains unclear whether the benefits were due to educational reminders or the electronic indicator, teaching alone is unlikely to lead to sustained practice changes. This intervention is highly generalizable as it involved a simple modification to one of the most widely used EHRs in the US.

USING NATURAL LANGUAGE PROCESSING TO AUTOMATE GRADING OF STUDENT'S PATIENT NOTES: A PILOT STUDY OF MACHINE LEARNING TEXT CLASSIFICATION.

Adina Kalet[1]; So-Young Oh[1]; Marina Marin[1]; Yili Yu[2]; Heather Dumorne[1]; Yindalon Aphinyanaphongs[1]. [1]New York University School of Medicine, New York, NY; [2]New York University, New York, NY. (Control ID #2702520)

BACKGROUND: At NYU, as part of a comprehensive objective structured clinical skills exam, experienced medical educators judge clinical knowledge, decision-making, and clinical reasoning skills of trainees based on their patient notes. Despite being rubric-driven, this task requires tremendous time and effort to establish consistent scoring, delaying and limiting individualized feedback. We conducted pilot machine learning text classification studies to establish if accurate automated scoring of clinical notes is possible.

METHODS: As a use case, we tested 100 student written clinical notes from 7 standardized patient cases (Vision Loss, Tel Diarrhea, Difficulty Sleeping, Shoulder Pain, Failure To Thrive, Abdominal, Pain, Palpitations) that had been scored for quality of clinical reasoning by faculty on a 1–4 scale. In order to assess performance of NLP strategies to categorize students in meaningful groups we dichotomized students based on their faculty given scores by case into "failing" (score of 1, 5–18 students per case) and "passing" (score 2,3,4). We treated each task as a binary classification task in a text classification pipeline. First, we treated each note as a bag of tokens and weight each token with term frequency-inverse document frequency (TFIDF) a numerical statistic that reflects how important a word is to a document. We then applied 3 different classification algorithms (random forests, support vector machines, and Bayesian logistic regression) and measured discriminatory performance using Area Under Curve (AUC) in a cross validation evaluation design.

RESULTS: TFDIF performed with AUCs between 0.669 and 0.905. Logistic regression provided the highest AUC in four cases: Difficulty Sleeping (0.905), Shoulder Pain (0.618), Failure To Thrive (0.717) and Abdominal Pain (0.892). As we observed the highest AUCs in Difficulty Sleeping and Abdominal Pain cases, we have begun to refine the algorithm for these two cases by identifying the importance features that lead faculty to give students to a higher grade and improve the accuracy of NLP based scoring. Promising features include the presence and sequence of certain words in the problem representation, sentence length in the management section, ranking of the differential diagnosis, sequence between key words (e.g. rule out appendicitis), and evidence of "thinkingness" or what many call semantic qualifiers.

CONCLUSIONS: With additional effort to build targeted case specific classifiers for clinical content and reasoning, a validated machine-learning model may achieve partial or full automation of grading of the notes. This work, which builds on decades of clinical decision-making and critical reasoning

research, may provide medical trainees with more and potentially better feedback; facilitating learning of clinical reasoning, freeing faculty to coach this process, and in the long run impacting healthcare quality and patient safety.

USING NATURAL LANGUAGE PROCESSING TO EXTRACT SOCIAL DETERMINANTS OF HEALTH AND IMPROVE 30-DAY READMISSION MODELS Salomeh Keyhani[1, 3]; Marzieh Vali[3]; Brett South[4, 5]; Lee Christensen[4, 5]; Danielle Mowery[4, 5]; Wendy Chapman[4, 5]; Louise Walter[2]. [1]University of California at San Francisco, San Francisco, CA; [2]University of California, San Francisco, San Francisco, CA; [3]San Francisco VA Medical Center, San Francisco, CA; [4]University of Utah, Salt Lake City Utah, UT; [5]Salt Lake City VA Medical Center, Salt Lake City, UT. (Control ID #2705177)

BACKGROUND: The Hospital Readmission Reduction program administered by the Centers for Medicare and Medicaid Services (CMS) penalizes hospitals with above average 30-day readmission rates. Hospitals caring for disadvantaged populations might be penalized by current 30-day readmission models that do not include the social determinants of health (SDOH) of the patients served. Measures of SDOH (e.g. living alone, social support, housing, and substance abuse) are inadequately available in Medicare data. Yet many of these variables are available in the free text of electronic health record or in VA clinical databases which are comprised of data collected as part of care. We compared VA models that include measures of SDOH to CMS based models created using only administrative data.

METHODS: First we developed two sets of SDOH variables: 1) three variables created from VA data (drug abuse, alcohol abuse and erratic health care use) and 2) three variables extracted from the free text of the medical record using natural language processing (living situation, housing situation and social support). The NLP algorithm was derived and validated on notes from 500 patient. We then identified all 15,095 patients 65 and older admitted with congestive heart failure to the VA in 2012 and applied CMS inclusion and exclusion criteria to the sample leaving 8,471 patients. We randomly selected 1500 hospital admissions and extracted all patients' notes in the year prior to admission. We identified 235,517 notes and pruned the note set to 77,975 notes based on relevance to the domains of interest. We extracted complete readmission data by collecting data on hospital readmissions in both the VA and Medicare program. We first developed a CMS-based 30-day readmission model that included age and comorbid conditions based on ICD9 codes (model 1) using logistic regression. Second, we compared this model to a model that included SDOH measures derived from national VA clinical databases (model 2). Finally, we compared these two models to a model that included all variables in model 1 and 2 in addition to SDOH measures extracted using NLP (model 3).

RESULTS: Interrater agreement (NLP algorithm vs. human chart review) was excellent (Cohen's Kappa >0.8). The 30-day readmission rate was 22.7%. In univariate analysis adequate social support (OR = 0.64, 95% 0.43–0.98) was associated with lower likelihood of 30-day readmission. Marginal housing (OR = 1.83, 95% CI 1.03–3.15), drug abuse (OR = 1.61, 95% CI 1.03–2.46), and erratic health service use (OR = 1.61, 95% CI 1.25–2.06)), were associated with a higher likelihood of 30 day readmission. After adjusting for age and comorbid conditions in model 3, only erratic health service use remained significantly associated with a higher likelihood of 30-day readmission. The C-Statistic for model 1, model 2 and model 3 was 0.60, 0.62 and 0.63 respectively.

CONCLUSIONS: Measures of SDOH are associated with 30-day readmission but have a minmal effect on the performance of the readmission model.

USING NORMALIZATION PROCESS THEORY TO UNDERSTAND WORKFLOW IMPLICATIONS OF DECISION SUPPORT IMPLEMENTATION ACROSS DIVERSE PRIMARY CARE SETTINGS Rebecca G. Mishuris[5]; Joseph Palmisano[5]; Lauren McCullagh[2]; Rachel Hess[3]; David Feldstein[4]; Paul D. Smith[4]; Thomas McGinn[1]; Devin M. Mann[6]. [1]Hofstra North SHore-LIJ, Manhasset, NY; [2]Hofstra North Shore LIJ School of Medicine, Manhasset, NY; [3]University of Utah, Salt Lake City, UT; [4]University of Wisconsin School of Medicine and Public Health, Madison, WI; [5]Boston University School of Medicine, Boston, MA; [6]New York University School of Medicine, New York City, NY. (Control ID #2702509)

BACKGROUND: Effective implementation of new technologies into clinical workflow continues to be hampered by lack of integration into daily activities. Normalization process theory (NPT) can be utilized to describe the kinds of "work" necessary to implement complex new healthcare practices and technologies. We used NPT to assess the facilitators, barriers and "work" of implementation of two clinical decision support (CDS) tools - integrated clinical prediction rules (iCPRs) to assess the likelihood of and appropriate treatment for Group A streptococcus pharyngitis or bacterial pneumonia- across diverse primary care settings' electronic health records (EHRs).

METHODS: We conducted baseline and 6-month follow-up quantitative surveys at two academic institutions' primary care clinics that were randomized to the intervention group of the larger randomized controlled iCPR study. The survey was adapted from the previously validated NPT toolkit which analyzes the four domains of implementation of complex interventions: sense-making, participation, action, and monitoring. NPT domains were then summarized among all completed survey responses ($n = 60$) and examined for potential associations by role (clinic manager ($n = 31$), medical director ($n = 29$)), institution (Wisconsin ($n = 42$), Utah ($n = 18$)) and time (baseline ($n = 33$), 6 months ($n = 27$)). Summary measures are presented as domain median by group. Associations were investigated via Wilcoxon Rank Sum and Kruskal-Wallis tests as appropriate within time-point (baseline and 6 months). Generalized estimating equations (GEE) were used for analyses of domains over time.

RESULTS: At baseline, the median score for each NPT domain was the same across roles and institutions. Median values for each NPT domain declined from baseline to 6 months across both roles and institutions. Among clinic managers, only participation declined significantly at 6 months ($p = 0.003$). Among medical directors, all domains scored lower at 6 months ($p < 0.003$ for each domain). The action domain score decreased significantly ($p = 0.03$) from baseline to 6 months among Utah respondents. All domains were lower at 6 months than baseline among Wisconsin respondents ($p \leq 0.008$ for each domain).

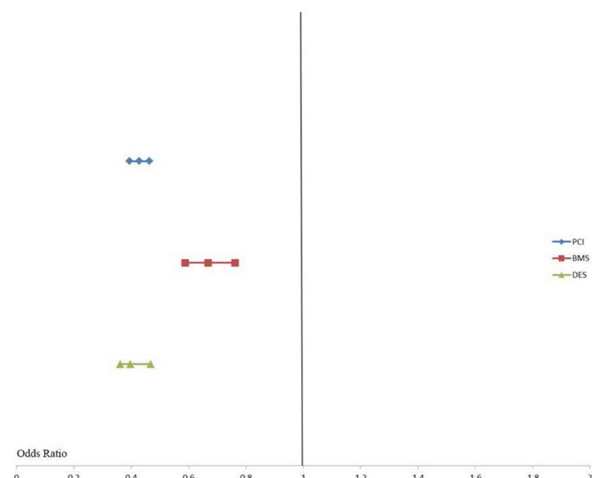
CONCLUSIONS: To the best of our knowledge, this study employed NPT for the first time to assess the implementation of new CDS in EHRs across diverse primary care settings at two institutions. Using NPT to evaluate this implementation provides insight into work domains which can be addressed with participants to improve integration of the new CDS tools and persistent efforts to ensure success of implementation. The decline in engagement from baseline to follow-up may suggest the need for more frequent contact with intervention sites to maintain momentum. NPT provides a framework for evaluation of technology and workflow innovation implementations in healthcare settings.

USING PRACTICE FACILITATION IN PRIMARY CARE SETTINGS TO REDUCE RISK FACTORS FOR CARDIOVASCULAR DISEASE: PHYSICIANS' BURNOUT ANALYSIS Batel Blechter; Nan Jiang; Keith Goldfeld; Nina Siman; Carolyn Berry; Donna Shelley. NYU School of Medicine, New York, NY. (Control ID #2702873)

BACKGROUND: National surveys indicate high rates of burnout, particularly among primary care physicians. Despite concerns about the impact of burnout on health outcomes, this relationship is not well studied. HealthyHearts NYC, funded through the EvidenceNOW initiative of the Agency for Healthcare Research and Quality is evaluating the effectiveness of practice facilitation to improve adoption of Million Hearts' evidence-based ABCS guidelines (Aspirin, Blood pressure control (BP), Cholesterol management, and Smoking cessation) in small-to-medium size primary care practices. This study examined the association between site characteristics and physicians' burnout, as well as the relationship with the ABCS outcomes.
METHODS: We present data on 99 small practices working with the NYCDOHMH Primary Care Information Project, and 8 Federally Qualified Health Centers (FQHC) from the Community Health Care Association of New York State. Each provider from participating practice sites completed a survey that included a validated question assessing burnout that used a 5-point scale ranging from 1- no symptoms of burnout to 5- completely burned out. For sites with multiple providers, we calculated a site burnout score by extracting the maximum score within each site. The burnout level was dichotomously coded as 1- burned out, and 0- not burned out. Each site completed a practice survey to report site characteristics, including the number of providers (1 vs. 2 or more), Patient Centered Medical Home (PCMH) status (recognized vs. not recognized), average number of patient visits per week, and total number of support staff. We used logistic regression analysis to assess the association of practice site characteristics and burnout. We also calculated a composite measure for patients with multiple CVD risk factors to capture the extent to which targets are met across three of the outcome measures (ABC). We used t-tests to assess the difference in ABCS and composite measures by burnout status.
RESULTS: Overall, 19% of physicians reported burnout. A significant difference was detected for all ABCS measures by the sites' burnout status. Sites reporting burnout had higher rates of meeting aspirin, smoking, and composite measure targets, but lower rates of meeting BP and cholesterol target measures and were more likely to have achieved PCMH recognition. FQHCs reported higher rates of burnout compared with small practices.
CONCLUSIONS: The overall rates of burnout were lower than reported in previous surveys. Lower burnout rates among small independent practices compared with FQHCs may be related to small practice providers' greater level autonomy. We will present additional data exploring organizational factors that may explain variation in burnout across these different practice settings. Finally, previous research has similarly found inconsistent associations between quality and burnout. Further studies are required to determine whether healthier workplaces also result in higher quality care.

UTILIZATION OF PERCUTANEOUS CORONARY INTERVENTION IN PATIENTS WITH DEMENTIA PRESENTING WITH ACUTE MYOCARDIAL INFARCTION - INSIGHTS FROM NATIONAL INPATIENT SAMPLE Siva Sagar Taduru[1]; Shubha Deep Roy[1]; Madhuri Ramakrishnan[1]; Dushyant Ramakrishnan[2]; Paramdeep S. Baweja[1]. [1]University of Missouri Kansas City, Kansas City, MO; [2]Osmania Medical College, Hyderabad, India. (Control ID #2706470)

BACKGROUND: The prevalence of acute myocardial infarction (AMI) and dementia increases with age. The management of AMI frequently involves percutaneous coronary intervention (PCI). It is essential to be on dual antiplatelet agents after PCI with stent. A recent study showed that invasive management of AMI in patients with dementia has a survival benefit. However, management of AMI in patients with dementia has traditionally been more conservative. There is limited data on utilization of PCI in patients with dementia in recent years.
METHODS: We searched the National Inpatient Sample (NIS) 2013 using International Classification of Diseases (ICD-9-CM) codes for patients older than 18 years with dementia (290.xx, 294.xx, 310.0, 331.xx) who presented with AMI(410.xx). We used propensity score to establish matched cohorts to control for baseline imbalances in patients with and without dementia. We used Chi squared test and ANOVA to compare categorical and continuous variables respectively. We performed Multivariate binary logistic regression to identify adjusted odds-ratio (AOR) between the groups.
RESULTS: We identified a total of 839,070 (weighted) patients with AMI admitted in 2013. A total of 72,975 (8.7%) patients had dementia. A total of 279,285 (33%) PCIs were performed. PCI rates were 35.7 and 8.4% in non-dementia and dementia groups. We identified a total of 72,945 patients in each group after propensity score matching (PSM). A total of 19,155 (13.1%) PCIs were identified in matched cohorts. PCI rates were 18 and 8.4% in non-dementia and dementia groups after PSM. Drug eluting stents (DES) and bare metal stents (BMS) were placed in 4.5 and 2.8% patients in dementia cohort respectively. AOR for undergoing PCI in dementia cohort was 0.428 (CI = 0.395–0.463; $p < 0.0001$) compared to non-dementia cohort. AOR for DES in dementia cohort was 0.398 (CI = 0.362–0.468; $p < 0.0001$) and AOR for BMS in dementia cohort was 0.669 (CI = 0.588–0.762; $p < 0.0001$) compared to non-dementia cohort.
CONCLUSIONS: Our study shows that PCI is highly underutilized in patients with dementia despite the survival benefit it offers.



VA PHYSICIANS' PERSPECTIVES AND EXPERIENCES REGARDING PRESCRIPTION DRUG MONITORING PROGRAMS: A MULTI-STATE QUALITATIVE STUDY Thomas R. Radomski[2, 4]; Felicia R. Bixler[4]; Susan L. Zickmund[6]; Katielynn M. Roman[4]; Jennifer A. Hale[4]; Leslie R. Hausmann[4]; Carolyn T. Thorpe[1, 4]; Joshua M. Thorpe[1, 4]; K J. Suda[7]; Kevin T. Stroupe[7]; Fran E. Cunningham[8]; Adam Gordon[3, 4]; Chester Good[4]; Michael J. Fine[4]; Walid F. Gellad[5]. [1]University of Pittsburgh, Pittsburgh, PA;

[2]University of Pittsburgh School of Medicine, Pittsburgh, PA; [3]University of Pittsburgh and VA Pittsburgh Healthcare System, Pittsburgh, PA; [4]VA Pittsburgh Healthcare System, Pittsburgh, PA; [5]VA Pittsburgh/University of Pittsburgh, Pittsburgh, PA; [6]VA Salt Lake City Healthcare System, Salt Lake City, UT; [7]Center of Innovation for Complex Chronic Heatlhcare, Hines, IL; [8]Hines VA Hospital, Hines, IL. (Control ID #2698135)

BACKGROUND: Although the Veterans Health Administration (VA) has implemented robust strategies to monitor prescription opioid dispensing, these strategies do not account for opioids prescribed to thousands of VA patients by providers outside the VA. State-based Prescription Drug Monitoring Programs (PDMPs) track dispensed opioid prescriptions and are a potential tool to identify VA patients' receipt of opioids from non-VA sources, but their use can be time consuming and administratively burdensome. Our objective was to evaluate VA physicians' perspectives and experiences regarding use of PDMPs to monitor Veterans' opioid use from non-VA sources.

METHODS: From 2/2016 - 8/2016, we interviewed 42 VA primary care physicians who had prescribed opioids to ≥15 Veterans in 2015. We sampled physicians from 2 states with PDMPs (MA, IL) and one state without physician access to a PDMP (PA). We conducted semi-structured telephone interviews that addressed the following topics regarding PDMPs: overall perceptions and experiences, ideas to improve use, and barriers/facilitators to use. Interviews were audio-recorded and transcribed verbatim. Two trained qualitative analysts developed a codebook, independently coded 20% of the transcripts, and assessed inter-coder reliability (kappa = 0.70) before the master coder coded the remaining transcripts.

RESULTS: We identified 3 overarching themes. First, physicians universally supported PDMPs (MA, IL) or desired access to one (PA), despite noting additional time and administrative burdens associated with their use. To improve use, physicians suggested: 1) linking PDMPs with the VA electronic health record, 2) using templated notes to document PDMP use, and 3) delegating routine PDMP queries to ancillary staff. Second, PDMP use challenged physicians' underlying biases regarding opioid misuse. "I used to kind of make a value judgement of my patients about whether or not I felt they were reliable and made prescribing choices based upon that," said one physician. "And in doing this (using a PDMP), I've realized that all of those things have to go out the window." Third, physicians felt the limited data contained within their state's PDMP was a barrier to optimal use. One physician said, "It (the PDMP) only gives me information about Massachusetts. So, for our patients who might be accessing medications in bordering states - I have no idea if that's happening or not, and I wish I did." Physicians from Illinois also had access to neighboring states' PDMPs, but desired national data, including current data from the VA.

CONCLUSIONS: Despite the time and administrative burdens associated with their use, VA Physicians uniformly supported PDMPs and acknowledged how they challenged their biases regarding opioid misuse. Our findings can help the VA meet the requirements of the Comprehensive Addiction and Recovery Act, which requires use of PDMP data by VA physicians, and may also inform efforts outside the VA to implement use of PDMPs into practice.

VACCINATION & OSTEOPOROSIS SCREENING RATES IN PATIENTS WITH ULCERATIVE COLITIS

Julia B. Diamant[1, 3]; Connor Wayman[3]; Jill Waalen[4]; Laura J. Nicholson[2]; Gauree G. Konijeti[3, 1]. [1]Scripps Translational Science Insitute, Rancho Santa Fe, CA; [2]Scripps Translational Science Institute, La Jolla, CA; [3]Scripps Clinic, La Jolla, CA; [4]The Scripps Research Institute, La Jolla, CA. (Control ID #2702249)

BACKGROUND: Despite defined preventive care quality metrics from the American Gastroenterology Association to improve care for patients with ulcerative colitis (UC), adherence is thought to remain low, and determinants of adherence would aid in optimizing practice patterns. The aim of this study was to assess whether quality metric adherence in patients with UC is common and is it influenced by the age of onset of disease.

METHODS: We performed a retrospective cross-sectional study of 631 patients with UC seen at an outpatient GI clinic between January 1, 2014 and December 31, 2015. Electronic medical records (EMR), available after 2010, were reviewed for UC history, laboratory testing and procedures, and medical therapies. Unpaired t-tests and chi-squared analysis were used to compare differences in compliance to quality measures by UC onset before or after age 50.

RESULTS: Approximately 75% ($n = 477$) of UC patients had disease onset before age 50, with a mean age of onset of 31. Overall adherence to quality measures was similar and well documented between the two groups if receiving Anti-TNF therapy, including hepatitis B and tuberculosis screening. However, rates of documented adherence to influenza and pneumococcal vaccination, as well as osteoporosis screening, was significantly low among those with UC, particularly those with onset before age 50. (See Table)

CONCLUSIONS: Documented compliance for IBD-specific quality measures is higher for patients with age of UC onset at 50 and older, particularly with respect to vaccinations and osteoporosis screening. This may reflect general compliance with ACIP guidelines for the elderly and a widespread lack of understanding of the elevated risk of future immunocompromise and bone mineral density compromise prematurely in patients with UC. This study demonstrates that gastroenterologists provide critical preventive care in patients recieving anti-TNF therapy. However, they may not provide appropriate preventive and screening care to patients with UC not on biologic therapy, rendering it incumbent upon primary care physicians to recognize the general health risks associated with IBD and provide appropriate screening and preventive measures to such patients. Improvement in adherence to accepted quality standards is needed for UC patients collectively to improve quality of care, particularly those diagnosed at earlier ages.

Quality Metrics by UC Age of Onset

	Age of onset <50 ($n = 477$)	Age of onset ≥50 ($n = 154$)	ρ
Age, (SD)	31 (9.6)	62 (9.2)	<0.01
UC Duration, mean, (SD)	17 (13)	8 (6)	0.10
Influenza Vax 2014 & 2015, n(%)	144 (30.3)	87 (54.7)	<0.01
Pneumococcal Vax, w/in past 5 yrs, n(%)	98 (20.6)	68 (42.8)	<0.01
DEXA, n(%)	137 (29)	71 (45)	<0.01
Anti-TNF Rx, n(%)	82 (17.2)	19 (12)	0.12
HepB assessment prior to Anti-TNF, n(%)	74 (90.2)	18 (94.7)	0.54
Latent TB assessment prior to Anti-TNF, n(%)	77 (93.9)	18 (94.7)	0.89

*DEXA: dual-energy X-ray absorptiometry; TNF: tumor necrosis factor; TB: tuberculosis.

VALIDATING A CLINICAL REASONING ASSESSMENT STRATEGY TO IDENTIFY ACTIONABLE FEEDBACK FOR STRUGGLING MEDICAL STUDENTS

Yvonne N. Covin[2]; Neda Wick[3]; Blake R. Barker[1]; Palma Longo[3]. [1]UT Southwestern Medical Center at Dallas, Dallas, TX; [2]University of Texas Southwestern Medical Center, Arlington, TX; [3]University of Texas Southwestern, Dallas, TX. (Control ID #2704890)

BACKGROUND: Although clinical reasoning is a foundational skill for physicians, educators have limited tools for standardized assessment to result in actionable feedback to medical students. We sought to assess the potential utility of a novel Think Aloud Protocol assessment strategy, Clinical Reasoning Task (CRT), to identify specific deficits among third-year medical students compared to the current validated multiple-choice instrument, the Clinical Data Interpretation (CDI) Test, which provides a global assessment of clinical knowledge but does not assess proficiency in specific clinical reasoning tasks.
METHODS: We conducted a pilot study of third-year medical students during their Internal Medicine clerkship at one large US medical school. We assessed clinical reasoning using the CDI among all students before a group project-based learning exercise, during which each group created a SOAP note. One student from each group then participated in a structured Think Aloud Protocol, which consisted of a structured interview assessing the justification for assessment, differential diagnosis and plan for the patient case. Each Think Aloud Protocol interview was recorded and scored by two independent reviewers using the validated CRT to identify actionable deficits in the clinical reasoning process (kappa = 0.88). We assessed CRT to CDI correlation with the Pearson correlation coefficient.
RESULTS: Eighteen students participated in the study. The mean CDI score among all participants was 46.2 (SD = 7.0). Among Think Aloud participants, the average CDI score was 44.6 (SD = 7.3). Think Aloud participants used only 11 of the possible 24 tasks. On average, each student uttered 15.8 tasks [range 8–23] to discuss the case. The most frequently used task was "select diagnostic investigations." Think Aloud Participant CRT and CDI scores were strongly positively correlated, but did not reach statistical significance ($R = 0.7$, $p = 0.07$).
CONCLUSIONS: Assessment of Think Aloud protocols using the validated CRT provides a global assessment of medical student clinical reasoning ability that correlates with assessment via the existing CDI, but also additional provides students with actionable feedback on specific deficits in clinical reasoning. Think Aloud used in conjunction with the CRT may be more helpful in identifying specific skills for remediation among medical students struggling with clinical reasoning and problem solving.

Clinical Reasoning Tasks	Number of Students Using Task	Mean (including repeated utterances)	Range
Identify active issues	5	1.3	1-2
Assess priorities	3	1	1-3
Reprioritize	6	1.7	1-3
Consider alternative diagnoses and underlying cause(s)	6	2.2	1-3
Identify precipitants or triggers to the current problem(s)	1	0.2	0-1
Select diagnostic investigations	6	4	3-5
Determine the most likely diagnosis and underlying cause(s)	6	1.7	1-3
Identify modifiable risk factors	3	0.5	0-1
Identify complications associated with the diagnosis, diagnostic investigations, or treatment	5	1.5	0-3
Establish management plans	5	1.7	0-3
Determine follow-up and consultation strategies	1	0.2	0-1

VALIDATION OF A COMPOSITE HEALTH SCORE TO PREDICT 90-DAY ALL-CAUSE HOSPITALIZATION IN A POPULATION OF GENERAL MEDICINE AND FAMILY MEDICINE PATIENTS SEEN AT TWO LARGE, ACADEMIC FACULTY PRACTICES

Jamie A. Jarmul[1, 2]; Annie Whitney[3]; Mark Gwynne[4]; Sam Weir[4]; Aaron Miller[1]; Robb Malone[3]; Darren A. DeWalt[1]. [1]UNC-Chapel Hill, Durham, NC; [2]UNC Gillings School of Public Health, Chapel Hill, NC; [3]UNC Health Care, Chapel Hill, NC; [4]UNC School of Medicine, Chapel Hill, NC. (Control ID #2698388)

BACKGROUND: Reducing the rate of potentially preventable hospitalizations is a high priority for clinically integrated health care delivery systems participating in accountable care organizations. To most efficiently target "admissions prevention" efforts, we developed an EMR-based admissions risk model (the "Composite Health Score", or CHS) to help identify patients at the highest risk for hospitalization. The objective of this study was to prospectively evaluate the ability of the CHS to accurately identify patients at risk for hospitalization within 90 days and to investigate various thresholds for defining a "high risk" subpopulation.
METHODS: Study design: Prospective, observational cohort study Population and Setting: 39,231 patients (>18 years old) attributed to primary care physicians at UNC Internal Medicine Clinic and UNC Family Medicine Clinic on 8/1/2016. Measures: A "snapshot" of the CHS for each patient was recorded on 8/1/2016. 90-day all-cause hospitalization was defined as any hospital admission to one of the UNC Health Care-affiliated system hospitals between 8/2/2016 and 11/2/2016. Analytic procedures: We used logistic regression analysis to evaluate the association of the CHS with 90-day all-cause hospitalization in all patients as well as in subpopulation of patients who had not had any hospitalizations/ED visits in the past year. We also evaluated the discrimination of the CHS to predict 90-day all-cause hospitalizations using the C-statistic, and investigated the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) associated with a threshold of 25 to define "high risk" patient populations.
RESULTS: For the entire patient population, the average (± SD) CHS was 6.3 ± 7.2. There were a total of 2,708 hospitalizations within the study time period (average rate of 23 admissions per 1000 patients per month); the average CHS was 16.9 ± 12.6 within that subset of patients. In the overall analysis, for every 1 point increase in a patient's CHS, their odds of being hospitalized in the next 90 days increased by 1.15-fold (95% CI: 1.141-1.151; C-statistic 0.877). In patients without a hospitalization or ED visit in the past year, the odds of being hospitalized within the next 90 days increased 1.27-fold for every 1 point increase in the CHS (95% CI: 1.251-1.293; C-statistic 0.882). If a patient's CHS was over 25, their odds of being hospitalized in the next 90 days was 16-fold greater than patients with CHS less than 25 (95% CI: 14.2-17.9). Using a CHS cut-off of 25 correctly classified the 90-day hospitalization status of 93% of patients, and had a sensitivity of 21%, specificity of 98%, PPV of 44 and NPV of 95%.
CONCLUSIONS: The CHS is highly predictive of 90-day all-cause hospitalization in population of patients seen at two large academic faculty practices. A threshold of 25 correctly classifies the 90-day hospitalization status of 93% of patients and thus can reasonably be used to target admissions prevention efforts.

VALIDATION OF A COMPUTERIZED ADAPTIVE TEST FOR DEPRESSION AND ANXIETY IN PRIMARY CARE

Alexa Minc[1]; Andrea E. Kass[1]; Neda Laiteerapong[2]; Robert Gibbons[1]. [1]The University of Chicago, Chicago, IL; [2]University of Chicago, Chicago, IL. (Control ID #2706018)

BACKGROUND: In primary care, there is a great need to screen and ensure adequate treatment for mental health conditions. Approximately half of patients with major depressive disorder (MDD) and generalized anxiety disorder (GAD) are unrecognized and over half of those with mental illness go untreated. Brief screening tools exist for depression and anxiety, such as the Patient Health Questionnaire-2 or −9 (PHQ-2 or PHQ-9) and Generalized Anxiety Disorder-7 (GAD-7). However, since computers are ubiquitous in clinical practice, online screens for mental health conditions may be more accurate, efficient, and agreeable to patients than questionnaires. Computerized adaptive tests (CATs) are screening tools that adapt the order and number of questions administered based on patient responses for a more tailored assessment, personalized to their level of severity. We sought to validate a CAT for mental health (CAT-MH) conditions in a primary care population.

METHODS: We recruited adult primary care patients prior to their appointments. Participants completed 3 assessments for depression and anxiety: the CAT-MH, questionnaires (PHQ-2, PHQ-9, GAD-7), and gold standard Structured Clinical Interview for DSM-5 Disorders (SCID). To assess depression, the CAT-MH selected questions from a bank of 452 validated symptom-based questions. To assess anxiety, the CAT-MH selected from a bank of 467 validated questions. CAT-MH scores range from 0 (no symptoms) to 100 (severe symptoms).

RESULTS: 271 patients completed the study (402 approached, 285 consented, 14 incomplete). Based on the SCID, 31 patients were diagnosed with MDD and 29 with GAD. To diagnose MDD, the CAT-MH administered an average of 4.2 ± 0.5 questions, and if positive, an additional 7.6 ± 1.9 to assess severity. To assess anxiety, the CAT-MH administered an average of 11.8 ± 4.1 questions. For MDD screening, the CAT-MH and PHQ-9 had higher accuracy than PHQ-2 (AUC 0.85 and 0.83 vs. 0.71, respectively). Sensitivity was higher for the CAT-MH and PHQ-9 than PHQ-2 (0.77 and 0.75 vs. 0.58); specificities were similar (0.93 and 0.94 vs. 0.93). As CAT-MH depression severity scores increased, odds of a MDD diagnosis based on the SCID increased (OR 10.7; 95% CI 3.7-18.2). For GAD screening, CAT-MH had high predictive accuracy (AUC 0.93, 95% CI 0.90-0.97) to the GAD-7 (AUC = 0.97, 95% CI 0.96-0.99) and odds of predicting a GAD diagnosis increased with increasing score (OR 10.1; 95% CI 7.0-13.3). More patients preferred the CAT-MH (53%) than the interview (33%) or questionnaires (14%).

CONCLUSIONS: The CAT-MH is a valid tool for depression and anxiety screening and severity assessment in primary care. CATs may provide a more accurate and patient-centered method of screening for mental health conditions compared to brief questionnaires. Use of the PHQ-2 for depression screening may need to be reconsidered in primary care.

VALIDATION OF A COMPUTERIZED METHOD FOR CALCULATING CTPA YIELD IN THE EMERGENCY DEPARTMENT

Alexander O'Connell[1]; Safiya Richardson[2]; Jonathan Gong[2]; Vinodh Mechery[1]; Guang Qui[2]; Thomas McGinn[2]. [1]Hofstra Northwell School of Medicine, Ridgewood, NY; [2]Northwell Health, Manhasset, NY. (Control ID #2691076)

BACKGROUND: The diagnostic uncertainty inherent to the clinical assessment for pulmonary embolism (PE) coupled with the possibly fatal consequence of a missed diagnosis has led to increasing utilization of computed tomography pulmonary angiography (CTPA) in the Emergency Department (ED). This has caused growing concerns about the harms of overuse. A recent prospective study found CTPA caused twice as many patients to develop contrast induced nephropathy (14%) as it was able to diagnose with PE. The lifetime malignancy risk can be as high as 2.76% in young female patients. Given the potential for significant iatrogenic harm from overuse, it is important to monitor appropriateness of use by estimating CTPA yield, the percentage of tests positive for PE. The outcome measure "CTPA Yield" is a critical measure needed to better understand how to study and monitor overuse of CT technology. CTPA yield has not been previously studied or validated for use in diagnostic studies for PE. In our study we propose and validate a computerized method for calculating CTPA yield in the ED.

METHODS: The electronic medical record databases at two tertiary care academic hospitals, North Shore University Hospital (NSUH) and Long Island Jewish Medical Center (LIJMC), were queried for CTPA orders completed in the ED over a one month period. From these visits we selected those with a linked inpatient admission and an inpatient discharge diagnosis of PE (ICD-9-CM 415.19/ICD-10- CM I26.99). The CTPA yield was calculated as the number of CTPA orders with an associated inpatient discharge diagnosis of PE divided by the total number of orders for CTPA completed. This calculated yield was then validated by performing a manual chart review which included reading the free text radiology reports for each CTPA performed.

RESULTS: Between both sites, 325 CTPA orders were completed and 27 were found to have an associated inpatient discharge diagnosis of PE. This returned a calculated CTPA yield of 8.31%. Manual chart review revealed 28 positive scans for a true CTPA yield of 8.61%. The one discordant scan was tied to a patient who was discharged directly from the ED, and as a result never received an inpatient discharge diagnosis. During the chart review at NSUH it was noted that 7% of CTPAs were ordered to evaluate for an aortic dissection, all of which had linked orders for CT angiography of the abdomen and pelvis. All CTPA studies with linked orders for CT angiography of the abdomen and pelvis were removed from the total list of CTPAs for both hospitals.

CONCLUSIONS: This is a successful validation study of a computerized method for calculating CTPA yield in the ED. Using this method of EMR data extraction allows for an accurate determination of CTPA yield without time consuming manual chart reviews. This computerized method for calculating CTPA yield provides health systems with the means to monitor for CTPA overuse in the ED and to assess the impact of interventions to reduce overuse, thereby preventing iatrogenic harm.

VALIDATION OF THE 4-ITEM SCREENING COMPONENT OF THE TAPS TOOL TO IDENTIFY UNHEALTHY SUBSTANCE USE AMONG PRIMARY CARE PATIENTS

Robert Schwartz[1]; Jan Gryczynski[1]; Jennifer McNeely[2]; litzy Wu[3]; Gaurav Sharma[4]; Jacquie king[4]; Eve M. Jelstrom[4]; courtney nordeck[1]; Anjalee Sharma[1]; Shannon Mitchell[1]; Kevin O'Grady[5]; Dace Svikis[6]; Lauretta Cathers[6]; Geetha Subramaniam[7]. [1]Friends Research Institute, Baltimore, MD; [2]NYU School of Medicine, New York, NY; [3]Duke University, Durham, NC; [4]Emmes Corporation, Rockville, MD; [5]University of Maryland, College Park, MD; [6]Virginia Commonwealth University, Richmond, MD; [7]National Institute on Drug Abuse, Rockville, MD. (Control ID #2708980)

BACKGROUND: There is a need for a rapid substance use screening instrument to detect unhealthy tobacco, alcohol, and other drug use among primary care patients. The Tobacco, Alcohol, Prescription Medications, and other Substances Tool (TAPS Tool) is a combined 2-part screening and brief assessment developed for adult primary care patients. Its screening component (TAPS-1) consists of 4 items asking about past 12-month use of four substance categories

(any tobacco, 5 or more drinks/day for men [4 for women] of alcohol, any illicit drug use, and any non-medical use of prescription drugs. Categorical response options are: never, less than monthly, monthly, weekly, and daily or almost daily. The objective of this preplanned secondary analysis was to validate the TAPS-1 against the DSM-5 substance use disorder (SUD) criteria.

METHODS: This was a multi-site study evaluating the concurrent validity of the TAPS-1 compared to SUD criteria conducted among 2,000 adult primary care patients in 5 clinics located in 4 Eastern US states. Participants completed the TAPS Tool in a self- administered version on a tablet computer and in an interviewer-administered format, in random order. They were then administered a modified version of the Composite International Diagnostic Interview (CIDI) to determine DSM-5 criteria. Optimal cut points for identifying SUDs were obtained using receiver operating characteristics (ROC) analysis to obtain sensitivity (sens), specificity (spec), positive predictive value (PPV), negative predictive value (NPV), and area under the curve (AUC).

RESULTS: The optimal cut-point on the interviewer-administered TAPS-1 for identifying SUDs was '≥ monthly use' for tobacco (sens = .95, spec = .80, PPV = .62, NPV = .98, AUC = .88) and for alcohol (sens = .68, spec = .87, PPV = .45, NPV = .94, AUC = .77). In contrast, 'any use' was the optimal cut-point for illicit drugs (sens = .93, spec = .86, PPV = .50, NPV = .99, AUC = .89) and for non-medical use of prescription drugs (sens = .90, spec = .95, PPV = .41, NPV = 1.0, AUC = .93). The self-administered format had similar performance.

CONCLUSIONS: The TAPS-1 was able to rapidly screen adult primary care patients for SUDs. Thus, the TAPS-1 could assist health care providers in determining which patients might need a focused, in-depth substance use assessment.

VALIDATION OF THE PRINCIPAL DIAGNOSIS IN THE 30-DAY RISK STANDARDIZED READMISSION RATE IN A LARGE ACADEMIC TERTIARY CARE HOSPITAL Molly J. Horstman[2, 3]; Glynda Raynaldo[1]; Lindsey Jordan[1]; Laura A. Petersen[2, 3]. [1]Michael E. Debakey Medical Center and Baylor College of Medicine, Houston, TX; [2]Baylor College of Medicine, Houston, TX; [3]Michael E. DeBakey VA Medical Center, Houston, TX. (Control ID #2704256)

BACKGROUND: CMS and other entities have focused on reduction of readmissions as a national quality improvement goal. The 30-day risk standardized readmission rate is derived from administrative data and requires the accurate coding of a principal diagnosis. We sought to validate the coded principal diagnosis for patients admitted with pneumonia and to determine if local efforts to improve inpatient coding improved data validity.

METHODS: Two attending physicians reviewed all index admissions with a principal diagnosis of pneumonia from Fiscal Years (FY) 2014–2015 at a large, tertiary care teaching hospital using a standardized abstraction form. Index admissions that did not meet the data definition for the 30-day risk-standardized readmission rate were excluded. Each reviewer independently determined a principal diagnosis for each admission. Disagreements between reviewers were resolved by consensus when possible, or by a third reviewer when needed. In FY 2015, the Michael E. DeBakey VA Medical Center implemented a comprehensive intervention to improve medical documentation and coding. The bundle included resident and attending education and twice-weekly coding huddles with physicians and coders. The proportion of admissions with a confirmed principal diagnosis of pneumonia or alternative diagnosis were compared before and after the coding intervention using a chi square test, and kappa statistics were used to measure interrater reliability.

RESULTS: In FY 2014, 156 admissions met the inclusion criteria. Of these, 29 (18.6%) admissions had a principal diagnosis of pneumonia on chart review. The remaining 127 (81.4%) admissions were determined to have a more appropriate alternative principal diagnosis, most commonly sepsis (n = 88) and acute hypoxic respiratory failure ($n = 20$). In FY 2015, only 92 admissions met the inclusion criteria likely due to an increase in the use of observation status. Of these, 18 (19.6%) admissions had a principal diagnosis of pneumonia on chart review. The remaining 74 (80.4%) admissions were determined to have an alternative principal diagnosis (sepsis $n = 51$, acute hypoxic respiratory failure $n = 17$). The intervention did not change the proportion of admissions with a confirmed coded principal diagnosis of pneumonia ($p = 0.85$). Interrater reliability was moderate (kappa = 0.42).

CONCLUSIONS: We found that less than one fifth of admissions were correctly categorized with a principal diagnosis of pneumonia. This proportion did not improve meaningfully with a coding intervention. Our findings call into question the validity of data used in reporting 30-day readmission rates. The disagreement between experienced physicians regarding the appropriate principal diagnosis highlights the challenges clinicians face in clinical documentation. Recent data definition changes from CMS to include a principal diagnosis of sepsis with a secondary diagnosis of pneumonia as a pneumonia admission may improve the validity of the data.

VALUE-BASED PRIMARY CARE OUTCOMES: VALIDATING AN ALGORITHM FOR INCIDENT MYOCARDIAL INFARCTION AND ASSESSING TRENDS OVER 10 yearS Jeffrey M. Ashburner[2]; Daniel M. Blumenthal[2]; Steven Mcdermott[2]; Wei He[1]; Steven J. Atlas[2]. [1]MGH, Boston, MA; [2]Massachusetts General Hospital, Boston, MA. (Control ID #2705447)

BACKGROUND: Most primary care (PC) quality measures assess care processes or intermediate outcomes. Delivering value-based services requires assessing outcomes that directly contribute to health. We developed and validated an electronic algorithm to identify patients seen within a large PC network with incident myocardial infarction (MI); identified incident MIs over a 10 year period; and examined changes in prevalence of pre-existing chronic diseases over time.

METHODS: The cohort includes adults aged 18+ with incident MI cared for in a 19-practice PC network between 2006–2015, a period when the network grew from 143,995 to 163,279 patients. We identified patients with an inpatient primary discharge diagnosis of MI or two outpatient visits with problem list terms or billing code diagnoses for MI. We excluded outpatient MI diagnoses identified in patients new to the network without an inpatient diagnosis to exclude prevalent events. We applied this algorithm to each calendar year. We randomly chose up to 2 cases per practice in each year ($n = 312$) and 25 controls per practice ($n = 475$) for chart review validation.Fifty randomly selected patients with newly diagnosed coronary artery disease (CAD) not identified as having a MI were assessed to identify missed incident events occurring outside our network. A research nurse performed blinded electronic chart reviews. We assessed the number and proportion of patients with incident MI per year, and the proportion with established cardiovascular disease (CVD) (CAD, peripheral and cerebrovascular disease), hypertension, and diabetes before the incident MI. We examined trends over time using the Cochran-Armitage test.

RESULTS: Chart review validation of 787 patients yielded a sensitivity of 96%, specificity of 91%, positive predictive value of 86%, and negative predictive value of 98%. Among 50 patients with a new CAD diagnosis without incident MI, 46 (92%) did not have a MI, while 4 (8%) had a MI.

Of the 4, 2 occurred before joining the PC network, and 2 (4%) were incident MIs missed by the algorithm. Between 2006–2015, the annual in-network incidence of MI ranged from 0.09% ($n = 130$ in 2009) to 0.13% ($n = 192$ in 2011). The average age of MI patients was 67.5 years, and 65.6% were male. The proportion of MI patients with pre-existing CVD (14.7% in 2006, 28.1% in 2015) or hypertension (46.9% in 2006, 65.9% in 2015) increased over time (all $p < 0.001$), while the proportion with pre-existing diabetes did not (23.1% in 2006, 25.2% in 2015; $p = 0.8$). The proportion with any chronic condition increased from 51.8% in 2006 to 68.3% in 2015 ($p < 0.001$).

CONCLUSIONS: We developed and validated an outcome measure for incident MI in a PC network. Though rates of MI were stable, the percentage of patients with pre-existing chronic disease risk factors for MI increased over 10 years. The low incidence of MI in this large network suggests that composite measures which include multiple outcomes (e.g. MI and stroke) may be needed to accurately assess value-based PC quality.

VARIABILITY IN THE COMPLETION OF TRANSITIONAL CARE MANAGEMENT ELEMENTS AT POST-DISCHARGE PRIMARY CARE VISITS Salina Bakshi[1, 2]; Karen Sherritt[1, 2]; Michelle Potter[1, 2]; Jeffrey L. Schnipper[1, 2]; Lipika Samal[1, 2]. [1]Brigham and Women's Hospital, Boston, MA; [2]Harvard Medical School, Boston, MA. (Control ID #2706205)

BACKGROUND: The Partners PCORI Transitions Study was designed to improve transitions of care after hospital discharge. While many patients are scheduled for follow-up appointments with their primary care physicians (PCP), there is no standard of care for these visits. Medicare's Transitional Care Management (TCM) Services Guidelines describes a set of potential tasks for post-discharge visits, but PCPs may be unaware of these guidelines. Our study examined variation in documented completion of TCM elements during these visits.

METHODS: Patients admitted to medical or surgical units at two hospitals were eligible for the study if they received primary care at one of 18 practices within the Partners accountable care organization. Patients were eligible if they were discharged from hospital to home between October 2013 and September 2015. Patients were excluded if they were re-admitted to the hospital directly from their PCP's office. We examined post-discharge notes for eight TCM elements based on Medicare's TCM Services Guidelines. These include elements such as "Review of Discharge Summary" and "Assessment of Disease Management." Completion of services was based on a set of definitions iteratively refined for reliability and conducted by a research assistant working with a clinician-investigator and a resident in internal medicine. We calculated a "TCM score," which was the unweighted sum of the number of TCM elements documented during the visit.

RESULTS: We reviewed 46 post-discharge visits, representing 34 different physicians. About half (54%) of patients were male, 59% were white, and 48% were married. The majority of the visits (63%) were conducted by the patient's PCP, while the others were conducted by a different provider in the practice. The mean unweighted TCM score was 3.66 (range 0–7). No visits which fulfilled all eight elements. Rate of completion of each element ranged from 11% (discussion of home-based resources) to 77% (assessment of disease control; Table 1).

CONCLUSIONS: On average, the post-discharge visit fulfilled less than half of recommended transitional care elements, at least as documented in visit notes. There was great variation in documented completion of these services, both by TCM element and by visit. Our findings suggest that the Medicare TCM Services Guidelines, as currently implemented, may be insufficient to ensure consistent completion of transitional care elements during post-discharge visits.

Documented Completion of TCM Elements During Post-Discharge Primary Care Visits

TCM Element	Proportion Documented as Completed
Review of discharge summary	68%
Assessment of disease control	77%
Treatment change	51%
Review of pending studies	34%
Scheduling follow-up with other providers	36%
Discussion of community & home based resources	11%
Patient and caregiver education	30%
Medication reconciliation or education	60%

VARIATION IN CHOICE OF DIABETES PREVENTION STRATEGY BY GENDER, RACE AND ETHNICITY AFTER A PREDIABETES SHARED DECISION MAKING VISIT WITH A PHARMACIST: THE PREDIABETES INFORMED DECISION AND EDUCATION (PRIDE) STUDY. Jacqueline Martin[1, 2]; Jonathan Grotts[1, 2]; O. Kenrik Duru[2, 1]; Tannaz Moin[3]; Janet Chon[1, 2]; Chi-Hong Tseng[1, 2]; Richard Maranon[1, 2]; Keith Norris[1, 2]; Gerardo Moreno[2, 1]; Susan Ettner[2, 1]; Carol Mangione[1, 2]. [1]David Geffen School of Medicine at UCLA, Los Angeles, CA; [2]UCLA, Los Angeles, CA; [3]UCLA/VA Greater Los Angeles, Los Angeles, CA. (Control ID #2707022)

BACKGROUND: Approximately 1 in 3 American adults have prediabetes (pre-DM) and 11% are predicted to develop diabetes over a 3-year period. Currently very few persons with pre-DM are engaged in evidence-based diabetes prevention strategies including intensive lifestyle change and/or metformin. The goals of these analyses are: 1) assess the impact of a pre-DM shared decision making (SDM) visit with a pharmacist on overall rates of selection of an intensive lifestyle program (Diabetes Prevention Program/DPP) and/or use of metformin (MF); and 2) examine variation in treatment choice by demographic and clinical characteristics.

METHODS: The study population included 365 participants with pre-DM from 10 primary care practices from the intervention arm of a cluster-randomized trial of SDM designed to evaluate uptake of diabetes prevention. Eligible participants were between the ages of 18 and 65 years with a body mass index (BMI) > 24 m/kg^2 (>22 m/kg^2 if Asian), and an A1c between 5.7-6.4%. At the completion of the SDM visit with a clinical pharmacist, patients could make one of 4 treatment choices (DPP, MF, DPP + MF, or no treatment). Variation in treatment choice by age, race/ethnicity, gender, BMI and A1c was assessed with a multivariate logistic regression model.

RESULTS: A total of 365 study participants were enrolled with a mean (SD) age of 56.3 years (11.5), BMI of 30.4 kg/m2 (5.2), and A1c of 6.0%. The sample included 44.1% White, 21.4% Asian, 16.4% Hispanic, and 13.2% African American participants, as well as 58.6% women. Among these subjects, 209 (57%) chose DPP, 33 (9%) chose MF alone, 61 (17%) chose both DPP + MF, and 62 (17%) declined both treatments. In analyses adjusted for age, race/ethnicity, BMI, and A1c, when compared to women, men were significantly less likely to choose DPP or DPP + MF (OR = 0.59, $p = .04$) and subjects with higher BMI were more likely to select a choice that included DPP (OR = 1.1 per unit increase in BMI, $p = .001$). No other characteristics were significantly associated with choosing DPP. Younger age (<50 years reference, 50–59 [OR = 0.77], > 60 [OR = 0.4], $p = .01$) and higher BMI was significantly associated with choosing MF with or without DPP, (OR = 1.08, $p = .005$).

CONCLUSIONS: Overall 83% of subjects with pre-DM selected an active diabetes prevention strategy after participating in a pharmacist led SDM visit. This level of engagement in diabetes prevention is much higher than what has been reported in the literature. However, the selection of specific diabetes prevention treatments after a SDM visit varied by gender, age and BMI with those with the highest BMIs significantly more likely to select both prevention strategies either alone or simultaneously. We did not find an association between A1c level and choosing any diabetes prevention strategy, suggesting that the participants may not have perceived an increased risk of diabetes with higher baseline A1c.

VARIATION IN PHYSICIANS' DECISIONS ON ANTIHYPERTENSIVE TREATMENT IN OLDEST-OLD AND FRAIL INDIVIDUALS ACROSS 29 COUNTRIES Sven Streit[2]; Marjolein Verschoor[2]; Nicolas Rodondi[2, 3]; Daiana Bonfim[4]; Robert A. (Control ID #2685840)

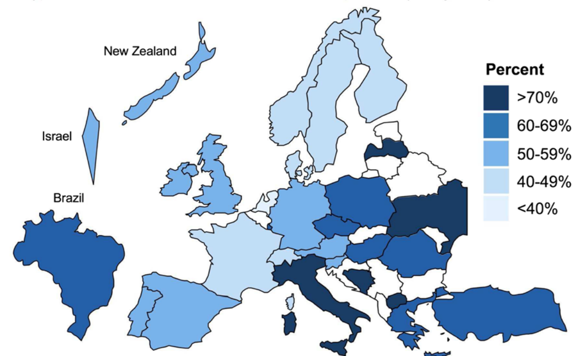
BACKGROUND: In oldest-old patients (>80), few trials showed efficacy of treating hypertension and they included mostly the healthiest elderly. The resulting lack of knowledge has led to inconsistent guidelines, mainly based on systolic blood pressure (SBP), cardiovascular disease (CVD) but not on frailty despite the high prevalence in oldest-old. This may lead to variation how primary care physicians (PCP) treat hypertension. Our aim was to investigate treatment variation of PCPs in oldest-olds across countries and to identify the role of frailty in that decision.

METHODS: Using a survey, we compared cases of oldest-old varying in SBP, CVD, and frailty. PCPs were asked if they would start antihypertensive treatment in each case. In 2016, we invited PCPs in Europe, Brazil, Israel, and New Zealand. We compared the percentage of cases that would be treated per countries. A logistic mixed-effects model was used to derive odds ratio (OR) for frailty with 95% confidence intervals (CI), adjusted for SBP, CVD, and PCP characteristics (sex, location and prevalence of oldest-old per PCP office, experience, and guideline adherence when treating hypertension in oldest-old). The mixed-effects model was used to account for the multiple assessments per PCP.

RESULTS: The 29 countries yielded 2,543 participating PCPs (response rate 3–93% per country): 52% were female, 51% located in a city, 71% reported a high prevalence of oldest-old in their offices, 38% had >20 years of experience, and 69% reported adherence to guidelines. Across countries, considerable variation was found in the decision to start antihypertensive treatment in the oldest-old ranging from 34–88% (Figure 1). In 24/29 (83%) countries, frailty was associated with PCPs' decision not to start treatment even after adjustment for SBP, CVD, and PCP characteristics (OR 0.53, 95%CI 0.48–0.59; ORs per country 0.11–1.78).

CONCLUSIONS: Across countries, we found considerable variation in starting antihypertensive medication in oldest-old. The frail oldest-old had an OR 0.53 of receiving antihypertensive treatment. Future hypertension trials should also include frail patients to acquire evidence on the efficacy of antihypertensive treatment in oldest-old patients with frailty, with the aim to get evidence-based data for clinical decision-making.

Figure 1. National percentages in which primary care physicians decide to start antihypertensive treatment in cases of oldest-old patients (unadjusted).



VARIATIONS IN ADHERENCE TO SYNDROME-SPECIFIC PREVENTIVE HEALTHCARE AMONG ADOLESCENTS AND ADULTS WITH DOWN SYNDROME Kristin M. Jensen[1, 2]; Elizabeth J. Campagna[2]; Elizabeth Juarez-Colunga[2, 2]; Desmond K. Runyan[2]; Allan V. Prochazka[1]. [1]University of Colorado School of Medicine, Aurora, CO; [2]University of Colorado, Aurora, CO. (Control ID #2705404)

BACKGROUND: Persons with Down syndrome (DS) have risks of comorbidities across their lifespan, for which syndrome-specific recommendations exist. Little is known about adherence to DS-specific recommendations, particularly with regards to the influence of the age-focus of primary care provider (PCP). In this study, we evaluate adherence to DS-specific recommendations among adolescents and adults with DS.

METHODS: Using Medicaid claims data (2006–2010) in CA, CO, MI, and PA, we defined our cohort as DS patients ≥12yo enrolled in Medicaid for ≥45/60 mo without concurrent Medicare. Patients without a PCP were excluded (total cohort 3501). Providers were considered PCPs if they billed ≥10 well exams in a year. PCPs with ≥80% of their well-exams billed as well-child or well-adult were categorized as child- or adult-focused, respectively. The remaining PCPs were classified as mixed-focus. DS screenings recommended every 1-2 yr include thyroid, vision, and hearing. Additional DS screenings prompted by clinical suspicion include sleep apnea and acquired valve disease. We used Pearson's chi-squared tests to compare adherence to these screening activities at least once within 5 yr by PCP focus within age groups.

RESULTS: 52% of our cohort was male, with 21% adolescent (12–17yo), 32% transition aged (18–25yo), and 47% adult (≥26yo). 52% had a child-focused PCP (12–17yo 73%, 18–25yo 54%, ≥26yo 40%), with the remaining split equally between adult- and mixed-focused PCPs. Hearing and vision screenings were comparable between PCP types in all age groups. Adult-focused PCPs had increased adherence to thyroid screenings among 18–25yo ($p < 0.001$) and ≥26yo ($p = 0.006$). Screening for acquired valve disease and sleep apnea was similar between PCP types across age groups, except in 18–25yo where more patients with child-focused PCPs underwent sleep apnea screening ($p = 0.009$).

CONCLUSIONS: We observed little variation in adherence to DS-specific recommendations by patient age or PCP focus with marked variation in adherence between individual screening measures. This represents a significant opportunity to improve syndrome-specific care in adolescents and adults with DS.

	Total	12-17yo		18-25yo		≥26yo	
PCP Focus		C/M	A	C	A	C	A/M
DS-Specific Screenings Recommended Every 1-2 yrs

VETERAN PATIENTS' PERSPECTIVES ON RECENT RE-HOSPITALIZATION: QUALITATIVE FINDINGS Lauretta E. Grau[2]; Sheila Antony[1]; Rebecca Brienza[1]. [1]VA Connecticut Healthcare System, West Haven, CT; [2]Yale School of Public Health, New Haven, CT. (Control ID #2705726)

BACKGROUND: VA patients are at high risk of readmission due to their lower socioeconomic status, older age, poor social supports, and multiple comorbidities. The current study was undertaken in response to VA interest in reducing readmission risk and enhancing quality of healthcare by exploring patients' perceptions about putative factors contributing to their readmission and their perspectives on how to reduce the likelihood of readmission.

METHODS: Subjects were purposively sampled at the VA Connecticut hospital in West Haven. All were inpatients, 18+ years of age, re-hospitalized to internal medicine within 30 days of last discharge, medically stable, and competent to provide consent. Interviews were audiotaped, lasted 20–30 min, and asked about perceived health status after last discharge, reason for readmission, and access to and support from primary care. They were also asked about demographics. All audiotaped interviews were transcribed verbatim, de-identified, independently coded (LG, SA), and analyzed using thematic analysis. Coding discrepancies were resolved by consensus. Data collection continued until theoretical saturation was achieved. The study was approved by the West Haven, VA IRB.

RESULTS: The study sample comprised 17 males and 1 female VA patients; all were Caucasian, elderly (mean age 71.6;11.1 SD), and financially secure but on limited budgets. Approximately half lived with family or a spouse; many had serious medical conditions or histories of affective disorders. Themes about precipitating factors in readmission included logistical/structural barriers to accessing primary care providers (PCP), limited PCP involvement patients sought emergency care, and patients' belief that readmission was inevitable. Themes related to the discharge process and post-discharge services included beliefs of having been prematurely discharged, inadequate understanding of post-discharge plan, and poorly coordinated post-discharge services. Most patients highly valued their VA Primary and inpatient care but recommended increasing PCP involvement in their inpatient care, reducing transportation and distance barriers to primary and specialty care, expanding pre-discharge services, and improving post-discharge service coordination in order to reduce risk of re-hospitalization.

CONCLUSIONS: Limited contact with the medical system prior to returning to the hospital, limited access to care due to clinic hours and distance, and inadequate services pre- and post-discharge were seen by patients to contribute to their readmission. They suggested proactive outreach to high-risk patients following discharge, expanded access to outpatient care, and increased coordination and communication between all relevant inpatient and outpatient services in preparation for discharge and after-care could improve VA healthcare delivery.

VIDEO VISITS CAN BE BOTH EFFICIENT AND EFFECTIVE: A SYSTEMATIC REVIEW Michael C. Gao; Peggy Leung. NewYork-Presbyterian/Weill Cornell, New York, NY. (Control ID #2699081)

BACKGROUND: Telemedicine has the potential to lower cost and to reach patients where regular care cannot. However, existing reviews have come to varying conclusions as to its clinical appropriateness. One challenge is that telemedicine technologies are heterogenous and include remote monitoring, direct-to-consumer apps, asynchronous communication (e.g. e-mail consults), and synchronous communication (e.g. video visits). In this study, we systematically review randomized-controlled trials (RCTs) investigating one important component, the use of video visits, and describe their findings in terms of clinical outcomes, patient costs, process measures, and patient and provider satisfaction.

METHODS: We conducted a systematic literature searches in Medline, Embase, and Cochrane from their inception through August 2016. Major search terms included telemedicine, virtual or video visit, and remote consultation. In addition, reference and article related searches were conducted in Ovid and Pubmed. We included English-language manuscripts that (1) were RCTs, (2) compared video visits at the patient's residence to standard outpatient care, and (3) contained MD, DO, or NP providers. Studies were excluded if the video visit portion was ancillary to the digital platform as a whole, e.g. visits triggered by telemonitoring of pacemakers. Two researchers independently reviewed all retrieved articles to identify studies meeting eligibility criteria and to abstract pertinent data. The Clinical Appraisal Scales Programme (CASP) RCT checklist, a validated 22 point scale, was used to evaluate study quality.

RESULTS: Of the 1785 articles identified, seven met our inclusion criteria. The mean CASP score was 15.1 and ranged from 9 to 19 points. Five studies had visit reasons relevant to primary care, including Type 2 Diabetes (T2DM), HIV, Parkinson's Disease (PD), and two described post-operative management in Urology and in Orthopedics. Video platforms used included enterprise software (VSee, Vidyo, SBR Health), consumer software (Skype), custom-built software, and video-conferencing phones. Five out of seven studies reported clinical outcomes: both T2DM studies showed greater HbA1C improvement by video visits, one PD study showed greater quality of life and motor improvements, and the remaining two studies found no significant differences. Three studies reported patient non-visit costs (e.g. travel, days off work), and all significantly favored video visits. Three studies reported process measures (e.g. percent of appointments kept, visit time, wait time) and none showed significant differences. Five studies reported either patient or provider satisfaction measures and none found significant differences.
CONCLUSIONS: Although additional research is needed, video visits have the potential to lower patients' cost of access while simultaneously providing perceived high-quality care. In some chronic conditions, video visits may even lead to improved clinical outcomes.

WE HAVE HIV, IT DOESN'T HAVE US: ADDRESSING STIGMA THROUGH A VIRTUAL COMMUNITY FOR PEOPLE LIVING WITH HIV Tabor E. Flickinger; Claire L. DeBolt; Alison Kosmacki; Ava Lena Waldman; Karen Ingersoll; Rebecca Dillingham. University of Virginia, Charlottesville, VA. (Control ID #2703468)

BACKGROUND: Stigma against persons living with HIV (PLWH) has negative consequences, including poor mental health and lower treatment adherence. We designed a clinic-based smartphone app for PLWH that includes an anonymous private online support group. We analyzed how stigma was discussed within this virtual community of PLWH.
METHODS: The Positive Links program is based at an academic outpatient Ryan White Clinic in southwestern Virginia. For this pilot study, 77 patients were enrolled and given smartphones with the Positive Links app installed. The app was designed through an iterative, user-based process and includes the opportunity to interact with other users on a community message board (CMB). CMB content was analyzed qualitatively using constant comparisons methodology to explore themes of stigma. Posts were classified as stigma-related if they referred to positive or negative social implications of HIV status. Coding was performed by three coders who achieved good reliability (kappa 0.86).
RESULTS: Of the 77 participants, 63% were male; 49% black non-Hispanic; and 72% below the federal poverty level. Over 30 months, participants made 2300 posts on the CMB. Participants expressed a lack of self-worth (feeling undeserving of love) and negative framings of HIV status (suggesting HIV diagnosis is a negative result of past actions). In contrast, other participants expressed affirmation of self-worth (one still has value despite HIV+ status) and positive framings of HIV status (how HIV diagnosis has positively impacted life). Negative interpersonal themes were disrupted relationships, fear of HIV transmission, feelings of loneliness or isolation, negative past or anticipated experiences with disclosure, and negative consequences of failing to disclose status. Positive interpersonal themes were finding true friends or family (suggests that HIV status has allowed person to create stronger relationships), and positive past or anticipated experiences with disclosure. Interactions in stigma-related threads included sharing negative emotions with CMB, asking questions related to stigma, sharing need to talk, sharing one's story, as well as offering companionship/support, blessings, instructional advice in stigma-related situations, and encouraging positive thinking and a will to overcome.
CONCLUSIONS: CMB participants expressed negative experiences of internalized and interpersonal stigma. They also shared positive experiences of overcoming stigma by affirming self-worth, reframing HIV status in a positive way, and finding friends and family who accepted them. The Positive Links community offered support to each other in addressing issues of stigma within themselves and in their relationships. Next steps include quantifying frequencies of stigma-related post types and mixed-methods analysis of posting behavior and outcomes for participants. Online communities have potential to help patients find acceptance and develop resilience by overcoming adversity together.

WE NEED EXTRA CARE: TRANSGENDER PEOPLE OF COLOR DESCRIBE HEALTHCARE PRIORITIES AND FACILITATORS TO ACCESS Zoe Ginsburg[1]; Mollie B. Nisen[1]; Elliot Goodenough[3]; Madeleine Lipshie-Williams[1]; Jules Chyten-Brennan[2]; Viraj V. Patel[1]. [1]Albert Einstein College of Medicine, Bronx, NY; [2]Montefiore, New York, NY; [3]Montefiore Medical Center, Bronx, NY. (Control ID #2706089)

BACKGROUND: Transgender people have poor health outcomes in nearly every measure compared to cisgender people, and experience health care discrimination. These disparities are worse for transgender people of color (TPOC). While researchers have explored barriers to care, little has focused on transgender patients' priorities for their own healthcare, facilitators to care, and none is specific to TPOC. We conducted a qualitative study to explore priorities for and facilitators to healthcare for TPOC in the Bronx.
METHODS: We conducted 3 focus groups in September 2016 (2 in English and 1 in Spanish), led by a trained, experienced, bilingual peer-facilitator. Participants ($n = 22$) were recruited through key informants in the Bronx transgender community and convenience sampling social media. Inclusion criteria included being over 18, identifying as transgender or gender non-conforming, fluency in English or Spanish, and had or may access healthcare in the Bronx. We used grounded theory approach to analysis.
RESULTS: All participants were non-white: half (11/22) were black, and 6 were Spanish speakers. Nearly half (10) were transwomen (self-identified women who were assigned-male-at-birth), 8 were transmen (self-identified men who were assigned-female-at-birth) and 3 were non-binary (did not currently identify as male or female). The average age was 35.7 (23–59), over 80% (17) were insured, with the majority having Medicaid (10/17). Three key themes or priorities to facilitate transgender healthcare access emerged: (1) transgender specific resource allocation, (2) using existing transgender peer networks, and (3) ongoing mechanisms to incorporate feedback. Participants framed these 3 themes in the context of general distrust of the medical system. First, (1) TPOC look for resources allocated specifically for transgender people to overcome existing barriers to care, including training for all staff and clinicians, having healthcare workers who are trans, and media and materials featuring TPOC. Second, (2) existing transgender networks are a rich conduit for information sharing and can quickly spread (mis)trust. Third (3), despite historical distrust of medical systems, TPOC are willing to invest energy to advise on culturally appropriate practices; feedback mechanisms may foster mutual trust. Participants expressed interest in a community advisory board and on the condition they are compensated for their time and expertise, and saw suggestions being implemented.
CONCLUSIONS: TPOC look for resource allocation and staff training specifically for transgender clients as a proxy for competency and medical safety, and

rely on peer networks for information and support over "official" resources. These results suggest healthcare systems can facilitate access by hiring transgender people themselves, and creating responsive, ongoing feedback mechanisms. Despite medical system distrust, participants were willing to be involved in new models of care provided their input is valued and operationalized.

WHAT ACCOUNTS FOR THE VARIATION IN AVOIDABLE ED USE AMONG MEDICARE ENROLLEES? Amresh D. Hanchate[2, 1]; William E. Baker[1]; Michael Paasche-Orlow[1]; Sophia Dyer[1]; Jean Degeorge[3]; James Feldman[1]. [1]Boston University School of Medicine, Boston, MA; [2]VA Boston Healthcare System, Boston, MA; [3]Boston Medical Center, Boston, MA. (Control ID #2701245)

BACKGROUND: Avoidable ED (AED) use is associated with lack of insurance and Medicaid coverage; sources of AED use among those with stable coverage is unknown. We sought to estimate regional variation in AED use for Medicare patients and its association with patient health status, socioeconomic indicators, and provider availability.

METHODS: We identified 2010 ED visits in a national sample ($N = 999{,}999$) of Medicare Fee for Service enrollees aged 66 and older. AED use was identified based on outpatient ED discharges classified as "non-emergent" or "emergent but primary care treatable" using the NYU-Billings' algorithm. Our primary outcome was the number of AED visits per 100 person-years ("AED rate"). We also examined the number of all ED visits per 100 person-years ("ED rate"). Using Dartmouth's hospital referral region (HRR) as the area unit, we estimated age-sex adjusted AED and ED rates, and grouped all HRRs ($N = 306$) into quartiles. We examined concordance between AED and ED rate quartiles. Using Poisson regression models we assessed the share of patient health status (comorbidities), socioeconomic indicators (minority race/ethnicity, dual Medicaid coverage, low income) and provider availability (metropolitan area, proximity to hospital) in accounting for interquartile differences in AED rate.

RESULTS: The national AED rate (13.9, 95% CI 13.7–14.1) was 24% of overall ED rate (58.3, 95% CI 58.2 59.2). HRR-level variation in AED rate ranged from 6.8 (95% CI 5.3 8.3) in Lancaster, PA to 27.8 (95% CI 23.6 31.2) in Bangor, ME. Relative to HRRs in the lowest rate quartile, HRRs in the highest quartile had a 74% higher AED rate (incidence rate ratio (IRR) 1.74, 95% CI 1.67–1.81). Concordance between regional AED and ED rates was poor (kappa = 0.32, 95% CI 0.25–0.38); AED rates were relatively higher but ED rates relatively lower in Midwest and West regions. Adjusting for health status, socioeconomic indicators, and provider availability reduced quartile 1 vs. quartile 4 difference in AED rate by 21% (IRR 1.58, 95% CI 1.51–1.65). Provider availability was associated with the largest variation in AED rate (13.4%), followed by socioeconomic indicators (9.8%) and patient health status (<0.1%). Specifically compared to metropolitan statistical areas, higher adjusted AED was observed in micropolitan statistical areas (IRR 1.13, 95% CI 1.09–1.18) and non-urban areas (IRR 1.25, 95% CI 1.25–1.35); among socioeconomic indicators, Medicaid dual coverage (IRR 1.43, 95% CI 1.37–1.48) and black race (IRR 1.47, 95% CI 1.43–1.51) were associated with higher AED relative to white enrollees without Medicaid coverage.

CONCLUSIONS: AED rates vary by HRR, even among Medicare enrollees with similar health status. Associations of provider availability and socioeconomic indicators with AED use point to potential opportunities for targeted efforts to safely reduce AED use by reducing barriers to timely and convenient outpatient care. Additional sources of regional variation need to be explored.

WHAT CONSTITUTES AN "INDEPENDENT STATISTICAL ANALYSIS" OF AN RCT? Ann Abraham[5]; Rosa Ahn[3]; Alexandra Woodbridge[5]; Susan Saba[6]; Erin Madden[2]; Deborah R. Korenstein[1]; Salomeh Keyhani[4]. [1]Memorial Sloan Kettering Cancer Center, Pelham, NY; [2]NCIRE, SAn Francisco, CA; [3]Oregon Health and Science University, Portland, OR; [4]University of California at San Francisco, San Francisco, CA; [5]San Francisco VA Medical Center, San Francisco, CA; [6]Stanford University School of Medicine, Palo Alto, CA. (Control ID #2700445)

BACKGROUND: The term "independent statistical analysis" is used to suggest impartiality and robustness of trial data and analysis. We conducted a descriptive study to examine how the term "independent statistical analysis" is used in published randomized controlled trials (RCT) examining the efficacy of drugs.

METHODS: We searched MEDLINE for all RCTs with abstracts in the English language published in 2013. We randomly selected 496 trials for review, including trials with a primary efficacy outcome and excluding those that did not specify the drug of interest. One hundred ninety trials met inclusion criteria and underwent review independently by two reviewers, including the Methods and Acknowledgement sections, for terms describing an independent statistical analysis or independent statistician. Disagreements were resolved by discussion. Papers reporting independent statistical analysis were further reviewed for data on the role of the statistician in data analysis, the statistician's access to data, and the employer of the statistician. We also abstracted for funding source and role of the sponsor with regards to data management and analysis. All information was abstracted by one reviewer and verified by a second reviewer.

RESULTS: Among the 190 trials that met inclusion criteria, 17 (8.9%) reported independent statistical analysis. Among the 17 trials, the majority (14, 82.3%) were funded by industry and most (12, 70.6%) were published in high impact journals (impact factor > 10). The independent statistician(s) was clearly identified in the majority of the papers (70.6%).The role of independent statisticians varied across trials; they led the analysis in 6 (35.3%), validated the sponsors analysis in 5 (29.4%), and provided statistical assistance in 3 (17.6%). In about a quarter of the trials, the role of the statistician was not specified. Independent statisticians had complete access to the data in 8 trials (47.1%), and limited access in 3 (17.6%); 6 (35.3%) trials did not specify. The majority of statisticians were employed by academia, such as universities, academic research organizations or non-profit hospitals (13, 76.5%) with the remainder employed by contract research organizations (4, 23.5%). In 7 (41.1%) trials with independent statistical analysis the sponsor was not involved in data collection, management, or analysis; in 7 (41.1%) the sponsor was involved in these data functions, in 2 (11.8%) trials the sponsor performed the analysis in parallel with the independent statistician, and in 1 (5.8%) sponsor relationship to data was unspecified.

CONCLUSIONS: Independent statistical analyses of RCTs focused on drug efficacy are found mostly in industry funded studies published in high impact journals. However, while the term is used in the literature, there does not appear to be a uniform definition for what constitutes an independent statistical analysis.

WHAT DEFINES AN HONORS STUDENT? A TEACHING WARD ATTENDING PERSPECTIVE Lauren Nicholas (Nico) Herrera[3]; Ryan Khodadadi[3]; Winter Williams[1]; Erinn Schmit[3]; Nina Mingioni[4]; Andrew R. Hoellein[2]; Karen L. Law[5]; Christopher Knudson[5]; Carlos Estrada[1]. [1]The University of Alabama at Birmingham, Birmingham, AL; [2]University of Kentucky, Lexington, KY; [3]University of Alabama at Birmingham,

Birmingham, AL; [4]Thomas Jefferson University, Philadelphia, PA; [5]Emory University, Atlanta, GA. (Control ID #2703040)

BACKGROUND: Nationwide, 20–40% of clerkship students receive the top grade. However, little is known on the key characteristics that define high-performing students. We examined teaching ward attendings' opinions of characteristics that define honors medical students.

METHODS: *Design*: cross-sectional. *Setting*: seven teaching sites in the US. *Participants*: teaching ward attendings in internal medicine [IM] and pediatrics clerkships (2013–2016). *Exclusion*: subspecialty and consults services. *Measures*: survey framed around ACGME competencies and other characteristics, question posed: "How much emphasis do you place on each of the following characteristics when designating a student as 'honors' (or top grade)?" (24-items; 1 = less emphasis, 10 = more emphasis). Survey was pilot tested after cognitive interviews. *Analysis*: factor analysis and Cronbach's alpha (>0.9 is considered excellent, >0.8 good, >0.7 acceptable, >0.6 modest, <0.6 poor).

RESULTS: Response rate was 65% (224/344); 33% were internists, 25% hospitalists, 21% IM subspecialists, 12% pediatricians, and 9% others (or no data). The top five characteristics were taking ownership, clinical reasoning, dependability, high ethical standards, and curiosity (in descending order, mean range 9.3 to 9.0). The bottom five characteristics were prioritizes patient safety, understands social determinants of health for care transitions, comments from staff, coordination of care, and physical exam skills (in descending order, mean range 7.4 to 7.2). On factor analysis, 22 items fit into three factors with Eigenvalues > 1 accounting for 86% of the variance. The internal consistency was good (Cronbach's alpha 0.85 to 0.86). *Factor 1* was the most important domain, mean 8.7 (95% confidence interval [CI] 8.5 to 8.8), and included multiple ACGME competencies: professionalism, interpersonal and communication skills [ICS], medical knowledge [MK](curiosity), patient care [PC](interviewing skills), and problem-based learning and improvement [PBLI](seeks/responds to feedback). *Factor 2* was the next most important, mean 7.8 (95% CI 7.6 to 8.0), and included ICS and a general positive attitude (interactions with patients and their families, comments from patients, residents, and staff, appropriate confidence, handles stress well, positive). *Factor 3* was last, mean 7.4 (95% CI 7.2 to 7.6), and included PBLI (sets learning goals, appraises evidence), SBP (prioritizes patient safety, coordinates patient care, understands social determinants of health for care transitions), patient care (physical exam skills), and medical knowledge (applies evidence).

CONCLUSIONS: Clinical reasoning, professionalism, communication skills, and curiosity were the most important characteristics to teaching ward attendings when considering medical students worthy of honors designation during clerkships. Our findings underscore the importance of other approaches to recognize excellence; clerkship directors could find ways to assess PBLI, SBP, and physical exam.

WHAT DO HIGH RISK PATIENTS VALUE IN CARE MANAGEMENT PROGRAMS? Ishani Ganguli[1, 2]; Endel J. Orav[1]; Eric M. Weil[4, 3]; Timothy G. Ferris[4, 3]; Christine Vogeli[4, 3]. [1]Brigham and Women's Hospital, Chestnut Hill, MA; [2]Harvard Medical School, Boston, MA; [3]Partners HealthCare, Boston, MA; [4]Massachusetts General Hospital, Boston, MA. (Control ID #2706952)

BACKGROUND: There is growing interest in coordinating care for high risk patients through care management programs. These programs have shown high patient satisfaction and variable ability to reduce cost and utilization, but we know little about what medically complex patients value in them. Therefore, we surveyed patients in a primary care-based program to explore their awareness and perceived utility of its offerings.

METHODS: We conducted a cross-sectional phone survey of participants in the Boston-based Partners Integrated Care Management Program in Dec 2015-Jan 2016. Our main outcome was the number of issues (out of 8, Figure) on which patients reported "very helpful" discussions with their care team in the past year. We analyzed awareness of one's care manager as an intermediate outcome, then as a primary predictor, along with demographics, time in the program, health attitudes, and worries as secondary predictors. We built a logistic regression model to determine predictors of care manager awareness and an ordinal logistic regression model to examine the adjusted effect of awareness on the main outcome.

RESULTS: The survey response rate was 31% ($n = 1182$); nonrespondents were similar to respondents in age, sex, race, area-level poverty and education, insurance type, years in program, and Impact Pro risk score. More respondents reported worrying about family (72.8%) or about financial issues (52.5%) than about their own health (41.6%). 73.7% reported knowing their care manager, particularly women (OR 1.33,95%CI 1.01,1.77) and those with more years in the program (OR 1.16,95%CI 1.03,1.30). Respondents reported varying rates of discussions (Figure) and 81% noted at least one very helpful discussion. Those who were aware of their care manager reported very helpful discussions on more topics (OR 2.77,95%CI 2.15–3.56), as did women (OR 1.25,95%CI 1.00,1.55), younger respondents (OR 0.98,95%CI 0.97,0.99), and those with higher risk score (OR 1.04,95%CI 1.02,1.06), preference for deferring treatment decisions to doctors (OR 2.00,95%CI 1.60,2.50), and reported control over their health (OR 1.67, 95%CI 1.33,2.10).

CONCLUSIONS: Our results suggest high risk patients worry about socio-economic issues affecting health more than their health itself. Varying discussion rates across topics highlight opportunities for more meaningful engagement. Promoting awareness of care managers may help participants make better use of these programs.

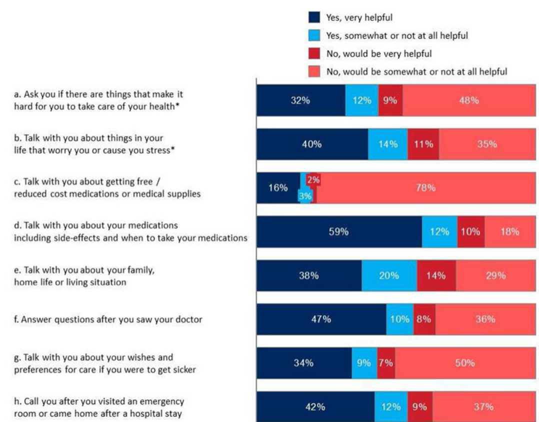

Figure. For each of the items, the respondent was asked if anyone in his or her primary care doctor's office had done the stated task. If the answer was yes, he or she was asked how helpful it was. If the answer was no, he/she was asked how helpful it might be in the future.
*Adapted from Massachusetts Health Quality Partners (MHQP) and Consumer Assessment of Healthcare Providers and Systems (CAHPS) surveys

WHAT DO PATIENTS REALLY DO WHEN THEY FAST? PATIENTS' PRACTICES AND PERCEPTIONS TOWARDS FASTING BLOOD WORK Ami DeWaters; Jamael Thomas; Daniel Mejia; Bryan Elwood; Michael E. Bowen. UT Southwestern Medical Center, Dallas, TX. (Control ID #2700020)

BACKGROUND: Fasting glucose is an important screening and diagnostic test for diabetes. However, little is known about patients' behaviors and

attitudes towards fasting blood work. To improve our understanding, we conducted a survey to assess patients' practices and perceptions of fasting blood work in clinical practice.
METHODS: We designed and administered a survey to assess fasting behaviors in a convenience sample of patients presenting for outpatient blood work at an academic medical center in the fall of 2016. We invited English speaking adults age 18 or older, who presented to the lab between 6:30 and 10:00 AM to participate. We subsequently reviewed the EHR and extracted demographics, comorbidities, and laboratory results from the laboratory visit on the day of the survey. Participants who had nothing to eat or drink except water for at least 8 hours were considered fasting, in accordance with the American Diabetes Association (ADA) fasting definition. We describe the frequencies of fasting behaviors and examine differences in characteristics between fasting and non-fasting participants using Chi2 and Fisher's Exact tests as appropriate.
RESULTS: In this 6 week pilot study, we collected 79 surveys toward the study goal of 550. On average, survey participants were 52 years old, 58% female, 30% non-white, and 22% had diagnosed diabetes. Overall, 75% (N = 59) of participants self-identified as fasting, and 93% of those met our fasting definition. Surprisingly, 53% of all participants felt it was important to fast for every blood test, and 42% of those who self-reported fasting (N = 59) reported receiving no directions to fast from their healthcare providers. Only 3.8% of participants had documentation of fasting instructions in clinic notes or patient instructions on chart review. However, 43% (N = 34) of all participants reported they were told to fast by a healthcare provider with 91% meeting our gold standard fasting definition. We observed no differences in fasting behavior by patient characteristics, including by common comorbidities such as hypertension and hyperlipidemia. Importantly, 94% of patients with diagnosed diabetes (N = 17) fasted on the day of the survey, and 100% reported taking their diabetes medications as prescribed the day of their lab visit, including 5 of 6 patients on insulin. Of the 19 patients without diabetes who fasted unbeknownst to their clinicians and had a glucose measured, 3 cases of prediabetes and 1 case of diabetes were missed.
CONCLUSIONS: Patients commonly fast for routine laboratory tests and adhere to ADA fasting guidelines even if not told to do so by their healthcare providers. Fasting is common among patients with diabetes taking hypoglycemic medications, which poses significant safety concerns. Development of standardized protocols to assess and report fasting status when patients present for routine blood work may improve recognition and diagnosis of prediabetes and diabetes in clinical practice.

WHAT DOES COMMUNICATION SKILLS PERFORMANCE IN A HIGH-STAKES 3RD YEAR OSCE TELL US ABOUT THE TRANSITION TO RESIDENCY? Colleen C. Gillespie[2]; Sondra Zabar[1, 3]; Ruth Crowe[1]; Jasmine A. Ross[2]; Kathleen Hanley[2, 3]; Lisa Altshuler[2]; Adina Kalet[2, 2]. [1]NYU School of Mediicne, New York, NY; [2]NYU School of Medicine, New York, NY; [3]Gouverneur Healthcare Services, New York, NY. (Control ID #2706318)

BACKGROUND: It is critically important for medical schools to understand how well prepared their graduates are for residency and yet we do not have a full understanding of how well competencies, assessed in medical school, transfer to residency. This study explores how communication skills measured in a high-stakes, rigorous, comprehensive OSCE in the 3rd year of medical school are related to performance in a similar OSCE in residency and to Residency Program Directors' ratings of intern competence.
METHODS: We analyzed communication skills from three time points in a longitudinal cohort of NYU graduates who entered our Internal Medicine Residency (n = 42). 39 provided consent for their GME-UME data to be compiled into a longitudinal, de-identified educational research database through an IRB-approved Registry. Communication skills were measured using a behaviorally anchored 15-item checklist across the 8-station, pass/fail, MS3 OSCE and then midway through PGY2 of residency in a 6-station OSCE (score = % of items rated well done). SPs also provided an overall rating of communication skills (not recommend, with reservations, recommend, highly recommend). In between, at the end of intern year, residents were also rated by their Program Directors on communication skills (and other competencies) using a 4-pt scale.
RESULTS: OSCE communication performance assessed in medical school was modestly associated with performance in residency (r = .26, p = .07) but not with Program Directors' ratings of residents' communication skills as interns (r = .11, p = .28). Number of cases in which medical students were "not recommended" for their communication skills was negatively associated with residency OSCE communication scores (r = −.33, p = .05) and positively associated with number of "not recommends" (r = .46,p = .01) but not with Directors' ratings of interns (r = −.08, p = .49). Number of not recommends independently explained more variance in subsequent residency communication scores than did medical school performance (9% vs. 5%). While average OSCE communication scores improved from medical school to residency (65 to 71%), those with 2 or more "not recommends" improved significantly more than those with 1 or no "not recommends. Overall, most learners' (21/39) communication scores improved substantially; less than a quarter (7) decreased; and about a quarter (11) were stable.
CONCLUSIONS: While communication scores from medical school are associated with similarly measured scores in residency, SPs' decisions to "not recommend" students appear to serve as an independent indicator of future skill deficits. Patterns of change, however, are not necessarily straightforward: students with the most "not recommends" improved the most. The ability to track competency assessments longitudinally is essential for understanding the transition from medical school to residency and future research will benefit from larger sample sizes and the inclusion of learner characteristics that may explain developmental patterns.

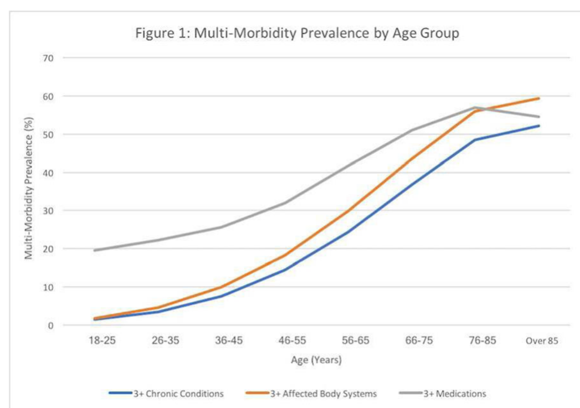
WHO ARE THE MEDICALLY COMPLEX PATIENTS IN CANADIAN PRIMARY CARE? A COMPARATIVE ASSESSMENT OF MEASURES OF MULTI-MORBIDITY Ashley Jensen; Tyler Williamson; Paul E. Ronksley; Gabriel E. Fabreau; Alicia J. Polachek; Amanda Cheung; Kerry McBrien. University of Calgary, Calgary, AB, Canada. (Control ID #2704030)

BACKGROUND: Multi-morbidity, the presence of more than one chronic health condition, is common among primary care (PC) patients and often used as an indicator of medical complexity. Prior estimates of multi-morbidity prevalence have varied widely due to a lack of standardized measures; more precise measures are needed to aid development of interventions for medically complex patients. Our objective was to compare three measures of multi-morbidity and describe the prevalence of multi-morbidity among Canadian PC patients.
METHODS: We employed a retrospective cohort design using secondary data from the Canadian Primary Care Sentinel Surveillance Network. We examined multi-morbidity in a cohort of 577,530 adult patients from 9 provinces and

territories. We included patients with at least two PC visits between 2011 and 2015, with at least one occurring during the most recent year. Multi-morbidity was defined using three approaches selected for simplicity, existing evidence and content validity: count of chronic conditions (from a list of 33 possible); count of affected body systems; and count of medications prescribed in a 1-year period. We then compared demographic characteristics and PC utilization across the resulting three cohorts.

RESULTS: Among our patient cohort, 59.4% were female and the mean age was 50.1 years. The prevalence of multi-morbidity was 33.1% for 2 or more chronic conditions, 33.5% for 2 or more affected body systems and 34.5% for 3 or more medications. Significant overlap was noted between the multi-morbidity cohorts identified by condition and affected body system counts, however, only 42.8% of the cohort identified by medication counts were common to either of the other two. All measures of multi-morbidity showed increasing prevalence by age (Figure 1). For all measures a high degree of multi-morbidity (90th percentile and above) was associated with higher PC utilization.

CONCLUSIONS: Counts of chronic conditions and affected body systems identified similar multi-morbid cohorts. Medication counts, however, did not correlate with the other measures, so caution is needed when using this as a proxy for multi-morbidity. Clearly defined measures of multi-morbidity will enhance PC research and inform the development of targeted interventions for medically complex patients.



WHY IS EVERYONE BREATHING 20 TIMES A MINUTE? PATTERNS OF RECORDED RESPIRATORY RATE IN HOSPITALIZED ADULTS.

Jack Badawy[1]; Oanh K. Nguyen[2]; Christopher Clark[1]; Ethan Halm[3]; Anil N. Makam[1]. [1]UT Southwestern, Dallas, TX; [2]UT Southwestern Medical Center, Dallas, TX; [3]Univ of TX Southwestern Med Ctr, Dallas, TX. (Control ID #2701244)

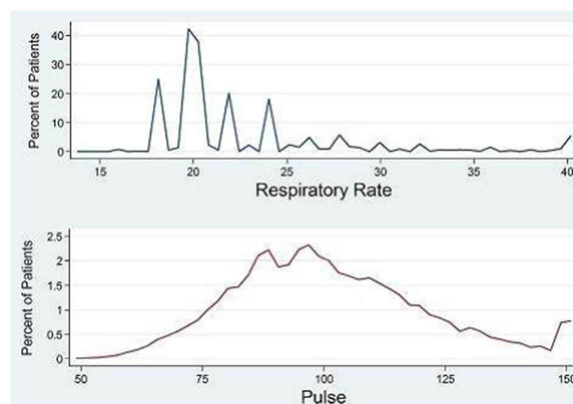
BACKGROUND: Respiratory rate (RR) is an independent predictor of adverse outcomes across a variety of conditions among hospitalized adults. Thus, accurate assessment is necessary to recognize disease severity and prognosis. Prior studies suggest that recorded RR is inaccurate compared to objective measures. We sought to assess the potential accuracy of recorded RR in medical inpatients.

METHODS: This was a descriptive, retrospective observational cohort study of consecutive adult admissions from 2009–10 from 6 diverse hospitals excluding those in the ICU. We assessed the distribution in recorded RR as a proxy for accuracy, since accurately recorded RRs should be normally distributed when compared to heart rate (HR). We assessed patterns of RR using descriptive statistics and the coefficient of variation (CV) during hospitalization and for specific subgroups expected to have abnormal breathing, and thus greater variation (cardiopulmonary illness and hypoxemia).

RESULTS: We included 28,511 patients, representing 220,665 unique hospital days. Mean age was 62 years, 54% female and 40% non-white. Recorded RR was not normal distributed as compared to HR (Figure). RRs were clustered at 18 and 20 breaths/minute with a right skewed pattern. The minimum was equal to the maximum RR in 26% of hospital days. The maximum RR equaled 18 or 20 in 75% of all hospital days. There was little variation over the duration of the hospitalization (CV of 0.2 for the first day, 0.15 for two days prior to discharge, and 0.12 for day of discharge). Patients with cardiopulmonary illness (CV 0.22 vs. 0.19) or with hypoxemia (CV 0.23 vs. 0.18) had only modestly greater variation in RRs than those without.

CONCLUSIONS: Among a large, diverse multicenter cohort of adults hospitalized for a broad range of medical conditions, we found that recorded RR was not normally distributed, and that there was little variation in the recorded RR on admission and throughout hospitalization even among those with cardiopulmonary compromise. The clustering of values suggests that the recorded RR is likely an estimate, with 18 and 20 used in place for 'normal'. Inaccurate recording of the RR may lead to misclassification of disease severity and prognosis, and potentially jeopardize patient safety.

Distribution of Maximum RR on Admission.



WIDESPREAD ADOPTION OF ELECTRONIC SPECIALTY REFERRALS IN A LARGE SAFETY-NET SYSTEM ENABLES RAPID ACCESS TO SPECIALTY CARE

Michael L. Barnett[2]; Ateev Mehrotra[1]; Hal F. Yee[3]; Paul Giboney[3]. [1]Harvard Medical School, Boston, MA; [2]Harvard T.H. Chan School of Public Health, Boston, MA; [3]Los Angeles County Department of Health Care Services, Los Angeles, CA. (Control ID #2705800)

BACKGROUND: Lack of timely access to specialty care is a persistent challenge in safety-net systems. To address this challenge, in 2012 the Los Angeles Department of Health Services (DHS), a large public health system with a population of 670,000 patients, implemented an electronic specialty referral system ("eConsult") to improve specialty access. In the eConsult model, primary care providers (PCPs) request all specialty input electronically. Frequently the question can be addressed through an electronic "curbside" dialogue between a PCP and specialist thereby precluding a face-to-face visit. In this evaluation, we examined trends in eConsult volume and assessed whether eConsult implementation led to sustained improvement in specialty access.

METHODS: We performed an observational analysis of all eConsult requests from 2012–2015 ($n = 395{,}050$). To address the increasing adoption of eConsult by new providers, we also examined a subsample of eConsults 2014–2015 from PCPs active on eConsult prior to 2014 ($n = 60{,}864$ eConsults). We tracked the volume of eConsult requests, time until first eConsult response, time until a scheduled appointment after eConsult request, and the fraction of eConsults resolved without a visit vs. scheduled for a face-to-face visit. To test for statistical significance, we used t-tests or for time trends, bivariate linear regression with a linear term for quarter.

RESULTS: From 2012–2015, eConsult volume grew rapidly from 86 to 12,082 monthly requests, an 8% increase in volume per month ($p < 0.001$). By 2015, the median time to first response for an eConsult request was slightly under 24 hours (0.99 days) and 25.0% of eConsult requests were resolved without a visit. Among PCPs active on eConsult before 2014, the median time to a face-to-face appointment after an eConsult decreased 17.4% from 63 days in 2014 to 52 days in 2015 ($p < 0.001$), while the percentage of appointments scheduled within 30 days increased from 24.0 to 30.2% ($p < 0.001$). From 2014–2015, we found no significant change in the average monthly volume of eConsults resulting in a face-to-face visit ($p = 0.90$).

CONCLUSIONS: These findings illustrate the successful adoption of an eConsult system in a population with historically poor specialty access. Four years after initial implementation, the median response time to an eConsult was under 1 day, 25% of eConsults were resolved without a visit and the median time to appointment continued to decrease though wait times remained more than 50 days. These changes occurred without an increase in face-to-face visits, implying a decreased backlog of patients waiting for appointments, with no evidence of 'pent up' demand leading to increased utilization. eConsults are a promising mechanism to improve specialty access in safety net populations.

WOMEN VETERANS' VIEWS ON THE ROLE OF PEER SUPPORT TO IMPROVE HEART HEALTH Karen M. Goldstein[6, 4]; Leah Zullig[6, 4]; Sara Andrews[5]; Mary E. Grewe[2]; Michele Heisler[1]; Eugene Oddone[6, 4]; Corrine Voils[3, 4]. [1]Ann Arbor VA/University of Michigan, Ann Arbor, MI; [2]Department of Veteran Affairs, Durham, NC; [3]Durham VA Medical Center, Duke University Medical Center, Durham, NC; [4]Duke University School of Medicine, Durham, NC; [5]Research Triangle Institute International, Durham, NC; [6]Durham VA, Durham, NC. (Control ID #2698746)

BACKGROUND: Women veterans are at high risk for cardiovascular disease (CVD) due to high rates of both traditional (e.g., smoking) and non-traditional risk factors (e.g., depression). One approach to support behavioral change for CVD risk reduction is peer support. But while studies have proven peer support effective in improving chronic disease management among men veterans, similar studies in women veterans are needed. Toward this goal, we sought to identify which aspects of peer support and which modalities for providing peer support are preferred by women veterans at risk for CVD.

METHODS: We conducted 25 semi-structured telephone interviews with women veterans aged 35 to 64 years who are at risk for developing CVD (defined as having hypertension, hyperlipidemia, diabetes, obesity, or currently smoking). Interview questions elicited preferences for types of peer support (e.g., appraisal, informational, emotional) and ideal structure of peer support interventions. We analyzed interview text using directed content analysis.

RESULTS: Mean participant age was 50 years (range: 35 to 63). Participants identified as African-American (56%), White (20%), Multi-racial (20%), and Other (4%). Sixty-four percent were divorced/widowed or never married, and 4% participants lived alone. Four key themes emerged. First, women veterans anticipated that to help engagement in healthy activities (e.g., exercising or healthy eating) a peer partner could provide accountability and external motivation. Second, preferences for peer partners included sharing a common health goal, physical proximity to peer partner, and having a positive and engaged attitude. Third, women felt a need to build trust at the start of a peer partnership, preferably via in-person social interactions. Finally, women noted potential barriers to peer support including disliking overt emotional support or 'cheerleading'.

CONCLUSIONS: As an intervention to support heart healthy behaviors, women veterans endorsed peer support. Peer support interventions will need to account for preferences in peer matching and provide opportunities for peers to become acquainted through socially-oriented activities.

Women veterans' quotes on peer support

Theme	Quote
Accountability/ motivation	"So I want someone more like me that's not going to say 'We can do it tomorrow'. No, you push me. I need that and vice versa."
Preferences for Peer Partner	"We'd need positive attitudes first and foremost. You need to want to really do it and there shouldn't be anyone condemning the next person. It's a struggle already."
Need to build trust	"Once I make that face-to-face…I could call some on the phone….it doesn't matter because we've established that trust."
Importance of socializing	"If you get out and you socialize together, it kinda strengthens the bond….it would be seen more as fun instead of a chore."
Potential barriers	"You want some positive feedback, and not from your girlfriends saying 'You go girl'…I don't need a cheerleader."

CLINICAL VIGNETTES

"MOM, WHERE'S THAT BAG OF MEDS?": USING A HOME VISIT TO DIAGNOSE POLYPHARMACY Maureen McCamley; Theresa Vettese. Emory University School of Medicine, Atlanta, GA. (Control ID #2705219)

LEARNING OBJECTIVE #1: Identify polypharmacy as a cause of rapidly progressive dementia

LEARNING OBJECTIVE #2: Recognize the utility of home visits in an internal medicine training program

CASE: Ms. R is a 56yo African American female with hypertension, diabetes, depression, and possible bipolar disorder who was seen in follow up with concerns from family about memory loss. She scored a 6/30 on the MOCA, and was sent for labs and referred to memory clinic. A week later she was admitted for memory loss, falls, and confusion. She underwent extensive workup including brain CT and MRI, EEG, LP, and a paraneoplastic panel which were unremarkable. At that time there was concern for a Parkinsonian syndrome vs infectious vs adverse medication effects and she was to follow up in neurology clinic. She was readmitted a week later for similar complaints and had a repeat brain CT. Three weeks later, a home visit revealed 27 bottles of 14 different medications. An extensive reconciliation was performed simplifying her to five oral medications, and the remainder were removed from the home. At a follow up appointment two months later, she and her family noted significant improvement. A repeat MOCA was performed, and she scored a 17/30

IMPACT: This case highlights a common problem in primary care: communication gaps that lead to harm from polypharmacy in a high risk patient. Our experience emphasized the need to identify patients whose low health literacy, socioeconomic status, or engagement across multiple systems put them at high risk of adverse outcomes due to lack of communication. The case also identifies the impact home visits can have on clinical reasoning during residency.
DISCUSSION: The lack of communication either directly or through the EMR between her PCP, inpatient teams, and psychiatrist led to her essentially stockpiling medications at home, leading to a significant dementia. She underwent multiple unnecessary invasive procedures over repeated hospitalizations, putting her at significantly increased risk for iatrogenic complications, including CT scans, a lumbar puncture, and MRIs. An early home visit intervention could likely have prevented these complications. We will review the literature on home visits, specifically data pertaining to interventions involving high risk patients, as well as the inclusion of home visits in a residency curriculum. Given the impact of this case on our own clinical practice, we will argue the value of adding home visits as part of the clinical development of internal medicine (and specifically primary care) residents. In an environment that is emphasizing value based care, the economic impact of this case is especially relevant. We will discuss how targeted home visits can significantly increase outcomes and quality of care while simultaneously decreasing cost.

ACUTE MYOCARDIAL INFARCTION IN A YOUNG PATIENT WITH SYSTEMIC LUPUS ERYTHEMATOSUS Daniel Wann[1]; Kamil F. Faridi[2]; Pablo Quintero[2]; Kalon Ho[2]; Jonathan S. Hausmann[2, 3]. [1]Beth Israel Deaconess Medical Center, Brookline, MA; [2]Beth Israel Deaconess Medical Center, Boston, MA; [3]Boston Children's Hospital, Boston, MA. (Control ID #2693646)

LEARNING OBJECTIVE #1: Recognize that patients with systemic lupus erythematosus (SLE) have an increased risk of coronary artery disease (CAD) compared to the general population.
LEARNING OBJECTIVE #2: Appreciate the importance of diagnosing and managing of cardiovascular risk factors in patients with SLE.
CASE: A 35 year-old man presented to the emergency department (ED) after a sudden loss of consciousness and bystander-initiated CPR. His medical history is notable for hyperlipidemia and systemic lupus erythematosus (SLE) complicated by class V lupus nephritis. He was intermittently non-compliant with his medications which included prednisone, mycophenolate mofetil (MMF), and hydroxychloroquine. He was a non-smoker and denied illicit drug use. Upon arrival to the ED, an echocardiogram revealed a left ventricular ejection fraction of 25% with multiple regional wall-motion abnormalities. Labs were notable for a troponin-T peak of 22.1, CK-MB >600, negative toxicology screen, total cholesterol of 276, LDL of 226, and HDL of 19. Coronary angiography showed diffuse three-vessel coronary artery disease and an acute occlusion of the ramus intermedius; a bare metal stent was successfully placed in the ramus.. He was discharged after a two-week course and prescribed aspirin, atorvastatin, ticagrelor, metoprolol succinate, lisinopril, furosemide, hydroxychloroquine, MMF, and prednisone. One month later he again experienced a loss of consciousness and was brought to the ED with signs of cardiogenic shock. Coronary angiography showed stable disease and a patent stent, but echocardiogram showed worsening cardiac function. He received a left ventricular assist device and experienced a prolonged hospital course.
IMPACT: This case raised our awareness of the substantial risk of CAD in patients with SLE. We will change our practice by striving to identify and appropriately manage CAD risk factors in every patient with SLE, even if they are young.
DISCUSSION: SLE is a major risk factor for CAD; patients have as much as a 10-fold increase in CAD as compared to the general population. Patients with SLE have increased prevalence of traditional CAD risk factors including hypertension, hyperlipidemia, and a sedentary lifestyle, and they may be exacerbated by the presence of lupus nephritis or the use of glucocorticoids. The chronic inflammation associated with SLE may also independently contribute to accelerated atherosclerosis and premature CAD. Because of the elevated risk of CAD in patients with SLE, recognition and management of traditional CAD risk factors is imperative even in young patients. In addition to regular monitoring of lupus activity, patients with SLE should have at least yearly measurements of blood glucose and cholesterol, as well as close monitoring of blood pressure and body mass index. Patients with SLE may benefit from co-management with a cardiologist to help identify and manage modifiable risk factors to prevent morbidity and mortality related to CAD.

ACUTE RENAL FAILURE IN A MEDICALLY COMPLICATED PATIENT Emi Okamoto. Hospital University of Pennsylvania, Philadelphia, PA. (Control ID #2706816)

LEARNING OBJECTIVE #1: Recognize the role for renal biopsy in diagnosing acutely worsening renal function
CASE: RF is a 73 year-old male with a history of alcoholic cirrhosis, obstructive sleep apnea, pulmonary hypertension, diabetes, atrial fibrillation, and osteoarthritis with prior bilateral knee replacement who presented with a rising creatinine while on treatment for an methicillin resistant Staph aureus (MRSA) joint infection. He initially presented 3 weeks prior to this presentation with right knee pain and an aspiration of the prosthetic joint showed 80,000 WBC and grew MRSA on culture. He was initially treated with vancomycin and piperacillin-tazobactim for 8 days then transitioned to vancomycin and rifampin for outpatient treatment. Eight days after discharge, routine labs showed a creatinine of 3.0 mg/dL and a vancomycin trough of 32 mg/L and he was admitted to the hospital, though otherwise asymptomatic. Initial urinalysis showed microscopic hematuria, red blood cell casts, and dysmorphic red blood cells. He had 2 grams protein in 24 hour urine collection, as well as negative/normal ANCA, ANA, and compliments. Empiric prednisone was started at 1 mg/kg and his creatinine stabilized at 4.2 mg/dL. Empiric albumin challenge was unsuccessful. A renal biopsy showed interstitial edema and inflammation with infiltrates consistent with acute interstitial nephritis as well as tubular damage. He was discharged on daptomycin and 80 mg prednisone with outpatient follow up.
IMPACT: Acute renal failure is a challenging diagnosis with broad differential. The plausible differential included post-infectious glomerulonephritis, vancomycin toxicity, interstitial nephritis, diabetic nephropathy, and hepatorenal syndrome. During his inpatient time, we anchored on post-infectious glomerulonephritis, particularly because dysmorphic red blood cells is thought pathognomonic for glomerular injury. As well, this is an increasingly well-recognized entity with Staph aureus and the time course also fit perfectly for the case. Ultimately, a renal biopsy was crucial to elucidate the actual cause and avoid drug re-exposure.
DISCUSSION: Acute interstitial nephritis is often caused by medications, with methicillin the first prototypical drug. Now multiple agents have been identified, notably including NSAIDs, other penicillin derivatives, and rifampin. It is still relatively rare, occurring on only 2–3% of renal biopsies. The mechanism of action is thought to be cellular immune-mediated, and it is particularly important

to recognize as re-exposure to the insulting agent will re-induce injury. Generally kidney function recovers with removal of the offending agent, and corticosteroids have a questionable role in aiding recovery.

DRUG INDUCED LEUKOCYTOCLASTIC VASCULITIS: MEROPENEM A RARE CAUSE Kinanah Yaseen; Mohammad Al-Omari; Bassam AL- Haddad. Cleveland Clinic, Westlake, OH. (Control ID #2706844)

LEARNING OBJECTIVE #1: <span style=”color:black; font-family:arial,sans-serif; font-size:14 pt; line-height:107%; margin:0px”><span style=”margin:0px”>

CASE: A 50 year old man with medical history of hepatitis C, type 2 diabetes, end stage renal disease on hemodialysis, coronary artery disease, and hypertension presented to our facility with very painful, blackish skin lesions on his dorsal aspect of left hand and medial aspect of right wrist. One month prior to his current admission patient was treated with meropenem for left foot abscess and ulcer. His physical exam revealed stable vital signs, but 3x2 cm raised blackish lesions over his right medial wrist and dorsal aspect of hand as well as on his both elbows, In addition to bilateral wrist swelling and tenderness. Laboratory studies showed elevated ESR, CRP, positive hepatitis C antibodies with high viral load but normal ENA panel, cry globulin antibodies, p-ANCA antibodies, c-ANCA antibodies, complement level, rheumatoid factor and negative urine toxicology. Later on, he underwent punch skin biopsy which was consistent with leukocytoclastic vasculitis. Meropenem was discontinued and patient was started on oral steroid. Subsequently, his skin lesions started to dry out, and heal but he was left with deep necrotic ulcer over his third MCP which required skin graft.

IMPACT: The use of meropenem has recently increased due to resistance patterns of bacteria, and it is important to recognize this potential adverse effect of this drug.

DISCUSSION: Drug-induced leukocytoclastic vasculitis is an inflammation of blood vessels triggered by various drugs including several antibiotics, allopurinol, and anti-seizure medications. To best of our knowledge, we report the first case of meropenem-induced leukocytoclastic vasculitis. Drug-induced LCV accounts about 10% of all vasculitis cases, and penicillin, sulfonamide, quinolones, allopurinol, propylthiouracil, valproic acid, phenytoin, anti-TNF alpha agents, and hydralazine are well known causes of LCV. Drug induced LCV should be suspected in any patient with a new onset of skin rash, a temporal relationship with the offending drug, and resolution of symptoms with discontinuation of the drug. Physician should be aware that meropenem-induced LCV is one of the rare side effects of this medication. The only reported case to date of imipenem-induced leukocytoclastic vasculitis (3) was in 1997, when a patient was treated with imipenem-cilastatin for a postoperative infection then developed maculopapular rash.

LYME IN THE COCONUT: A CASE OF MISDIAGNOSIS AND ANCHOR BIAS Jason Unger; daniel selig. Walter Reed National Military Medical Center, Bethesda, MD. (Control ID #2707382)

LEARNING OBJECTIVE #1: Understanding how Anchor Bias affects diagnostic decision making

LEARNING OBJECTIVE #2: Understanding how clinical decision making is affected with multiple disease processes presenting at once

CASE: This is a 55 year old previously healthy Airman reservist, whose father died of brain cancer in his 50’s. He presented to the oversees Military Hospital Emergency Room after falling. Per report, he saw a straight blade upon standing in teh barber shop, then “turned white,” and subsequently fell and hit his head. Initial CT head in the Emergency Departmen showed no evidence of trauma, and he was discharged. He returned to the ED 10 days later though after reporting syncopal events. Repeat CT head demonstrated a new right frontal lobe hypodensity.The radiologist was most reportedly most concerned for infection versus malignancy at that time. His hospital course was complicated by intermittent episodes of complete heart block. Given the patient’s CT findings and family history of brain cancer, the neurologist at the overseas facility recommended medical evacuation to a tertiary care center in the United States for neurosurgical evaluation for stereotactic brain biopsy. At the receiving facility reviewed all images and as well as new imaging, and thought that the findings were not consistent with infection or malignancy. Rather, imaging was most concerning for brain contusion, with possible coup-counter pattern from his initial fall and posterior head injury. During his hospital stay there was no signs of high grade heart block noted on EKG or telemetry. The patient was discharged two days later.

IMPACT: Approximately one week after discharge, the primary ICU team was notified that the patients initial Lyme titers from Germany had resulted, and were markedly positive. Hw hS no further episodes of heart block and was discharged home with antibiotics for treatment of Lyme disease.

DISCUSSION: In medicine, we are thought to rule out common potentially acute and deadly causes of illness first. After the potentially fatal disease have been ruled out, we are then to consider more benign and possibly more common causes of disease. The English Franciscan Frior, William of Occam’s was the first to report on this phenomenon. He described how we normally seek to select a single parsimonious explanation for a series of events by choosing the unifying hypothesis with the fewest underlying assumptions. The counter to this in Medicine is often referred to as Hickam’s Dictum. Dr John Hickum, a 1950’s is commonly quoted as saying in the vernicular: “ A patient can have as many diseases at one time as they Darn well please.” In this case, the anchoring on the potentially concerning imaging findings on the follow up head CT, lead to a shift in focus away from the ultimate diagnosis. The complicating factor of the syncopal events was ultimately attributed to the additional diagnosis of cardiac lyme, for which he was treated, and has had no reported syncopal events since that time.

SARCOIDOSIS MIMICKING METASTATIC ENDOMETRIAL ADENOCARCINOMA Raghunandan Ghimire[1]; Manita Chapagain[2]; Jack Ringler[1]. [1]Berkshire Medical Center, Pittsfield, MA; [2]Holy Family Red Crescent Medical College, Dhaka, Bangladesh. (Control ID #2708180)

LEARNING OBJECTIVE #1: Distinguish between Sarcoidosis and metastatic cancer with similar presentation

LEARNING OBJECTIVE #2: Manage a case of lymphadenopathy with histology diagnosis

CASE: A 52 year old woman was worked up for post menopausal vaginal bleeding. Biopsy of the endometrial tissue showed endometrial carcinoma endometroid type Grade 1. She underwent laparoscopic hysterectomy and bilateral salphingo-oopherectomy.The disease recurred 1 ½ years later when a vaginal nodule was biopsied. CT scan of chest abdomen and pelvis showed pelvic peritoneal soft tissue nodules measuring 1.5X1cm on right and

1.1X1.1 cm on left,heterogenous attenuation of vaginal cuff, consistent with recurrent disease. Several mediastinal lymph nodes were seen. Few scattered retrocaval, mesenteric and retroperitoneal lymph nodes were also seen. The patient was treated with chemotherapy with Carboplatin and Taxol. CT scan of chest and abdomen after 5 months showed shrinkage of pelvic nodules, but increasing mediastinal lymphadenopathy and bilateral hilar adenopathy, highly suspicious for malignant lymph nodes. A PET scan showed hypermetabolic adenopathy noted in the mediastinum suggesting metastatic disease. Biopsy of the mediastinal mass revealed anthracotic lymph node with non caseating granuloma, negative for organisms, negative for AFB and fungal stains. Histology result suggested sarcoidosis without evidence of malignancy. With no local or systemic symptoms, watchful monitoring of the symptoms with surveillance was suggested.

IMPACT: The development of lymphadenopathy in the context of stage 4 cancer should raise concern for metastasis.No treatment should be started before histological diagnosis as treatment for sarcoid and metastasis are different.The unusual diagnosis of thoracic sarcoid lesion has taught us lesson regarding importance of appropriate diagnosis before starting the treatment.This case could be one of the cases in the literature which can add an evidence for association of sarcoidosis with endometrial cancer.

DISCUSSION: The relationship between sarcoidosis and malignancy is complex and incompletely understood. Several meta-analyses have suggested an association between incident Sarcoidosis and subsequent development of cancer. There are only few reports of sarcoidosis diagnosed after the treatment of cancer and initially mistaken for progression of cancer. There are also case reports of sarcoidal changes surrounding malignant pathology.The diagnostic dilemma due to sarcoid lesions mimicking metastatic disease in patients with malignancy can lead to delayed and inappropriate treatment. Histological diagnosis is mandatory before starting treatment in such patients.With advances in cancer immunology and sarcoidosis research, one can hope for a better clinical understanding of the rare circumstances where malignant and sarcoidal pathologies concur.

SEVERE HYPERTRIGLYCERIDEMIA INDUCED ACUTE PANCREATITIS: MANAGEMENT STRATEGY IN A RURAL SETUP

Umair Iqbal[2]; Mohammad Arsalan Siddiqui[1]; Ahmad Chaudhary[2]; Hafsa Anwar[3]; Madiha Alvi[2]. [1]Henry Ford Hospital, Detroit, MI; [2]bassett medical center, Cooperstown, NY; [3]Dow University of Health Sciences, Karachi, Pakistan. (Control ID #2700891)

LEARNING OBJECTIVE #1: Intravenous Insulin has similar efficacy to plasmapheresis in emergent management of HTG induced AP

LEARNING OBJECTIVE #2: Patients with TG > 500 mg/dl are recommended to undergo genetic testing to rule out disorders associated with lipid metabolism.

CASE: 44 year old male with history of diabetes mellitus and hypertension presented with severe epigastric abdominal pain radiated to the back associated with several episodes of vomiting for past 24 h. He denies fever, chills, diarrhea, black tarry stools and weight loss. He denied history of excessive alcohol use. His medications included metformin and insulin glargine. On presentation he was vitally stable and had generalized abdominal tenderness, audible bowel sounds with no palpable hepatosplenomegaly. Labs revealed lipase of 5006 U/L (50–290 U/L), amylase of 299 U/L (30–110 U/L). CT abdomen revealed moderate peri-pancreatic edema concerning for acute pancreatitis (AP). Triglycerides levels (TG) were severely elevated to 6672 mg/dl (55–150 mg/dl). He was started on conventional treatment of AP with IV hydration and analgesia. Given our rural setup and absence of availability of plasmapheresis (PP) for rapid correction of HTG, patient was started on insulin infusion 0.1 units/kg/hr along with D5W to maintain euglycemia. He was continued on that regimen with hourly blood glucose monitoring until TG were <500 mg/dl which was achieved on day 8. He was discharged on atorvastatin and fenofibrate with a referral to a lipidologist to rule out genetic causes of hypertriglyceridemia (HTG).

IMPACT: In a clinical setup where PP is not readily available for acute management of HTG induced AP, use of IV insulin with IV dextrose is an effective alternative treatment strategy. Rapid reduction in TG levels to <500 mg/dl is associated with improved clinical outcomes.

DISCUSSION: HTG is the third most common cause and is responsible for almost 1–4% of AP. The incidence of AP in patients with TG > 2000 up to 20. In patients who developed an episode of AP secondary to severe HTG, the goal is to bring the TG less than 500 as early as possible because it is associated with improved clinical outcome. PP is usually considered first-line therapy for severe HTG with many studies supporting its clinical utility. In a case series of 7 patient, 41% decrease in TG was reported with single plasma exchange. In absence of availability of PP, alternate treatment modalities with intravenous (IV) insulin should be considered. Standard approach is 0.1-0.3 units/kg/hr of regular insulin IV along with dextrose saline to maintain euglycemia until TG come down to <500. There are no randomized controlled trials which compare efficacy of insulin with PP in treatment of severe HTG. Therefore, treatment is usually based on availability and preference. Long-term goal for patients who had episodes of AP secondary to HTG, is to prevent further episodes by optimizing lipid lowering therapy and lifestyle modification. Non-compliant patients may need periodic PP to prevent episodes of AP.

STIFF AS A LEAD PIPE Haleh Moazen; Amir Ansari-Ezabadi. Montefiore Medical Center, Bronx, NY. (Control ID #2700760)

LEARNING OBJECTIVE #1: Recognize the clinical features and appropriate management of neuroleptic malignant syndrome.

CASE: A forty year old woman with a history of impulse control disorder was admitted after being found unresponsive at her group home.At baseline, the patient was ambulatory and talkative.Vitals revealed tachycardia and fever.Physical exam was remarkable for the patient being obtunded and having diffuse lead pipe rigidity.Laboratory tests showed rhabdomyolysis and leukocytosis.History revealed that the patient was prescribed ziprasidone and olanzapine.Olanzapine was discontinued two weeks prior to admission.Chest wall rigidity resulted in hypoventilation and respiratory distress requiring intubation.Intravenous fluid, antipyretic,dantrolene,amantadine and bromocriptine were initiated for presumed neuroleptic malignant syndrome.The patient improved and was extubated. Recommendations were to hold neuroleptic medication for two weeks.The patient was restarted on low dose olanzapine and has remained stable.

IMPACT: Internists are increasingly prescribing neuroleptics to control the psychosis commonly associated with dementia.Hospitalists are involved in the care of a large number of psychiatric patients maintained on neuroleptics that present to the hospital with fever and change in mental status.The widespread use of neuroleptic medication within the medical community necessitates that physicians recognize the clinical features and appropriate management of neuroleptic malignant syndrome.

DISCUSSION: Neuroleptic malignant syndrome occurs with either initiation of the neuroleptic therapy or a change in the drug dosage. The onset of the

syndrome does not correlate with the duration of neuroleptic exposure.Neuroleptic malignant syndrome has a significant mortality rate of 10–20% if not diagnosed early.Sudden and profound dopaminergic blockade or depletion in the central nervous system is the probable mechanism of the disease.Diffuse lead pipe muscle rigidity is an early manifestation of the syndrome.Other finding includes altered mental status,autonomic instability and hyperthermia.Complications are related to the sustained muscle rigidity resulting in rhabdomyolysis,renal failure and respiratory failure.Aggressive hydration,antipyretic,direct muscle relaxant,removal of the neuroleptic agent and dopamine agonist such as amantadine and bromocriptine should be administered.A two week minimum washout period is needed before reinstating the neuroleptic medication.Resumption of therapy should be with low dose agents with slow upward titration.Other medications have been reported to cause the syndrome through synergistic interactions or an undefined mechanism.Neuroleptic malignant syndrome is a life threatening condition.Enhanced awareness and prompt recognition of the early clinical signs of this syndrome and greater vigilance on the part of physicians who treat patients receiving agents that affect dopaminergic activity will assist in substantially reducing the mortality of this disease.

A "FLU"KE CASE OF ARTHRALGIA Anne Press; Katherine N. Riedy; Monica Gupta. NYU School of Medicine, New York, NY. (Control ID #2702931)

LEARNING OBJECTIVE #1: Recognize a rare cause of polyarthralgias.
LEARNING OBJECTIVE #2: Treat septic arthritis secondary to Haemophilus influenzae.
CASE: A 50 year-old male with no significant medical history presented with three days of arthralgias. He reported pain, erythema, and swelling in his left shoulder three days prior to admission associated with fevers up to 102 °F. Over the next 72 hours, the joint pain migrated to his right shoulder, bilateral knees, and ankles. He denied rash, dysuria, or abdominal pain. He denied intravenous drug use. He reported an unprotected sexual encounter with a male one week prior. On admission he was hemodynamically stable, afebrile, and in no acute distress. Exam was notable for edema of all four extremities and limited range of motion in all joints. White blood cell count was 13.4 mg/nL with 89% neutrophils, erythrocyte sedimentation rate 55 mm/hr, and c- reactive protein 39 mg/L. ANA, C3, C4, HIV antibody, and HIV PCR were negative. Total IgA, IgG, IgM levels were within normal limits. Blood cultures and joint aspiration cultures were positive for noncapsulated Biotype I Haemophilus influenzae (H. influenzae). Transesophageal echocardiogram showed fibrinous stranding on the aortic valve concerning for bacterial seeding. Of note, PSA was within normal limits and FOBT was negative. The patient was treated for H. influenzae septic arthritis, bacteremia, and endocarditis with serial joint aspirations, intravenous dexamethasone, and four weeks of ceftriaxone with significant improvement in his symptoms.
IMPACT: While uncommon, H. influenzae can cause invasive septic polyarthritis in an immunocompetent patient. There are limited cases in the literature of an immunocompetent adult presenting with septic polyarthritis secondary to noncapsulated H. influenzae.
DISCUSSION: H. influenzae can cause numerous diseases including meningitis, epiglottitis, pneumonia, and endocarditis. H. influenzae was previously a common cause of septic arthritis in the pediatric population, however the incidence has decreased significantly since the introduction of vaccinations. H. influenzae rarely causes septic arthritis in adults and very few cases have been reported in the literature, and of those, most subjects were immunocompromised. Prompt diagnosis and aggressive treatment with combined surgical and medical treatment can result in optimal recovery. Serial aspirations or surgical wash out with prolonged antibiotic therapy is the standard of care. In the pediatric population, steroids have been shown to decrease cartilage degradation and improve post-infection healing. As such, steroids were also used in this case. It is important to consider this as a cause of septic polyarthritis as early detection is crucial to preventing sepsis, permanent destruction of the joints, and in this case, valve destruction from infective endocarditis. Steroids should also be considered in treatment of the adult population given this patient's significant improvement.

A 30,000-FOOT-VIEW OF A PATIENT WITH SICKLE CELL TRAIT
Emily Japp; Ginger Wey. Albert Einstein College of Medicine/Montefiore Medical Center, New York, NY. (Control ID #2706383)

LEARNING OBJECTIVE #1: Recognize the hematologic complications associated with sickle cell trait.
LEARNING OBJECTIVE #2: Identify the potential triggers of sickling events in patients with sickle cell trait.
CASE: A 26-year-old Hispanic male with hepatitis B and sickle cell trait presented with 4 days of left upper quadrant pain associated with pleuritic chest pain. His symptoms began after recent air travel to Mexico and ingestion of alcohol. He was briefly hospitalized in Mexico and received supportive care for gastroenteritis. He denied fever, palpitations, nausea, vomiting, or diarrhea. He was afebrile, tachycardic, and tachypneic. Cardiopulmonary examination was normal. His abdomen was non-distended, and the left upper quadrant was tender to palpation. Significant labs included: Hgb 14.8 g/dL, Hct 41.3%, WBC 10.7 k/uL, indirect bilirubin 1.7 mg/dL, reticulocyte count 2.5%, LDH 684 U/L, and haptoglobin < 8 mg/dL. On ultrasound, the liver was normal size and the spleen was enlarged to 13.6 × 13.8 × 6.2 cm, with a hypoechoic band consistent with an infarct. Hgb electrophoresis revealed HgbS 40.9 and HgbA 54.2%, with positive sickling activity. The patient was treated with analgeics to improvement.
IMPACT: The diagnosis of an acute splenic infarct can be challenging and even delayed in patients with sickle cell trait, in whom hematologic complications are typically rare. This case contributes to the pre-existing literature on the occurence of sickling crises in carriers after exposure to conditions causing hypoxia, dehydration, or acidosis.
DISCUSSION: Sickle cell trait is a carrier condition in which one allele of the β-globin gene possesses a substitution mutation. Its prevalence is up to 30% in Sub-Saharan Africa, where it is protective against *P. falciparum* malaria. In the U.S., the prevalence is highest in African Americans, and ranges from 7–10%. Patients with sickle cell trait rarely have hematologic manifestations, but may be susceptible to renal or splenic infarctions, splenic sequestration, venous thromboembolism, rhabdomyolysis, or sudden death induced by bodily stress. In particular, case reports describe splenic infarctions triggered by low oxygen tension present at high altitudes, associated with activities such as flying or hiking. In these case reports, most patients were male, non-black, and had > 40% HgbS during the events. Dehydration and local tissue hypoxia are also postulated to be contributing factors. Splenic infarctions can be asymptomatic in up to 40% of patients. The most common presenting symptom is left upper quadrant pain, and can be associated with fever, chills, nausea, vomiting, pleuritic chest pain, or left shoulder pain. The diagnosis can be made by ultrasound, but because the infarct appearance can change with time, the preferred method is computed tomography with contrast. Treatment is largely supportive, with supplemental

oxygen, hydration, and analgesics. Splenectomy is rare, since there are few cases of splenic infarction, and most do not progress to rupture.

A BLOOD CLOT TALE Rashmi Advani; Tulay Aksoy. Montefiore Medical Center Moses and Weiler Division, Bronx, NY. (Control ID #2702566)

LEARNING OBJECTIVE #1: Identify the indication for screening for May Thurner syndrome (MTS) in patients with recurrent deep vein thrombosis (DVT)

LEARNING OBJECTIVE #2: Assess the appropriate management of MTS in patients with an acute DVT

CASE: 38 year-old woman presented with worsening left lower extremity swelling for one month. She had a medical history of recurrent left-sided DVTs: first was 10 years ago while six weeks pregnant and second was diagnosed one month prior to presentation. She was on Rivaraxoban for the past one month. She reported no prolonged immobilization, recent surgeries, travel, family history of clots, smoking or oral contraceptive use. Prior hypercoagulability workup was negative. On exam, left leg was erythematous, swollen and tender. Given the progression of the swelling on the same side with previous history, CT scan of abdomen and pelvis with contrast was done, which revealed progression of left common femoral DVT and pathologic compression of the left common iliac vein by the right common iliac artery. She was discharged on Lovenox without intervention. A week after, she presented with further progression of left leg swelling. At that point, she underwent endovascular stenting with angioplasty and was discharged on anticoagulation.

IMPACT: This case is important in identifying the right diagnostic and therapeutic approach in patients with recurrent DVT, either with or without an identifiable risk factor. It also reminds us to include common anatomical vascular variances, such as MTS in the differential diagnosis of recurrent DVTs.

DISCUSSION: Deep vein thrombosis (DVT) is encountered by internists in both the inpatient and outpatient setting. About two-thirds of cases are provoked from major risk factors such as recent hospitalization, trauma, surgery or immobilization. Minor risk factors include obesity, malignancy, pregnancy, and use of oral contraceptives or hormone replacement therapy. DVTs diagnosed without the above risk factors may prompt evaluation into inherited hypercoaguable disorders or anatomic vascular abnormalities such as May Thurner Syndrome (MTS). MTS is an under-diagnosed condition marked by an anatomical variant in which the right common iliac artery overlies the left common iliac vein resulting in mainly left-sided iliofemoral DVT. The prevalence of MTS is approximately 30 and is commonly diagnosed in young women, however is likely an underestimation as patients are initially asymptomatic. Screening for MTS should be considered in the setting of multiple recurrent, same-sided DVTs, especially if progressing while on anticoagulation. Contrast venography is the gold standard in diagnosis; however, no standard screening protocol has yet been established. Appropriate treatment includes endovascular stenting, angioplasty with anticoagulation. Use of anticoagulation alone and delay in endovascular intervention can lead to a recurrence or worsening of DVT.

A CASE FOR PROPHYLAXIS IN AUTOIMMUNE-RELATED INTERSTITIAL LUNG DISEASE Adrienne N. Poon[1]; Suchita Kumar[2]; Robert Maximos[3]. [1]George Washington School of Medicine and Health Sciences, Clifton, NJ; [2]GW School of Medicine & Health Sciences, Washington, DC; [3]Veterans Affairs Medical Center, Washington, DC. (Control ID #2706850)

LEARNING OBJECTIVE #1: Recognize the need for PCP prophylaxis in interstitial lung disease (ILD) on immunosuppression

LEARNING OBJECTIVE #2: Assess for development of autoimmune disease in patients with ILD and non-specific markers

CASE: A 62 year old man with a history of interstitial lung disease, hypertension, hyperlipidemia, and depression presented with shortness of breath. A year prior, CT scan had shown groundglass opacities in bilateral lung zone peripheries suggestive of interstitial lung disease. Open lung biopsy had found small airway injury with organizing pneumonia (OP) and fibrotic non-specific interstial pneumonia (NSIP). He was on high-dose steroids that were tapered then abruptly discontinued 2 months ago. He had a sister with NSIP as well as mixed connective tissue disorder. Medications included: Albuterol, fluticasone, tiotropium, lisinopril, metoprolol, furosemide, pravastatin, and duloxetine. Vitals on admission: T 99.1, BP 104/63, RR 18, HR 94, spO2 85% on oxygen. Physical exam revealed diffuse bilateral inspiratory crackles as well as 3+ bilateral edema. Labs included: WBC 9.75 K/uL, 14.8 hemoglobin g/dL, 140 platelets, creatinine of 1.4, and lactate 1.4 mEq/L, procalcitonin 2.23 ng/ml, LDH 1078 U/L, ANA 1:40 speckled pattern. CT thorax revealed bilateral ground glass opacities. He was empirically covered with vancomycin, zosyn, azithromycin, valganciclovir, trimethoprim-sulfamethoxazole and then atovaquone due to worsening renal failure. Due to worsening respiratory failure, he was acutely intubated. Silver gram stain was positive for pneumocystis jiroveci pneumonia (PJP) and all medications were stopped and he was switched to clindamycin and primaquine due to disease severity.

IMPACT: OP/NSIP related to Undifferentiated Connective Tissue Disease (UCTD) may predispose to acute respiratory failure in immunosuppressed patients at risk for PJP. Physicians should consider prescribing PCP prophylaxis in immunosuppressed non-HIV patients. Routine monitoring of rheumatological markers in patients presenting with undifferentiated autoimmune-related ILD should be performed.

DISCUSSION: OP/NSIP overlap including autoimmune-related cases such as UCTD in this patient predisposes to unfavorable disease progression. Evidence is controversial as to whether patients with autoimmune diseases on immunosuppression should be given PJP prophylaxis. This patient had multiple risk factors for presentation in acute respiratory failure including OP/NSIP as well as medication-related immunosuppression predisposing to PJP that often has delayed diagnosis in non-HIV patients. This patient was likely PJP colonized with immune reconstitution reaction given abrupt withdrawal of steroids despite mixed evidence in ILD. Given the variability of PJP risk, strategies such as monitoring CD4 count or using PJP PCR may be helpful in risk-stratifying patients and determining initiation or withdrawal of prophylaxis. Immunosuppressants should also be tapered slowly given the risks of immunoreconstitution disease.

A CASE OF ACUTE, SYMPTOMATIC HEPATITIS C IN A PATIENT WITH INJECTION DRUG USE Anshul K. Srivastava; Jessica Taylor. Boston Medical Center, Boston, MA. (Control ID #2706142)

LEARNING OBJECTIVE #1: Recognize acute HCV infection; counsel on clearance rates and indications for treatment

LEARNING OBJECTIVE #2: Differentiate acute liver injury from acute liver failure

CASE: A 38-year-old man with severe opioid use disorder (OUD) was admitted for musculoskeletal pain and noted to have mild transaminitis. His hepatitis C virus (HCV) antibody, previously negative, was weakly reactive. His viral load was 81,860,787 IU/mL and genotype was 1B. He endorsed

recent needle sharing and was started on buprenorphine for his severe OUD. Outpatient follow-up was arranged. At his primary care visit, the patient reported nausea, vomiting, fatigue, clay-colored stools, jaundice, and subjective mild confusion. He was readmitted given progression of acute liver injury (ALI) and concern for possible acute liver failure (ALF). Labs showed AST 2921 u/L, ALT 2294 u/L, total bilirubin 33.2 mg/dL, and INR 1.1. Ceruloplasmin, autoimmune markers, and iron levels were unremarkable, and acute HCV was felt to be the etiology of his ALI. A liver biopsy confirmed acute viral hepatitis. Patient did not develop encephalopathy or coagulation abnormalities to suggest ALF. Patient's liver function tests and symptoms slowly improved. He is doing well in recovery from OUD. He is being monitored for spontaneous clearance of HCV and has not started direct acting antiviral (DAA) therapy.

IMPACT: Chronic HCV is prevalent in people who inject drugs and is managed by the authors in primary care; however, acute, symptomatic HCV is uncommon. This case prompted the authors to review clearance rates and indications for early treatment of acute HCV in order to counsel the patient on his expected course.

DISCUSSION: Although the overwhelming majority of acute HCV infections are asymptomatic, this case highlights the importance of considering acute HCV in cases of unexplained transaminitis or ALI. Testing should include both anti-HCV antibodies and HCV RNA. Our patient was eager to begin treatment. However, spontaneous clearance occurs in 20-50% of acute HCV cases. Higher clearance rates are seen in young patients, females, and those with genotype 1, a high initial viral load, and symptomatic acute infection. Prior to availability of DAA's, cure rates with interferon-based regimens were higher when treatment was started acutely. There is no advantage to early treatment in the era of DAA's, which are highly effective in chronic HCV. Six months of monitoring to allow for spontaneous clearance are now recommended. Acute treatment is reserved for those with no access to DAA's, underlying liver disease, high transmission risk, or ALF. A key step in this patient's case was distinguishing ALI from ALF. ALF occurs when liver injury, an INR ≥ 1.5, and encephalopathy are seen in a patient without underlying liver disease; given high risk of mortality, ALF should be managed at a liver transplant center. Our patient did not go on to develop ALF, supporting data that ALF is rare in acute HCV.

A CASE OF ACYCLOVIR-INDUCED ENCEPHALOPATHY PRESENTING WITH ATYPICAL FINDINGS

Guramrinder S. Thind; Prashant Patel; Richard Roach. Western Michigan University School of Medicine, Kalamazoo, MI. (Control ID #2700895)

LEARNING OBJECTIVE #1: Recognize acyclovir neurotoxicity as a cause of encephalopathy in dialysis-dependent patients.

LEARNING OBJECTIVE #2: Identify potential cerebral spinal fluid (CSF) abnormalities in acyclovir-induced encephalopathy.

CASE: An 82-year old male with a history of end stage renal disease (ESRD) was transferred from a nursing home with altered mental status. Patient had been getting progressively more confused and somnolent for the past 4–5 days. Notably, patient was diagnosed with herpes zoster by his primary care physician five days ago, and was started on a course of valacyclovir 1 grams three times a day. Evidently, the dose of valacyclovir was not adjusted for his renal impairment. Initial workup revealed a questionable right-sided infiltrate on chest X-ray. He was started on antibiotics for presumed pneumonia. However, his mentation did not improve and a lumbar puncture was performed on the third day. CSF studies revealed 37 WBCs/hpf (100% monocytes), protei*n* = 64 mg/dL, and glucose = 52 mg/dL. His antimicrobial therapy was switched to ceftriaxone, ampicillin, and acyclovir. At this point, infectious disease service was consulted. An MRI of the brain was done and was unremarkable. Acyclovir-induced encephalopathy was high on differential, but patient's CSF findings were concerning for viral encephalitis. Herpes simplex virus (HSV) and varicella zoster virus (VZV) were considered as potential etiologies. Nonetheless, all antimicrobials were discontinued and patient was scheduled for an 5 hour dialysis session. The very next day, patient showed immense improvement in his mental status and was much more wakeful. Thereafter, CSF PCR tests for both HSV and VZV came back negative. Patient had complete recovery and was discharged from the hospital on day 7.

IMPACT: This case reinforces the importance or renal dosage of medications, and the importance of history taking in the diagnosis of acyclovir-induced encephalopathy. It creates awareness of a unique situation where two differentials have polar opposite therapeutic implications. CSF studies may show mild pleocytosis in acyclovir-induced encephalopathy, and this can easily be confused with viral encephalitis. Extended-session dialysis may enhance acyclovir clearance.

DISCUSSION: Valacyclovir is the prodrug of acyclovir, 90% of which is excreted renally. It is for this reason that acyclovir neurotoxicity is much more common in patients with ESRD. Our patient received six times the recommended dose of valacyclovir for ESRD patients. Absence of fever and meningeal signs, history of high-dose acyclovir treatment, and its temporal relationship with onset of symptoms can help distinguish acyclovir-induced encephalopathy from viral encephalitis. CSF lymphocytic pleocytosis is typically associated with viral encephalitis. However, it is also a non-specific marker of neurovascular inflammation and has been reported in sporadic case reports of acyclovir-induced encephalopathy. Acyclovir is dialyzable and this fact can be used exploited for therapeutic purposes.

A CASE OF ANKYLOSING SPONDYLITIS PRESENTING FEVER AND ENTHESITIS IN UNCOMMON LOCATIONS

Ryo Sasaki[1]; Naoki Kanda[2, 1]; Dai Akine[1]; Ayako Kumabe[1]; Yu Yamamoto[1]; Shuji Hatakeyama[1]; Masami Matsumura[2, 1]. [1]Jichi Medical University, Shimotsuke, Japan; [2]Jichi Medical University Hospital, Tochigi, Japan. (Control ID #2704190)

LEARNING OBJECTIVE #1: Diagnose ankylosing spondylitis based on history including past symptoms.

LEARNING OBJECTIVE #2: Recognize fever and enthesitis in uncommon locations as manifestations of ankylosing spondylitis.

CASE: A 58-year-old Japanese man presented with a two-month history of myalgia of the extremities accompanied with morning stiffness, bilateral temporal regions pain, and one-month history of fever exceeding 38 degrees Celsius. On physical examination, tenderness in temporal muscles, shoulders, and elbows was noted. Erythrocyte sedimentation ratio was 122 mm per hour. Antinuclear antibodies and rheumatoid factor were negative. We suspected polymyalgia rheumatica associated with giant cell arteritis. Head magnetic resonance imaging (MRI) disclosed no abnormality in temporal artery, but bilateral contrast enhancement of temporal muscles. Bilateral temporal artery biopsy showed no findings of vasculitis. We reevaluated the history and physical examination findings in detail. He reported that he had had refractory neck pain since his twenties and disturbed range of motion in neck and lumbar spine. The precise tender lesions in shoulders and elbows were biceps branchii tendon and triceps branchii tendon. MRI with contrast enhancement showed

enthesitis in the tendon of deltoid muscle, subscapularis muscle, and biceps and triceps branchii muscle. Computed tomography revealed abnormal ossification bridges connecting successive thoracic vertebral bodies and sclerosis in sacroiliac joint. He was diagnosed with ankylosing spondylitis (AS). The effect of non-steroidal anti-inflammatory drugs was insufficient. He was started on tumor necrosis factor inhibitor and discharged.

IMPACT: How did this case change my practice? In the diagnostic approach to fever of unknown origin (FUO), it drew attention to the fact that more attention must be paid to not only the present illness but also past symptoms.

DISCUSSION: An important clue to the correct diagnosis in patients with FUO is specific symptoms or signs other than fever. In this case, the clue to the diagnosis of AS was the patient's past symptoms, e.g., refractory neck pain and disturbed range of motion in his neck and lumbar spine. Fever is rarely associated with spondyloarthritis (SpA). The major feature of SpA is chronic low back pain. An enthesitis is thought to be a specific symptom for SpA, and it commonly occurs at the insertion of the Achilles tendon and plantar fascia in the heel. In this case, the enthesitis was noted in the tendon of deltoid muscle, subscapularis muscle, and biceps and triceps branchii muscle. Thus, the contrast enhancement of temporal muscles on MRI suggests temporal muscle enthesitis. To the best of our knowledge, there is no literature describing temporal muscle enthesitis. The present case showed rare manifestations of ankylosing spondylitis presenting as FUO and enthesitis in uncommon lesions. The clue to the correct diagnosis was listening to the past symptoms and precise physical examination in this case.

A CASE OF BLURRY VISION SHEDS LIGHT ON GAPS IN THE CARE OF TRANSGENDER PATIENTS Jill Zabih. University of Nebraska Medical Center, Omaha, NE. (Control ID #2692814)

LEARNING OBJECTIVE #1: Identify transgender-affirming hospital policies that are easily implemented to create safe and efficacious care for this patient population.

LEARNING OBJECTIVE #2: Understand which historical features and laboratory findings help differentiate between type 1 and type 2 diabetes in an adult with new-onset diabetes.

CASE: A 23 year-old male to female transgender woman presented with 10 days of blurred vision and progressive generalized weakness. Her medications included only estradiol and spironolactone which had been increased 2 weeks prior. She noted that she had progressive nausea and vomiting for the past week as well as increased thirst. She also noted increased urination since her spironolactone was increased. She had no other medical history aside from gender dysphoria. She had a long-term supportive male partner. She was noted to be mildly tachycardic but normotensive. She was a well-appearing African-American female. Her mucous membranes were dry with decreased salivary pooling. Her heart was regular, tachycardic, without murmur. Her visual acuity was normal but subjectively blurred. Her strength was 5/5 throughout but patient was fatigued by maneuvers. Her extremities were warm without any edema. Laboratory analysis revealed bicarbonate of 13 and an anion gap of 30. Glucose was 667. Subsequent laboratory analysis showed an A1c of 12.2. C-peptide was low at 0.5. Glutamic acid decarboxylase antibody was elevated at >250 consistent with a diagnosis of type 1 diabetes. Throughout this patient's hospitalization, male pronouns were accidentally used both in the electronic medical record and while referring to the patient which was understandably upsetting to her.

IMPACT: The impact of this case is two-fold. First, it serves as a reminder that although new-onset type 2 diabetes is more common in adults, it's important to consider the diagnosis of type 1 diabetes for which there is often a diagnostic delay. Secondly, more education regarding appropriate care and respect of transgender patients is needed. We must implement non-discrimination hospital policies as well as changes in our electronic medical record to help educate and alert staff to patient wishes.

DISCUSSION: New-onset diabetes is commonly encountered by the general internist. A methodical approach to differentiating between type 1 and type 2 diabetes is important as delaying insulin therapy in a patient with type 1 diabetes can be life-threatening. Important clues to type 1 diabetes include family or personal history of autoimmune disease, thin body habitus, diabetic ketoacidosis, low c-peptide, and/or positive autoantibodies. Transgender patients face many barriers to safe and equitable medical care including historical biases, lack of protective hospital policies, and lack of staff education. Strategies which can improve the care of this vulnerable patient population include adding transgender "flags" to the chart confirming preferred name and pronouns, room assignments consistent with patient's gender identity, and ongoing staff education.

A CASE OF CEFEPIME-INDUCED ENCEPHALOPATHY IN PATIENT WITH MULTIPLE SCLEROSIS Sahil K. Virdi; Christopher Andrade; Doris Yang; Colette Knight; Robert L. Goodman. Montefiore Medical Center, Wakefield Division, Bronx, NY. (Control ID #2701330)

LEARNING OBJECTIVE #1: Recognize cefepime as a potential cause of significant neurological adverse effects.

CASE: 48 year-old woman with multiple sclerosis, sacral ulcer with osteomyelitis, on suppressive antibiotic therapy and recurrent urinary tract infections with retention was admitted for abdominal pain and constipation. Physical exam showed suprapubic fullness and tenderness and spastic paralysis of the legs. Initial labs revealed leukocytosis: white blood cells: 14.1 k/uL, acute kidney injury: creatinine 2.82 mg/dL and pyuria: urine WBC >100/HPF. Abdominal CT revealed urinary obstruction and copious amounts of stool in the rectum, which resolved after catheterization and bowel regimen, respectively. Ceftriaxone was started for urinary tract infection. Urine culture had no growth, likely due to suppressive antibiotic therapy for sacral osteomyelitis. After catheterization, renal function improved, but leukocytosis failed to improve. Cefepime was initiated to cover possible *Pseudomonas*. Within 24 hours the patient developed hallucinations. Her neurologic exam was most significant for altered mentation, which worsened progressively. Her altered state could not be attributed to multiple sclerosis. Metabolic cause secondary to cefepime or underlying infection was suspected. Cefepime was held, no other antibiotic was started and she returned to baseline in two days.

IMPACT: Knowing the neurological adverse effects of cefepime and timely identification can decrease morbidity in patients.

DISCUSSION: Adverse effects of cefepime are considered mild, but neurotoxic effects, such as myoclonus, seizures and encephalopathy have been described in patients with renal insufficiency due to decreased clearance. Renal dysfunction also makes the blood brain barrier more permeable, facilitating influx of uremic neurotoxins, and possibly cefepime, into the brain, which can lead to these side effects. However, similar cases have been reported in patients with normal renal function. We describe cefepime-induced encephalopathy in a patient with multiple sclerosis. At the time cefepime was given, patient's renal function had normalized, eliminating decreased clearance as a cause of the neurotoxic effects. Multiple sclerosis is known to disrupt blood brain barrier, possibly promoting the influx of cefepime to the brain, leading to encephalopathy. This diagnosis was

also supported by the resolution of symptoms after discontinuation of the drug in a time frame similar to previously reported cases. In addition, infective etiology was unlikely as the patient was off antibiotics when the encephalopathy resolved. Cefepime has been implicated for serious neurological adverse effects. In this case, multiple sclerosis could have precipitated cefepime-induced encephalopathy. However, similar cases need to be reported to determine if there is a true association. Nevertheless, caution is advised when using cefepime in patients with neurological disorders.

A CASE OF CHOLESTASIS ASSOCIATED WITH TRIMETHOPRIM-SULFAMETHOXAZOLE ADMINISTRATION Mary Barrosse-Antle; Anna Moran; Jeffrey R. Jaeger. University of Pennsylvania School of Medicine, Philadelphia, PA. (Control ID #2702905)

LEARNING OBJECTIVE #1: Recognize trimethoprim-sulfamethoxazole as a potential cause of severe cholestasis

CASE: The patient is a previously healthy 29-year-old male who developed cholestasis after taking trimethoprim-sulfamethoxazole (T/S) that had been administered for treatment of a wound infection. He presented seven days after starting the medication with right upper quadrant pain, nausea, dark urine, pale stools, jaundice, pruritus, and weight loss. He denied fever, rash, or significant alcohol use. Liver function tests at presentation showed AST 104 U/L (13–39 U/L), ALT 263 U/L (7–52 U/L), alkaline phosphatase 292 U/L (34–104 U/L), and total bilirubin (TB) 12.2 mg/dL (0.3–1.0 mg/dL). After 21 days of worsening jaundice, he was admitted to the hospital, where his lab tests showed AST 30 U/L, ALT 44, alkaline phosphatase 257 U/L, and TB 26.3 mg/dL. ANA, ASMA, AMA, hepatitis A, hepatitis B, hepatitis C, CMV, and HIV were negative. CT abdomen showed a normal-appearing liver and collecting system with no ductal dilation. Liver biopsy showed marked cholestasis with mild portal and lobular chronic inflammation and no significant fibrosis. No bile duct atrophy was identified. Minimal steatosis, and mild reticuloendothelial stainable iron were seen. His pruritus was refractory to diphenhydramine, ursodiol, cholestyramine, and naltrexone but responded to rifampin. At the time of discharge, TB was 38.5, with minimal transaminitis and preserved synthetic function.

IMPACT: This case reinforced the importance of considering drug toxicity, especially T/S toxicity, in the differential diagnosis of cholestasis. It also expanded our repertoire of symptomatic treatments of pruritus to include rifampin.

DISCUSSION: T/S is an antibiotic that is rarely associated with clinically significant liver injury. Previously described patterns of hepatotoxicity include hepatocellular, cholestatic, and mixed hepatocellular-cholestatic injury. There are many variants of T/S-induced liver injury that encompass a wide pathologic and clinical spectrum. While the most frequently described injury is hepatocellular necrosus, some patients can have simple cholestasis with minimal inflammatory infiltrate and no fibrosis that resolves spontaneously. Among cholestatic reactions, the most serious variant is labeled "vanishing bile duct syndrome," and is marked by an early hepatitic phase followed by severe, prolonged cholestasis associated with significant loss of bile ducts on biopsy. T/S-induced cholestatic liver injury is characterized by onset of symptoms within 4 days to one month of start of therapy, with reported peak total bilirubin levels ranging from 2.5 to 40.4. Normalization of TB is the norm, occurring from several weeks to 1 year after discontinuation of T/S. However, patients with vanishing bile duct syndrome can require liver transplantation due to clinical deterioration. Our patient's symptoms,course, and pathologic findings are consistent with cases of simple T/S-induced cholestasis described in the literature.

A CASE OF CHRONIC TOPHACEOUS GOUT Katherine Ni; Maiko Kondo; Verity Schaye. NYU School of Medicine, New York, NY. (Control ID #2697996)

LEARNING OBJECTIVE #1: Recognize the clinical presentation and physical exam findings of chronic tophaceous gout

LEARNING OBJECTIVE #2: Discuss the management and complications of tophaceous gout

CASE: A 40 year-old man with no past medical history presented with 8 months of worsening pain and deforming growths in multiple joints. He first noticed intermittent pain and swelling in the heels of both feet 2 years prior to admission, which progressed to constant pain in his feet, knees, hands, and elbows. Starting 8 months ago, distinct nodules formed on the affected joints; these occasionally burst and released a "toothpaste-like" discharge. He increasingly had difficulty walking and using his hands. The patient had not sought any medical care since emigrating from Mexico 8 years ago, due to lack of insurance. On exam, he had diffuse subcutaneous nodules on the feet, ankles, knees, elbows, earlobes, and hands, most concentrated in the joint spaces. They were firm, non-tender, and yellow to white in color. One nodule was draining a chalky white exudate. He had numerous cyst-like lesions on the shaft of the penis, restricting movement of the foreskin. Range of motion was severely impaired in all extremities. He had a uric acid level of 10.4, alkaline phosphatase of 164, and C-reactive protein of 16.5. Rheumatologic serologies were negative. X-rays of the affected joints showed osteopenic bone, with areas of periarticular erosions, joint space narrowing, and subchondral sclerosis with overlying tophi, all consistent with advanced gout. Fluid from the draining tophus revealed large collections of monosodium urate crystals.

IMPACT: This case is a reminder that physicians should be prepared to recognize and manage not only acute gout flares, but also advanced presentations of chronic gout. Particularly when working in populations with limited healthcare access, the diagnosis and treatment of gout may be considerably delayed. Perhaps more importantly from an internist's perspective, recognizing and treating the sequelae and comorbidities of gout may reduce morbidity and mortality in these patients.

DISCUSSION: In gout patients, the presence of one or more tophi is an indication to begin urate-lowering therapy (ULT), using xanthase-oxidase inhibitors, which decrease production of urate, and uricosuric agents, which increase renal excretion of uric acid. ULT targets a serum urate of <6 mg/dL; in severe cases, a target of <5 mg/dL is often used. If serum urate remains elevated on both agents, the next step is to add pegloticase, a recombinant uricase that converts urate into the renally cleared allantoin. Even with optimal control of hyperuricemia, tophi may persist for years before disappearing. Notably, all gout patients are at increased risk for cardiovascular disease, metabolic syndrome, and renal disease. However, patients with tophi have additional complications of joint and bone destruction, compressive neuropathies, and ulceration and infection of the tophi. The presence of tophi is also an independent predictor of mortality.

A CASE OF CNS VASCULITIS IN A PATIENT WITH WALDENSTROM MACROGLOBULINEMIA Tanawan Riangwiwat[1]; Chris Y. Wu[1]; Beau Nakamoto[2]. [1]University of Hawaii, Honolulu, HI; [2]Straub Clinics and Hospital, Honolulu, HI. (Control ID #2701353)

LEARNING OBJECTIVE #1: Recognized Waldenstrom macroglobulinemia as a cause of vasculitis

LEARNING OBJECTIVE #2: Recognized treatment of vasculitis due to Waldenstrom macroglobulinemia

CASE: A 66 year-old woman with Waldenstrom macroglobulinemia (WM), hypertension, and hyperlipidemia presented with acute altered mental status. She had been diagnosed with WM by bone marrow biopsy and was treated with rituximab, then maintained on thalidomide until 2 months prior to presentation. Vital signs were normal. Patient was fully oriented. She was unable to spell the word 'WORLD' backwards, but had normal repetition. Cranial nerves II-XII, strength, sensation, cerebellar tests, and Babinski reflex were all intact. Non-contrast head CT was normal. MRI brain showed acute infarctions involving the cortical surface of the parietal lobes. Lumbar puncture showed mildly elevated proteins. WM labs showed elevated IgM of 2250 mg/dL [reference range 40–260], normal IgA level, low IgG of 236 mg/dL [reference range 741–1861]. Serum viscosity was 1.8 cP [reference range 1.1 - 1.8]. Infectious workup, autoimmune and systemic vasculitis workup (including cryoglobulinemia) were negative. Due to acute left hemiparesis, repeat brain MRI was obtained on the second day, which showed multifocal cortical infarctions. MRA showed small peripheral branches of the cerebral arteries, and cerebral angiogram confirmed multifocal small vessel vasculitis. Cyclophosphamide was added, and the patient's mental status and neurologic deficits gradually improved. Patient was discharged with prednisone and cyclophosphamide.

IMPACT: Our patient presented with multifocal acute cortical ischemic strokes after discontinuation of WM treatment for 2 months. The mechanism of WM causing stroke was previously described as vasculitis with the presence of cryoglobulins, immunoglobulins that precipitate at temperatures < 37 °C and that can lead to immune complex-mediated vasculitis. To my knowledge, WM causing central nervous system (CNS) vasculitis in absence of cryoglobulins and hyperviscosity syndrome has never been described.

DISCUSSION: WM is an indolent B cell lymphoproliferative disorder characterized by a monoclonal IgM protein in the serum. Neurologic complications in WM are mostly manifesting as peripheral neuropathy or as clinical symptoms of hyperviscosity. Our patient was negative for cryoglobulins, secondary causes of CNS vasculitis, and elevated serum viscosity. However, cutaneous and systemic vasculitis has been uncommonly associated with other lymphoproliferative disorders in the absence of cryoglobulins. It's plausible that WM may lead to CNS vasculitis independent of cryoglobulins. The termination of maintenance immunosuppressive therapy in our patient led to the development of CNS vasculitis as vasculitis is an autoimmune phenomenon. Importantly, our patient experienced stabilization and improvement of symptoms upon treatment with steroids and cyclophosphamide, both of which are also useful in managing WM.

A CASE OF DRUG-INDUCED HEMOLYTIC ANEMIA Shana Berwick; Jennifer M. Manne-Goehler. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #2706674)

LEARNING OBJECTIVE #1: Review key laboratory features of drug-induced hemolytic anemia (DIHA) and diagnose this condition in the appropriate clinical context

CASE: EL is a 57 year-old male who presented as an outpatient with 10 days of upper respiratory symptoms and was prescribed Augmentin. However, his fevers persisted. On admission his exam was notable for mild jaundice and labs were notable for anemia, reticulocytosis, elevated LDH, indirect hyperbilirubinemia and a low haptoglobin, consistent with hemolytic anemia. The work-up of this hemolytic anemia included a direct antiglobulin test (DAT) positive for C3 and negative for IgG, and a negative cold agglutinin screen. A comprehensive panel of inflammatory and autoimmune tests returned negative. After discontinuing Augmentin, the hemolysis quickly resolved.

IMPACT: Interpretation of the DAT in its clinical context is key to diagnosing DIHA as the DAT can be positive for IgG and/or C3. Despite a growing number of drugs associated with DIHA, the diagnosis is often overlooked as it requires a high index of suspicion, a consideration of chronology between drug administration and hemolysis, and an understanding of serologic results. As such, the incidence of DIHA is underestimated.

DISCUSSION: The DAT is a common tool for distinguishing between classes of hemolytic anemia. DAT uses monoclonal antihuman globulin to promote agglutination of erythrocytes that have IgG and/or complement bound to their surface. A positive DAT test confers a differential diagnosis of (1) alloimmune (transfusion related) hemolytic anemia, (2) autoimmune hemolytic anemia, or (3) drug induced hemolytic anemia. There are two mechanisms for DIHA: drug-dependent and drug-independent. In the first, the drug binds to the RBC creating an immunogenic surface that triggers IgG- or immune complex-mediated hemolysis only in the presence of the drug. By contrast, drug independent antibodies are those that bind to the RBC surface even in the drugs absence. Both processes can be mediated by either IgG or complement and thus DIHA can be DAT IgG and/or C3 positive. A literature review from 2007 implicates over 125 drugs involved in DIHA, of which 42% were antimicrobials, 15% were anti-inflammatory and 11% were anti-neoplastics [1]. Among antibiotics, cefotetan, ceftriaxone and piperacillin were the most common culprits. Interestingly, beta-lactamase inhibitors, as found in Augmentin, appear to facilitate the interaction of antibiotics with RBCs and catalyze DIHA [2]. In this case the presence of an anti-C3 antibody, a negative cold agglutinin screen in addition to the history of recent Augmentin usage narrowed the differential to drug-induced hemolytic anemia. [1] Garratty, G. Drug-induced immune hemolytic anemia. *Hematology Am Soc Hematol Educ Program*. 2009:73–9. [2] Gmur, J et al. Amoxicillin-induced immune hemolysis. *Acta Haematol*. 1985;74(4):230–3.

A CASE OF ECTOPIC CUSHING'S SYNDROME David W. Lin; Keerti Murari. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2706245)

LEARNING OBJECTIVE #1: Diagnose and manage Cushing syndrome (CS) due to ectopic adrenocorticotropic hormone (ACTH) secretion (EAS)

LEARNING OBJECTIVE #2: Assess the role of bilateral adrenalectomy in rapidly progressive EAS

CASE: A 79 YO F with PMH of atrial fibrillation, hypothyroidism, and type 2 DM presented with altered mental status. Exam on presentation was notable for hypertension and delirium, but weight gain, central obesity and striae were absent. Labs were notable for hypokalemia, hypernatremia, high AM cortisol 76 ug/dL, high ACTH 593 pg/mL, high 24-hour urine free cortisol >16,500 ug/d, and high chromogranin A 10,100 ng/mL. CT-HCAP showed no pituitary macroadenoma, but did reveal a sigmoid colonic mass with several masses in the liver likely representing metastases, and bilateral adrenal thickening. A colonoscopy with biopsy showed low-grade dysplasia suggestive of invasive adenocarcinoma, but the specimen was insufficient for a pathological diagnosis. She was kept on ketoconazole and surgery was consulted for bilateral

adrenalectomy. However, she soon developed sepsis likely due to an aspiration pneumonia and was started on empiric antibiotics. She then developed septic shock, was made DNR/DNI, and transferred to inpatient palliative care where she died 12 days after admission.
IMPACT: Our case highlighted the high morbidity and mortality associated with sepsis in patients with rapidly evolving EAS, and explores the role of urgent bilateral adrenalectomy in such patients. Additionally, there have only been a few case reports of colonic malignancies as sources for EAS.
DISCUSSION: There are approximately 300 new cases of EAS per year. The classic Cushingoid features are not always seen in patients with rapidly progressive EAS such as ours. Carcinoid and small-cell lung carcinoma are the most common malignancies associated with EAS. However, there are only a few case reports in the literature of colorectal tumors as sources of EAS. Persistently elevated serum cortisol levels in CS carry high morbidity and mortality due to impaired immunity and a predisposition to infections. In one study, EAS patients with serum cortisol concentrations above 40 mcg/dL or urinary cortisol excretion greater than 2000 mcg/day were likely to have severe infections. In another retrospective cohort study of 418 patients with CS at two large tertiary endocrine referral centers, infection/sepsis accounted for 21.6% of deaths, and patients with EAS had poor survival compared to other causes of CS with 77.6% probability of 5-year survival. Thus, rapid control of cortisol secretion with steroidogenesis inhibitors like ketoconazole, metyrapone, and mitotane is indicated, though they may be effective only for a short time in up to 50% of patients. In patients that continue to deteriorate despite medical management, there is evidence that urgent bilateral adrenalectomy may be lifesaving in severe and rapidly evolving EAS.

A CASE OF HAMMAN'S SYNDROME AFTER A PROLONGED LABOUR Sidra Khalid; Suryanarayan Mohapatra; Basem Haddad. Fariview Hospital - Cleveland Clinic, Cleveland, OH. (Control ID #2706670)

LEARNING OBJECTIVE #1: − to recognize Hamman's syndrome in the differential diagnosis of chest pain in postpartum patients
CASE: A 27-year-old female gravida 3, para 0 and 2 miscarriages in the past was 39 weeks pregnant when she delivered a viable female newborn through a spontaneous vaginal delivery in a right occipito-posterior position. Her labour was prolonged and during it she developed a non-radiating mild chest pain and crepitus over her upper chest and right chin. She is a non-smoker with a non-significant past medical and surgical history. She had history of second hand smoking from parents till age 17 years. There was no family history of any lung disease. Her vitals were temp. 36.9 °C, heart rate 83/min, respiration rate 18/min, blood pressure 118/66 mmHg, and SpO2 99% on room air. The rest of the physical examination was unremarkable, except for crepitus at the base of the neck and on the anterior chest wall. Her chest x-ray showed cervical subcutaneous emphysema with extensive pneumomediastinum and pneumopericardium. She was transferred to the intensive care unit for further monitoring. A CT scan chest was performed which revealed extensive pneumomediastinum with no evidence of tracheal or bronchial injury; extensive subcutaneous emphysema overlying the lower cervical neck and extending over the anterior right hemithorax. Esophagogram showed no evidence of esophageal rupture. Cardiothoracic surgery was consulted and expectant management was decided. As she continued to have improvement of her symptoms and with no evidence of cardiovascular collapse, she was observed clinically for the resolution of her pneumomediastinum.
IMPACT: Through this case, a rare cause of pneumomediastinum has been highlighted in a postpartum patient. Patients with prolonged or complicated vaginal deliveries, who present with chest pain and crepitus over the anterior chest wall, should be investigated further for pneumomediastinum. Awareness of this rare condition in this particular patient population will reduce morbidity and mortality, as in severe cases it can lead to cardiovascular collapse and death.
DISCUSSION: Hamman's syndrome is pneumomediastinum associated with subcutaneous emphysema. It occurs during labour with an incidence of 1 in 100, 000 vaginal deliveries. Its main symptom is severe chest pain and sign is crepitus in the chest and neck. Diagnosis is confirmed through a chest x-ray or CT scan of the thorax. It is a self-limiting condition, but it can lead to malignant pneumomediastinum in which the trapped air can lead to cardiovascular collapse. Management is a conservative approach in stable patients, which includes oxygen, analgesics, anti-tussives and anti-anxiety medications. It is an important to distinguish Hamman's syndrome from other life-threatening postpartum conditions such as pulmonary embolism, amniotic fluid embolism, aortic dissection, myocardial infarction, and pneumothorax.

A CASE OF ISOLATED ACQUIRED FACTOR VIII INHIBITOR Ranya Selim; Sarah A. Gorgis; Waleed Al-Darzi; Elsheikh Abdelrahim; Bruno Digiovine. Henry Ford Hospital, Detroit, MI. (Control ID #2701989)

LEARNING OBJECTIVE #1: Diagnose and manage the presence of factor VIII inhibitor.
CASE: We present the case of a 76-year-old lady with a history of breast cancer post mastectomy who was transferred to our Intensive Care Unit (ICU) for acute blood loss anemia. The patient had initially presented 3 weeks prior to an outside hospital (OSH) after a fall with a hemoglobin of 4.7 g/dL (from 11.7 g/dL), PTT at 73, creatinine at 3.8 mg/dL, and BUN at 55 mg/dL. CT demonstrated a large intramuscular hematoma anterior to the right femur and a retroperitoneal hematoma. She was given several units of blood, and hemoglobin remained stable. Femoral dialysis catheter placement was then attempted due to worsening renal function with resultant profuse bleeding. Given her persistent bleeding of unknown etiology, she was transferred for escalation of care. On arrival to the ICU, the patient required suturing of the femoral site. Workup of her elevated PPT was initiated. Monoclonal protein evaluation, cardiolipin antibodies, beta 2 glycoprotein were all within normal limits. ANA was mildly positive. Her Factor VIII levels were <1% with elevated inhibitor level. Mixing study was consistent with presence of an inhibitor. She was believed to have acquired factor VIII inhibitor. CT was done to rule out an associated malignancy and was negative. She was given 4 days of high dose decadron, followed by daily cyclophosphamide and prednisone, as well as intermittent doses of Novoseven (factor VII), Obizur (factor VIII), and later Feiba (longer acting factor VII). She did not require further doses as her hemoglobin remained stable with resolution of bleeding. She was discharged on low dose oral prednisone maintenance therapy.
IMPACT: Our case highlights the importance of consideration of other etiologies for coagulopathy, especially in patients with no known coagulopathic disorders. Though factor VIII inhibitor is uncommon, it could be an aqcuired disorder in adults with otherwise unexplained elevation in PTT.
DISCUSSION: Acquired Factor VIII inhibitor is a rare disorder that may present with severe bleeding episodes that may be life-threatening, with mortality rates up to 22%. The most commonly associated illnesses reported in the literature include autoimmune disorders and malignancy/pre-malignant

states. Diagnosis is made both clinically and based on laboratory evaluation; an isolated prolonged PTT (normal PT and platelets), and a mixing study consistent with the presence of an inhibitor, in the absence of heparin contamination and lupus anticoagulant. Factor VIII activity should be measured, and the strength of inhibitor quantified. Acute bleeding episodes with low-titer inhibitors can be treated using human factor VIII concentrates, whereas factor VIII bypassing agents (prothrombin complex concentrates or recombinant activated factor VII) are effective in the presence of high-titer inhibitors. The first-line treatment for the eradication of factor VIII autoantibodies is a combination of steroids and cyclophosphamide.

A CASE OF LIFE-THREATENING SEPTICEMIA FOLLOWING GLUTEAL AUGMENTATION Saliha Saleem; Dipen B. Khanapara; Marilou Corpuz. Montefiore Medical Center, Bronx, NY. (Control ID #2705793)

LEARNING OBJECTIVE #1: Recognize the severe complications of autologous gluteal augmentation.

LEARNING OBJECTIVE #2: Recognize potential pathogenicity of Propionibacteria following surgical manipulation.

CASE: A 34-year-old woman presented with left buttock pain and fever. She had undergone fat gluteal augmentation surgery two weeks before admission. She presented with fever, hypotension, tachycardia, and a 12 × 8 cm indurated area on the left buttock.Pertinent labs for her included WBC of 35.4 k/ul and lactic acid of 2.5 mmol/L. CT scan abdomen/pelvis revealed an ill-defined fluid collection within the left gluteus maximus. She was managed in ICU for septic shock. 175 ml of foul-smelling pus was drained; cultures grew Propionibacterium avidum. Despite broad spectrum antibiotics, she continued to have leukocytosis, fever, and progressive necrotizing cellulitis extending to her lower back and right buttock, which necessitated three additional sessions of incision and drainage. Tissue pathology revealed necrotic infection of the skin and soft tissue. Her hospital length of stay was two weeks.

IMPACT: Although labeled as low risk, cosmetic procedures like gluteal augmentation can cause extensive and life-threatening infection with subsequent disfigurement. It is critical that complications of necrotizing soft tissue infections be recognized early, as they require close monitoring with appropriate medical management and timely surgery.

DISCUSSION: Augmentation gluteoplasty has been reported to have increased by 3400% from 2002 to 2014. The American Society of Plastic Surgeons identified gluteal implants and lifts as the fastest-growing types of plastic surgery in the United States. Surgeries with silicone prostheses and autologous fat grafting have complication rates of 21.6 and 9.9%, respectively. Reported complications in autologous fat injections are seroma (3.5%), under-correction (2.2%), infection (2%), pain or sciatalgia (1.7%), lipo-necrosis, and fat embolism. There is a paucity of information in the literature on infectious complications with fat grafting. Reported infections were caused by Bacteroides, Enterococcus, and yeast. Our patient is a unique case of P. avidum necrotizing infection of the skin and soft tissue leading to severe sepsis. Propionibacteria are gram-positive anaerobic bacilli, usually considered as normal flora, and frequently found in pilosebaceous follicles of humid areas (axilla, groin, perianal region). Our patient's preceding surgery or trauma may have predisposed to P. avidum infection. With increasing popularity of cosmetic surgeries, physicians should be cognizant of these rare yet serious infections, and patients should be warned about these possible risks.

A CASE OF LISTERIA OSTEOMYELITIS CAUSED BY TNF-α INHIBITOR Takafumi Kubota[2]; Ivor Cammack[1]; Shadia Constantine[3]. [1]Keijinkai, Yoichi, Japan; [2]Teine Keijinkai Hosipital, Sapporo, Japan; [3]Teine Keijinkai Hospital, Sapporo, Japan. (Control ID #2704596)

LEARNING OBJECTIVE #1: Recognise that listeria can cause osteomyelitis in patients taking TNF-α inhibitors.

LEARNING OBJECTIVE #2: Recognise that treatment duration of Listeria osteomyelitis is variable, and ESR monitoring can be a useful guide.

CASE: A 73-year-old Japanese man presented with a 6 month history of a progressively enlarging mass located at his left ankle. He denied fever, weight loss, pain or pitting edema. His longstanding medical conditions include rheumatoid arthritis, ischaemic heart disease and dyslipidemia. He also has a past history of methotrexate induced lymphoproliferative disorder. His medications are adalimumab (a TNF-α inhibitor), methylprednisolone, aspirin, clopidogrel, lansoprazole and nicorandil. On physical exam, his vital signs were within normal limits He had classic signs of RA with rheumatoid nodules on his upper limbs, and swan-neck deformities of the hand. There was a well defined 4 cm mass superficial to the medial malleolus of his left ankle. It was not red or tender. There was joint involvement. The rest of his exam was normal. Blood results showed a normocytic anemia (Hb 8.4 g/dl), hyponatremia Na 130 mEq/L, WBC 16650 and CRP 176. Our initial working diagnosis was a flare of rheumatoid arthritis and he was treated symptomatically awaiting further investigation. Xray, CT and MRI images showed bony destruction of the tibia, talus and multiple granulomas around the left ankle. A biopsy was performed on day 10 which cultured listeria from the adjacent bone. A diagnosis of listeria osteomyelitis was made and he was started on intravenous ampicillin 2 g 6 hourly + gentamycin 90 mg 8 hourly. He underwent surgical resection of affected bone at the 4 week mark. The planned antibiotic duration was for 15 weeks, with weekly ESR monitoring.Treatment was ceased early at the 14 week mark as his ESR had reduced to 40 mm/hr.

IMPACT: This case highlighted the risk of infection from uncommon pathogens in patients on TNF-α inhibitors. We were surprised to make a diagnosis of osteomyelitis in this patient 14 days into his admission. The culture results made the diagnosis seem obvious, but I learnt that this is an important diagnosis not to miss. Also of interest was the granuloma formation which made us suspect tuberculosis, but in fact his culture came back as pyogenic granuloma without bacteria and Listeria osteomyelitis.

DISCUSSION: TNF-α inhibitors have become increasingly popular in the suppression of autoimmune conditions, but it is important to be aware of the increased risk of infections with intracellulcar organisms such as *Mycobacterum tuberculosis* and *Listeria monocytogenes*. Listeria osteomyelitis, a rare condition, is treated with surgical resection of infected bone and prolonged courses of antibiotics. To determine the duration of the antibiotics therapy, we found weekly ESR measurements to be useful.

A CASE OF MICROSCOPIC POLYANGIITIS COMPLICATED BY DIFFUSE ALVEOLAR HEMORRHAGE Aravdeep Jhand[1]; Blake Titterington[2]; Jeffrey Macaraeg[1]; Vishisht Mehta[1]; Gene Pershwitz[1]; Venkata Andukuri[1]. [1]Creighton University, Omaha, NE; [2]Creighton University School of Medicine, Omaha, NE. (Control ID #2707314)

LEARNING OBJECTIVE #1: Recognize clinical manifestations of Microscopic Polyangiitis.

LEARNING OBJECTIVE #2: Identify the indications for empiric immunosuppressive therapy.

CASE: A thirty-seven year old Caucasian male presented with a 3-week history of productive cough with blood-tinged sputum and wheezing. Patient also reported 80 lbs. of unintentional weight loss over the last year. At initial presentation, his blood pressure was 138/80 mmHg, pulse rate 84 per minute, respiratory rate 16 breaths per minute and body temperature 37° C. Physical examination showed a young and healthy male in no acute distress. A petechial rash was noticed bilaterally on the soles of his feet. Initial lab work-up revealed hemoglobin of 7.9 gm/dl and hematocrit of 24.2%, blood urea nitrogen 28 mg/dl, serum creatinine 3.87 mg/dl. Urinalysis was positive for hematuria and bilateral infiltrates were seen on plain radiograph of the chest. A high resolution computed tomography scan revealed ground glass opacities in bilateral lower lobes of the lungs. Serological testing for histoplasmosis was negative. Serum anti-nuclear antibody was negative and complement levels (C3 and C4) were normal. Further testing for potential vasculitis was undertaken which was positive for p-ANCA (1:160) but negative for myeloperoxidase (MPO) and anti-glomerular basement membrane antibody. A renal biopsy was performed for confirmatory diagnosis. While waiting for the results of the biopsy, patient underwent bronchoscopy with alveolar lavage (BAL) which was consistent with Diffuse Alveolar Hemorrhage(DAH). Thus, urgent therapeutic plasma exchange was performed and induction immunosuppressive therapy with IV pulse steroids and Rituximab was initiated for presumed Microscopic Polyangiitis (MPA). Three sessions of plasma exchange were completed and patient was transitioned to oral steroids. Renal biopsy results later revealed crescenteric glomerulonephritis thus confirming the diagnosis of MPA. Two weeks after initiating treatment, his kidney function had improved and patient reported no hemoptysis.

IMPACT: This case highlights the importance of prompt recognition of DAH in patients suspected or diagnosed with ANCA associated vasculitis (AAV) since early initiation of immunosuppressive therapy can be life-saving. In clinical scenarios where suspicion for AAV is high, empiric treatment should not be delayed while waiting for confirmatory tissue biopsy.

DISCUSSION: MPA is a small vessel necrotizing vasculitis and can involve various organ systems including the lungs, kidneys, skin etc. Nearly 90% of patients are ANCA positive and it is primarily associated with MPO-ANCA. Biopsy remains the gold standard for diagnosis and should be performed in suspected cases. A presumptive diagnosis can be made based upon clinical findings such as DAH and ANCA positivity in cases where biopsy cannot be performed or is delayed. Treatment involves immunosuppressive drugs such as Glucocorticoids, Cyclophosphamide, Rituximab and Methotrexate.

A CASE OF MISTAKEN IDENTITIES: INAPPROPRIATE IV OPANA USE CAUSING TTP-LIKE ILLNESS

Amy D. Lu[2]; Edgar Raymund Ramirez[1]; Raquel A. Buranosky[2]. [1]UPMC, Pittsburgh, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2703643)

LEARNING OBJECTIVE #1: Recognize clinical features of drug-induced thrombotic microangiopathy (DITMA).

LEARNING OBJECTIVE #2: Manage DITMA with supportive care and rare plasmapheresis.

CASE: A 53 year-old woman with a history of multiple sclerosis on interferon-beta, chronic pain on extended release oxymorphone (Opana®) presented after witnessed generalized tonic-clonic seizure. In preceding days, she was lethargic and confused. Her medications included interferon-beta at 30mcg per week and known to abuse IV injected Opana. On arrival, she was febrile to 38.4 °C, hypertensive to 204/119, tachycardic at 146 bpm, tachypneic to 36, and saturating at 94% on room air. She was obtunded with roving eye movements, no purposeful movements, and did not withdraw to noxious stimuli. She was subsequently intubated for airway protection. Serology showed white blood cell count of 26.8, hemoglobin of 11.7 gm/dl, and platelets of 18,000. Basic metabolic panel showed bicarbonate 17, BUN 46, and creatinine 2.58. LDH was elevated to 2541 IU/L with undetectable haptoglobin, and peripheral blood smear showed 5–10 schistocytes/hpf. Urine drug screen was positive for opioids. Brain MRI showed extensive, multilobar cortical and subcortical T2 hyperintensity and small bilateral thalamic hemorrhages consistent with posterior reversible encephalopathy syndrome (PRES). She was admitted to medical ICU for plasmapheresis. She received one round of apheresis with recovery of platelets to 57,000. ADAMTS13 autoantibody and activity were both normal. Given the clinical picture, a diagnosis of drug-induced TMA most likely due to IV Opana use was made. Full recovery was made within 5 days without further apheresis or steroids.

IMPACT: DITMA should be considered in anyone with new microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute kidney injury (AKI) as AKI is less commonly seen in primary TTP. In light of the opioid epidemic, providers should be aware that inappropriate use of IV Opana may cause DITMA which can be generally managed without plasmapheresis.

DISCUSSION: TTP is a rare disorder that is classically defined as the pentad of fever, MAHA, thrombocytopenia, renal failure and neurologic abnormalities though only MAHA and thrombocytopenia are required for diagnosis. DITMA presents similarly to TTP but with a much higher incidence of AKI. Diagnosis of DITMA may be made with a combination of MAHA, thrombocytopenia, and history of implicated drugs such as chemotherapeutics, immunosuppressants, or quinine. Interferon has been associated with DITMA in a dose dependent manner with doses greater than 50mcg per week, which did not apply in our patient. Use of IV Opana has also been linked to DITMA via toxicity-mediated mechanism with range of clinical presentation from mild illness to multisystem organ failure. Plasmapheresis may be unavoidable initially in a clinically deteriorating patient who presents with concern for TTP, but DITMA generally has excellent prognosis with supportive care alone.

A CASE OF NONISCHEMIC DILATED CARDIOMYOPATHY IN A 26M WITH POLYSUBSTANCE USE DISORDER AND HISTORY OF INCARCERATION: INTRODUCING A STRUCTURAL VULNERABILITY CHECKLIST TO OPTIMIZE PATIENT CARE AND OUTCOMES

Kimberly Sue. Massachusetts General Hospital, Cambridge, MA. (Control ID #2698996)

LEARNING OBJECTIVE #1: To introduce clinicians to a new assessment tool to assess structural determinants of health (“structural vulnerability”) to include diagnostics and data regarding our patients’ upstream sources of ill health, including structures of power and oppression, in order that providers can better recognize their biases and optimize care for “socially complicated” patients.

LEARNING OBJECTIVE #2: Understand the sources of structural vulnerability, history, physical exam findings, differential diagnosis and possible treatments for a 26 M with history of substance use disorder and incarceration on presentation to the Cardiac Intensive Care Unit.

CASE: This is a case of a 26 M h/o polysubstance use (cocaine, marijuana), bipolar disorder, trauma who was admitted to a tertiary care hospital with signs

and symptoms of decompensated heart failure. TTE revealed EF of 10%. He underwent both diagnostic workup at that time for his profound heart failure as well as tailored therapy. He was discharged with heart failure follow-up. Later, the patient was re-admitted to the hospital from jail where the medical team advocated for an ICD placement given that a LifeVest was deemed technically difficult for the patient given his complex circumstances. He was again admitted with signs and symptoms of volume overload and his erratic behavior was cited as argument against his transplant candidacy. The patient's significant cardiovascular pathology compounded with co-morbid psychiatric and behavioral problems presented challenges for all care teams involved. Using a structural vulnerability checklist (see Bourgois, Holmes, Sue, and Quesada, 2016, Academic Medicine) can help front line clinicians to identify the most significant barriers to providing optimal care outside of technical diagnostic criteria that still heavily influence the well-being and ultimate outcomes of patients. Utilizing this checklist for this particular patient would reveal several sources of ongoing structural vulnerability contributing to this patient's poor outcomes.

IMPACT: This case bring the perspective of medical anthropology theory to illustrate the way in which we must incorporate social determinants of health into our initial and ongoing assessments and plans for patients. Clinicians should be empowered with the framework and language to prioritize and address these critical social measures as part of comprehensive medical assessments.

DISCUSSION: Here we present a difficult medical case in a patient whose care has significant ethical and psychosocial overlays. Frontline clinicians can utilize a structural vulnerability assessment checklist as presented here to identify sources of ongoing barriers to health. We believe the implementation of such a tool in medical schools, emergency rooms and on the wards can have significant benefits if the tool is integrated into routine care. We hope to pilot the use of this project at Harvard and UCSF among medical students for both feasibility and ease of understanding for clinicians.

A CASE OF POST-OPERATIVE DEEP VEIN THROMBOSIS IN A HYPERCOAGULABLE PATIENT ON APIXABAN Sasha-ann K. East; Sheetal Patel. Rutgers Robert Wood Johnson Medical School, Highland Park, NJ. (Control ID #2705136)

LEARNING OBJECTIVE #1: Hypercoagulable disorders pose an increased lifetime risk of developing venous thromboembolic events (VTE). It is established that patients with these disorders usually need lifelong anticoagulation once they have more than one thromboembolic event. With the emergence of novel oral anticoagulants (NOAC), management of these patients has been streamlined. However, in times of medical illness or surgery, NOACs may not be optimal. These patients may require more aggressive individualized therapy to prevent VTE.

CASE: This case involves a 48-year-old gentleman with a past medical history of a prothrombin gene mutation complicated by two episodes of provoked VTE four and ten months prior. He had been taking Apixaban, a NOAC, indefinitely as a result. He elected to undergo total hip replacement for osteoarthritis. At the time of the operation, the patient had stopped taking Apixaban for 48 h under the advisement of his hematologist. The patient tolerated the surgery well without any bleeding complications. Apixaban 5 milligrams (mg) was restarted within six hours after surgery and continued twice daily. The next day, the patient underwent physical therapy and tolerated early ambulation. However, he started to have right lower extremity pain and swelling. An ultrasound of the right lower extremity was significant for an acute proximal deep vein thrombus. Apixaban was then increased to 10 mg twice daily. The patient's symptoms and leg swelling improved over the next two days and he was discharged on the higher dose of Apixaban.

IMPACT: It may be best to transition high risk patients to LMWH therapy peri-operatively and early post-op until NOACs are proven to be an effective alternative.

DISCUSSION: NOACs are a mainstream method of anticoagulation for various types of pro-thrombotic illnesses and predispositions. This is due to their ability to be therapeutic at onset, the convenience of not requiring periodic monitoring of drug levels, shorter half-lives, and ease of compliance. However, hypercoagulable patients may not respond to the standard doses of NOACs during times of stress. Unfortunately, there are not many studies testing the effectiveness of NOACs at different dosage levels in preventing VTE among high risk populations. Furthermore, the standard coagulation assays have not been reliable measurements of NOAC activity. Studies have primarily focused on heparin products and vitamin K antagonists for VTE prevention. Across multiple studies, low-molecular-weight heparin (LMWH) seems to provide better outcomes for high risk surgical and medically ill patients. This is especially true, when therapy is guided by monitoring Factor Xa levels. The patient in this case is a high risk for VTE complications due to his prothrombin gene mutation and the type of surgery he underwent. Despite every precaution to limit the interval off Apixaban and encourage early ambulation, he still developed a DVT in-hospital.

A CASE OF PULMONARY NODULOCYSTIC AMYLOIDOSIS IN A PATIENT WITH LYMPHOMA Sandheep Venkataraman[2]; Sahil K. Virdi[2]; Saad B. Jamil[2]; Olena Slinchenkova[1]. [1]Montefiore Medical center, Brooklyn, NY; [2]Montefiore Medical Center, Wakefield Division, Bronx, NY. (Control ID #2706702)

LEARNING OBJECTIVE #1: Recognize the features of localized pulmonary amyloidosis and the possible association with lymphoma.

CASE: A 58 year old woman with a history of breast cancer status post mastectomy, recently diagnosed mucosa-associated lymphoid tissue (MALT) lymphoma at the Ampulla of Vater, and human immunodeficiency virus (HIV) infection, presented with fever and lightheadedness. She was febrile (temperature of 102 F), tachycardic, and had decreased bilateral breath sounds. Her WBC and CD4 counts were normal. HIV viral load was undetectable. Chest CT revealed bilateral large thin-walled cystic lesions with diffuse ground glass nodules. Infectious work up was unremarkable. Fine-needle biopsy revealed light chain amyloidosis with lambda plasma cell infiltration. Serum protein electrophoresis showed high gamma globulins and low albumin/globulin ratio. PET scan revealed multiple bilateral lung opacities, metastatic disease involving Ampulla of Vater, lymph nodes, gastrointestinal tract and spleen. Further workup was deferred by the patient.

IMPACT: Pulmonary amyloidosis should be considered in the differential for nodular/cystic lesions of the lungs, especially in a patient with a hematological malignancy. Tissue biopsy is essential is making a diagnosis.

DISCUSSION: Amyloidosis is the extracellular deposition of fibrillar proteins in Beta-pleated sheets, showing green birefringence on Congo red staining. It is divided into: AL (primary/light chain amyloidosis) and AA (secondary amyloidosis). AL is the most common form seen in developed nations and involves the deposition of monoclonal immunoglobulin light chains. In the United States, approximately 4,500 new cases are diagnosed every year. It predominantly affects males between ages 50 and 80. It can present with a variety of symptoms as it can involve multiple organs. The kidney and liver are involved in 70% of the cases, the heart is involved in 60%, and the lungs in 50% of the

patients. Lung involvement can be localized or as part of systemic amyloidosis. The main patterns of respiratory tract involvement are tracheobronchial, nodular parenchymal, diffuse alveolar septal, and lymphatic. The clinical presentation and imaging findings are nonspecific. However, the localized nodular form, as seen in our case, presents as a solitary nodule or as multiple nodules of varying size, and can be easily mistaken for lung cancer. Tissue diagnosis is thus essential to establish the diagnosis. Though pulmonary amyloidosis can occur alone, there have been reports of an association with multiple myeloma, extra-nodal B-cell MALT lymphoma of the gastrointestinal tract, and lymphoproliferation of pulmonary origin. Localized pulmonary amyloidosis is relatively benign with a good prognosis. However, the prognosis with systemic involvement is poor. Localized deposition does not require chemotherapy. Local therapy in the form of surgical/laser excision and radiotherapy may be needed in patients developing obstructive symptoms.

A CASE OF PURPLE URINE BAG SYNDROME IN AN ELDERLY WOMAN WITH A CHRONIC UNILATERAL NEPHROSTOMY

Elizabeth Cummings; Kevin Chen. Yale School of Medicine, New Haven, CT. (Control ID #2706032)

LEARNING OBJECTIVE #1: Recognize purple urine bag syndrome and its treatment

LEARNING OBJECTIVE #2: Assess the relationship between purple urine bag syndrome and related urologic and renal pathology

CASE: A 67-year-old woman presented with one day of abdominal pain and vomiting. Her medical history was notable for chronic kidney disease, nephrolithiasis secondary to right ureteral stricture with a chronic right-sided nephrostomy tube, and constipation from methadone use. Starting one month prior to admission, she had noticed intermittent flank pain around her nephrostomy site, decreased total urine output, and increased urinary frequency without dysuria. On examination, she was afebrile and her nephrostomy tubing and collection bag were noted to be dark purple. Laboratory studies were notable for no leukocytosis and urine studies showing clear yellow urine, pH 8.0, positive for bacteria, leukocyte esterase, and nitrites. Urine culture was not performed during this admission due to ceftriaxone administration in the emergency department, but urine cultures from her nephrostomy during multiple previous admissions had consistently yielded mixed gram-positive and gram-negative flora, consistent with colonization. She was given three doses of ceftriaxone, which was then discontinued due to low suspicion for infection. Her nephrostomy tubing and bag were changed, and the purple bag discoloration resolved.

IMPACT: Purple urine bag syndrome (PUBS) is a rare phenomenon that, while often benign, can also be associated with difficult-to-treat urinary tract infection. This case demonstrates the syndrome in the setting of a unilateral nephrostomy tube rather than a bladder-dwelling catheter—an occurrence very rarely reported- and emphasizes the need for clinical context in case-by-case determination of its management.

DISCUSSION: The mechanism by which PUBS occurs is not fully understood, but it is thought to occur when certain bacteria metabolize compounds in the urine into red and blue pigments, which then mix in a catheter bag to create a purple color. Risk factors for PUBS include female gender, advanced age, having an indwelling urinary catheter, constipation, and dehydration. While the color of the catheter bag can be alarming, PUBS can represent benign colonization. However, PUBS can also indicate underlying complicated urinary tract infection. It is thus important to carefully consider each case individually and to closely monitor patients with PUBS. In addition, indoxyl sulfate, a metabolite of dietary tryptophan that is later metabolized by gut bacteria to produce pigment compounds, may have adverse effects in patients with chronic kidney disease. For PUBS without underlying infection, regular exchange of catheters or nephrostomy tubes, if still needed, may resolve the issue. For PUBS associated with urinary tract infection, treatment of the infection as well as exchange of catheters is recommended.

A CASE OF RESPIRATORY INFECTION COMPLICATED BY EUGLYCEMIC DIABETIC KETOACIDOSIS IN A PATIENT ON EMPAGLIFLOZIN THERAPY Emi Okamoto. Hospital University of Pennsylvania, Philadelphia, PA. (Control ID #2703952)

LEARNING OBJECTIVE #1: Understand the concept of euglycemic diabetic ketoacidosis (euDKA) and recognize it in patients taking SGLT2 inhibitors

CASE: VW is a 70 year-old male with a history of hypertension, type 2 diabetes mellitus, and paroxysmal atrial fibrillation who initially presented to the hospital with 2 days of dyspnea and productive cough. His prescription medications included glipizide and empaglifozin-linagliptin for diabetes control. In the emergency department, he had increased work of breathing with a respiratory rate of 26 per minute, a heart rate of 115 beats per minute, and temperature of 100.7. His lung sounds were course diffusely. His blood gas was pH 7.30, pCO2 29, pO2 75 on room air and initial laboratory results included glucose 146 mg/dL, anion gap of 16, and lactic acid 1.4 mmol/L. His chest radiograph was concerning for multifocal pneumonia. He was given vancomycin, cefepime, and azithromycin and one liter of normal saline. He was put on bi-level positive airway pressure (BiPAP) for increased work of breathing and admitted to the medical intensive care unit. When his work of breathing continued deteriorating, he was intubated with a high minute ventilation. A beta-hydroxybutyric acid was checked and was 2.42 mmol/L (normal < 0.27 mmol/L). Urinalysis showed >1000 glucose and positive for ketones. He was started on an insulin drip with dextrose 5% with ½ normal saline and subsequently his acidosis corrected. He uneventfully extubated around 12 hours after intubation to nasal cannula. Respiratory PCR showed Haemophilus parainfluenza. He was discharged after a course of ceftriaxone on room air.

IMPACT: This case demonstrates a rather unique case of diabetic ketoacidosis (DKA) where the patient had otherwise an acceptable range of blood glucose for a hospitalized patient. His work of breathing was increased to achieve a compensatory respiratory alkalosis, however given his respiratory infection he was unable to maintain this and required intubation. An early recognition of the euglycemic DKA, along with quick action to reverse it, may have prevented the need for intubation.

DISCUSSION: Diabetic ketoacidosis (DKA) is a well-known entity and a common reason for hospitalization which internists and intensivists routinely manage. DKA is precipitated by an absolute insulin deficiency, causing decreased glucose utilization and thus increased fat oxidation. It is often recognized easily by a concomitant severe hyperglycemia. With the advent of the sodium glucose cotransporter 2 (SGLT2) inhibitors like empagliflozin there has been a rising number of cases of euglycemic diabetic ketoacidodis (euDKA), or cases with only relatively mild increases in serum glucose <300 mmol/L. The SGLT2 channel is in the proximal tubule of the kidney and responsible for glucose reabsorption, and inhibition decreases serum glucose by inducing glycosuria. Thus there is less stimulation for insulin secretion, which may predispose a patient to an absolute insulin deficiency causing DKA.

A CASE OF SEVERE AUTO-IMMUNE HEMOLYTIC ANEMIA WITH PANCYTOPENIA: A RARE PRESENTATION OF COBALAMIN DEFICIENCY Raagini Jawa[2]; Katherine Zeitler[1]. [1]Boston Medical Center, Boston, MA; [2]Boston University Medical School, Plaistow, NH. (Control ID #2706640)

LEARNING OBJECTIVE #1: To recognize Vitamin B12 deficiency as being on the differential for pancytopenia and hemolytic anemia.

LEARNING OBJECTIVE #2: To understand that prompt management of Vitamin B12 deficiency leads to complete resolution of clinical signs and symptoms

CASE: 45 year old Honduran female with past medical history of type 2 Diabetes, hypertension, hyperlipidemia, menorrhagia presented with two months of progressive lightheadedness and one episode of pre-syncope on day of hospital admission. She also complained of new drenching night sweats for the past several weeks, painful lower extremity paresthesias. She denied any loss of consciousness, shortness of breath, chest pain, unintentional weight loss, fevers, chills, lack of energy. She had no personal or family history of malignancy, abnormal bleeding/ bruising/clotting. She reported heavy irregular menstrual cycles. She ate three non-vegetarian meals a day and was recently started on Metformin. On exam she was found to have conjunctival pallor, atrophic glossitis. Her labs were significant for wbc 1.8, Hg 5.1, HCT 15, platelets 75 (57% lymphocytes, many schistocytes) MCV 109, AST 63 ALT 32, LDH: 2739, Iron 72, TIBC 221, Tsat 32%, Ferritin 120, Retic count: 2.0. Peripheral smear showed leukopenia, hypersegmented neutrophils, thrombocytopenia, and many shistocytes. She was transfused 2 units packed red blood cells. The rest of her labs were significant for Homocysteine 73, MMA 5920, Gastric Parietal Ab: 51.6, negative Coombs, DIC panel, and Flow cytometry for acute leukemia. Given her elevated MCV, Folate: 13, Vit B12 < 146 she was started on immediate repletion with parenteral Vitamin B12 and continued with regular repletion for life. Her Metformin was also discontinued and she was started on alternative oral hypoglycemic agents.

IMPACT: This case serves to broaden our differential for a patient presenting with night sweats and pancytopenia. Cobalamin deficiency is important to recognize as complete resolution clinical signs and symptoms can be achieved with prompt recognition and appopriate management.

DISCUSSION: Severe vitamin B12 deficiency takes a long time to develop and can be due pernicious anemia, infections like HIV or H Pylori, inadequate dietary intake and certain medications. In severe cases of B12 deficiency, the patient can present with profound pancytopenia due to bone marrow suppression and poor quality RBCs leading to intramedullary hemolysis. Typical clinical exam findings include weight loss, progressive anemia, atrophic glossitis, paresthesia/numbness/ tingling/ataxia which can progress to severe neurologic weakness, spasticity, clonus, paraplegia. Since our patient had elevated high MMA, Homocysteine, and positive Gastric Parietal Ab, the diagnosis of Pernicious Anemia was made. Metformin use has been associated with B_{12} deficiency so this medication was discontinued. After initiations of parenteral Vitamin B12, patient had symptomatic improvement of lightheadedness, paresthesias and resolution of her anemia.

A CASE OF SEVERE, BUT ASYMPTOMATIC HEPATITIS

Mary Michaels; Danielle Jones. Emory University, Atlanta, GA. (Control ID #2706540)

LEARNING OBJECTIVE #1: Review etiologies and patterns of markedly elevated liver enzymes

LEARNING OBJECTIVE #2: Examine the relationship between HIV and chronic HBV infection

CASE: A 38 year old white male with past medical history of HIV and extensive vascular repair of his LLE following a traumatic laceration of his left femoral artery and associated non-healing wounds presented with spontaneous bleeding from his chronic wounds of his left leg. Patient admitted to taking substantial amounts of unknown analgesics containing acetaminophen recently, as well as several herbal supplements. He recently stopped taking his ARVs due to cost. Social history revealed consumption of 2–4 alcoholic beverages per day. Vital signs were normal and physical exam was unremarkable aside from eschars on his left lower leg. Labs showed AST/ALT of 2153/870 U/L, total bilirubin of 2.5 mg/dL, INR of 1.7, and normal alkaline phosphatase. He had a normal serum acetaminophen level, but patient was given N-acetyl cysteine for concern for acetaminophen toxicity with rising LFTs. Patient was admitted and remained asymptomatic. AST/ALT continued to rise and peaked at 6317/3838 U/L. Hepatitis serologies returned with a positive HBV core antibody and positive HBV E antibody. HBV DNA was present at 1315 IU/mL, but HBV surface antigen was negative. Smooth muscle antibody was also weakly positive at 1:20. He continued to be asymptomatic receiving only supportive care and was discharged with LFTs close to normal.

IMPACT: This is an unusual presentation of a reactivation of chronic HBV in the setting of HIV.

DISCUSSION: Our patient had an acute, severe hepatocellular pattern of LFT elevation in the setting of multiple risk factors, but was surprisingly asymptomatic. Differential diagnosis of this acute elevation (in this case was >100 times the upper limit of normal) include ischemic injury (>10-50 × ULN), toxic injury (>10 × ULN), and acute viral hepatitis (>10 × ULN). RUQ ultrasound was negative for vascular disease and he was not hypotensive following the bleeding from his leg. Recent discontinuation of ARVs likely precipitated a flare in his chronic HBV infection, and the severe increase in LFTs was compounded by alcohol and acetaminophen use. His smooth muscle antibody was only weakly positive at 1:20. A level of >1:80 is generally accepted as positive for autoimmune hepatitis, and lower titers can be caused by acute viral hepatitis. HIV-HBV coinfection is common, and the progression to chronic HBV is more frequent in patients with HIV. It was unusual that our patient had HBsAg negative viremia, but it is possible for HIV positive patients to lose the HBsAg positivity and have reactivation with positive HBV DNA in the serum. HIV also changes the natural history of chronic HBV by causing faster progression to fibrosis and cirrhosis, a lower rate of spontaneous seroconversion to the HBe and HBs antigens, and a greater risk of reactivation in inactive carriers, which is likely what happened in this case.

A CASE OF STREPTOCCUS PYOGENES SEPTIC JOINT SECONDARY TO PHARYNGITIS Jeffrey A. Schwartz; Keerti Murari; Aveena Kochar. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2706409)

LEARNING OBJECTIVE #1: Recognize septic arthritis as a complication of S. pyogenes bacteremia and the importance of early medical and surgical intervention

CASE: 64 YO M with PMH of type 2 DM presented with a 1-week of sore throat, fever, chills, and neck swelling. Initially the patient was febrile (40.4 C) and tachycardic (106) with a tender left-sided neck mass and mucosal edema of the left posterior pharyngeal wall on exam. Labs were notable for WBC of

32,000, ESR 55, and CRP 186. CT-imaging of the neck revealed a 4.5 cm mass in the left neck suspicious for a suppurative lymph node. Our patient soon developed severe right knee pain with decrease range of motion. Joint aspiration of the knee showed gram positive cocci in pairs and 88,500 nucleated cells (83% PMNs). Blood cultures grew pan-sensitive S. pyogenes. He was started on ceftriaxone and vancomycin and subsequently narrowed to ceftriaxone alone. He underwent arthroscopic knee drainage for septic joint. A repeat CT of his neck revealed interval development of a multiloculated abscess or necrotic lymph node deep to the left sternocleidomastoid. He was discharged on a 2 week course of amoxicillin with follow-up for CT-guided biopsy to evaluate for possible underlying malignancy.

IMPACT: This case increased our awareness of the potential risks posed by untreated strep pharyngitis, especially in patients with risk factors such as DM II, immunodeficiency, or malignancy. This case suggests that patients with such risk-factors should receive more intensive care than the general population.

DISCUSSION: While GAS represents only 0.6% of all cases of bacteremia reported (Meggel et al., 2006), GAS bacteremia has been associated with higher morbidity due to complications of necrotizing fasciitis, septic shock, DIC, and ICU admission compared to other types of strep bacteremia. Therefore, early recognition and management are critical to prognosis (Schattner et al., 1998). An estimated 57% of cases of invasive GAS evolve into Systemic Toxic Shock Syndrome (STSS) with an eventual mortality rate of 33% (Gotto et al., 2014). Secondary joint infection is commonly seen with S. aureus, S. pneumonia or gonoccocal infections with GAS septic joints representing only 1.7% of all cases. These patients typically have more severe clinical presentations than their GBS and GCGS counterparts (Gotto et al., 2014). Our case demonstrates that GAS pharyngitis can result in systemic infection especially in the context of known risk-factors such as DM II and malignancy. In cases of bacteremia, intensive antibiotic therapy is required to prevent complications such as septic joint and STSS. Antibiotic regimens should include a beta-lactam agent with the possible addition of clindamycin. In addition, GAS septic joint requires early arthrosopic surgical drainage to prevent further joint damage and decrease risk of mortality.

A CASE OF TEA-AND-TOAST DIET CAUSING SEVERE HYPONATREMIA Lauren Roles[1]; Rodolfo Batarse[2]; Hanna Mendoza[3]; Richard Loftus[1]. [1]Eisenhower Medical Center, Rancho Mirage, CA; [2]Dept. Nephrology, Eisenhower Medical Center, Rancho Mirage, CA; [3]UC Riverside School of Medicine, Riverside, CA. (Control ID #2706737)

LEARNING OBJECTIVE #1: Recognize the clinical features of hyponatremia secondary to low solute intake

LEARNING OBJECTIVE #2: Manage 'tea-and-toast' hyponatremia without rapid over-correction of sodium

CASE: Mr. R was a 26-year-old, developmentally delayed male with spina bifida, hydrocephalus status-post VP shunt, and hypertension. After a diagnosis of chronic kidney disease 10 weeks prior, his mother was instructed to restrict his salt intake, which unintentionally resulted in severe caloric restriction to 1/3 of his usual diet. Meanwhile, fluid intake increased to more than 3 L daily. Following 48 hours of lethargy, Mr. R was admitted to an outside hospital with serum sodium of 90 mmol/L and creatinine of 2.6 mg/dL. He was given an unclear amount of normal saline IV (at least 500 cc) and transferred to our regional medical center, where initial sodium was 93 mmol/L and creatinine was 2.6 mg/dL. Initial urine studies showed creatinine 19.8 mg/dL, sodium <20 meq/L, BUN 122 mg/dL, osmolality 103 mOsm/kg, and protein-to-creatinine ratio of 20.05. Urinalysis and culture were consistent with urinary tract infection due to *Candida albicans* in the setting of an indwelling Foley catheter. Blood cultures were negative throughout admission. CT head showed no acute intracranial processes or VP shunt abnormalities. Subsequent tests found TSH, cortisol, and urate within normal limits. Mr. R was treated with normal saline IV, increasing his sodium from 93 to 106 mmol/L by hospital day 3, at which time he had a generalized seizure and was started on levetiracetam, which was discontinued in favor of phenytoin 3 days later. Over 22 days, Mr. R's hyponatremia resolved with administration of normal saline and placement of a G-tube allowing adequate nutrition. His mental status returned to baseline.

IMPACT: To the best of our knowledge, Mr. R's initial sodium is amongst the lowest documented survived serum sodium levels in the medical literature. We found only one case with lower survived sodium, 74 mmol/L, which resulted from acute absorption of distension medium during hysteroscopy and was corrected within hours.[1] Mr. R's case contributes to the medical literature by demonstrating survival of an exceptionally severe, non-acute, hyponatremia with a sodium of only 90 mmol/L.

DISCUSSION: As is well documented in cases of beer potomania, patients with limited access to solute and excessive fluid intake are at risk of overwhelming the renal capacity to maximally dilute urine and therefore produce sufficient urine volume to maintain normal serum sodium [2]. This results in a euvolemic hyponatremia that rapidly corrects due to the resulting diuresis that occurs with re-introduction of solute, such as normal saline. These patients are at high risk of over-rapid correction of hyponatremia, with resulting osmotic demyelination syndrome[2]. As demonstrated by the case of Mr. R, severe hyponatremia may occur via the same mechanism in non-alcoholic patients at risk for poor dietary intake ('tea-and-toast' diet) with high volumes of fluid intake[3].

A CASE OF TUBERCULOUS PYOMYOSITIS Alejandra Bustillo[2]; Schuyler D. Livingston[1]. [1]Emory University School of Medicine, Decatur, GA; [2]Emory University School of Medicine, Atlanta, GA. (Control ID #2706446)

LEARNING OBJECTIVE #1: Diagnose tuberculous pyomyositis as a rare, but treatable manifestation of extrapulmonary tuberculosis

CASE: A 60 year-old, HIV-positive, incarcerated man presented with two months of progressive right forearm swelling and redness. Three days prior to presentation, he had developed fevers, night sweats, and chills but denied cough or weight loss. He had a history of pulmonary *M. fortuitum* that was treated six years prior. He was not on antiretroviral therapy. Vitals signs were: BP: 98/69, HR 109, RR 18, Temp 38°C, SpO2: 98% on room air. Exam was significant for right forearm warmth, induration, and erythema without drainage, with intact distal pulses and neurologic function. Labs were significant for: WBC 8.9×10^3/mcL, CD4 count 37/mcL, CRP 9.56 mg/dL, ESR 80 mm/hr. CT of the arm showed a large multi-loculated, septated fluid collection extending from the humerus to the anterior ulna suspicious for abscess or hematoma, as well as diffuse decreased muscle enhancement concerning for myonecrosis. A CXR showed a new left upper lobe nodularity. He underwent surgical debridement which showed purulent fat necrosis on the subcutaneous planes between the biceps and brachioradialis muscles. He was started on broad spectrum antibiotics, yet he continued to spike fevers. One day after surgery,

the tissue cultures stained positive for AFB. He was started on empiric RIPE therapy and placed on respiratory isolation while awaiting sputum cultures and MTB-PCR on the tissue specimen. PCR and culture results confirmed the diagnosis of disseminated tuberculosis.

IMPACT: Though tuberculous pyomyositis is the least frequent location of extraspinal musculoskeletal TB reported in the literature, it is important to be aware of its existence since prompt identification and treatment result in better outcomes. In evaluating patients with indolent, soft tissue masses, it is important to consider tuberculosis as a culprit, especially in immunocompromised, high-risk patients.

DISCUSSION: Pyogenic myositis has three classical clinical stages: invasive, purulent, and systemic. Tuberculous pyomyositis, on the other hand, may present as indolent, soft tissue masses that do not respond to typical treatment. In this case, a nontuberculous mycobacterial infection was initially considered given the history of pulmonary *M. fortuitum*. Patients with AIDS not only face an increased risk of TB, but have a higher rate of extrapulmonary disease. With the advanced immune deficiency and new apical lung nodule, the positive AFB stain of the tissue indicated a high probability of tuberculosis. The diagnosis of tuberculous pyomyositis may be delayed due to imaging similarities to abscesses or pyogenic myositis. Initiation of RIPE therapy, even after effective surgical drainage, is critical to prevent recurrence. When considering slow-growing soft tissue masses in patients with a high-risk for TB, it is important to involve specialists early in order to guide empiric therapy while awaiting confirmatory testing.

A CASE REPORT OF EPSTEIN - BARR VIRUS (EBV) MUCO-CUTANEOUS ULCER OF THE COLON SECONDARY TO AGE-RELATED IMMUNOSENESCENCE PRESENTING AS INFLAMMATORY MASS.

Mohammed Osman[1, 2]; Mohammed Al Salihi[1, 2]; Emad Abusitta[1, 2]; Samer Al Hadidi[1, 2]. [1]Hurley Medical Center, Flint, MI; [2]Michigan State University, Flint, MI. (Control ID #2688834)

LEARNING OBJECTIVE #1: Recognize the new entity of EBV associated muco-cutaneous ulcer as part of the spectrum of EBV lymphoproliferative disorders.

LEARNING OBJECTIVE #2: Recognize that EBV muco-cutaneous ulcer can present as inflammatory colonic mass.

CASE: A 64 year old Caucasian female presented to the hospital referred from her Gastroenterologist for further investigations with the main concern of carcinoma of the colon or chronic bowel ischemia. Initially she presented to her Gastroenterologist with the complaints of abdominal pain and intermittent diarrhea of one year duration. The patient described colicky abdominal pain, poorly localized to the left side of the abdomen, increased in intensity after meals. She reported losing ten pounds over the past 6 months. Abdominal examination revealed tenderness over the left upper quadrant with normal bowel sound. The patient lab investigations were significant for Hemoglobin of 10.8 (Ref: 12-16G/DL), MCV 85(Ref: 80–100 Fl), MCH 27(Ref: 26–34 PG). The patient had a colonoscopy which showed partially necrotic, ulcerated, soft, tumor obstructing the lumen of the proximal transverse colon. Multiple biopsies were taken and she was then transferred to the hospital. At the hospital the patient had a Computed tomography (CT) of the abdomen which showed wall thickening of the cecum and terminal ileum and mildly prominent mesenteric lymph nodes. The results of biopsies which were taken during colonoscopy showed focal ulceration with granulation tissue formation. The patient was continued to be managed conservatively but her symptoms persisted so a decision was made to go for exploratory laparotomy, during the procedure there was an inflammatory mass at the cecum. Due to the finding it was decided to procced with right hemicolectomy. After the surgery the patient symptoms improved. The results of the histopathology came back as EBV positive lymphoproliferative disorder best classified as EBV positive muco-cutaneous ulcer.

IMPACT: The case will add to the literature the fact that a rare presentation of EBV muco-cutaneous ulcer can be associated with inflammatory mass which can mimic cancer.

DISCUSSION: EBV-positive muco-cutaneous ulcer (EBVMCU) was first described and proposed as a distinct clinical entity in 2010 by Dr. Elaine Jaffe's group at the National Cancer Institute. They described 26 cases in which patients exhibited a common clinical presentation of muco-cutaneous ulcers that had a unique histology and immunophenotype among EBV-associated lymphoproliferative disorders. Since then many case reports described (EBVMCU) usually in the setting of immunosuppression which can be primarily, Iatrogenic or age related immunosenescence. Most of these ulcers have an indolent course, although in some cases it can progress to other forms of EBV lymphoproliferative disorders. In our case we describe an unusual presentation of (EBVMCU) which created confusion and raised the concern of cancer due to associated inflammatory mass and subsequently led to invasive intervention.

A CLOSTRIDIAL CONSEQUENCE OF COLONOSCOPY

Jonathan Feld; Andrew J. Hale. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #2708276)

LEARNING OBJECTIVE #1: Identify spinal infection as a source of back pain after lower gastrointestinal endoscopic procedures

LEARNING OBJECTIVE #2: Recognize *Clostridium perfringens* as a rare pathogen causing discitis and spinal osteomyelitis

CASE: A 65 year-old woman presented with one month of worsening lower back pain. Ten months prior to admission she developed severe lower back pain, and was found to have L5 nerve root impingement on magnetic resonance imaging. She had mild improvement with conservative management. She then developed hematochezia one month prior to admission, and colonoscopy showed bleeding from internal hemorrhoids. On presentation, the patient developed acute worsening of her lower back pain. Vital signs were significant for tachycardia. On exam, the lumbar spine was tender and warm, and she had pain with movement. She had no sensory deficits or incontinence of the bowels or bladder. She denied any intravenous drug use or spinal procedures. Labs were significant for an erythrocyte sedimentation rate of 95 and C-reactive protein of 146 mg/L. Magnetic resonance imaging of the spine showed discitis and osteomyelitis at L1-L2. She was started on broad-spectrum antibiotics and on hospital day three she underwent an L1-L2 vertebrectomy with fusion. Bone cultures grew *C. perfringens*. Antimicrobials were narrowed to ceftriaxone and metronidazole, and she completed an eight-week course. At two-month follow-up, the patient was ambulating without back pain and at her baseline functional status.

IMPACT: In managing lower back pain, many practitioners are familiar with red flag signs that suggest more timely imaging is necessary. Of importance, colonoscopy is absent as a risk criterion in common guidelines. Here we present an atypical vector for a rare pathogen causing osteomyelitis, presenting as acute on chronic lower back pain. Clinicians should maintain suspicion for underlying infection in patients with lower back pain who have recently had lower gastrointestinal endoscopic procedures.

DISCUSSION: In this case, we present a 65 year-old woman who developed a *C. perfringens* discitis and osteomyelitis after a colonoscopy performed one month earlier. The proposed mechanism of infection is iatrogenic subclinical damage to the colon, in which *C. perfringens* likely was residing and was able to cause bacteremia with consequent seeding of her spine. Vertebral osteomyelitis is a rare presentation for *C. perfringens*. Prior work has demonstrated that post-procedural bacteremia occurs in 2.2% of colonoscopies, though it is typically clinically insignificant. The patient's longstanding back injury likely meant she had abnormal spinal anatomy, which may have predisposed her to bacterial seeding of the site. Lower back pain is the second most common reason for all physician visits in the United States. Additionally, colonoscopy is one of the most common medical procedures. Although the differential diagnosis for lower back pain is broad, complications related to recent colonoscopy are rarely ever reported or considered.

A COMMON UNCOMMON CAUSE OF CARDIAC ARREST

Richard J. Silvera; Darlene LeFrancois. Montefiore Medical Center, New York, NY. (Control ID #2707400)

LEARNING OBJECTIVE #1: Recognize anaphylaxis as an atypical cause of cardiac arrest

LEARNING OBJECTIVE #2: Identify a characteristic presentation of Indolent Systemic Mastocytosis (ISM)

CASE: 57 year old woman presented with abdominal pain for 5 days accompanied by non-bloody diarrhea "too numerous in episodes to count", subjective fevers, and nausea with 2 episodes of vomiting. She has a history of recurrent prolonged episodes of abdominal pain and diarrhea over the last 4 years reportedly diagnosed as diverticulitis, a severe NSAID and aspirin allergy (immediate pruritus and pre-syncope), memory complaints, and "migraine" headaches. Her exam was only notable for mild generalized abdominal tenderness. Imaging revealed diffuse colitis. Soon after cefoxitin, metronidazole, and morphine she experienced nausea, chest pain, and shortness of breath, became pale, and unresponsive. Advanced cardiac life support was initiated for pulseless electrical activity; return to spontaneous circulation was achieved in 10 min. Serum tryptase 4 hours post-event was 150 ng/mL; subsequent measurements 2 and 11 days later were 29 ng/mL and 35 ng/mL. Bone marrow biopsy revealed the *KIT* D816 mutation and elevated mast cell count, yielding a diagnosis of ISM.

IMPACT: Anaphylaxis, often associated with allergy, can also be caused by systemic mastocytosis. In addition, chronic mast cell mediator release can yield chronic gastrointestinal, musculoskeletal, and neuropsychiatric complaints.

DISCUSSION: SM is an uncommon disease characterized by dense infiltration of mast cells in the bone marrow or another tissue with elevated serum tryptase, *KIT* D816 mutation, atypical mast cells, or atypical function of peripheral mast cells. The most common subtype of SM, ISM, represents 60% of cases and generally follows a benign course, conferring neither elevated risk of hematologic malignancy nor tissue destruction. SM typically presents in adults with symptoms of acute (explosive "allergic") and/or chronic mast cell mediator release, or mast cell infiltration of various organs. Acute mast cell degranulation symptoms include flushing, pruritus, nausea, vomiting, diarrhea, muscle pain, palpitations, syncope or near-syncope, headache, and fatigue. A variety of triggers may precipitate release: exercise, temperature extremes, alcohol, infection, emotional distress, insect stings, and medications including antibiotics, opioids, muscle relaxants, and iodized contrast. Chronic mast cell release can yield chronic gastrointestinal complaints like abdominal pain and diarrhea (reported in 80% of SM patients), neuropsychiatric issues with memory, mood, or headaches, and musculoskeletal problems such as bone pain or osteoporosis. This case represents a characteristic presentation of ISM. We theorize that this patient's symptoms of colitis, headaches and memory issues, recurrent anaphylaxis-like episodes with NSAIDs, and her acute vascular collapse were likely triggered by medications; all secondary to mast cell mediator release due to ISM.

A COMPLICATED CASE OF P. OVALE MALARIA…YES IT CAN HAPPEN! Nabila S. Azad; Paul Long; Edward C. López. Boston Medical Center, Boston, MA. (Control ID #2704078)

LEARNING OBJECTIVE #1: Diagnose delayed-onset *Plasmodium ovale* malaria in a returning traveler.

LEARNING OBJECTIVE #2: Recognize pancytopenia as an unusual presentation of *Plasmodium ovale* infection.

CASE: A previously healthy 27-year-old female nurse presented to the hospital with eight days of fevers, chills and malaise. She had returned from a two-year trip to Zambia and Tanzania about six months prior, where she had taken prophylactic antimalarials for part of her stay. She presented to her primary care physician's office three days prior to admission where she tested negative for influenza A/B and EBV. Because of worsening symptoms, she presented to the ER. Initial vitals were notable for temperature of 101 F, blood pressure 76/45 mmHg, and pulse 120 beats per minute. Physical exam was remarkable for pallor and splenomegaly. Labs showed total white blood cell 1700/UL, hemoglobin 10.7 g/dL and platelets 35,000/UL. Work-up for infectious causes including HIV infection, anaplasmosis, ehrlichiosis, Lyme disease and babesiosis was negative. Although, malaria antigen was also negative, blood smear was positive for 0.9% parasitemia. She was started on oral artemether-lumefantrine. Despite therapy, pancytopenia worsened, notably for an absolute neutrophil count of 500/UL. Her bloodstream parasites were identified as *Plasmodium ovale* (*P. ovale*) and later confirmed by the Centers for Disease Control and Prevention. She was discharged after a three day course of artemether-lumefantrine. She was readmitted to another hospital within two weeks with fevers and was empirically treated with oral atovaquone-proguanil. Of note, during the second admission her blood counts were within normal limits and serial blood smears were negative for malaria. She later successfully completed a fourteen day course of primaquine.

IMPACT: This case emphasizes the importance of a detailed travel history when evaluating patients with fever and hematologic abnormalities, as *P. ovale* malaria can present late. Rarely, *P. ovale* can cause marked pancytopenia and these patients require close monitoring in the hospital.

DISCUSSION: It is important to be aware of species of Plasmodium that can remain latent for weeks to months, such as *P. ovale*, *P. vivax* and *P. malariae*. Cases of delayed primary *P. ovale* attack have been reported as late as 4 years after exposure. The delayed presentations of *P. ovale* are more commonly seen in travelers previously exposed to antimalarial agents. There are case reports of *P. ovale* causing mild leukopenia and thrombocytopenia. However, cases with neutropenia and severe thrombocytopenia with platelets <50,000 are rare. Although pancytopenia is not part of the criteria used to define severe malaria, its presence raises the question about the parasite burden in infected patients. Currently, the mechanism of pancytopenia in malaria remains unknown. A hyper-inflammatory state leading to bone marrow suppression and/or cellular destruction in response to the parasites may play a role in producing pancytopenia.

A CURIOUS CASE OF CONSTANT SNACKING Nicholas Hendren[1]; Timothy J. Brown[1]; Thalvinder Sangha[1]; Jonathan Weissler[2]. [1]University of Texas-Southwestern, Irving, TX; [2]University of Texas-Southwestern, Dallas, TX. (Control ID #2700273)

LEARNING OBJECTIVE #1: Manage a medical regimen for hypoglycemia due to an insulinoma

LEARNING OBJECTIVE #2: Recognize Whipple's triad

CASE: A 53 year-old woman presented with two years of worsening episodic tremors, sweating, weight gain and confusion that rapidly improved with juice (Whipple's triad). This led to nearly constant snacking. Labs revealed elevated levels of serum insulin, serum proinsulin and serum C-peptide. Computed tomography (CT) of the abdomen revealed a pancreatic tail mass and numerous masses in the liver measuring up to 10 cm concerning for metastatic malignancy. Upon review of prior CT scans, it appeared the pancreatic mass was present for at least six years. Given her symptoms consistent with Whipple's triad, an elevated endogenous insulin level and abdominal masses, she was diagnosed with a metastatic insulinoma. A liver biopsy was consistent with a well-differentiated neuroendocrine tumor (WHO grade 2). The burden of her disease precluded surgical management, necessitating medical management. Her blood glucoses were initially stabilized with subcutaneous octreotide injections and diazoxide tablets. At endocrinology follow-up, she was transitioned to monotherapy with pasireotide long-acting release 60 mg subcutaneous monthly injections which provided sustained control of her blood sugars at one month clinc follow-up.

IMPACT: Insulinoma-induced hypoglycemia is a rare, but important condition that should be considered in the differential of hypoglycemia that is readily identified classically by Whipple's triad. Insulinoma-induced hypoglycemia treated with long-acting pasireotide injections has rarely been described in the literature. Our case demonstrates a classic case of symptomatic hypoglycemia managed with monthly pasireotide injections with an adequate clinical response.

DISCUSSION: Insulinomas have an incidence of 4 cases per 1 million patient-years and are benign in more than 90% of cases. Curative treatment of these tumors is usually surgical, with medical therapy available for those who are not surgical candidates. Such patients typically have a median survival of less than two years. In patients presenting with symptomatic hypoglycemia, medical therapy must be initiated. Frequent carbohydrate meals and diazoxide is effective in reducing hypoglycemic symptoms in 50–60% of patients. Unlike benign insulinomas, 70% of malignant insulinomas express a somatostatin receptor and respond to somatostatin analogues. Lanreotide and octreotide are somatostatin analogues that have demonstrated efficacy in reducing hypoglycemia. Metastatic insulinomas are rarely treated with long-acting pasireotide injections to control hypoglycemia with sparse literature documenting clinical use. Pasireotide could potentially improve glycemic control compared to shorter-acting analogues given the difference in half-life and reducing medication burden for patients. This clinical case supports further investigation of pasireotide for management of symptomatic hypoglycemia due to an insulinoma.

A CURIOUS CUTANEOUS CASE FROM CENTRAL AMERICA Rahul Kamath; Ekta Kakkar; Stephen B. Greenberg; Laila Woc-Colburn; Rosa Schmidt. Baylor College of Medicine, Houston, TX. (Control ID #2702271)

LEARNING OBJECTIVE #1: Recognize, diagnose, and manage patients with cutaneous leishmaniasis

CASE: A 28-year-old male Cuban immigrant with no past medical history presents to the emergency department (ED) with a chronic, worsening wound on his left knee. The lesion began as a papule three months prior to admission during travel through several Central and South American countries including Panama and grew into an ulcer associated with occasional pruritus. Treatment with oral and topical antibiotics in Panama was ineffective. At initial presentation in the ED, physical exam revealed a 7.5 centimeter × 6.0 centimeter diameter painless, crusted ulcer with surrounding induration and firm plaques. He was subsequently seen in Dermatology clinic four days after initial presentation, where a punch biopsy revealed non-caseating granulomatous dermatitis. Dermatology suspected he had a deep fungal or mycobacterial infection, but treatment with empiric minocycline and fluconazole failed to resolve the lesion. Ultimately, acid-fast bacilli and fungal cultures were negative and bacterial cultures were positive only for coagulase negative staphylococci susceptible to minocycline. Suspicion for cutaneous leishmaniasis was high and tissue specimen from a repeat biopsy sent to the Centers for Disease Control and Prevention yielded a positive real-time polymerase chain reaction (PCR) for *Leishmania* with DNA sequencing positive for *Leishmania panamensis*. Treatment was initiated with liposomal amphotericin B at three mg/kg/day for five days. He was to return for two further infusions but was unfortunately lost to follow-up.

IMPACT: Cutaneous leishmaniasis should always be on the differential for patients with skin wounds and recent travel in Central and South America, especially when antibiotics do not improve the lesion. New world cutaneous leishmaniasis, which includes infection by *L. panamensis*, has a prolonged course and increased severity compared to old world cutaneous leishmaniasis. Biopsy for diagnosis has a high specificity but low sensitivity for diagnosis, and can reveal dermal inflammation, granulomas, and sometimes the amastigotes themselves. Confirmation by PCR is often necessary.

DISCUSSION: The *Viannia* subgenus of *Leishmania*, which includes *L. panamensis* and *L. braziliensis*, are the most common causes of New World mucocutaneous leishmaniasis. Studies show that mucocutaneous leishmaniases can present months to years following a cutaneous lesion, perhaps supporting the need for early systemic therapy. Thus, while treatment guidelines for leishmaniasis remain unclear, speciation can aid in determining treatment type and modality. While local therapy with paromomycin ointment or intralesionsal antimonials is an option, the size of our patient's lesion and the species' association with mucosal leishmaniasis led us to choose systemic therapy. WHO guidelines recommend pentamidine, pentavalent antimonials, miltefosine, or liposomal amphotericin B; we chose the latter due to its ready availability.

A DEADLY COMPLICATION OF CONSTIPATION - STERCORAL COLITIS Shana T. Rakowsky; Andrew J. Hale. Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #2709517)

LEARNING OBJECTIVE #1: Stercoral colitis is an important complication of chronic constipation and can result in significant morbidity and mortality

LEARNING OBJECTIVE #2: Constipation and stercoral colitis should be considered in elderly patients with altered mental status or sepsis

CASE: A 95 year-old woman residing in a nursing home presented with altered mental status and fevers. Per report, she had not passed a bowel movement for the preceding three days. Her physical exam was remarkable in that she was lethargic, had dry mucous membranes, and tenderness to palpation across her lower abdomen with a firm mass appreciated. She was

started on intravenous fluids and broad-spectrum antibiotics. Extensive infectious work-up was negative. Due to concern for malignancy given the firm mass in her abdomen, a computed tomography scan was obtained. This revealed a massively distended rectosigmoid colon with stool impaction and perirectal stranding, consistent with severe stercoral colitis. Manual disimpaction and a bowel regimen were attempted. However, despite these interventions, she had ongoing septic physiology. Surgery was consulted and felt a hemi-colectomy may be needed given the degree of ischemia. After extensive discussions, the family opted for non-invasive management and the patient's care was transitioned to comfort focused measures.

IMPACT: Constipation is a common occurrence among adults older than 50 years and is commonly encountered in both primary care and the inpatient setting. Risk factors for developing constipation in this population include female gender, increasing age, living in institutionalized setting, frequent hospitalizations, and depression. Constipation can manifest as delirium in the elderly patient and can lead to severe complications.

DISCUSSION: Stercoral colitis is an important complication of constipation and can be life threatening. Stercoral colitis occurs when a large amount of stool becomes impacted in the colon, causing distention of the colonic lumen and resultant necrosis. Diagnosis can be made with computed tomography scan showing large fecal load associated with bowel wall edema or pericolonic fat stranding. Initial management includes manual disimpaction and bowel cleansing. In addition, endoscopy has a unique role to allow for direct visualization, breakdown, and lavage to encourage passage of stool. However, stercoral colitis is associated with a significant risk of mortality given the subsequent development of sepsis secondary to necrosis, ulceration or perforation. In these more severe cases, surgical intervention, such as bowel resection, is required to prevent serious consequences. Our patient presented with sepsis and altered mental status that was found to be from stercoral colitis, related to chronic constipation. Ultimately, this was a terminal condition without surgical intervention, which was not within our patient's goals of care. This case highlights that constipation, if left untreated, can result in significant morbidity and mortality.

A DEADLY CULTURE CLASH TO SAVE SOME CASH: TOXIC INGESTION OF FORAGED FOOD Andrew Simmelink. Carolinas Medical Center, Charlotte, NC. (Control ID #2706390)

LEARNING OBJECTIVE #1: Assess cultural traditions in immigrant populations affecting public health

LEARNING OBJECTIVE #2: Recognize the symptoms and severity of toxic food ingestion

CASE: A 28yo Burmese female presents with painless jaundice. One week after arriving in the U.S. she developed joint pain, fatigue, and vomiting, progressing in 1 week to jaundice and dark urine, denying any sick contacts, confusion, diarrhea, drug, tobacco, alcohol, prescribed or OTC meds including herbals. Examination revealed a fully alert and oriented Asian lady with stable vitals, ocular jaundice, and a soft, nontender, nondistended abdomen without hepatosplenomegaly. Labs included: an unremarkable CBC, INR 1.2, unremarkable BMP, lactic acid 5.0 mM, albumin 2.9 g/dL, total bilirubin 12.8 mg/dL, direct bili 7.8 mg/dL, ALP 242, ALT 2102, AST 1728, GGT 127, Ferritin 1039 ng/mL, negative hepatitis panel, HIV, EBV, & CMV PCRs, positive ANA 1:640 speckled pattern, negative anti-mitochondrial Ab and anti-smooth muscle-Ab, and normal alpha-1-antitrypsin and ceruloplasmin levels. RUQ ultrasound showed a normal gallbladder without pericholecystic fluid, ductal pathology, or ascites, with a patent portal vein, and a normal liver. Liver biopsy showed a cholestatic liver with portal & lobular inflammation, ceroid-laden microphages, and apoptotic hepatocytes without biliary proliferation, iron, PAS globules, and trichrome stain with focal sinusoidal fibrosis. Not until discharge did she admit scavenging mushrooms prior to symptom onset, due to similar appeance of safe mushrooms in Burma.

IMPACT: This revealed the broad geographic area Aminata phalloides thrives in, and to keep in mind cultural traditions as catalysts for sickness

DISCUSSION: This patient suffered from toxin-induced acute liver injury. Though the exact cause is unknown, clues exist. Pathology showed patterns of acute toxin induced liver injury, while autoimmune/infectious etiologies were less likely due to testing. Next is the scavenging timeline and recognition of the mushroom. The suspected culprit aminata phalloides "death cap" accounts for >90% lethal ingestions. However, >50% have no symptoms even if ingested, resulting in >85% ingestions undiagnosed. Amanita has a wide distribution spanning Europe, Asia, Africa, and the entire Americas, with 28 species. Two main toxins include amatoxin & phalloidin: phallotoxin disrupts enterocyte membranes, while amatoxin inhibits hepatocyte protein synthesis. Aminata induced acute liver failure survival is 85%, with 46% spontaneous, while toxin-induced acute liver injury has 100% survival, with 80% spontaneous not requiring liver transplant (LT). Treatment is supportive, with adjuncts of dialysis, N-acetylcysteine (NAC), high-dose penicillin and silibinin, and LT in severe status 1 UNOS cases. Nearly 90% receive NAC for reactive oxygen species reduction despite skant evidence. Despite resected livers demonstrating 0-30% viability, many cases of multi-system organ failure survive without LT, emphasizing an optimal strategy is still not defined.

A DEADLY MUCOR AFFECTING AN IMMUNOCOMPETENT PATIENT Naomi Habib[2]; Mohit Pahuja[1]; Samir Allos[2]; Andrew Little[3]; Salaheddine Tomeh[4]; Omar Gonzalez[2, 5]. [1]St. Josephs Hospital and Medical Center, Phoenix, AZ; [2]St Joseph's Hospital and Medical Center/Creighton University Medical School, Phoenix, AZ; [3]Barrows Neurological Institute, Phoenix, AZ; [4]St Joseph's Hospital and Medical Center, Phoenix, AZ; [5]St. Joseph's Hospital and Medical Center, Phoenix, AZ. (Control ID #2706725)

LEARNING OBJECTIVE #1: Recognize that *Apophysomyces spesis* (*AS*) is a rare form of mucor that can cause devastating disease and preferentially affects immunocompetent individuals.

CASE: A 44-year old male farmer developed facial edema, fevers and chills after a dental procedure in Mexico, progressing to left eye blindness despite antibiotics. On presentation, he had left side proptosis with fixed left pupil, absent extraocular movements, and trismus. Laboratory revealed WBC = 31,300. MRI head showed infected paranasal sinuses involving left orbital, temporomandibular joint and masticator spaces with soft tissue edema, in addition to ischemic optic neuritis, orbital cellulitis and abscess posterior to the pituitary gland. He underwent left maxillary antrostomy and ethmoidectomy followed by left eye enucleation. He received broad-spectrum antibiotics and dual antifungal coverage (Isavocunazomium and liposomal Amphotericin B). In the next 24 hours, his soft palate became necrotic and he lost right eye vision and pupillary reflex. An MRI revealed right orbital abscess and right optic infarct. He underwent right eye exenteration, tracheostomy and radical upper maxillectomy. Surgical specimens submitted for microbiology and pathology revealed the presence of mucormycosis (MS), with *AS* confirmed by polyfungal DNA analysis. Despite treatment with

double antifungal agents his mental status remained compromised and a follow-up MRI demonstrated extensive vasculitis with cavernous sinus thrombosis, left internal carotid stenosis and worsening cerebritis. He required an endovascular neurosurgical intervention. His current clinical status remains stable; he is now on isavocunazonium monotherapy due to renal insufficiency with liposomal Amphotericin B (received 4 weeks).

IMPACT: Clinicians should maintain a low threshold of suspicion for *AS* in the setting of rapidly progressive necrotizing infection in immunocompetent patients, as this is a medical-surgical emergency with high mortality.

DISCUSSION: MS is the second most common cause of fungal infection in immunocompromised patients with 40–70% mortality despite treatment. In 70–80% of cases, MS is caused by *Rhizopus*, *Mucor*, and *Lichtheimia* strains. *AS* occurs in <1% of cases, and is unique in that it affects mainly immunocompetent individuals (50–75%). Though rare, it is ubiquitous in soil and vegetation. Infections occur most commonly with traumatic inoculation, and 11 iatrogenic *AS* infections have been reported (secondary to surgery, IM or SC injections, and skin tests). Our patient is a farmer who worked in direct contact with vegetation, and hence it is unclear whether he self-introduced the infection or it was iatrogenic. MS is an angio-invasive disease that causes thrombosis and ultimately tissue necrosis. Nerve invasion is reported with AS. Common infection sites reported with AS are cutaneous and subcutaneous, mainly in the thorax and extremities. Rhino-orbital infections are less common but occur more frequently in immunocompetent patients.

A DECEPTIVELY ORGANIZED LUNG MASS Cuong H. Quach; Sarah Lagedrost; Sheira Schlair. Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY. (Control ID #2703860)

LEARNING OBJECTIVE #1: Recognize organizing pneumonia (OP) as a cause of lung mass.

LEARNING OBJECTIVE #2: Describe the clinical features and management of OP.

CASE: A 73 year-old man presented to the hospital with 1–2 months of progressive dyspnea on exertion. History was notable for a 68 pack-year smoking history, COPD, and PVD. He had decreased breath sounds at the right middle and lower lung fields, and rales in the left lower field. Chest x-ray revealed a large free-flowing right-sided pleural effusion. Thoracentesis drained 1.1 L of serous fluid with 30,000 RBCs and LDH of 491 U/L, consistent with an exudate. Cytology showed rare atypical cells thought likely reactive mesothelial cells. Chest CT demonstrated a heterogeneous necrotic mass in the right hemithorax, as well as right upper lobe nodules and a left lung opacity, accompanied by slightly enlarged para-aortic, paratracheal, hilar and subcarinal lymph nodes. CT-guided core needle biopsy demonstrated repeat cytology negative for malignant cells, and showed no carcinoma or granulomas but revealed bronchiolitis, focal intraalveolar hemorrhage, foamy macrophages and reactive pneumocytes. Stain for acid fast bacilli was negative; the impression was organizing pneumonia (OP).

IMPACT: Lung mass is a frequent clinical problem, and maintaining a broad differential is imperative to obtain an accurate diagnosis. In this patient, pleural fluid cytology did not reveal malignancy, and biopsy revealed OP. While this patient may ultimately be diagnosed with malignancy with secondary OP, this case illustrates the broad differential diagnosis of lung mass, as well as the need to consider underlying etiologies of OP when it is discovered.

DISCUSSION: OP is a nonspecific inflammatory reaction, sometimes secondary to such conditions as connective tissue disease, malignancy, drugs, infection, or pulmonary infarction. When there is no identifiable underlying cause, as in many cases, it is classified as cryptogenic OP. Features of OP include fibroblastic buds of granulation tissue and foamy macrophages in the bronchioles and alveolar ducts and spaces. On high resolution CT, its distribution is often patchy and peribronchiolar; however, a subset of OP termed "focal organizing pneumonias" may be radiographically indistinguishable from primary and metastatic lung tumors. Such focal OP may appear on chest CT as round or oval nodules or masses with irregular margins. Cryptogenic and secondary OP can be diagnosed with BAL and transbronchoscopic biopsy, and also with video-assisted thoracoscopic surgery if needed. Focal OP usually requires biopsy to rule out malignancy. Many patients treated with steroids for cryptogenic and secondary OP typically do well, although those with secondary OP require a longer course. Focal OP does not require steroid therapy. General practitioners should consider organizing pneumonia as a possible etiology of lung mass, and a diagnosis of organizing pneumonia should generate a search for underlying causes.

A DEFICIENCY IN Z59.0 Amir Meiri[1]; Matthew Moll[4]; Amresh D. Hanchate[3]; Michael Paasche-Orlow[2]. [1]Boston Medical Center, Boston, MA; [2]Boston University, Boston, MA; [3]Boston University School of Medicine, Boston, MA; [4]Brigham and Women's Hospital, Boston, MA. (Control ID #2702583)

LEARNING OBJECTIVE #1: Describe the implications of failing to include homelessness in the CMS readmissions penalty risk adjustment

CASE: A 65-year-old homeless Hispanic male presented with 2 days of productive cough and fever. His physical exam was notable for: RR 24 br/m, O2 sat 88% on 4 L NC and crackles in his lung bases. His labs were notable for: WBC 11.9×10^9 cells/L, lactate 2.4 mg/dL, BNP 161 pg/mL and negative troponins. The CXR showed diffuse lung opacities, suspicious for multifocal pneumonia, and the CT pulmonary angiogram was negative for pulmonary emboli. The patient has been homeless for 10 years and moved to Boston from Miami four months earlier. He was discharged two days prior with improving pneumonia symptoms after IV antibiotics and a prescription for oral antibiotics; however, his medications were stolen at the shelter. The patient was discharged again with antibiotics in hand, but no further contingencies.

IMPACT: The case illustrates a limitation of the Hospital Readmission Reduction Program (HRRP), due to the absence of homelessness in the risk adjustment calculation. It provides an opportunity to introduce a national health policy concern and potential remedies for improvement.

DISCUSSION: This case demonstrates how homelessness can cause early hospital readmission, and reflects the implications of billing and coding. The Boston homeless population is 3.8 times more likely to return within 30 days compared to housed Medicaid patients. This case highlights an important limitation of CMS's Hospital Readmissions Reduction Program (HRRP). Under the HRRP CMS penalizes hospitals with the highest rates of 30-day readmissions. The calculation CMS uses to compare hospitals adjusts for age, sex, and comorbidities but fails to include homelessness. The absence of homelessness in the calculator unfairly penalizes safety-net hospitals, as seen with higher rates of penalization for these hospitals post-ACA. Safety-net hospitals need more funding to care for such patients - not less. The example of homelessness is an extreme exhibition of this problem. The absence of homelessness from the CMS calculation contributes to an unintended consequence of this program as currently administered - worsening health equity. HRRP runs primarily off billing codes. The calculator could be modified by incorporating ICD-

10 code Z59.0, homelessness and its variants. The extent to which providers report this code is unclear. However, inclusion of Z59.0 into the risk adjustment would incentivize hospitals to report this status, triggering improved screening and coding for homelessness and reduce unfair penalties for safety-net hospitals. This would be a step in the right direction, but would likely be insufficient to reduce avoidable readmissions for homeless patients. A combined approach of correcting the risk-adjustment algorithm and incentives for safety-net hospitals to improve post-discharge services for homeless patients is likely to decrease readmissions, cost, and improve health equity and outcomes.

A DEMYELINATING DRUG Nabil D. Baddour; Ahmed G. Mohiuddin; Jenny M. Ngo. Tulane University, New Orleans, LA. (Control ID #2705128)

LEARNING OBJECTIVE #1: Recognize the association of demyelinating disease and TNF α-inhibitors

LEARNING OBJECTIVE #2: Demonstrate the diagnostic difficulty of distinguishing demyelinating disorders

CASE: A 35-year-old man with a history of rheumatoid arthritis (RA) developed lower extremity weakness for 5 days. Symptoms progressed to include bowel and bladder incontinence. Medications included weekly adalimumab for the previous 8 months. On exam, he described numbness from his hips downward and a positive Lhermitte's sign. Motor strength in the lower extremities was diminished with positive clonus bilaterally and decreased rectal tone. MRI of the brain and spine revealed multiple non-enhancing lesions scattered throughout the hemispheric white matter and all levels of the spine. CSF analysis yielded elevated IgG, total protein and oligoclonal bands. A diagnosis of demyelinating disease secondary to TNF α-inhibition was suspected. Adalimumab was discontinued and a 5-day course of IV methylprednisolone followed by oral prednisone taper was initiated. The patient was discharged to inpatient rehab for 3 weeks with complete resolution of symptoms.

IMPACT: TNFα-inhibitors have greatly improved clinical outcomes for patients suffering from rheumatologic disease. While neutropenia and increased risk of opportunistic infections are well-known side effects of these medications, there are an increasing number of reports of demyelination and multiple-sclerosis (MS) type syndromes.

DISCUSSION: In the past ten years, TNFα-inhibition associated demyelination has been reported in the literature. While the appearance of demyelination is evident on imaging, differentiating between MS-like demyelination and overt MS remains problematic. Pre-treatment MRI is not routinely obtained, so it is unclear whether these clinical findings are a result of a new process or unmasking of latent MS. A link between RA and MS has been suggested, but supporting data for this association comes primarily from the incidence of MS-like syndromes following TNFα-inhibition as described above. Our patient uniquely demonstrated this difficulty in diagnosis. Diagnostically, he demonstrated neurologic symptoms and multiple non-enhancing lesions in space, but not in time, thus failing to meet McDonald criteria for a diagnosis of MS. This case demonstrated a high likelihood of causal relationship based upon temporal association, improvement with removal of the medication, and biologic plausibility of TNFα-inhibitor induced demyelination. Given the efficacy of these drugs, internists should be aware of potentially adverse neurologic events in patients and discontinue TNFα-inhibitors should such ccomplications arise. Also internists may consider an MRI in patients prior to the initiation of therapy.

A DIAGNOSIS OF RARE SOFT TISSUE TUMOR PRESENTING AS UNILATERAL INGUINAL MASS Pojchawan Yampikulsakul[1]; Norbert Sule[2]; Pichapong Tunsupon[1]. [1]State University of New York at Buffalo, Buffalo, NY; [2]Roswell Park Cancer Institute, Buffalo, NY. (Control ID #2683889)

LEARNING OBJECTIVE #1: Discuss the differential diagnoses and malignant features of inguinal mass

CASE: 36 year-old man presented for evaluation of a left groin mass for a week. Patient concerned of an inguinal hernia as he had history of right inguinal hernia repair 10 years ago. He denied constitutional symptoms, unprotected sexual intercourse, dysuria or urethral discharge. Physical exam revealed a mobile, non-reducible left groin mass approximately 3 cm in diameter on both supine and upright position, firm consistency with mild tenderness to palpation. There was no cutaneous erythema or ulceration. Genital exam was normal. Neurological exam of the lower extremities was intact. HIV antibody test was negative. Patient was prescribed doxycycline for treatment of presumed infectious lymphadenitis. Further work up ultrasound of the left groin demonstrated 4 × 5 cm solid ovoid lesion with internal blood flow. Computed tomography of the abdomen demonstrated subcutaneous soft tissue mass at the superior aspect of the left inguinal region measuring 5 × 6 cm. The consistency of the lesion was homogeneous with area of focal hypodensity. Other inguinal and pelvic lymph nodes were normal. The left inguinal mass continued to enlarge despite treatment with antibiotic. The biopsy of the lesion revealed high-grade undifferentiated pleomorphic sarcoma. Patient was referred to oncologist for further evaluation.

IMPACT: The delayed diagnosis of soft tissue sarcoma is not uncommon because most of the etiologies of soft tissue mass are benign and painless. The delayed work up due to assumption of benignity will subsequently lead to poor outcome.

DISCUSSION: Inguinal mass is one of the most common chief complaints in primary care setting. The differential diagnoses include benign etiologies e.g. inguinal hernia, reactive lymphadenopathy, aneurysm and malignant tumor e.g. sarcoma, metastatic carcinoma, melanoma or lymphoma. In our case, the finding of non-reducible and firm consistency of the mass with the ultrasound finding are incompatible with inguinal hernia. The reactive lymphadenopathy is less likely, as there are no signs of infection. Thus, malignant tumor is highly suspicious. Pleomorphic sarcoma is a rare and aggressive tumor found predominantly in male gender age 30–80 years (mean 59 years). The United Kingdom Department of Health recommends urgent referral when 1) the soft tissue mass is more than 5 cm in diameter, 2) rapidly growing mass, 3) painful mass, 4) deep muscle fascia involvement, and 5) recurrence of a soft tissue mass after surgical resection. Among these factors, the depth of the tumor involvement was the most sensitive marker of malignancy, followed by size more than 5 cm and a history of rapid growth, all of which present in this patient. The most common anatomic distribution of soft tissue sarcoma is thigh, buttock and groin accounting up to 46%. Internists must be cognizant of the malignant features of the inguinal mass and prompt referral to diagnostic specialist.

A DIAGNOSTIC CONUNDRUM IN A CASE OF BACK PAIN
ShihFan Sun. UCLA, Los Angeles, CA. (Control ID #2701609)

LEARNING OBJECTIVE #1: Recognize the insidious nature of discitis/osteomyelitis caused by HACEK organisms.

CASE: An 89 year old female with hypertension, hyperlipidemia, presented to emergency room with 6 days of low back pain without clear inciting event. The

pain persisted at rest, worsened with movement and limited her mobility. NSAIDs or norco provided minimal relief. She denied symptoms suggestive of radiculopathy, cauda equina, or infection. Her medications included atorvastatin and amlodipine. She had no prior surgeries, volunteered at the hospital, and denied tobacco, alcohol and drug use. Her vital signs were within normal limits. Physical exam was notable for tenderness to palpation on right superior iliac crest, no midline tenderness, negative straight leg raise test, and no focal neurological deficits. Her initial labs showed leukocytosis to 15, otherwise unremarkable. CT abdomen and pelvis with contrast showed multilevel degenerative disc disease at the thoracolumbar spine without acute fracture or evidence of infection. Her urinalysis and chest x-ray were unremarkable. Her back pain was presumed to be musculoskeletal but was difficult to control. She was overly sedated on oxycodone and dilaudid. She was febrile on day 2 and 4 of hospitalization, which were attributed to aspiration pneumonitis in the setting of over sedation from narcotics. She was empirically treated with vancomycin and zosyn for one day. Her leukocytosis downtrended even before initiating antibiotics. TTE showed no vegetation. She was discharged on day 6 of hospitalization with stable pain regimen. Her blood cultures were negative to date on discharge. She was readmitted 10 days after discharge for Aggregatibacter Aphrophilus bacteremia, which resulted from previous blood cultures 6 days after collection. MRI lumbar spine with and without contrast showed L1-L2 discitis osteomyelitis with superimposed right psoas abscess without epidural abscess. She was treated with 6 weeks of ceftriaxone without complications.

IMPACT: This case raised my awareness of HACEK infections. This patient could have presented to a clinic without overt signs of infection, and been sent home with treatment for musculoskeletal pain. This case has challenged me to reevaluate my threshold in ordering further tests to differentiate benign and malignant causes of back pain in certain patient populations.

DISCUSSION: HACEK organisms are uncommon human infections, but are known to cause bone and joint infections, and infective endocarditis involving native valves. In one study, only 39% of patients with Aggregatibacter Aphrophilus infection recalled having recent dental procedure. Since back pain is a very common complaint in both inpatient and outpatient settings, it is important to recognize the insidious nature of HACEK infections, maintain a high index of suspicion for such infections, especially in older patients with refractory back pain, and follow up these patients closely so that timely treatment can be initiated if needed.

A DRESS TO IMPRESS Ashley Kang; Lynn Zaremski; Kimberly Cartmill. Montefiore Medical Center, Bronx, NY. (Control ID #2706751)

LEARNING OBJECTIVE #1: Identify cephalexin as a potential causative agent in DRESS.

LEARNING OBJECTIVE #2: Recognize the presentation and management of DRESS.

CASE: A 60 year-old woman presented to the hospital with five days of fever, odynophagia, dyspnea, and cough. A month prior to presentation, she was treated with IV antibiotics for cellulitis and discharged on cephalexin. Two weeks later, she developed a waxing and waning pruritic rash. On admission, the patient was febrile, tachycardic, and hypotensive (90/47) with a diffuse erythematous maculopapular rash. Labs included WBC 12.3, eosinophils 1.1, ALT 42. Levaquin, Flagyl, and vancomycin were started for suspected pneumonia. A week later she developed respiratory failure requiring intubation, biventricular heart failure, and acute kidney injury. Repeat labs showed WBC 25.2, eosinophils 7.0, and ALT 74. Methylprednisolone IV was started for drug reaction with eosinophilia and systemic symptoms (DRESS).

IMPACT: Cephalosporins are not commonly known to cause DRESS. In this case, cephalexin was new to the patient and fit the timeline of events. This case highlights that uncommon but life-threatening reactions can occur with initiation of any new drug.

DISCUSSION: DRESS is an immune response to a specific drug that typically presents two to eight weeks after the offending agent is ingested. Antiepileptics and sulfonamides are most commonly implicated, but antiretrovirals, antidepressants, and NSAIDs have also been reported. This case of DRESS with multi-organ involvement highlights cephalexin as a causative agent. The patient met RegiSCAR criteria for DRESS with fever over 38C, internal organ involvement, blood abnormalities, hospitalization, and rash with presumed inciting agent. While not fully understood, the pathogenesis involves an immune reaction by activated T cells. Visceral organ involvement occurs in approximately 90% of cases. Liver injury is most common (50–60%) and in severe cases can cause fulminant hepatic failure. Cardiac complications occur in up to 24% of patients, manifesting as hypersensitivity myocarditis or acute necrotizing eosinophilic myocarditis. Both can result in heart failure. The management of DRESS includes rapid identification and discontinuation of the inciting agent. However, patients may present with symptoms even after discontinuation. The cornerstone of treatment involves immunosuppression with corticosteroids. In more severe cases, IVIG and cytotoxic agents can be used. Complete recovery may take up to several months. Our patient was admitted with an initial diagnosis of severe sepsis, and anchoring bias may have delayed the initiation of corticosteroids. Physicians should recognize that cephalexin can cause DRESS and have a high clinical suspicion of this potentially deadly disease in any patient with rash, systemic involvement, and initiation of a new drug within the time frame.

A FAILURE OF COMMUNICATION IN A CASE OF TUBERCULOSIS PERICARDITIS Colleen Tenan. Weill Cornell Medical College, New York, NY. (Control ID #2703965)

LEARNING OBJECTIVE #1: Recognize the challenges and failures of communication with low English proficiency (LEP) populations, especially with regard to hospital discharge.

LEARNING OBJECTIVE #2: Assess how language barriers may hinder a patient's quality of care and adherence with follow-up.

CASE: A 49 year-old Mandarin-speaking man with a recent diagnosis of tuberculosis (TB), complicated by two recent admissions to an outside hospital (OSH) for pericarditis s/p pericardial window and peritonitis, presented with increasing SOB and lower extremity swelling. Physical exam was notable for tachycardia, decreased breath sounds at the R base, abdominal distention and 3+ pitting edema of bilateral lower extremities. The diagnosis of constrictive pericarditis was made on echo and cardiac MRI. OSH records noted a diagnosis of pulmonary TB based on sputum cultures, however the patient denied knowledge of this diagnosis. The patient's discharge paperwork, which provided crucial information regarding his discharge medications and clinic follow-up, was written exclusively in English. There was no record of the patient following-up with the infectious disease, liver or cardiology clinics, and although the Department of Health confirmed that the patient was started on RIPE therapy, he was off of his TB medications for one week prior to admission for unknown reasons.

IMPACT: Despite Section 1557 of the Affordable Care Act (ACA) mandating that qualified interpreters must be offered to all LEP patients (for both oral and written information), utilization of these services remains low in practice. Considering the number of important topics discussed with patients during discharge, it is especially crucial that pertinent discharge information be communicated to LEP patients in a manner he or she can understand.

DISCUSSION: Despite approximately 25.1 million people in the US classified as LEP, documented utilization rates of professional interpreter services among healthcare providers are frequently less than 50%. Multiple studies have demonstrated that LEP patients have an increased odds-ratio of being readmitted than English-speaking patients, and that LEP patients who have documented use of interpreter phones have, on average, shorter length of stay than those with no interpreter use. Additionally, it has been demonstrated that language barriers and inability to communicate with staff contribute to feelings of alienation and decreased likelihood of LEP patients vocalizing concerns while hospitalized. In response to this widespread problem, the ACA mandates that qualified interpreters be provided to all LEP patients and recommends against the use of friends/family members as interpreters. In practice, more funding is necessary to implement protocols for interpreter use with LEP patients, which will improve the quality of healthcare delivered to populations who have historically had limited access to care.

A FATAL CASE OF HEPARIN-INDUCED THROMBOCYTOPENIA COEXISTING WITH SECONDARY ANTIPHOSPHOLIPID SYNDROME. Tolulope Ogriki; Barry Fomberstein. Montefiore Medical Center, Bronx, NY. (Control ID #2706171)

LEARNING OBJECTIVE #1: Recognize the diagnostic dilemma associated with thrombotic vasculopathies.

LEARNING OBJECTIVE #2: Recognize the clinical features of Catastrophic Antiphospholipid Syndrome (CAPS).

CASE: A 65 year-old African American woman presented with 3 weeks of shortness of breath and reduced urine output. Blood pressure was elevated at 210/78 mmHg. Lung and extremity exams revealed bilateral crackles and pitting pedal edema, respectively. Labs were suggestive of Acute Kidney Injury requiring Hemodialysis. Hospital course was complicated by atrial flutter, splenic infarct, and thrombosis involving the skin, arteries, and veins. Intravenous Heparin was initiated, but was switched to Argatroban after she developed Heparin Induced Thrombocytopenia (HIT), confirmed by positive serotonin release assay, one month into admission. She also developed lower extremity ulcers and gangrene requiring right above knee amputation. Histology of the ulcers confirmed thrombotic vasculopathy with cutaneous infarcts. Immunology revealed positive antinuclear antibody, antismith antibody, Lupus anticoagulant, and Beta2 Glycoprotein IgA antibody, diagnostic for Systemic Lupus Erythematosus (SLE) and suggestive of Antiphospholipid Syndrome (APS). She received intravenous steroids for SLE. Intravenous Immunoglobulin (IVIG) and plasmapheresis were considered but not initiated as she did not quite meet the diagnostic criteria for CAPS. She continued to develop necrotic skin lesions and later developed sepsis, shock, respiratory failure, and died.

IMPACT: In clinical practice, some patients fail to meet the diagnostic criteria for APS and CAPS. Terms like “Probable CAPS” and “CAPS-like disease” have been used in literature for such patients. Treatment should be aggressive as soon as CAPS is suspected because delay may result in death. There may also be two disease entities existing together.

DISCUSSION: Hallmarks of APS are vascular thrombosis in the presence of antiphospholipid antibodies: Anticardiolipin antibodies (IgG +/− IgM), Anti-beta2 glycoprotein (IgG +/− IgM), and lupus anticoagulant. APS is confirmed if these antibodies remain positive twelve weeks after initial testing. APS may occur primarily or secondary to autoimmune diseases like SLE. CAPS describes a frequently fatal course seen in patients with APS; it causes widespread thrombosis, often leading rapidly to multi-organ failure. Other features are stroke, endocarditis, pulmonary embolism, glomerulonephritis, and osteonecrosis. An important differential diagnosis of CAPS is HIT because both are characterized by widespread thrombosis. HIT, however, causes thrombocytopenia in the setting of heparin exposure. It is crucial to make the distinction between HIT and CAPS as treatment is different. In HIT, heparin must be discontinued and another anticoagulant initiated instead. CAPS is treated with anticoagulants, glucocorticoids, plasma exchange, and IVIG. Rituximab and eculizimab may also be used. Mortality is significantly reduced if aggressive treatment is instituted promptly.

A FOCUSED PHYSICAL EXAMINATION: WHERE THE ANSWER LAY Ryuichi Sada[2]; Yuji Nishihara[2]; Sandra Y. Moody[1]. [1]Kameda Medica Center & UCSF/SFVAMC, Kamogawa City, Japan; [2]Kameda Medical Center, Kamogawa, Japan. (Control ID #2702990)

LEARNING OBJECTIVE #1: Remitting seronegative symmetrical synovitis with pitting edema (RS3PE) is frequently concurrent with malignancy.

LEARNING OBJECTIVE #2: Focused physical examination usually reveals important clues to the cause of illness even in the case of paraneoplastic rheumatic syndrome.

CASE: A 74-year-old male farmer with diabetic nephropathy and hypertension presented with a high fever, joint pain, and morning stiffness in both hands and shoulders. Daily fevers with difficulty walking and grasping items developed three weeks before admission. He performed his farm work without difficulty previously. One week before admission, he visited our clinic and reported 5-kg weight loss, anorexia, and bilateral leg edema. His medications included nifedipine, candesartan, omeprazole, metformin, sitagliptin, glimepiride, and acetaminophen. Sitagliptin was stopped because it can cause severe joint pain. On follow-up visit a week later, he had no improvement in his symptoms and was admitted for evaluation. On physical examination, he appeared uncomfortable. His temperature was 38.9 °C, blood pressure 114/54 mmHg, heart rate 101 per minute, and respiratory rate 16 per minute. He had a positive painful arc sign in both shoulders and a positive Prayer sign in both hands. He also had moderate (2+) pitting edema in both legs. Temporal artery palpation, skin, and heart sounds were unremarkable. Laboratory data revealed an alkaline phosphatase of 711 IU/L, serum creatinine 1.74 mg/dl, C-reactive protein 9.17 mg/dl, and HbA1c 6.8%. Urinalysis showed 1+ protein. Additionally, two sets of blood cultures, rheumatoid factor, anti-citrullinated protein antibodies, antinuclear antibody, and anti-neutrophil cytoplasmic antibody were negative. His presentation was compatible with RS3PE. However, we performed a focused physical examination to look for signs of malignancy and noted an enlarged submental lymph node (2 × 2 cm). Prostate exam was normal. Computed tomography confirmed enlarged submental lymph nodes. Upper and lower endoscopy was negative. Submental lymph node biopsy showed marginal zone B cell

lymphoma (MZBCL); bone marrow biopsy was negative. We started three cycles of rituximab 375 mg/m^2 and prednisolone 15 mg/day. He achieved clinical remission of both diseases after one year.

IMPACT: This case highlights the importance of malignancy screening in patients with RS3PE. A focused physical exam and judicious malignancy workup can aid in detecting concurrent malignancy in patients suspected of RS3PE.

DISCUSSION: To our knowledge, this is the first report of MZBCL mimicking RS3PE. RS3PE frequently presents as paraneoplastic rheumatic syndrome. Solid organ tumors involving genitourinary and gastrointestinal tracts mainly occur with RS3PE. Moreover, hematologic malignancies including lymphoma have also been reported as a main cause of paraneoplastic RS3PE. Clinicians should be aware of the risk of concurrent malignancy in patients with RS3PE.

A GOOD CONVERSATION STARTER: USING GONOCOCCAL PHARNYGITIS TO IDENTIFY MSM PATIENTS WHO MAY BENEFIT FROM PREP Elijah Douglass. NYP Cornell, New York, NY. (Control ID #2706366)

LEARNING OBJECTIVE #1: Diagnose gonococcal pharnygitis

LEARNING OBJECTIVE #2: Identify high risk patients who would benefit from PrEP

CASE: 28 y/o MSM presented to clinic with CC sore throat. He was seen at urgent care 1 week prior where he was diagnosed with strep pharyngitis and prescribed 1 week of amoxicillin. He continued to have a sore throat and odynophagia without evidence of systemic infection. Since his last clinic visit 3 months prior he had had 2 new sexual partners with whom he had unprotected receptive and insertive oral and anal intercourse. His last sexual contact was 2 weeks prior to the visit with a man he did not know. He had no known medical problems except genital chlamydia treated several years earlier and took no medications. Social history was significant for having sex with men, inconsistent condom use, and occasional use of MDMA and cocaine. Exam was notable for normal vitals, pharyngeal exudates and oropharyngeal erythema with no cervical lymphadenopathy. There were no genital or perianal lesions and no urethral discharge. Pharyngeal and rectal chlamydia swabs, GC/Chlamydia urine NAAT, RPR, and HIV RNA PCR were sent. He was empirically treated with single doses of IM ceftriaxone and PO azithromycin. Several days later his pharyngeal swab resulted positive for gonorrhea. The remaining labs, including HIV RNA PCR, were negative. At that time he was asked to return for a follow up visit to discuss pre-exposure prophylaxis (PrEP) and was eventually started on Tenofovir/emtricitabine (Truvada).

IMPACT: Gonorrhea is an uncommon cause of pharyngitis and should help identify a patient who is at high risk for other STIs. Initiation of PrEP should be discussed with MSMs at high risk for contracting HIV.

DISCUSSION: The CDC recommends offering/initiating PrEP in patients who are at increased risk of contracting HIV. The patient described above has multiple risk factors including: MSM status, multiple sexual partners, inconsistent condom use, drug use, and history of STIs. LGBT patients are less likely to interface with the healthcare system and providers should be sure to discuss PrEP once increased risk has been identified. Deferring to future visits leaves patients at high risk – PrEP may reduce the rate of HIV transmission by more than 95%. The decision to start PrEP should be a joint decision between provider and patient. It is important to discuss the routine monitoring required and to remind patients that while PrEP may decrease their risk of HIV it will not impact their risk of contracting other STIs and condoms are still the most effective way to prevent them. Follow up is recommended every three months for HIV, GC/chlamydia, syphilis, and, when appropriate, HCV testing. Serum creatinine should be measured initially and then every 6 months in patients without risk factors for renal disease. Gonorrhea is an uncommon cause of pharyngitis but should remain on the differential in patients at high risk. Treatment is the same as for genital infection: one time doses of IM ceftriaxone and PO azithromycin.

A GRAVE CASE OF JAUNDICE Nicholas F. Stienstra; Michael Schwartz; Lily Yan; Fausto Ortiz. Boston Medical Center, Boston, MA. (Control ID #2701035)

LEARNING OBJECTIVE #1: Identify the differential diagnosis for cholestatic hepatotoxicity

LEARNING OBJECTIVE #2: Treat thyrotoxicosis when thionamides are contraindicated

CASE: A healthy 35-year-old male presented with one week of painless jaundice. He reported pruritus, acholic stools, weakness, and palpitations. He denied fevers, abdominal pain, significant alcohol use, intravenous drug use, and high risk sexual behaviors. Examination revealed diffuse icterus, an enlarged thyroid, a fine tremor with outstretched arms, and no hepatosplenomegaly or abdominal tenderness. Labs revealed AST 135, ALT 270, alkaline phosphatase 370, total bilirubin 15.4 (direct 10.4), and INR 1.79. Work-up for intrahepatic etiologies was negative for viral infection, autoimmune hepatitis, primary biliary cirrhosis, Wilson's disease, and hemochromatosis. Abdominal ultrasound, CT, and MRCP showed no portal vein thrombosis, primary sclerosing cholangitis, choledocholithiasis, or neoplasm. Thyroid studies revealed an undetectable TSH (<0.01) and elevated T3, free T4, and thyroid stimulating immunoglobulin (596, 6.9, and 287 respectively). Thyroid ultrasound revealed an enlarged, hyperemic thyroid gland, consistent with Graves' disease. Methimazole and propylthiouracil were not initiated as thionamides can cause cholestatic and hepatocellular injury. Instead, alternative treatments were used: dexamethasone to inhibit peripheral conversion of T4 to T3, cholestyramine for pruritus and to lower circulating thyroid hormone, and potassium iodide to suppress thyroid hormone synthesis through the Wolff-Chaikoff effect (1,2). These medications normalized his thyroid hormone levels and LFTs which allowed for methimazole initiation as a bridge to definitive management with outpatient thyroidectomy.

IMPACT: This case teaches that endocrinopathies such as Graves' disease must be considered in the differential diagnosis of a patient with abnormal liver enzymes. Additionally, when thionamides are contraindicated due to cholestasis, thyrotoxicosis can be managed with glucocorticoids, potassium iodide, and cholestyramine.

DISCUSSION: Severe liver injury due solely to Graves' disease is rare. Cholestasis and hepatotoxicity have a broad differential which includes infection, autoimmune conditions, toxins, malignancy and genetic disorders. This case illustrates that hyperthyroidism must also be considered. In cases of preexisting liver injury precluding use of thionamides, alternative therapy with glucocorticoids, potassium iodide, and cholestyramine may be used as a bridge to definitive treatment. 1. Panzer C, Beazley R, Braverman L. Rapid preoperative preparation for severe hyperthyroid Graves' disease. J Clin Endocrinol Metab. 2004 May;89(5):2142–4. 2. Mercado M, Mendoza-Zubieta V, Bautista-Osorio R, Espinoza-de los Monteros AL. Treatment of hyperthyroidism with a combination of methimazole and cholestyramine. A GUT FEELING: THE DUNBAR SYNDROME Shelly Kakar[2]; Nikhil Seth[2]; Adam Slivka[2]; Amar Kohli[1]. [1]UPMC, Mars, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2702978)

LEARNING OBJECTIVE #1: To think beyond the usual algorithm for functional chronic abdominal pain.

LEARNING OBJECTIVE #2: Recognize the management and treatment for median arcuate ligament syndrome.

CASE: A 59 year-old female with a known history of type 2 diabetes mellitus and chronic abdominal pain who was evaluated for a one-day history of severe, constant abdominal pain. Her pain was acute, diffuse and radiated to her back. Of note, patient had multiple previous hospital admissions with similar presentations and was diagnosed as pain secondary to fibromyalgia/visceral abdominal pain. On exam, she was afebrile, hemodynamically stable, and in no distress. Her abdominal exam revealed mild diffuse tenderness and no abdominal bruit was auscultated. Lipase was elevated to 2296 IU/L. CT revealed peripancreatic inflammation and a hyper-dense blush concerning for an inferior pancreaticoduodenal artery pseudoaneurysm rupture. An angiogram was pursued, revealing a pseudoaneurysm of the inferior pancreaticoduodenal artery along with celiac axis compression. This finding was consistent with Dunbar Syndrome, also known as median arcuate ligament syndrome (MALS). Subsequently, she underwent coil embolization of the gastroduodenal artery (GDA). She had complete resolution of abdominal pain afterward and was discharged the following day.

IMPACT: Median arcuate ligament syndrome should remain on the differential for anyone presenting with recurrent abdominal pain without a comprehensive work up. Definitive treatment is surgery and most patients will respond immediately and chronic abdominal pain symptoms will resolve.

DISCUSSION: MALS is a rare syndrome, occurring in 0.4% of the population, and is most often seen in females between the ages of 30–50. It is characterized by postprandial pain, weight loss, and occasionally an abdominal bruit. MALS is thought to be due to external compression of the celiac artery by a fibrous attachment, the median arcuate ligament. In nearly 10–24% of cases, this ligament crosses anteriorly to the celiac artery, causing compression and pain over time. The pathophysiology of pain is unclear but thought to be related to foregut ischemia as a result of poor gastric arterial flow. In a case review, collateralization of the GDA can lead to pseudoaneurysm formation in 3–18% of patients. The risk of rupture has yet to be established but there is no correlation between the size of an aneurysm and rupture.The diagnosis of MALS is with imaging, usually through CT angiography displaying focal narrowing of the celiac axis. Conventional imaging would have missed this diagnosis therefore; advanced imaging is warranted in certain clinical scenarios. Treatment is surgical, involving diversion of the celiac artery from the MAL. In conclusion, MALS is a rare syndrome, with a constellation of vague foregut symptoms and characterized by compression of the celiac artery on contrast-enhanced imaging. Pseudoaneurysm formation and rupture is the most common complication and best managed with angiographic intervention.

A HAITIAN MAN WITH TONGUE SWELLING: CLINICAL REASONING AND DIAGNOSTIC CHALLENGES IN RURAL HAITI Kenneth Pettersen[1]; Jacquelin Pierre[1, 2]; Manoucheka Canlatte[2]; Robin S. Goldman[1, 2]. [1]UCSF-HEAL Initiative, San Francisco, CA; [2]Zanmi Lasante, Hinche, Haiti. (Control ID #2706282)

LEARNING OBJECTIVE #1: Recognize ways that academic teaching hospitals can partner with low-income countries to overcome diagnostic challenges

LEARNING OBJECTIVE #2: Appreciate the shifting global burden of disease from infectious to non-infectious causes

CASE: A 52-year-old Haitian man presented to a hospital in rural Haiti with 3 months of progressive swelling of the throat, lips, and tongue, followed by a papulonodular facial rash. He denied sick contacts, night sweats or fevers but endorsed weight loss, 5 months of low back pain, paresthesias in his leg and numbness in his hands. He had no past medical history and worked locally as a merchant. Exam revealed severe macroglossia, cheilitis and firm submandibular swelling without erythema or tenderness. Diffuse, hypopigmented papules and nodules were present across the entire face and axilla. Lesions were not pruritic, anesthetic, or painful. There was asymmetric, 2+ pitting edema of all extremities and polyarthritis of the wrists, MCPs, and PIPs. 4/5 strength was noted in the upper extremities with decreased sensation in the distribution of the bilateral median nerves and right posterior tibial nerve. Limited workup revealed a hemoglobin of 8.4 g/dL (MCV 78), a creatinine of 0.6 mg/dL and a normal urinalysis. He was HIV, PPD, and RPR negative. Chest X-ray was normal, and lumbar X-ray revealed compression fractures of L3-5 vertebrae. Given the presence of leonine facies, a skin biopsy and clinical summary were sent to a referral hospital in Boston for AFB stains to evaluate for leprosy, which were negative. Subsequent workup showed positive Congo red stain, suggesting the diagnosis of amyloidosis, likely AL subtype.

IMPACT: Amyloidosis was highly consistent with the findings of this case, including leonine facies, polyneuropathy, cheilitis, and macroglossia. If this patient presented to a hospital in the US, amyloidosis would have been high on the differential. Yet, biases toward infectious diseases likely led to a diagnostic delay. The shifting prevalence of disease in low-income countries towards non-infectious causes should be better reflected in the differential diagnoses.

DISCUSSION: This case highlights the importance of creative utilization of diagnostic testing and expertise through collaboration to help solve clinical problems in resource-limited settings. Despite the lack of pathologists in Haiti, a diagnosis was made with the help of organizational ties between our partnering organization, Zanmi Lasante (ZL), and Brigham and Women's Hospital (BWH). The pathologists at BWH helped broaden the differential diagnosis prior to a pathological diagnosis. This highlights the role that academic hospitals can have in supporting healthcare practitioners in resource limited settings. Formalizing means of communication, such as online portals or email exchanges, could improve this process.

A LITTLE BIT HIGHER PLEASE! REPOSITIONING PRECORDIAL LEADS ON AN ELECTROCARDIOGRAM TO UNMASK BRUGADA SYNDROME. Teresa Ratajczak[2]; Ahmed El-Moghraby[1]; Amy L. Stacey[1]; Rey F. Arcenas[3]. [1]wright state university, Beavercreek, OH; [2]Wright State University, Dayton, OH; [3]Wright State University, Veteran Affairs Medical Center, Dayton, OH. (Control ID #2701728)

LEARNING OBJECTIVE #1: Recognize the utility of moving precordial ECG leads superiorly to unmask life-threatening arrhythmias like, Brugada syndrome.

CASE: A 42 year old male with history of epilepsy, hyperlipidemia and hypertension presented to the emergency department with complaints of weakness, fatigue and tunnel vision of two hours duration. His vitals and physical exam were unremarkable. Labs were within normal limits. An ECG showed nonspecific ST-T wave changes in the precordial leads. The patient was discharged home with the diagnosis of atypical seizure. The cardiologist

assigned to read the ECG noted that there was a suggestion of early repolarization or perhaps an incomplete Brugada pattern. The patient was evaluated in the cardiology clinic due to the suspicious ECG findings and seizure history. He relayed that he was diagnosed with epilepsy in 2011 and had been on Lamictal with adequate seizure control, suffering one or two breakthrough seizures yearly. An ECG was repeated. The right precordial leads V1-V3 were positioned superiorly in the 2nd-3rd from the 4th-5th intercostal spaces respectively. The characteristic Brugada type 1 pattern of coved ST segment elevations emerged. A diagnosis of Brugada syndrome was made. A loop recorder was implanted to see if patient's seizures are precipitated by syncope, characteristic of this disease, as it may require a cardioverter defibrillation implantation (ICD) in the future. The patient is followed closely.

IMPACT: Consider channelopathies, like Brugada syndrome, in the differential diagnosis for syncope. Enhance awareness that simple ECG maneuvers can uncover the Brugada pattern, resulting in potentially life-saving maneuvers to improve patient outcomes.

DISCUSSION: BrS is a familial channelopathy, with prevalence of 1–5 per 10,000 persons. The 2013 Heart and Rhythm Society guideline requires only the typical ECG changes for diagnosis. BrS type 1 requires demonstrating typical coved ST elevation with at least 2 mm J-point elevation and gradually descending ST segment, followed by a negative T-wave on ECG in the right precordial leads V1-V3. This can occur spontaneously or be elicited with provocative testing in the electrophysiological (EP) lab by intravenous administration of Class I antiarrhythmics. An alternative procedure does not require advanced cardiology training. By positioning the precordial leads superiorly in the 2nd-3th intercostal spaces, the condition can be unmasked. Patients with BrS are at risk for syncope and sudden cardiac death, which makes diagnosis of this disease crucial. In survivors of cardiac arrest or documented spontaneous sustained ventricular arrhythmia with or without syncope, ICD implantation is recommended. Education of healthcare providers about this diagnostic option is imperative.

A MALIGNANT COUGH IN A PATIENT WITH HIV/AIDS

Nupur Agrawal; Dr. Harsha Mudrakola. Baylor College of Medicine, Houston, TX. (Control ID #2704007)

LEARNING OBJECTIVE #1: Differentiate shortness of breath in patients with HIV/AIDS using a systematic approach

LEARNING OBJECTIVE #2: Recognize the cutaneous and extracutaneous manifestations of Kaposi sarcoma

CASE: A 29 year old male with HIV/AIDS only intermittently taking antiretroviral therapy (ART), *Pneumocystis jirovecii* pneumonia actively being treated with trimethoprim-sulfamethoxazole and prednisone, and cutaneous Kaposi sarcoma all diagnosed one month ago at an outside clinic presented to the hospital with worsening cough and shortness of breath. Initial vitals were notable for low grade fever of 99.9 °F, tachycardia to 130 s, and hypoxia with saturation of 88% on room air, which improved to 95% on two liters nasal cannula. Physical exam was notable for a cachectic, ill-appearing male with prominent cervical lymphadenopathy and numerous violaceous plaques of varying sizes present over the face, chest, abdomen, and back (photographed) and inside the oral cavity. Pulmonary exam revealed diffuse rhonchi along with absent breath sounds and dullness to percussion in the left lower lung field. CD4 count was 262/μL. Chest x-ray showed a large left hydropneumothorax, which was drained. Pleural studies showed an exudative effusion but were negative for bacterial, mycobacterial, fungal, and pneumocystis infection. Fluid cytology was negative for malignancy. The effusion rapidly reaccumulated, so bronchoscopy was performed. Numerous violaceous hyperpigmented lesions consistent with Kaposi sarcoma were seen in the trachea and bronchial tree (photographed), confirming a diagnosis of pulmonary Kaposi with pleural involvement.

IMPACT: Research advancements in HIV have rapidly improved available treatment options, but complex social situations create significant barriers to achieving medication adherence even with simplified ART regimens. While HIV-associated opportunistic infections and malignancies have declined in prevalence, this case poignantly illustrates the unique diagnostic and management challenges of untreated HIV and the need for physicians to obtain a thorough history and build a broad differential diagnosis.

DISCUSSION: The differential for shortness of breath in HIV-positive patients unable to tolerate ART is broad, and pulmonary Kaposi is rare even in this susceptible population; pulmonary involvement is reported in only 5 to 8% of cases of AIDS-related Kaposi sarcoma. In our patient's case, a CD4 count above 200/μL made certain opportunistic infections less likely, but an initial infectious workup was both warranted and performed given the sepsis-like nature of the patient's presenting symptoms. Negative infectious studies led to more invasive testing, which ultimately confirmed the diagnosis of pulmonary Kaposi. The patient's symptoms improved with pegylated liposomal doxorubicin. Gleaning an accurate history of intermittent ART use, performing a thorough physical exam, and using a systematic diagnostic approach enabled us to reach an accurate diagnosis in an efficient manner despite the rarity of the disease.

A MARROWING CASE OF PORTAL HYPERTENSION

Michael Massaro[1]; Christopher Caulfield[2]. [1]University of North Carolina, Chapel Hill, NC; [2]University of North Carolina School of Medicine, Chapel Hill, NC. (Control ID #2690372)

LEARNING OBJECTIVE #1: Recognize myelofibrosis as an underappreciated cause of portal hypertension.

CASE: 42 year old male immigrant from Mexico with no medical history presented with two weeks of abdominal distention, lower extremity swelling and jaundice. Around this time patient had an acute febrile illness with cough, rhinorrhea that resolved without intervention. States that associated with his symptoms he had malaise and fatigue. The patient did not take any medications or over the counter supplements besides green and black teas. He states he believed he may have had some type of parasitic infection as a child that resolved with an unknown medication. His physical exam was significant for jaundice, scleral icterus with abdominal distention and positive fluid wave with lower extremity edema. Laboratory data was significant for an elevated creatinine of 1.5, a total bilirubin of 1.6, alkaline phosphatase 1531, and a GGT of 541. The CBC revealed hemoglobin of 6.7 and platelet count of 105. Further studies revealed a positive ANA with titer 1:640 in a speckled pattern and negative hepatitis serologies. A liver ultrasound showed normal liver echotexture with patent vasculature. With his positive ANA he was started on prednisone for presumed autoimmune hepatitis while awaiting liver biopsy results. During his hospital course, he developed oliguric renal failure requiring dialysis. The biopsy returned with evidence of extramedullary hematopoiesis leading to hematology consult to pursue bone marrow biopsy which showed primary myelofibrosis.

IMPACT: This case emphasizes the necessity to consider other etiologies of common presentations such as portal hypertension when the clinical history or

data do not fully support the original presumptive diagnosis and the pitfalls of anchoring in clinical reasoning. This clinical case illustrates the need to consider other systemic disorders that affect the liver as an important cause when evaluating new cases of portal hypertension.

DISCUSSION: Idiopathic noncirrhotic portal hypertension is defined by the clinical syndrome of portal hypertension in the absence of liver disease with signs such as ascites, varices, edema. It is classically divided into five main categories including chronic infection, exposure to medications or toxins, immunologic disorders, thrombophilias, and genetic disorders. Primary myelofibrosis is a rare cause of noncirrhotic portal hypertension but a large percentage of patients with primary myelofibrosis have complications associated with the portal venous system as well as splenomegaly and hepatomegaly. Clinically evident hepatic disease usually occurs secondary to thrombotic complications in myelofibrosis but less commonly disease can develop without thrombosis due to extramedullary hematopoiesis in the hepatic sinusoids leading to portal hypertension.

A MYSTERIOUS CAUSE OF CHEST PAIN Zaid Abdel-Rahman[1]; Yaser Alkhatib[2]; Vrushali Dabak[2]. [1]Henry Ford Health System, Detroit, MI; [2]Henry Ford Health system, Detroit, MI. (Control ID #2701635)

LEARNING OBJECTIVE #1: Recognize the clinical features of primary cardiac tumors

LEARNING OBJECTIVE #2: Manage chest pain by ruling out the most serious and fatal etiologies first

CASE: A 42-year-old African American male with a past medical history significant for previously treated non-medullary thyroid carcinoma presented to our hospital with acute onset pleuritic chest pain and dyspnea on exertion. Initial workup revealed a slightly elevated Troponin-I along with a diffuse ST-segment elevation on electrocardiogram. Left sided heart catheterization with coronary angiogram did not show any obstructive lesions. No evidence of pulmonary embolism was seen on computed tomography (CT) angiogram. A transthoracic echocardiogram showed a large right atrial mass, which was further evaluated by a cardiac magnetic resonance imaging (MRI) and found to be involving the right atrial wall and pericardium with evidence of central necrosis on T2 signal. Patient underwent gross total resection of the mass, pathology showed areas of spindle cells and vascular spaces which stained positive for CD31 and CD34 indicating vascular differentiation consistent with angiosarcoma. Staging CT scan of the chest, abdomen and pelvis did not show evidence of distant metastasis. Patient received adjuvant chemotherapy with adriamycin and ifosfamide, post-chemotherapy cardiac MRI showed a possible evidence of persistent disease for which he received external beam radiation therapy (EBRT) to the remnant mass. Patient has been stable since then with no evidence of active disease for 2 years.

IMPACT: Chest pain is a common presenting complaint in many patients, while the etiology is benign in several occasions, the clinical approach would differ for each particular case depending on several factors which should be incorporated to formulate a specific diagnostic approach and subsequent therapy plan. Younger patients with chest pain should be investigated thoroughly after ruling out deadly cardiac, pulmonary or vascular conditions.

DISCUSSION: Primary cardiac tumors are very rare; based upon data from 22 large autopsy series the approximate frequency is 0.02%, corresponding to 200 tumors in 1 million autopsies. Malignant tumors constitute around one quarter of these with the majority being sarcomas. Cardiac angiosarcoma typically affects middle aged males and it usually involves the right atrium with pericardial, caval and tricuspid-valve invasion. Metastases are usually found at time of presentation in up to 89% of cases with lungs being the most common site. Presentation is variable depending on the site of involvement. It can be incidentally discovered or might cause symptoms secondary to embolization, direct invasion of adjacent structures or hemodynamic instability due to obstructing cardiac flow. The mainstay of treatment for cardiac tumors remains surgical resection, however chemotherapy and in some occasions radiation therapy are essential adjuvant modalities to achieve cure.

A NUMBING CASE OF ACQUIRED METHEMOGLOBINEMIA

Hawkins Gay. McGaw Medical Center, Northwestern University, Chicago, IL. (Control ID #2671950)

LEARNING OBJECTIVE #1: Recognize and diagnose acquired methemoglobinemia

LEARNING OBJECTIVE #2: Understand the treatment of acquired methemoglobinemia

CASE: A 55-year-old male presented to the hospital complaining of fevers, dyspnea and a productive cough. On admission examination he was noted to be febrile, tachypnic, and tachycardic, but alert and fully oriented with a normal blood pressure. He had decreased breath sounds in the right lung base, without rales or wheezing, and the rest of his examination was unremarkable. He was initially treated with cefepime and azithromycin for presumed pnuemonia, but shortly after admission develped new onset hypoxia and hypotension with altered mental status. He was transferred to the medical intensive care unit where laboratory analysis revealed a lactic acid of 6.1 mMol/L and an initial arterial blood gas (ABG) returned a pH of 7.40, pCO2 of 25 mmHg, pO2 of 85 mmHg, and measured O2sat of 94%. Given his increasing lactic acidosis, the decision was made to intubate the patient. During intubation, the patient was treated with endobronchial lidocaine as well as etomidate and succinylcholine for rapid sequence intubation. Roughly two hours post-intubation the patient became increasingly hypoxic while on 100% FiO2. A repeat ABG was notably brownish in color and returned a pH of 7.21, pCO2 of 25 mmHg, pO2 of 413 mmHg, and measured O2sat of 49%. Cooximetry was requested given the divergence in pO2 and O2sat, which revealed a methemoglobin level of 53%. IV methylene blue was delivered and subsequent ABGs, at one and two hours post administration, showed methemoglobin levels of 12 and 9%, with return of O2sat to greater than 90 and bright red coloration to the ABG sample. Unfortunately, despite recovery from acute methemoglobinemia, the patient ultimately succumbed to sepsis.

IMPACT: This case highlights the association of methemoglobinemia and topical anesthetics, of which we were previously unaware. These are commonly used agents on the medical wards and all side effects should be considered before administration.

DISCUSSION: Although rare, methemoglobinemia secondary to local lidocaine administration is well documented and described in the medical literature. Treatment of methemoglobinemia includes withdrawal of the offending agent (including removal of any remaining topical applicant), supportive care with 100% O2 therapy and circulatory support, as well as reversal of methemoglobin back to hemoglobin. The former therapy is generally accomplished through the administration of methylene blue which acts as a reducing agent converting ferric iron to ferrous iron. This case highlights the clinical and laboratory features of methemoglobinemia, a well-described, though rare and poorly recognized, side effect of topical lidocaine administration. Early recognition of methemoglobinemia is of primary importance as the condition is rapidly reversible with correct treatment, but can be serious, and even fatal, if left untreated.

A NUTTY CAUSE OF CHRONIC COUGH Juan N. Lessing[1]; Nicholas M. Mark[2]. [1]University of Colorado, Denver, CO; [2]University of Washington, Seattle, WA. (Control ID #2708433)

LEARNING OBJECTIVE #1: Understand common causes of chronic cough and initial steps for diagnosis and treatment.

LEARNING OBJECTIVE #2: Recognize when higher level referral and advanced diagnostics are necessary.

CASE: A 64-year-old man came to clinic with 6 years of cough. History was notable for several bouts of pneumonia and hospital admissions. His cough was occasionally productive though never with hemoptysis. He denied fever, weight loss, dyspnea, orthopnea or heartburn. Trials of acid suppressant, bronchodilator, and inhaled steroid did not improve symptoms. He previously smoked cigars. Vital signs were normal and he appeared well, with few auscultated focal expiratory wheezes. Remainder of exam and all basic labs were normal. Pulmonary function tests showed 20% volume loss. On further questioning, he recalled a specific day in 2009 when his cough began. A CXR and then CT scan revealed collapse of the right middle lobe (RML) with irregularities within the airway leading to it. Bronchoscopy demonstrated inflamed tissue surrounding a foreign body in the RML. The object was removed and determined to be a pistachio shell. Bronchial wall biopsies returned as squamous metaplasia without malignancy. Asking again about the day his cough began, he recalled choking while eating pistachios.

IMPACT: Cough, commonly encountered by general internists and specialists alike, is one of the most common reasons patients present to clinic. Defined as cough lasting longer than 8 weeks, the differential for chronic cough includes hundreds of etiologies, however the majority of cases are explained by 3 most common diagnoses: postnasal drip, asthma and gastroesophageal reflux disease. History often points to a likely culprit. Patients with typical presentations of chronic cough in the absence of "red flag" warning signs (e.g., weight loss or hemoptysis) can be safely followed while trying lifestyle modifications and acid suppressive and antitussive medication. Trial of short-acting beta agonist for obstructive lung disease is also usually appropriate. In the absence of a clear underlying cause, pulmonary function tests and CXR are reasonable first steps. Patients with risk factors for malignancy, those with warning symptoms, lack of symptom improvement, or radiographic abnormality require further work-up including consideration of computerized tomography. If abnormalities are seen on imaging or if work-up is unrevealing, bronchoscopy should be considered.

DISCUSSION: In this case, a man aspirated a pistachio shell that caused chronic airway irritation and inflammation causing over half a decade of chronic cough. Failure to recognize that lack of symptom improvement merits broadened diagnostic consideration led to diagnostic delay and potential for more grave consequences. Squamous metaplasia from chronic irritation is a risk factor for malignant transformation, and merits follow-up. Fortunately for our patient, shell removal led to rapid cough resolution and repeat bronchial biopsy six months later confirmed inflammation resolution.

A PATIENT WITH A BRAIN ABSCESS: WHAT IS TO BE DONE? Mariko Harada[2]; Yurika Iwasawa[2]; Sandra Y. Moody[1]; Eiichiro Sando[2, 3]; Yoko Tomoda[2]; Tetsuya Kobayashi[2]; Ryuichi Sada[2]; Makito Yaegashi[2]. [1]Kameda Medica Center & UCSF/SFVAMC, Kamogawa City, Japan; [2]Kameda Medical Center, Kamogawa, Japan; [3]Graduate School of Biomedical Sciences, Nagasaki University, Nagasaki city, Japan. (Control ID #2701852)

LEARNING OBJECTIVE #1: Find underlying etiologies, including pulmonary arterial-venous malformation (pAVM), in a patient with a brain abscess

LEARNING OBJECTIVE #2: Treat pAVMs with feeder arteries of greater than 3 mm in diameter to prevent cerebral ischemic events and brain abscesses

CASE: A 77-year-old woman with hypertension and hyperlipidemia presented with a two-day history of generalized pain and fever. On the day of admission, she was taken to an outside hospital by ambulance for altered level of consciousness. On physical examination, the patient was moderately altered with a Glasgow Coma Scale of E4V2M5. Other than a temperature of 40.4 °C, her vital signs were stable. She was found to have nuchal rigidity and a swollen warm tender left wrist, which was exacerbated by movement. Her cerebrospinal fluid (CSF) was consistent with bacterial meningitis with a white blood cell count of 295/mm^3 (86% polys, 14% monocytes), a glucose of 0 mg/dL, and total protein 299 mg/dL. The Gram stain of the CSF revealed gram-positive diplococci, suggestive of *Streptococcus pneumoniae*. After administration of ampicillin, ceftriaxone, and vancomycin, she was transferred to our hospital. Ceftriaxone and vancomycin were continued. On the fifth hospital day, despite improvement in her level of consciousness, her left upper extremity weakness persisted. Brain MRI revealed right temporal lobe and right ventricular abscesses. The antibiotics were changed to penicillin G since her blood and CSF cultures grew penicillin-sensitive *S. pneumoniae* (of note, she had received the 23-valent pneumococcal polysaccharide vaccine [PPSV23] the previous year). On the 28th hospital day, a chest computed tomography was performed to evaluate a cough, and a pAVM of the right lower lobe was incidentally found. Because the feeder artery was 6 mm in diameter, she underwent percutaneous embolization with sixteen coils, which successfully obliterated the feeder artery. Subsequently, a six-week course of intravenous antibiotics was completed after confirming regression of the brain abscess. The *S. pneumoniae* was serotype 7C, which is not covered by the PPSV23.

IMPACT: In a patient with a brain abscess of unknown origin, consider right-to-left arteriovenous shunting such as pAVM. Pulmonary AVM embolization may prevent cerebrovascular events and brain abscesses when the feeder artery is greater than 3 mm (Am J Roentgenol 2010;195:837–845).

DISCUSSION: Patients with brain abscesses may have underlying etiologies including pAVM. Finding pAVMs is of paramount importance since treatment could result in prevention of recurrent brain abscess and cerebrovascular accident with percutaneous embolization. Most (70–90%) cases of pAVM are associated with hereditary hemorrhagic telangiectasia (HHT) in western countries. Whereas in Japan, pAVMs are less frequently associated with HHT (8.4%). Thus, actively seeking pAVMs in patients with brain abscesses in the absence of HHT is an important consideration in Japan.

A PRESSING ISSUE WITH PROSTATIC RHABDOMYOSARCOMA Nicholas J. Kiefer[2]; Elise Coulson[1]; Jason Moran[1]. [1]Beth Israel Deaconess Medical Center, Boston, MA; [2]Beth Isreal Deaconess Medical Center, Brookline, MA. (Control ID #2701700)

LEARNING OBJECTIVE #1: Describe the pathophysiology of posterior reversible encephalopathy syndrome (PRES)

LEARNING OBJECTIVE #2: Recognize patients at risk for PRES

CASE: A 25 year old male with a PMH of migraines presented to the ED with a headache. He was found to have mildly elevated BP and a normal head CT, so he was discharged with PCP follow-up. He then re-presented one day later with left arm shaking, visual aura, and whole-body shaking concerning for seizure.

Additionally, he complained of lower abdominal pain and decreased urinary frequency. At that time, his vitals were notable for BP 191/125, and his labs were notable for a creatinine of 10.8. He had an MRI brain that showed multiple foci of cortical and subcortical vasogenic edema involving bilateral occipital lobes as well as right parietal and frontal lobes concerning for PRES. He was admitted to the MICU for further management. There, he was started on a diltiazem drip for BP control, and he had a CT that showed a large pelvic mass originating from the prostate gland and obstructing his ureters. He had bilateral percutaneous nephrostomy tubes placed with improvement of his kidney failure. Biopsy of a lymph node revealed rhabdomyosarcoma. As his BP improved through his course, his PRES symptoms resolved. He was transferred to a hospital near his hometown to initiate chemotherapy for his rare cancer.

IMPACT: This case illustrates that younger patients without a history of hypertension are more at risk for PRES in the right clinical setting. Additionally, despite the name of the syndrome, it need not be solely posterior and it may not even be reversible.

DISCUSSION: There are no formal diagnostic criteria for PRES, but the diagnosis is suggested in a patient with neurologic symptoms (headache, visual symptoms, seizures) and radiographic findings of symmetrical white-matter edema in the posterior cerebral hemispheres (particularly parieto-occipital regions) similar to our patient. Since risk factors include hypertensive disorders, renal disease, and immunosuppressive therapies, the pathogenesis of PRES seems to be related to cerebrovascular autoregulation and endothelial dysfunction. The cerebral arterioles dilate and constrict to maintain constant cerebral blood flow (CBF) through an auto-regulatory range of systemic blood pressures. However, there is an upper limit of systemic pressure at which point the cerebral arterioles can no longer constrict to maintain normal CBF. The elevated pressure in the cerebral circulation thus causes breakdown of the blood–brain-barrier (BBB) and results in hydrostatic edema. This auto-regulatory range is higher in patients with long-standing hypertension, so children and younger patients like the young man in this case are vulnerable to PRES at lower blood pressures. The BBB is also more susceptible to breakdown when there is endothelial dysfunction, such as with vasculitis or with chemotherapy.Thus, this patient will be at increased risk of re-occurrence of PRES during chemotherapy for his malignancy.

A PUZZLE OF A DIFFUSE RASH SOLVED WITH A FINAL PIECE

Andres Barrera; Leslie Cler. Methodist Dallas Medical Center, Dallas, TX. (Control ID #2694641)

LEARNING OBJECTIVE #1: Diagnose a disseminated gonococcal infection in an at risk teen

LEARNING OBJECTIVE #2: Distinguish between the causes of a diffuse macular rash

CASE: An 18 y/o female with no significant past medical, social, or surgical history presented to the emergency department with left wrist and left ankle pain and swelling that began three days before presentation and was progressive to the point that her left ankle and wrist became immobile due to pain. She has also noted the appearance of a palpable erythematous macular rash along her hands, feet, arms, and legs. She denied any fever, chills, night sweats, weight loss, diarrhea, appearance of mouth ulcers, vaginal discharge, dysuria or history of previous joint pain. She reported only one sexual contact with her boyfriend a month prior and claimed to be in a monogamous relationship. She had recurrent episodes of “sore throat” about once every two months last year for which she was treated for with ibuprofen and oral steroids. She was admitted for concerns of reactive arthritis versus possible rheumatic fever and was started on steroid therapy. Rheumatic fever was considered given the presence of one major criteria (polyarthritis), one minor criteria (markedly elevated CRP/ESR) and an elevated streptozyme titer of 600 stz units. An echocardiogram revealed a small posterior pericardial effusion. ANA, Rheumatoid Factor and C3/C4 came back negative. ANCA titer returned slightly positive at 1:20, but PR3 ABS and MPO ABS negative at 0.197 and 0.115 respectfully. Hepatitis and HIV antibody testing was negative. Gonorrhea and Neisseria Amplified DNA on urine returned negative. Synovial studies from the left wrist joint showed a mostly bloody fluid with WBC count of 430 and no crystals. Blood cultures were negative and initial gram stain on the synovial fluid revealed no organisms, so the decision was made to treat the patient for rheumatic fever. Our patient was initiated on penicillin V 500 mg BID, aspirin 2000 mg BID, and protonix. She was set to complete a treatment for rheumatic fever when, on the day of discharge, the synovial fluid culture grew Neisseria gonorrhoeae. Discharge was held and a diagnosis of disseminated gonococcal infection was made. Therapy was switched to IV ceftriaxone for two weeks with doxycycline overlapping for one week.

IMPACT: The CDC estimates that young people aged 15–24 years aquire half of all new STDs. Given this, the importance in identifying disseminated gonococcal infections especially in the young population cannot be understated.

DISCUSSION: This case shows the importance in casting a wide diagnostic net when faced with a puzzling rash and arthropathy. Although rheumatic fever was a possibility, it was ultimately disproven with the growth of gonorrhea in the synovial fluid. The importance of following up final culture results before finalizing a treatment course was also illustrated.

A RAPIDLY GROWING ORAL LESION

Eric Wang; Elena Lebudska. University of Coloardo, Denver, CO. (Control ID #2701731)

LEARNING OBJECTIVE #1: Develop a differential of the most common oral lesions

LEARNING OBJECTIVE #2: Recognize features of Diffuse Large B Cell Lymphoma (DLBCL)

CASE: A 55-year-old African American male with medical history of gout and chronic sinusitis presented to clinic with a painful oral lesion that had been growing rapidly over the preceding week. He denied fevers/chills but did report difficulty with swallowing solid foods and approximately 5–10 pound weight loss over the previous month. He was formerly a heavy drinker and denied any history of tobacco product use. He used no other illicit drugs and had no family history of oral cancers. He also denied any history of HSV or other oral infections, and had no recent sexual contacts. On exam, he was noted to have a 2 × 2 cm ulcerated lesion on his right upper palate with right sided non-tender cervical adenopathy. Due to the rapid progression of this lesion, an infectious cause was highest on the differential. He was provided oral lidocaine for symptomatic control and a swab was sent for viral HSV PCR, and serum HIV/Hep C were sent and all were found to be negative. Over the following week his oral lesion continued to grow with worsening pain and increasing dyspnea, particularly when lying flat. He went to the emergency department where CT head and neck confirmed right tonsillar mass with central area of necrosis and cervical lymphadenopathy. Biopsy of the lesion revealed DLBCL.

IMPACT: This case represents the need to develop a comprehensive approach to oral lesions, a common complaint with an expansive differential. Further,

this case demonstrates an atypical presentation of the most common Non-Hodgkin Lymphoma.

DISCUSSION: Oral lesions are a common complaint prompting patients to seek medical advice and care. There is an expansive differential for oral lesions encompassing three main categories: infectious, malignant and autoimmune. The most common oral lesions are infectious and include more common pathogens like candidiasis and herpes simplex virus. These are often differentiable by symptoms, appearance, and location. Of the malignant oral lesions, the most common oral cancer is squamous cell carcinoma making up greater than 80% of oral cancers. In this group risk factors include: tobacco use, alcohol consumption, Human papilloma virus (HPV), infection, and Epstein-Barr Virus (EBV). Autoimmune processes such as lupus and bullous pemphigoid can also manifest orally and are often associated with a classic set of systemic symptoms. DLBCL is the most common lymphoma and the most common of the Non-Hodgkin lymphomas. DLBCL will typically present as a rapidly developing mass and will frequently be associated with B symptoms. While the most typical presentation is intranodal, extranodal involvement Is common and as this oral mass demonstrates can occur in most tissue types. This case demonstrates an uncommon presentation of the most common lymphoma and establishes the important historical features and symptoms to help discern a diagnostic approach to oral lesions.

A RARE CASE OF AN ISOLATED DISTAL METASTATIC EXTRA-HEPATIC CHOLANGIOCARCINOMA Bryan Doherty[1]; Rebecca Cody[2]; Vinod E. Nambudiri[1]; William C. Palmer[3]. [1]Grand Strand Medical Center, Myrtle Beach, SC; [2]Coastal Cancer Center, Myrtle Beach, SC; [3]Mayo Clinic, Jacksonville, FL. (Control ID #2694557)

LEARNING OBJECTIVE #1: Describe a case of isolated metastatic extra-hepatic cholangiocarcinoma

LEARNING OBJECTIVE #2: Discuss the differential diagnoses of abdominal wall masses

CASE: A 77-year-old Caucasian female was referred to her gastroenterologist for colonoscopy following mild episodes of hematochezia for several months. Her medical history included an incidental extrahepatic cholangiocarcinoma (CCA) diagnosed 7 years prior on pathological evaluation of her gallbladder following open cholecystectomy. At that time, she had undergone partial liver resection and resection of lymph nodes without further evidence of disease. She had been followed with frequent visits and laboratory studies including CEA levels, all of which had been stable. On colonoscopic workup of her hematochezia, a large rectal mass was found. Biopsies were consistent with a benign villous adenoma. Upon follow-up, she also endorsed a new left lower quadrant abdominal mass. The mass was approximately 5 cm, tender, and lacked signs of skin involvement. Given the clinical findings, she underwent a CT scan, which suggested an abdominal wall mass arising near the umbilicus. The patient underwent exploratory laparotomy with transrectal excision of the rectal villous adenoma and separate excision of the abdominal wall mass, which was noted on laparoscopy to be invading the peritoneum and incorporated into abdominal adhesions. Frozen sections of the abdominal wall mass obtained during surgery revealed adenocarcinoma. Further pathological evaluation with H&E stained slides showed a well-differentiated adenocarcinoma consistent with her prior extrahepatic CCA. The rectal villous adenoma was benign. Additional workup revealed no further sites of metastatic disease.

IMPACT: Metastatic CCA to the abdominal wall is uncommon; most occurrences reported involve cutaneous lesions following percutaneous hepatobiliary drainage. This case adds to the literature an instance of metastatic disease at the site of adhesions after cholecystectomy.

DISCUSSION: CCA is a rare biliary adenocarcinoma. Extrahepatic CCA comprises approximately 75% of all cases with the vast majority located in the peri-portal region or in the gall bladder, as in our patient. Distal CCA, a subtype of extrahepatic CCA, tend to have distant metastases occur late in the course of the disease and are most often found in the liver, lungs, and peritoneum. Metastatic disease to the abdominal wall is rare and has been reported following percutaneous hepatobiliary drainage. During the workup for her abdominal wall mass, differential diagnoses included a bowel hernia, an abdominal wall hematoma, or a benign tumor, all of which are more common. The 5-year overall survival reported for stages 3 and 4 CCA are 10 and 0%, respectively. CEA is found to be elevated in 85% of patients with cholangiocarcinoma; levels were normal in our patient. She continued to follow with oncology and has no further recurrence of her metastatic CCA 11 years after resection of her abdominal wall mass.

A RARE CASE OF COMBINED HYPOCOMPLEMENTIC URTICARIAL VASCULITIS SYNDROME (HUVS) AND SLE. Azka Ali; Ali Ataya. University of Florida, Gainesville, FL. (Control ID #2705887)

LEARNING OBJECTIVE #1: Recognize the clinical features of HUVS

LEARNING OBJECTIVE #2: Recognize that combined HUVS and SLE is an underdiagnosed condition because of its rare nature, and its pathophysiology is not completely understood

CASE: A 25-year-old African American female presented complaining of a worsening rash in her back, arms, shoulder, and thighs, fatigue, and arthritis in feet, wrists and knees. Physical exam revealed faint, erythematous, hyperpigmented plaques on right upper arm and back. Musculoskeletal exam showed normal range of motion in all joints without synovitis. Her past medical history was also relevant for episodes of neck swelling on multiple occasions of unclear etiology, SLE, gastroesophageal reflux disease, and anxiety. Her surgical history included pericardial window and tooth extraction. Family history included hypertension in mother. Her medications were biotin, folic acid, hydroxycholoroquine, levothyroxine, and mycophenolate. Complements C3 (52), C4 (8), and C1q (102) were checked and were low. She underwent a punch biopsy of right upper back that showed urticarial vasculitis with lymphocytic infiltration confirming the diagnosis of hypocomplementemic urticarial vasculitic syndrome.

IMPACT: This case introduced us to an extremely rare syndrome that I was previously unaware of. HUVS is a rare disease that may mimic other autoimmune conditions such as SLE, there is even a smaller subset of patients that have combined SLE and HUVS syndrome. These patients meet American College of Rheumatology criteria as well as criteria for HUVS. These patients can have extensive renal and pulmonary involvement and need routine monitoring of their laboratory and pulmonary functions. This case emphasizes the significance of exploring an alternative diagnosis when unexpected findings such as urticarial vasculitis and history of angioedema are present.

DISCUSSION: Urticarial vasculitis (UV) can be divided into three forms: normocomplementemic vasculitis which is a self limited hypertensivity vasculitis, HUV which is not associated with a systemic illness and finally, HUVS which is a severe form of UV associated with a systemic illness. Some experts

consider HUVS as an independent disease from SLE while some consider it related to SLE. The diagnostic criteria include two major criteria (which is recurrent urticaria in more than 6 months and hypocomplementemia) and at least two minor criteria (arthralgias or arthritis, glomerulonephritis, ocular inflammation, abdominal pain, positive skin biopsy, positive C1q-test with decreased C1q level). Our patient met both major and at least two minor crtieria (arthritis, positive skin biopsy, and low C1q) (1). There is no specific treatment for HUVS. In our patient, since patient was on SLE therapy, she was treated briefly with steroids and had dapsone added to her regimen. 1. Buck A, Christensen J, McCarty M. Hypocomplementemic Urticarial Vasculitis Syndrome: A Case Report and Literature Review. *The Journal of Clinical and Aesthetic Dermatology.* 2012;5(1):36–46.

A RARE CASE OF GLOMERULONEPHRITIS Abiramy Maheswaran. University of Massachusetts School of Medicine, Worcester, MA. (Control ID #2670705)

LEARNING OBJECTIVE #1: Recognize the presentation of anti-glomerular basement membrane syndrome

LEARNING OBJECTIVE #2: Prognosticate patients with anti-glomerular basement membrane syndrome

CASE: A 62-year-old woman with hemochromatosis presented with one month of rashes, cyclic fevers, dyspnea, and edema. Imaging showed bilateral pleural effusions and ascites. Lab work revealed a creatinine of 1.77 mg/dL (baseline normal) and a leukocytosis of 22.3/mm^3. She became increasingly oliguric and developed uremia. Despite hydration, her creatinine worsened to > 6 mg/dL. Hemodialysis improved her edema and dyspnea. Anti-glomerular basement membrane (GBM) IgG antibody titers were > 800.0 units. A tunneled catheter was placed for urgent plasmapheresis. High dose methylprednisolone and cyclophosphamide were initiated. Renal biopsy revealed 100% crescents and 60–70% fibrotic changes. Despite achieving an anti-GBM titer of 22.8 units, she failed steroid taper and relapsed with a repeat anti-GBM titer of > 800.0 units. She was discharged on ongoing plasmapheresis, dialysis, methylprednisolone, and cyclophosphamide.

IMPACT: From symptom onset, one month lapsed before the patient was diagnosed. With the mindset of "common things are common", rare syndromes tend to be overlooked. Without therapy, patients with anti-GBM syndrome have survival and dialysis-free rates of 4 and 2% respectively at 12 months. A delay in diagnosis can be devastating. Early detection of rare entities is crucial to improving prognosis.

DISCUSSION: In anti-GBM syndrome, autoantibodies attack type IV collagen in the GBM of the kidneys. Patients present with systemic symptoms and signs of renal failure. Dyspnea is due to volume overload and improves with dialysis as in our patient. In Goodpasture syndrome, anti-GBM antibodies attack type IV collagen in the kidneys and the lungs. Presenting features include renal failure, hemoptysis, alveolar infiltrates due to hemorrhage, and dyspnea due to direct lung involvement. Anti-GBM syndrome presents in the fifth and sixth decades while Goodpasture syndrome affects younger males. Diagnosis is based on positive anti-GBM antibodies and a renal biopsy, which shows glomerular crescents and IgG deposition along capillaries. Patients with 100% crescents are unlikely to be weaned off dialysis. Those with < 30% crescents have better prognoses. Presenting creatinine < 5.7 mg/dL corresponds with better survival. Dialysis requirement within 72 hours, oliguria, or anuria correspond with worse survivals[1]. Empiric therapy includes plasmapheresis, steroids, and cyclophosphamide. Patients with poor prognostic factors are less likely to respond to therapy. Despite an initial creatinine of 1.77 mg/dL and not needing dialysis within 72 h, our patient's development of oliguria and 100% crescents on biopsy heralded her progression to dialysis-dependent end stage anti-GBM syndrome. 1. Levy JB et al. Long-Term Outcome of Anti-GBM Antibody Disease Treated with Plasma Exchange and Immunosuppression. Ann Intern Med. 2001;134:1033–1042.

A RARE CASE OF LYMPHOMA Binyue Chang. Providence Hospital, Columbia, SC. (Control ID #2672683)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of lymphoma

CASE: A 67 year old Caucasian female presented to emergency department for increasing weakness and fatigue. She was healthy until a few months ago, during which she had cholecystitis and received cholecystectomy. After that, she had failure to thrive with chronic diarrhea and was diagnosed with clostridium difficile and celiac disease. She was on vancomycin and gluten-free diet and discharged to nursing home for rehabilitation. However, it was compromised by increasing weakness and fatigue and she was sent back to hospital. 2 days after she was hospitalized, she was found to have altered mental status with generalized abdominal tenderness. CT of abdomen and pelvis showed intra-abdominal free air and free fluid concerning for bowel perforation. Dilatation of the proximal small bowel with relative decompression of the distal small bowel concerning for obstruction. Surgery was consulted and patient had an emergent laparoscopy followed by laparotomy and partial resection of Jejunum. Post operation, patient had severe sepsis with WBC of 42000 and venous lactate of 12.4. She required maximum pressure support with norepinephrine, phenylephrine, vasopressin and epinephrine. Despite aggressive treatment, patient passed away 2 days later. Biopsy of resected bowel was positive for Enteropathy associated T cell lymphoma (EATL).

IMPACT: Enteropathy associated T cell lymphoma (EATL) is a rare tumor that accounts for less than 5 percent of all gastrointestinal lymphomas and less than 1 percent of all non-Hodgkin lymphomas. Patients typically presented with abdominal pain. Often, it is associated with intestinal obstruction, perforation, or bleeding. Celiac disease or deterioration of celiac disease despite compliance with a gluten-free diet is a less common presentation.

DISCUSSION: Enteropathy associated T cell lymphoma (EATL) is a T cell lymphoma that arises in the gastrointestinal tract and is highly associated with celiac disease. It is an aggressive lymphoma with a poor prognosis and is usually diagnosed by the pathologic evaluation of resected small bowel. Patients with EATL are commonly malnourished at the time of diagnosis and have a poor performance status. Treatment consists of combination chemotherapy used for other aggressive T cell lymphomas. Patients who are candidates for autologous hematopoietic cell transplantation (HCT) may benefit from HCT in first remission

A RARE CAUSE OF SPLENOMEGALY IN A PATIENT WITH AIDS. Faraz Fiazuddin; Ritik Tiwari; Kanapa Kornsawad. University of Texas Health Science Center - San Antonio, San Antonio, TX. (Control ID #2687951)

LEARNING OBJECTIVE #1: To identify IRIS as a possible complication of iniitiating ART.

LEARNING OBJECTIVE #2: To identify manifestations of visceral KS in the setting of IRIS.

CASE: A 20 year-old man with history of untreated HIV presented with one month of left lower quadrant abdominal pain that radiated to the left groin. Review of systems was notable for oral intolerance, nausea, vomiting, and weight loss. His abdomen was diffusely tender and he also had multiple areas of tenderness bilaterally along the inguinal region. Labs showed a CD4+ count of 40 cells/mm3 with viral load of 222,000 copies/mL. CT abdomen revealed mesenteric and bilateral inguinal lymphadenopathy with no splenomegaly. An inguinal lymph node biopsy was obtained which revealed Kaposi sarcoma (KS). Meanwhile, he was started on antiretroviral therapy (ART) and discharged. The patient presented two weeks later with worsening abdominal pain and a palpable spleen. His viral load had decreased to 16,300 copies/mL with a stable CD4+ count. CT abdomen demonstrated an increase in spleen size from 11 cm to 17 cm. A spleen biopsy was performed which also revealed KS. The patient was now diagnosed with disseminated KS, prompting initiation of chemotherapy. This progression of KS was attributed to immune reconstitution inflammatory syndrome (IRIS) given the rapid reduction in viral load and recent initiation of ART.

IMPACT: Our case highlights a paradox that may be seen by hospitalists who admit AIDS patients recently started on ART. They can be deceived by lab values, such as HIV viral load and CD4+ count, which rapidly improve while the patient clinically worsens due to the deadly sequelae of IRIS.

DISCUSSION: Progressive KS is a potential sequela of IRIS that is associated with recent ART. The risk and severity of IRIS depends upon the extent of CD4+ T cell immune suppression prior to ART therapy and the degree of viral suppression or immune recovery once ART is initiated. In a retrospective case review of 196 patients, KS was one of three most common opportunistic infections in HIV positive patients. Incidence of IRIS was highest in patients with KS (29%), and patients with IRIS-associated visceral KS had 100% morbidity and mortality.

A RARE GIST TUMOR PRESENTING AS A BENIGN MASS ON ENDOSCOPY Marisa C. Terino; Eileen Plotkin. University of Connecticut Health Center, Farmington, CT. (Control ID #2700884)

LEARNING OBJECTIVE #1: To identify rare causes of gastrointestinal bleeding.

CASE: A 35 year-old female presented with nausea, vomiting and epigastric pain over 4 months. She denied any change in stool, weight loss or NSAID use. Medical history was significant for iron deficiency anemia. Physical exam demonstrated epigastric tenderness to palpation. A rectal exam was significant for brown, heme-positive stool. Laboratory results were consistent with an iron deficiency anemia; hemoglobin was 5.0 gm/dl. Chemistries and liver function tests were normal. An EGD was performed and identified a large fungating, submucosal mass with ulcerations within the gastric fundus and body. Biopsies of the lesions were without malignancy yet positive for H. Pylori infection. A CT scan showed multiple mass lesions present within the stomach, several with calcific densities. Extraluminal mesenteric extension was also present with adjacent adenopathy. No metastatic lesions were appreciated. A EUS visualized the mass originating from the intramural wall along the greater curvature of the stomach. It measured at least 7.5 cm in thickness with well-defined borders. An FNA demonstrated a small blue cell neoplasm. There were aggregates of small epitheloid cells without mitotic figures and both CD34 and CD117 were positive. One mutation in exon 18 was appreciated, resulting in an up regulation of tyrosine protein kinase (TPK) activity. Additionally, succinate dehydrogenase (SDH) was deficient. These findings were consistent with a rare variant of a gastrointestinal stromal tumor (GIST). A large exophytic and intraluminal mass was removed surgically. Grossly, the maximum tumor dimension was 13.5 cm and histologically the surgical specimens were consistent with that of the FNA. Adjuvant imatinib therapy was begun and the patient has been without recurrence after nearly one year.

IMPACT: This case posed a diagnostic challenge, as initial workup did not reveal significant pathology given negative biopsies. Additionally, it posed a treatment challenge given its rare oncogenic mechanism.

DISCUSSION: GISTs are the most common mesenchymal neoplasm of the alimentary tract, commonly seen in the stomach of males and females between 50–70 years of age and represent less than 1% of gastrointestinal malignancies. They arise from the interstitial cells of Cajal, which are the functional intermediates between smooth muscles cells and neural tissue. Typically, GISTs are driven by TPK receptor activating mutations, although approximately 10% of tumors will lack this finding (wild type). These wild type tumors are deficient in SDH, identified as the tumors' oncogenic mechanism. Although uncommon, it's typically seen in pediatric patients and it may pose a treatment dilemma as tumors do not respond to TPK inhibiting therapy unless an additional TPK activating mutation is present. Treatment strategies at this time are puzzling given the complexity which arrise when SDH is deficient, however surgical resection remains the mainstay of initial therapy.

A RARE NEUROLOGICAL PRESENTATION OF A HEMATOLOGICAL CONDITION Arundati Rao; Chandana Shekar. University of Connecticut School of Medicine, Farmington, CT. (Control ID #2705617)

LEARNING OBJECTIVE #1: Identification of Chorea as a presenting symptom of Polycythemia Vera

CASE: A 78 year old African American male presented to the hospital for restlessness and sudden onset involuntary movements of extremities two days prior to presentation. Review of systems was positive for bilateral conjunctival redness, two episodes of headache and intermittent generalized pruritus; all of which succeeded chorea. Physical examination revealed bilateral conjunctival injection, involuntary movements of all extremities and rashes all over the body secondary to scratching. Remaining examination including a complete neurological exam was unremarkable. Initial blood work revealed Hemoglobin 22.2 gm/dL, Hematocrit 77%, MCV 72 fL, Red cell Distribution Width 21%, Lactate Dehydrogenase 927 U/L, Hemoglobin A 97.2%, Hemoglobin A2 2.8%, Uric acid 9.4 mg/dL. JAK2 V617F mutated DNA was detected and measured at 11% of total JAK2 DNA. Erythropoietin level was 1.0mIU ml. Chemistries were significant for acute kidney injury with a creatinine of 1.5 mg/dL. Chest X ray showed cardiomegaly with tortuous thoracic aorta. Computed Tomography of the head showed congested cerebral vessels. Computed Tomography of the abdomen was negative for hepatomegaly, splenomegaly or tumors. He was diagnosed with polycythemia vera and evaluated by the hematology team. He underwent daily phlebotomy therapy with target hematocrit ≤45 and was subsequently started on hydroxyurea. He was evaluated by neurology and had no metabolic or anatomical cause for the chorea. Magnetic Resonance Imaging of the Brain did not show basal ganglia infarcts. Choreiform movements resolved with phlebotomy. He follows with hematology and has not had choreiform movements or needed phlebotomy ever since.

IMPACT: Polycythemia vera is a rare condition with prevalence of 44–57 per 100,000 in the USA. A thorough history to include subtle presentations can

guide diagnosis. This case demonstrates the importance of a wide differential to avoid missing a diagnosis. Literature suggests that lack of prompt treatment of chorea could lead to permanent neurological damage. Early recognition and treatment is critical to prevent significant morbidity and mortality. Given the rarity of polycythemic chorea, our case will be a valuable addition to literature.
DISCUSSION: Polycythemia vera is a myeloproliferative disorder of increased red blood cell mass. Neurological features include headache, blurred vision, paresthesia and slowed mentation. Chorea is a rare (0.5–5%) complication of polycythemia and when occurs, is common in females above 50 years of age. Pathophysiology of polycythemic chorea is unclear and has been suggested to be due to sluggish blood flow particularly around the basal ganglia, as an inverse relationship exists between packed cell volume and cerebral blood flow. It has been suggested that there is a reversible alteration in the corticobasal ganglia metabolism and disturbed dopaminergic function. Treating the underlying polycythemia vera will eventually resolve the chorea.

A RARE PRESENTATION OF ACUTE MYELOID LEUKEMIA PRESENTING WITH RAPIDLY PROGRESSIVE LEUKEMIC ASCITES
Meytal Shtayer[1]; Devi Sampat[1]; Yuji Yamada[1]; Ilan Shapira[2]. [1]Mount Sinai Beth Israel, New York, NY; [2]The Beth Israel Medical Center, New York, NY. (Control ID #2706429)

LEARNING OBJECTIVE #1: Recognizing granulocytic sarcoma and leukemic ascites as a feature of acute myeloid leukemia
CASE: A 46 year-old healthy man presented to an urgent care center with 4 weeks of abdominal distension, epigastric pain and a 10lbs weight loss. CT of the abdomen and pelvis showed a soft tissue mass at the root of the mesentery, thought to be a granulocytic sarcoma, with a large amount of ascites, thickening of the omentum, and enlarged retroperitoneal nodes. The patient was sent to the hospital for further work up which was significant for a white blood cell count of 26,300 with 20% myeloblasts and LDH level of 4127u/L. Paracentesis revealed predominance of myeloblasts in the ascitic fluid. Bone marrow biopsy showed hypercellular marrow with nearly complete replacement by myeloblasts, confirming the diagnosis of acute myeloid leukemia (AML) with cytogenetics significant for inversion 16 and trisomy 22. The patient was started on induction chemotherapy with Cytarabine for 7 days and Idarubicin daily for 3 days. Bone marrow biopsy at day 16 showed no residual leukemia. At day 33 the biopsy showed complete remission with normal male karyotype (46,XY). He then completed 4 cycles of consolidation chemotherapy with high-dose Cytarabine and has remained in complete cytogenetic and molecular remission with no evidence of disease since then.
IMPACT: In many cases with findings of bloating, ascites and a mass on imaging studies a diagnosis of solid tumor malignancy is favorable. It is important to obtain ascitic fluid sample to differentiate between the different possible causes. In our case the finding of myeloblasts in the ascetic fluid confirmed the diagnosis of AML.
DISCUSSION: This case highlights two rare manifestations of AML, granulocytic sarcoma (GS) and massive leukemic ascites. GS is usually present in 2–8% of patients with AML. It is associated with specific cytogenetic abnormalities, such as inversion 16, which is the most recurrent cytogenetic abnormality in AML and trisomy 22, which is the most common secondary chromosomal abnormality in patients with inversion 16. Together both cytogenetic abnormalities are favorable prognostic factors for relapse free survival in patients with AML and these patients are generally treated with chemotherapy alone, without allogeneic stem cell transplantation. Massive leukemic ascites, on the other hand, are very rare to find in patients with AML and their prognostic significance is not well understood. This case of AML with leukemic ascites and GS associated with 16 and trisomy 22 is particularly unusual and only one other case has been reported to our knowledge. The World Health Organization classification divides AML into distinct disease entities based on the underlying morphology, cytogenetic, immunophenotype and clinical data. While inversion 16 and trisomy 22 are considered favorable prognostic factors more data is needed to assess the prognostic significance of leukemic ascites and whether it should alter treatment recommendations.

A ROCK AND A HARD PLACE: CNS LYMPHOMA WITH ACTIVE TUBERCULOSIS
Kristopher R. Koch[1]; Darrell Nettlow[2]; Anthony Hartzler[1]. [1]University of Texas Health Science Center, San Antonio, TX; [2]San Antonio Military Medical Center, San Antonio, TX. (Control ID #2707478)

LEARNING OBJECTIVE #1: Manage CNS lymphoma with active tuberculosis
CASE: A 66 year old male with primary CNS large B-cell lymphoma, hepatitis C, presented from his rehabilitation center for 2 day history of increased left lower extremity swelling and erythema. Physical exam was notable for a left lower cellulitis and left sided paraplegia. Labs were significant for Wct 17.55, AST 72, ALT 132, Tbili 1.0, ALP 127 and negative for HIV. He was started on Keflex for a 7-day treatment. During early stage of his inpatient admission for cellulitis, he was found to have CT findings concerning for tuberculosis (TB). Sputum had 4+ acid-fast bacilli staining (AFB) and was initiated on rifampin, isoniazid, pyrazinamide, ethambutol (RIPE). Upon initiation of RIPE therapy, headaches increased in intensity, were unresponsive to pain medications. Dexamethasone dosing was increased. A head CT demonstrated stable size of the tumor with increased surrounding edema. He was determined not to be a candidate for radiation treatment due active tuberculosis and would receive radiation when his AFBs were negative. He was transitioned to prednisone 120 mg daily and began a steroid taper to aid in TB clearance, eventually decreasing to 60 mg daily. Headaches and left muscle sided muscle spasms worsened with titration, despite supportive treatment. AFBS were 4+ positive after 3 weeks of RIPE therapy. Headaches worsened with loss of vision and repeat imaging demonstrated worsening intracranial CNS lymphoma with midline shift. High dose steroids were reinitiated. LFTs continue to worsen and peaked with AST 206, ALT 147 and Tbili 8.5 and RIPE therapy was discontinued after one month. Social work assisted in placing patient for radiation of his CNS lymphoma. Patient was unable to go to the regional cancer center, due to no institutional policies in place for patients with TB and staff not fit-tested for N95 masks. Ultimately, a national cancer center approved radiation therapy for the patient's CNS Lymphoma and he was transferred for treatment.
IMPACT: Radiation therapy should be offered early in patients with tuberculosis and CNS lymphoma to improve tumor burden and decrease need for steroids. Institutional policies are needed for addressing tuberculosis in cancer patients requiring radiation therapy.
DISCUSSION: We report the difficulty of managing a patient with primary CNS large B-cell lymphoma, tuberculosis and hepatitis C. Rifampin induces CYP450 resulting in increased metabolism of prednisone, resulting in higher doses of steroids needed to reduce vasogenic edema. Steroids can lead to immunosuppression and decrease the tissue inflammatory effect, leading to decreased tuberculosis clearance and a prolonged course of active tuberculosis. Isoniazid, rifampicin and pyrazinamide are hepatic toxic and may lead to

worsening liver function, further complicating care. In patients with B-cell CNS lymphoma with active tuberculosis, radiation should be available to decrease steroid use and improve tuberculosis clearance.

A SECOND LOOK: THE UTILITY OF ABDOMINAL IMAGING AS SURVEILLANCE AFTER PANCREATIC CANCER RESECTION

Jeremiah J. Johnson. Penn State College of Medicine, Hummelstown, PA. (Control ID #2705627)

LEARNING OBJECTIVE #1: Recognize the limitations in current guidelines for pancreatic cancer screening post-surgical resection and the need for additional research.

CASE: A 76 year old male with a history of pancreatic cancer status post resection 2 years ago presented with a fever of 38 °C for 3 days. Further questioning revealed 2 days of mild stomach pain and a recent loss in appetite. On admission he had a temperature of 37.3 °C, a heart rate of 101, a blood pressure of 103/51, and a respiratory rate of 30. He had rales in both lower lung fields and pain on suprapubic palpation. Initial laboratory results included a WBC count of 14.9 K/mm^3 (81.1 neutrophils and 11.3% lymphocytes) and a glucose of 224 mg/dL. Due to his previous history of pancreatic cancer, a CA 19–9 was ordered and found to be elevated at 762.1 units/mL so an unenhanced CT of the abdomen was ordered. The CT showed increased pancreatic calcifications consistent with recurrent local pancreatic cancer. These findings were new compared to his surveillance serum CA 19–9 level 6 months ago and his abdominal CT 40 days ago which showed no signs of recurrence. It was determined that the patient was not a candidate for surgery and so, after a discussion of his medical options, he elected to pursue home hospice care where he died 13 days later.

IMPACT: Only 15–20% of those diagnosed with pancreatic cancer are candidates for a potentially curative surgical resection. In those cases, it is recommended by the National Comprehensive Cancer Network (NCCN) that CA 19–9 levels and CT scanning be done every 3–6 months to monitor for reoccurrence. This patient adhered to the accepted guidelines for pancreatic cancer screening but, despite this adherence, his clinical trajectory was not impacted.

DISCUSSION: In an era where good stewardship of healthcare resources is becoming increasingly essential, the question of whether or not routine scans for pancreatic cancer reoccurrence post-resection has an impact on survival is important. The risk for recurrence post-resection is 66-92 and the current recommendations by the NCCN for surveillance are based on the opinions of experts. In a study involving 2,217 patients who had undergone a surgical resection for pancreatic cancer, Witkowski et al. found that amongst the 10% of patients with superior survival, no substantial benefit was found for those who received regular CT scans compared to those that did not. Examining the cost-effectiveness of post-operative surveillance, Tzeng et al. found that beyond CA19-9 testing and clinical evaluation, more frequent CT use did not confer a significant survival benefit but did increase cost. This case demonstrates the potential limitations of imaging after pancreatic cancer resection and the need for additional research.

A SHEEPISH EXPLANATION FOR A LUNG MASS: A CASE OF PULMONARY ECHINOCOCCUS

Shiyun Chua; Paul Long. Boston Medical Center, Boston, MA. (Control ID #2703840)

LEARNING OBJECTIVE #1: Recognize pulmonary echinococcus as a cause of recurrent hemoptysis in an immigrant patient

LEARNING OBJECTIVE #2: Understand workup and management options for Echinococcosis

CASE: A 70-year-old male, former smoker, presented from Morocco with 3 months of daily small-volume hemoptysis associated with fever and chills. He had undergone prior workup, including a CT thorax showing a right lung mass, negative TB but bronchoscopy was unsuccesful. As symptoms persisted despite a long course of oral antibiotics, he came to the US for further care. Of note, he lived in rural Morocco and was a farmer of sheep. Exam was notable for a well-appearing male with scattered wheezing. Basic labs, including Hgb and WCC, were unremarkable. CT thorax showed a large right middle lobe (RML) rounded opacity with cavitation and associated RML collapse. He was admitted under airborne isolation. Subsequent workup including AFB, aspergillus, β-d-glucan and galactomannan was negative. Echinococcus and Filiaria serologies were sent. Hospital course was complicated by large-volume hemoptysis, for which he underwent IR-guided embolization of bronchial artery. After 5 days, Echinococcus IgG resulted and was positive. Abdominal ultrasound ruled out hepatic cysts. He was started on Albendazole prior to RML lobectomy. Although confirmatory Western blot was negative for Echinococcal IgG, pathology confirmed diagnosis. He remained well after 4 weeks of post-op Albendazole.

IMPACT: This case reminded me to consider all aspects of the patient's history in generating his illness script, maintaining a high level of suspicion for uncommon diagnoses like Echinococcus in a patient from an endemic country.

DISCUSSION: This case illustrates the importance of maintaining a broad differential, extending beyond pulmonary tuberculosis and malignancy, for patients presenting with recurrent hemoptysis from areas endemic for less common infections. For this patient, proximity to sheep and prior negative work-up in Morocco raised concerns for pulmonary echinococcus. Echinococcosis, caused by tapeworm E.granulosus or E.multilocularis, occurs where sheep live due to its life cycle. While liver and lung cysts are typical, the infection is most commonly asymptomatic, with patients being infected in childhood with latent disease for decades. Our patient displayed typical features of pulmonary Echinococcus with a cavitary lung cyst. Serologies can be useful both for diagnosis and follow-up. Studies have shown IgG ELISA to be most sensitive (84–94%) and specific (99%) as screening, though negative tests do not rule out pulmonary cysts (65% sensitive) which tend to elicit an antibody response less frequently than liver cysts (90% sensitive). After liver cysts were ruled out, our patient was treated with Albendazole as an optimizing measure prior to cyst resection. Current guidelines recommend resection as definitive treatment for pulmonary cysts, though a case report from South Africa showed complete resolution of bilateral cysts with medical treatment alone.

A SIMPLE URINARY TRACT INFECTION BUT WHAT LIES BENEATH?

Robert Chao; Denis Yusupov; Zohirul Islam. New York Presbyterian Brooklyn Methodist Hospital, New York, NY. (Control ID #2706168)

LEARNING OBJECTIVE #1: Recognize a ruptured hepatic cyst as a differential diagnosis in patients with acute anemia and abdominal pain

LEARNING OBJECTIVE #2: Manage hepatic cyst rupture

CASE: A 87-year-old female with a history of dementia and hyperthyroidism presented with lower abdominal pain, altered mental status and decreased appetite for two days. On physical examination, she was afebrile, normotensive, but had suprapubic tenderness on palpation and decreased skin turgor. Laboratory results revealed hemoglobin of 9.4 g/dL (baseline 11.9 g/dL two

months prior), mildly elevated transaminases and no leukocytosis. Urinalysis showed white blood cells and moderate leukocyte esterase. She was started on IV antibiotics for a presumed urinary tract infection. During her hospital course, her abdominal pain worsened and she began to have abdominal guarding and rebound tenderness on examination. Her hemoglobin continued to decrease to 6.9 g/dL. Hemolysis along with gastrointestinal and genitourinary sources of blood loss were ruled out. An intra-abdominal hemorrhage was suspected and a computed tomography of the abdomen revealed multiple simple cysts within the liver, most notably a 10 cm × 11 cm × 11 cm hematoma within a cyst along with ascites consistent with hemorrhage. No acute surgical interventions were necessary and the patient was managed conservatively for a spontaneous ruptured hepatic cyst with blood transfusions and close monitoring as she remained hemodynamically stable.

IMPACT: This case adds to the medical literature because hepatic cyst rupture is not only rare but is easily misdiagnosed and difficult to manage. This is in part due to the sparsity of literature on the subject but also due to its vague and non-specific signs and symptoms.

DISCUSSION: Congenital hepatic cysts have a prevalence of 2–5%, and are dilated remnants of aberrant intrahepatic bile ducts formed during embryogenesis. Other types of cysts include parasitic or neoplastic. Complications include compression, intracystic hemorrhage, infection, and rarely, rupture with very few case reports existing around the world. Symptoms of cystic rupture may mimic acute abdomen and are attributable to blood loss and the space occupying nature of these lesions. Patients typically complain of abdominal pain, loss of appetite, nausea, and alteration of mental status. Our patient was managed conservatively with supportive treatment as she was hemodynamically stable, allowing blood to clot with a potential to tamponade the source of bleed. Other treatment strategies include percutaneous aspiration with injection of sclerosing agents, laparoscopic deroofing, or liver resection. A ruptured hepatic cyst should be considered as a differential diagnosis in the proper setting, especially in patients with symptoms mimicking acute abdomen. Timely diagnosis will expedite treatment and significantly reduce mortality and improve patient's quality of life.

A SINISTER CASE OF RECURRENT ASTHMA EXACERBATIONS: EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

Lakshmi Kallur; Nanette Bentley; Adel El Abbassi. East Tennessee State University, Johnson City, TN. (Control ID #2706561)

LEARNING OBJECTIVE #1: Diagnosing vasculitis syndromes with initial presenting symptoms of recurrent asthma exacerbations in combination with underlying major system involvement and eosinophilia

CASE: A 34-year-old, non-smoker, female with a past medical history of bronchitis and sinusitis was referred to pulmonary clinic for cough, wheezing and dyspnea for one year. On physical exam, patient had a hoarse voice, non-productive cough, and diffuse wheezes. PFT showed FEV1 52% with 32% improvement in response to bronchodilator. A diagnosis of asthma was confirmed and she was given albuterol and combivent. In 9 months, patient was admitted to the hospital for pleuritic positional chest pain and dyspnea. On physical exam, she had sinus tachycardia and bilateral rales. Labs showed elevated troponins (2.67, 1.93, 2.98), peripheral eosinophilia of 44 and negative autoimmune panel. CT angiogram of the chest was indicative of bilateral infiltrates and a pericardial effusion. An echocardiogram showed a normal left ventricular ejection fraction. Due to high concerns of a cardiac event, a cardiac catheterization was performed, which was within normal limits, with high clinical suspicion of pericarditis. A diagnosis of eosinophilic granulomatosis with polyangiitis (EGPA) was made. A prolonged course of oral corticosteroids were initiated. Upon discharge, repeat office follow up at 3 months then 6 months revealed interval then complete resolution of pulmonary infiltrates, pericarditis and her remaining symptoms.

IMPACT: Clinicians have the opportunity to recognize EGPA earlier in the clinical course if suspicion remains high and before irreversible vasculitic consequences occur. New onset adult asthma that is persistent and non-refractory to medications should be investigated further.

DISCUSSION: EGPA was defined by the American College of Rheumatology by the presence of six criteria: asthma, eosinophilia of more than 10% in the peripheral blood, paranasal sinusitis, pulmonary infiltrates, histological proof of vasculitis with extravascular eosinophils and mononeuritis multiplex or polyneuropathy. The presence of four or more criteria yields a sensitivity of 85 and a specificity of 99.7%. EGPA comprises of three phases: 1 - a prodrome allergy phase marked by recurrent asthma, allergic rhinitis and recurrent sinusitis, 2 - eosinophilia and infiltration of major organs including heart, lung and gastrointestinal tract, and 3 - vasculitis commonly involving lungs, skin, and the peripheral nervous system. Treatment for EGPA remains to be immunosuppression through corticosteroids. Due to EGPA's predilection for affecting the lungs, a lung biopsy is considered gold standard for the diagnosis. The patient declined this invasive procedure due to a good response to steroids. We stress the importance of gathering a thorough history on presentation and correlating symptoms of recurrent asthma and eosinophilia in achieving a diagnosis of EGPA.

A STICKY SITUATION: HYPERMUCOVISCOUS KLEBSIELLA PNEUMONIAE CAUSING ALTERNATIVE PYOGENIC ABSCESS

Michelle Lo[2]; Alicia Cowley[1]; david wei[1]. [1]New York University, New York, NY; [2]new york university, New York, NY. (Control ID #2705337)

LEARNING OBJECTIVE #1: Recognize hypermucoviscous Klebsiella pneumoniae (hvKP) as an emerging strain in the US

LEARNING OBJECTIVE #2: Distinguish the criteria for diagnosis and treatment of hvKP compared to classic Klebsiella pneumoniae

CASE: A 49-year-old Malaysian female with chronic hepatitis B was admitted with one day of fever, chills, abdominal pain, and nonbloody, nonbilious vomiting. Admission vital signs showed fever to 39.3° Celsius, heart rate of 95 beats per minute, and blood pressure of 98/59 mmHg. Remarkable exam findings were diaphoresis and right upper quadrant tenderness with positive Murphy's sign. Labs were notable for leukocytosis of 14.4 × 10^3 cells/mcL, total bilirubin of 2.7 mg/dL with direct bilirubin of 1.3 mg/dL, and undetectable hepatitis B viral load. Patient underwent fluid resuscitation and was started on intravenous piperacillin-tazobactam for a presumed biliary infection. Computed tomography revealed an enlarging, heterogenous, septated mass with reticular enhancement concerning for hemangioma or malignancy. Later magnetic resonant cholangiopancreatography showed subsequent increase in the size of the mass and no evidence of biliary obstruction. The patient's persistent sepsis was attributed to the mass being an abscess, and a drain was placed. Cultures grew monomicrobial Klebsiella pneumoniae sensitive to ceftriaxone. Antibiotics were switched and supportive care was provided until the patient's fevers resolved and laboratory values returned to baseline.

IMPACT: Pyogenic liver abscess was previously an uncommon polymicrobial complication of intra- abdominal or biliary tract infection.

However, recently, cases of liver abscess containing hvKP have been observed. This case illustrates the need for improved understanding of hvKP disease reservoirs, transmission, and treatment.

DISCUSSION: Endogenous to the Asian Pacific Rim (Taiwan, Korea, Vietnam, Japan) and well studied in Taiwan, cases of hvKP are now increasingly being reported in the rest of the world. hvKP is semi-defined by a positive string test, whereby a bacteriology inoculation loop generates a viscous string greater than 5 mm in length when bacterial colonies are stretched on an agar plate. K1 or K2 capsular serotype may promote bacterial entry and survival. Risk of infection has been associated with relative immunodeficiency, such as in alcoholic and diabetic patients. Computed tomography is the preferred imaging modality for diagnosis, showing a solitary, septated abscess with a solid appearance. Unlike classic Klebsiella pneumoniae, which has recently become multi-drug resistant, including to extended spectrum beta-lactamases or carbapenamases, hvKP is susceptible to parenteral cephalosporins or aminoglycosides and is often associated with good clinical response and low mortality. However, lack of vigilance and delays in treatment may predispose patients to metastatic infections with multiorgan abscesses involving eyes, brain, spleen, and musculature.

A STRONG CASE OF DYSPNEA WITH EOSINOPHILIA Rachel Hammer; Michael Sciaudone. Tulane University, New Orleans, LA. (Control ID #2705749)

LEARNING OBJECTIVE #1: Recognize strongyloidiasis as a cause of non-ischemic cardiomyopathy.

LEARNING OBJECTIVE #2: Differentiate treatment for uncomplicated cases versus hyperinfection syndrome in the immunocompromised.

CASE: A 48 year-old man with no prior history was evaluated for hypertensive urgency of 200/130. The man reported an intermittent non-productive cough of approximately one year's duration and one month's worsening dyspnea on exertion, orthopnea, and lower extremity swelling. Of note, he emigrated from Honduras twenty years prior. He had no history of alcohol or drug use. Blood pressure normalized with administration of furosemide in the ED. Physical exam revealed rales in lung bases bilaterally, jugular venous distension, lower extremity pitting edema with serpiginous patches of erythema and excoriation, and a cardiac gallop. Labs showed peripheral eosinophilia, thrombocytopenia, elevated creatinine, hyperrbilirubinemia, hyperglycemia, and mild transaminitis. Transthoracic echocardiogram revealed a dilated left ventricle with global hypokinesis and severely depressed systolic function with an ejection fraction less than 15%. The patient was sufficiently diuresed, and subsequent left and right heart catheterizations were unremarkable. CT of the chest showed a small nodule in the right upper lobe. Tests for Coccidiosis, Trypanosoma cruzi, and Mycobacterium tuberculosis were negative, however the acid fast bacilli culture grew Mycobacterium fortuitum. A Strongyloides stercoralis antibody test was positive, and the patient was treated with two doses of oral ivermectin with one dose of intravenous ceftriaxone, and discharged. Two months later, his eosinophilia resolved, but he remained symptomatic with productive cough and weight loss, and was started on an outpatient course of oral ciprofloxacin and trimethoprim-sulfamethozole for M. fortuitum.

IMPACT: Strongyloides-infected patients may carry the parasite for years without prominent symptoms. Strongyloides persists in its hosts through a lifecycle of autoinfection, which increases parasite burden over time and can lead to hyperinfection syndrome.

DISCUSSION: Endemic throughout South America, Stronglyoides has a prevalence of up to one quarter of the population. In hyperinfection syndrome, filiariform larvae penetrate organ tissue, which most commonly is the heart, central nervous system, lungs and liver. We suspect chronic eosinophilia and disseminated filiaria to be the etiology of the non-ischemic dilated cardiomyopathy in this patient. Standard treatment of strongyloidiasis is ivermectin; however, mortality owing to transient bacteremia in the setting of hyperinfection syndrome is high. Therefore, bacteremia prophylaxis with gram negative rod coverage should be considered before antiparasitic agent initiation.

A SURPRISING CONNECTION Qiyuan Liu. University of South Alabama, Mobile, AL; Medstar Georgetown University Hospital, Washington, DC. (Control ID #2673770)

LEARNING OBJECTIVE #1: Recognize rheumatoid meningitis as a paraneoplastic syndrome of diffuse large B-cell lymphoma (DLBCL).

CASE: A 40-year-old male presented to emergency department with paresis and paresthesia for three weeks. Because of a recent history of thrombosis of abdominal aorta status post thromboendarterectomy, an abdominal CT angiogram was performed, showing patent blood flow in the aorta and an incidental finding of hepatomegaly with multiple areas of abnormal attenuation concerning for malignancy. However, triple-phase CT scan of the liver revealed areas of scattered hyper-density in the arterial phase, thought to be secondary to atypical infection. Biopsy of the liver lesions was thus not initially pursued. During the admission, the patient developed confusion and seizures. Cerebrospinal fluid (CSF) analysis showed 33 nucleated cells/mcL (72% lymphocytes), protein 813 mg/dL, and IgG 322 mg/dL with negative cytology for malignancy. Contrast-enhanced MRI brain showed extensive leptomeningeal enhancement, consistent with meningitis. MRI of spine was unremarkable. Dural biopsy showed dense fibroconnective tissue with scattered inflammatory cells. Serology tests showed positive rheumatoid factor (RF) and markedly elevated anti-cyclic citrullinated peptide (CCP) antibody, but negative for antinuclear antibody. A diagnosis of rheumatoid meningitis was made, and the patient was treated with intravenous immunoglobulin and prednisone. Since the paresis significantly improved and paresthesia resolved, the patient was discharged on hospital day 39. However, the patient was re-admitted with unexplained fever shortly after discharge. An underlying malignancy was suspected, and biopsy of the liver lesions showed DLBCL. Unfortunately, the patient's condition deteriorated quickly, and he expired on re-admission hospital day 20.

IMPACT: Rheumatoid meningitis is a rare disease that has not been reported as a paraneoplastic syndrome. Herein we report a case of rheumatoid meningitis arising as a paraneoplastic manifestation of DLBCL.

DISCUSSION: The clinical manifestations of rheumatoid meningitis are seizure, confusion, paresthesia, and paresis, all of which were manifested in this patient. CSF studies and brain MRI are helpful to support this diagnosis, as are positive RF and anti-CCP antibodies. Pathology of the meninges may demonstrate three different patterns: meningeal infiltration (as manifested in this patient), rheumatoid nodules, or vasculitis. The pathogenesis of paraneoplastic rheumatic disease is complex. Previous studies have found the higher prevalence of anti-CCP antibody in DLBCL patients compared to healthy controls though the significance of anti-CCP antibody was unknown. To our knowledge, this case is the first report of rheumatoid meningitis as a paraneoplastic syndrome. Recognition of rheumatoid meningitis that prompts further evaluation of underlying malignancy is important for the physician caring for a patient presenting with aseptic meningitis.

A SWEET DIAGNOSIS FOR A NON-RESOLVING RASH

Jian Liang Tan[1]; Kshitij Thakur[1]; Kah Poh Loh[2]; Edward Chan[1, 3]; Arezoo Ghaneie[1]; Shafinaz Akhter[1]; Sandiya Bindroo[1]. [1]Crozer-Chester Medical Center, Upland, PA; [2]University of Rochester Medical Center, Rochester, NY; [3]Hospital of the University of Pennsylvania, Philadelphia, PA. (Control ID #2671057)

LEARNING OBJECTIVE #1: Recognize the clinical features & diagnostic criteria of subcutaneous Sweet's syndrome.

CASE: A 74-year-old Caucasian female presented with fever, fatigue, and painful erythematous nodules. Her oncologic history was significant for myelodysplastic syndrome (MDS) diagnosed 3 years ago and was on Azacitidine. On initial presentation, her temperature was 101.4 °F. Physical examination was significant for anemia, tender erythematous vesicles on her right face and bilateral ear lobes extending to the right periocular area, and tender erythematous nodules on her buttocks. Complete blood count showed pancytopenia (WBCs of 2.0×10^9/L with ANC of 1500/mm^3, hemoglobin of 8.1 g/dL and platelet count of 16×10^9/L). Concerning for sepsis, she was started on antibiotics and antiviral agents. Despite that, she was persistently febrile with worsening of her plaque and nodular rash. Subsequently, a skin biopsy of her rash over the right shoulder showed subcutaneous lobular and septal infiltrates of neutrophils, sparing the dermis, consistent with neutrophilic panniculitis (NP). Special staining for bacteria, mycobacteria, and fungi infections were negative. Bone marrow biopsy did not show evidence of transformation of her MDS to acute myeloid leukemia (AML). A diagnosis of subcutaneous Sweet's syndrome (SSS) was made. She was started on prednisone 60 mg/day and had marked clinical improvement with resolution of fever within 24 hours.

IMPACT: Patient with a history of MDS presenting with fever and erythematous rashes not responding to antimicrobials, internists should consider SS as part of the differential diagnosis given the availability of effective treatment.

DISCUSSION: Myelodysplastic syndromes are clonal hematopoietic stem cells disorders, characterized by hematopoiesis failure, with increased risk to evolving into AML. A wide range of cutaneous lesions has been associated with MDS such as Sweet's syndrome (SS), pyoderma gangrenosum and erythema nodosum. Cutaneous involvement may signify the progression of underlying MDS to AML. Von den Driesch proposed two major criteria to define SS: 1) sudden onset of painful erythematous nodules and dense neutrophilic infiltrates in the dermis without leukocytoclastic vasculitis; 2) two or more of the minor criteria (fever >38^{0}C, association with underlying hematologic malignancy, excellent response to treatment with systemic steroids or abnormal laboratory value: ESR >20; CRP positive; WBCs >8000; >70% neutrophils). Our patient fulfilled the diagnostic criteria of SS with the exception that the neutrophils infiltration is within the subcutaneous tissue and not the dermis. Guhl et al. proposed that subcutaneous Sweet's syndrome (SSS) is a rare variant form of SS, clinically characterized by erythematous plaques or nodules, which has a histopathologic pattern of primary NP. Primary NP is characterized by neutrophilic infiltrates exclusively in the subcutaneous fat with minimal or no dermal involvement. Hence, the diagnosis of SSS was established.

A WINTER CASE OF WEST NILE ENCEPHALITIS WITH PECULIAR NEUROMUSCULAR AND NEUROIMAGING FINDINGS

Mahveen Sohail; Orhue Odaro; Kinjal Desai; Chethan Rao; Dipaben Modi. Baylor College of Medicine, Houston, TX. (Control ID #2705995)

LEARNING OBJECTIVE #1: Recognize that West Nile Neuroinvasive Disease can present with rare temporal lobe neuroimaging, sensory involvement, and autonomic instability.

LEARNING OBJECTIVE #2: Recognize that West Nile fever and West Nile Neuroinvasive Disease may present together in winter.

CASE: A 73-year-old Texan man with diabetes mellitus presented with acute onset confusion and witnessed seizure in November. A week prior to admission, patient complained of severe headache, fever, diarrhea and lower extremity weakness after a fishing trip, and eventually became unresponsive. He required mechanical ventilation for airway protection and anti-epileptics. On exam, patient was febrile to 102 °F with mosquito bites on his arms. Neurological exam was significant for comatose state, absent brainstem and deep tendon reflexes, and flaccid paraparesis. He developed autonomic instability with labile blood pressures. Lumbar puncture revealed 13 white blood cells/mm^3 (monocyte predominance), 23 fresh red blood cells/mm^3, glucose 99 mg/dL, elevated protein of 82 mg/dL, and a positive West Nile virus (WNV) IgM antibody; gram stain, HSV PCR, and the paraneoplastic and autoimmune panels were negative. Electroencephalograms showed severe diffuse brain slowing without seizures. MRI brain had T2 Flair and DWI changes in right hippocampus and posterior limb of internal capsule. Electromyography described severe subacute sensorimotor axonal polyneuropathy without prolonged distal latencies and normal conduction velocities. He received 5 days of IVIG without improvement and was terminally extubated.

IMPACT: West Nile Neuroinvasive Disease (WNND) may present with nonspecific physical exam and imaging findings. To our knowledge, this is the first case of WNND involving the temporal lobe in adults with neuroimaging suggestive of limbic encephalitis. Our patient also presented in the winter and developed autonomic instability and sensory deficits, which are all rare findings in WNND. Physician awareness of unusual presentations of WNND is paramount for early diagnosis and avoidance of unnecessary treatments.

DISCUSSION: Our patient presented with both clinical entities of West Nile: WN fever and WNND (present in less than 1% of cases). WNND causes a polio-like asymmetric paralysis with brainstem and respiratory involvement with or without encephalitis. Usually, sensory systems are spared in WNND. However, our patient had axonal polyneuropathy with paralysis which is likely due to inflammatory changes in the white matter tracts affecting spinal sensory pathways. Sympathetic ganglia involvement likely caused the autonomic instability, another very rare manifestation of WNND. We attribute his presentation in November to a warmer Texas winter. Further epidemiologic studies may be warranted if more such cases are reported. WNND can be very subtle in its early presentation due to its involvement of a myriad of neurological subsystems. High suspicion is mandated, especially given the similarities in its presentation to HSV and other viral encephalitides.

A WOMAN SEEKING ASYLUM WHO WAS SUBJECTED TO FEMALE GENITAL CUTTING (FGC) Katherine C. McKenzie; Monica Ferrer Socorro; Mytien Nguyen. Yale School of Medicine, New Haven, CT. (Control ID #2692801)

LEARNING OBJECTIVE #1: Recognize that women who have experienced female genital cutting legal have precedent for being granted asylum in the United States. Understand the legal and historical basis that supports asylum in this circumstance. Review World Health Classifications of (FGC).

LEARNING OBJECTIVE #2: Note the existence of FGC in some immigrant women who seek primary care. Review the physical findings and potential long-term complications of FGC in this population

CASE: AD was a 28-year-old woman who was forced to undergo FGC as a 12-year-old girl. The procedure was performed by non-medically trained elders in her community with unsterilized instruments. She experienced severe pain and fear while it was occurring. She bled heavily in the acute setting and was not able to walk without pain for 2 weeks. As an adult, she has chronic pain with intercourse and has experienced no pleasure with sex. Her exam revealed that the clitoris was absent. There was a faint, irregular scar extending from the anterior commissure of the labia majora to an area approximately 2 mm above the urethral opening. The labia minora was absent. These findings were consistent with a classification of World Health Organization type II FGC. (1) A medico-legal affidavit was written which documented the history of FGC, the physical findings and her long-term complications in AD. She was granted asylum for persecution based on "membership in a particular social group."

IMPACT: According to a recent UNICEF report, FGC is practiced in 30 countries, and at least 200 million girls and women alive today have undergone FGC. (2) Women who have experienced FGC are eligible to be granted asylum based on legal precedent in the US. (3) There are no health benefits from FGC. FGC is used as a way to safeguard a girl's virginity before marriage and promote fidelity in marriage. It is in direct opposition to the Universal Declaration of Human Rights. It is often condoned by parents who adhere to this long tradition in the community. In addition, girls, women and families may be socially and financially ostracized if they do not agree to the practice. Women who undergo FGC are at risk acutely for bleeding, infection and death and chronically for recurrent urinary infections, dyspareunia and childbirth complications.

DISCUSSION: For those physicians who evaluate asylum seekers it is important to understand the legal criteria upon which cases will be judged, the cultural context in which FGC occurs and the physical findings expected on exam. General internists who live in communities with immigrants will benefit from knowledge of the practice of FGC and its rationale as well as the physical findings and complications in patients for whom they care. 1. Organisation WH. Female genital mutilation. In: Fact sheet N°241 2014. http://www.who.int/mediacentre/factsheets/fs241/en/. 2. UNICEF. Female Genital Mutilation: A Global Concern. 2016. 3. ABDOMINAL DISTENTION AS THE PRESENTING MANIFESTATION OF AORTO-CAMERAL FISTULA Natasha Adlakha[2]; Paul Leis[1]; Craig Basman[2]; Ala Eltom M.D.[2]; Chad Kliger[2]. [1]Lenox Hill Hospital, Brooklyn, NY; [2]Lenox Hill Hospital, New York, NY. (Control ID #2704232)

LEARNING OBJECTIVE #1: Recognize aorto-cameral fistula (ACF) as an important sequelae of cardiothoracic surgery or endocarditis

CASE: A 56 year old female presented to the emergency room from her primary physician with increased abdominal distention and outpatient computed tomography (CT) significant for moderate ascites. She also complained of dyspnea on exertion, and lower extremity swelling. She had a past medical history of a Gerbode defect (left ventricular to right atrial shunt) complicated one year prior by infective endocarditis requiring aortic and mitral valve replacements with patch repair of the Gerbode defect and placement of a dual-chamber pacemaker for complete heart block. Her general appearance was older than her stated age and frail. Exam was remarkable for ascites, a loud, continuous murmur at the right-upper sternal border, jugular venous distention to her mandible, lower extremity edema. Labs significant for thrombocytopenia (94,000 K/uL), mild transaminitis, serum pro-Brain Natriuretic peptide 2176 pg/mL. Paracentesis was performed with straw colored fluid, negative for infection and serum albumin protein gradient of 1.8, total protein fluid 3.0 g/dL. A transthoracic and transesophageal echocardiogram revealed ejection fraction of 40%, pulmonary artery systolic pressure 50 mmHg, and a communication from proximal aortic root into the right atrium with high velocity left to right shunting (3.5 meters/second), suggestive of an aorto-cameral fistula. Cardiac CT demonstrated connection from the noncoronary aortic sinus to the right atrium.The patient was deemed to be a poor surgical candidate and a decision was made for percutaneous closure with improvement of symptoms at one month follow-up.

IMPACT: With an increasing survival of patients from cardiac surgery, it is important to recognize this complication and an aorto-cameral fistula should remain in the differential diagnosis in patients presenting with unexplained right heart failure symptoms and a history of infective endocarditis (IE). This case highlights the occurrence of an uncommon complication of infective endocarditis where delay in diagnosis can lead to significant morbidity and mortality.

DISCUSSION: An aorto-cameral fistula is an abnormal communication between the ascending aorta and a cardiac chamber, with variable presentation of unexplained acute pulmonary edema or right heart failure. It is a rare but important condition of the aorta that may occur secondary to aortic dissection, infective endocarditis, post surgical, or trauma with fistula formation. ACF has been reported anywhere from months to 30 years after IE with valve replacement. The incidence is extremely low with many cases only being diagnosed post mortem. In patients with native valve IE, the incidence of ACF is less than 2.2%. Treatment options include surgery, percutaneous closure, or conservative management.

ABDOMINAL PAIN COMING FROM THE VEIN Pei-hsing Lai; Tzu-hao Lee. Koo Fundation Sun Yat-Sen Cancer Center, Taipei, Taiwan. (Control ID #2687984)

LEARNING OBJECTIVE #1: Test for occult myeloproliferative neoplasm in patients with splanchnic vein thrombosis in the absence of cirrhosis and malignancy

LEARNING OBJECTIVE #2: Prescribe long term vitamin K antagonist for non-cirrhotic and non-malignant patients with splanchnic vein thrombosis

CASE: A 31-year-old otherwise healthy Asian man presented with two-week long progressive post-prandial abdominal cramps without other symptoms or signs, or clues of infections or liver disease. On physical exam, only moderate tenderness over epigastrium was noted. Lab tests showed only elevated ALT (78 U/L). Blood counts were normal. Abdominal ultrasound showed splenomegaly. Computerized tomography (CT) scan revealed diffuse thrombosis in portal, splenic, and superior mesenteric vein with engorged collateral veins in hepatic hilum and splenomegaly. Esophagogastroduodenoscopy confirmed no varices or ulcer. Positron emission tomography scan verified absence of abnormal hypermetabolic lesion. Tumor markers, hereditary thrombophilia work-up and anti-phospholipid syndrome antibodies were unremarkable. We prescribed therapeutic dose of low-molecular-weight heparin (LMWH), which was later switched to warfarin with a target international normalized ratio between 2 and 3, leading to gradual resolution of his symptoms. No bleeding occurred throughout his treatment. His follow-up CT 3 month later still showed thrombus with residual hepatosplenomegaly and mesentery edema, indicating

possibility of lifelong use of anticoagulants. Janus kinase 2 (JAK2)V617F mutation test was ordered and the result was positive, which is consistent with Philadelphia-chromosome negative myeloproliferative neoplasms (MPN)

IMPACT: Even though the prevalence of JAK2V617F mutation in Chinese non-malignant and non-cirrhotic patients with splanchic vein thrombosis is low, the test should not be overlooked despite the normal blood counts. Although in our case, the test result would not have changed the treatment decision or short-term outcome, it will affect longterm treatment, follow-up and prognosis.

DISCUSSION: The leading causes for splanchnic vein thrombosis (SVT) are liver cirrhosis and cancer. Non-malignant, non-cirrhotic causes make up 0.3% cases of portal vein thrombosis (PVT) and investigations for prothrombotic disorders are mandatory. We ordered the JAK2V617F mutation given the strong association between MPN and SVT, which made the final diagnosis. Our patient represented that SVT may be the first clinical manifestation of MPN. Treatment for SVT requires anticoagulation, with LMWH or unfractionated heparin in acute phase. Long-term vitamin K antagonist (VKA) is recommended in all SVT patients with MPN-related permanent prothrombotic state. Our patient demonstrated that VKA resolved thrombus in non-cirrhotic and non-malignant SVT patient without increasing bleeding. Direct oral anticoagulants may be an alternative in managing MPN related SVT

ACCIDENTAL FINDING OF ASYMPTOMATIC PULMONARY EMBOLISM IN PATIENT WITH ULCERATIVE COLITIS. Anthi Katsouli. Loyola University Medical Center, South Barrington, IL. (Control ID #2700479)

LEARNING OBJECTIVE #1: Recognizing that patients with inflammatory bowel disease (IBD) have an increased risk of venous thromboembolism.

LEARNING OBJECTIVE #2: Treating patients with active ulcerative colitis and pulmonary embolism poses a challenge to the physicians since anticoagulation therapy can increase the risk of bleeding.

CASE: A 55-year-old African American female with no past medical history presented with fever of 103 and abdominal pain with bloody diarrhea. Patient denied any recent travel or any antibiotic use. On physical examination, the temperature was 103.1 °F, the blood pressure was 115/71 mmHg, the pulse 138/min, the respiration rate was 24/min and oxygen saturation was 95% on room air. There was mild diffuse abdominal tenderness to palpation without rebound or guarding. Rectal examination revealed the presence of red blood but no palpable masses or hemorrhoids. Laboratory studies revealed hemoglobin 10.6 g/dl with a mean corpuscular volume of 91 fl, leukocyte count of 7,500/μL; serum biochemistry tests and liver enzymes were normal. Fecal leukocytes were present, but stool analysis was negative for infection or Clostridium difficile toxin. CT scan of the abdomen showed changes of segmental colitis involving the rectosigmoid colon. The lower chest was visualized as well which showed possible pulmonary thromboembolism to the medial basilar segment of the right lower lobe and CT chest angiography confirmed the segmental and sub segmental pulmonary artery embolism. Bilateral lower extremity venous ultrasound was negative for deep venous thrombosis. Hypercoagulable work up was negative. Colonoscopy and surgical pathology of colon biopsy confirmed the diagnosis of ulcerative colitis. She received bridging anticoagulation therapy with low molecular weight heparin. Her hemoglobin dropped to 7.5 g/dl after the initiation of anticoagulation but it was stabilized at 10 after transfusion of two units of packed red blood cells.

IMPACT: It is essential the role of mechanical and pharmacological prophylaxis. However, thromboprophylaxis in IBD patients, although guideline-recommended is still poorly implemented because of concerns about its safety and, over all, the lack of awareness of the magnitude of thrombotic risk in these patients.

DISCUSSION: Patients with active IBD have a threefold risk of deep vein thrombosis or pulmonary embolism compared to the general population. This risk is higher during disease flares with an "inflammatory burden" and during hospitalization due to multiple prothrombotic risk factors.The prevention of venous thromboembolism involves the correction of modifiable risk factors and the implementation of early thromboprophylaxis. The therapeutic management of these patients is challenging because massive hemorrhage is seen in 3% of patients with ulcerative colitis and requires emergency colectomy. If there is no indication for thrombolysis, low molecular weight heparin is the ideal treatment.

ACETAMINOPHEN RELATED CARDIOTOXICITY Ahmed Saleh; Ahmed Maher Abdelfattah; Kashif Chaudhry; Sachin Shah. Lahey Hospital & Medical Center, Burlington, MA. (Control ID #2706202)

LEARNING OBJECTIVE #1: Recognize myocardial necrosis as one of the possible complications of acetaminophen toxicity.

CASE: 24 year old female with history of bipolar disorder presented to an outside hospital after ingesting 300 tablets of acetaminophen for attempted suicide, and transferred to our institution. She arrived comatose and intubated with an acetaminophen level of 296 ug/mL (Ref. range:<=30 ug/mL). The course was complicated by fulminant hepatic failure followed by distributive shock with elevated lactic acid. Initial therapy included N-acetylcysteine, vasopressors and broad spectrum antibiotics. However, she continued to deteriorate. On day 2 of hospitalization, about 62 hours after acetaminophen ingestion, ST segment changes appeared on telemetry. ECG was remarkable for new anterolateral and inferior ST elevations, associated with a Troponin level > 50 ng/mL. Bedside echocardiogram revealed diffusely decreased left ventricular systolic function with ejection fraction of 40%. This was consistent with acute myocardial injury, speculated to be most likely secondary to acetaminophen toxicity. Given her worsening clinical status, it was decided not to undergo emergent cardiac catheterization. About 20 hours later, she passed away. Family declined autopsy.

IMPACT: Cardiotoxicity is a rare manifestation of acetaminophen toxicity with only few cases described in literature. Our case illustrates the possible cardiac effects of acetaminophen overdose and raises awareness for this rare presentation.

DISCUSSION: Myocardial necrosis from severe acetaminophen toxicity has been reported in literature. For instance, a case report from 2008 describes a 23 year old woman with a similar presentation. The patient's declining clinical status precluded cardiac catheterization and the patient died within 72 h. Autopsy revealed patent coronaries, and cardiac tissue histology displayed patchy sub-endocardial necrosis and hemorrhage in the ventricles and septum probably due to direct acetaminophen toxicity. Proposed mechanisms by which acetaminophen causes cardiac toxicity include depletion of sulfhydryl groups, thereby inhibiting nitric oxide and endothelial derived relaxing factor resulting in functional coronary ischemia. In addition, acetaminophen was shown to induce expression of genes involved in oxidative stress and apoptosis in the heart of rats. Finally, acetaminophen hepatotoxicity can cause metabolic derangements resulting in secondary cardiotoxicity. In summary, we report a case of acetaminophen overdose in a young patient who passed away after suffering from metabolic acidosis, distributive shock and myocardial injury. Although hepatotoxicity is the most common manifestation of acetaminophen overdose, cardiotoxicity can also take place and can be severe. This occurs

through various mechanisms, including functional coronary ischemia and direct myocardial damage. Early administration of N- acetylcysteine may be crucial to prevent cardiotoxicity.

ACHROMOBACTER XYLOSOXIDANS INFECTION PRESENTING AS NATIVE VALVE ENDOCARDITIS: A CASE REPORT AND UPDATED LITERATURE REVIEW. Shawhin Karimi[1]; Mohamed H. Yassin[2]; Jusjit Lalli[1]. [1]UPMC Mercy, Pittsburgh, PA; [2]UPMC, Pittsburgh, PA. (Control ID #2699854)

LEARNING OBJECTIVE #1: Recognizing Achromobacter xylosoxidans as a cause of infective endocarditis in at risk populations.

LEARNING OBJECTIVE #2: Assessing the possibility of chemotherapy infusions as being the source of infection and contacting the department of health and CDC when appropriate.

CASE: 73-year-old male with a history of COPD, type 2 DM, squamous cell carcinoma of the lung status post lobectomy, and marginal zone lymphoma currently receiving palliative chemotherapy presented with a complaint of shortness of breath and productive cough for one day. He otherwise denied any other symptoms. His last Rituximab infusion was 18 days prior to admission for his marginal zone lymphoma, and he recently received his first infusion of paclitaxel and carboplatin for palliative chemotherapy of his progressive lung cancer 8 days prior. The patient was hemodynamically stable. Physical examination revealed diffuse wheezing in the lungs but all other systems were otherwise benign. Laboratory workup revealed a creatinine 1.48 mg/dL, WBC of 3.3 K/μl, ESR 40 mm/h, and a negative troponin I. CT of chest revealed multiple lung nodules with scattered areas of atelectatic changes. Blood cultures returned positive for Achromobacter Xylosoxidans. TEE revealed a hyper-mobile 1.8 × 0.8 cm vegetation attached to one of the cordae tendinae of the mitral valve. Given his limited prognosis, surgery was deferred. Decision was made to start the patient on piperacillin/tazobactam and ciprofloxacin for 6 weeks duration and subsequent transition to oral Bactrim for life-long suppressive therapy. Due to the possibility of his chemotherapy infusion being the source of infection, department of health was contacted and no other source or contaminated patients associated with this particular organism were found.

IMPACT: The case made us aware of the implications of an infection with this bacteria and the potential sources that may nned to be investigated to prevent further spread.

DISCUSSION: Achromobacter xylosoxidans is a gram-negative bacilli known to be resistant to several classes of antibiotics. It is believed to be an opportunistic, low virulent organism, which flourishes in aqueous environments, causing various types of nosocomial infections and bacteremia. The case mortality of this organism has been reported by some literature to be as high as 64% in adult cases with endocarditis. A search of prior cases of endocarditis presumed to be secondary to A. xylosoxidans revealed 15 reported cases including ours, between 1981 and 2016. The mortality rate amongst the reported cases was found to be approximately 47%, with 75% of those cases being treated with antibiotics alone. Endocarditis and especially native valve endocarditis from Achromobacter xylosoxidans is extremely rare and requires careful antibiotic selection and early surgical intervention if appropriate. Careful consideration should be made to as to possible sources of the infection as well in order to protect other vulnerable patients from becoming infected.

ACQUIRED PORPHYRIA CUTANEA TARDA FROM UNDERLYING GENETIC DISEASE Janelle Duah[2, 1]; Kathleen White[1]; Rebecca Brienza[1, 2]. [1]VA Connecticut Healthcare System, West Haven, CT; [2]Yale University, New Haven, CT. (Control ID #2705762)

LEARNING OBJECTIVE #1: Recognizing key characteristics of porphyria cutanea tarda

LEARNING OBJECTIVE #2: Diagnosing possible underlying causes of PCT

CASE: 64-year-old Caucasian man with a PMH of hypertension, impaired fasting glucose, and mild alcohol use disorder presented for routine primary care visit with concern of "water-filled blisters" on his hands. The blisters appeared "randomly" over the past several years, less often in the wintertime. He reported that they would appear 2–3 times per month and would take 2–3 weeks to heal. He denied blistering anywhere else. He also reported dark colored urine. He denied work in rose bushes, contact with poison ivy, or changes in soaps, detergents, lotions, or colognes. Social history was significant for drinking 8–10 drinks 2–3×/wk but was negative for high risk sexual activity or IVDU. Family history was significant for his sister dying at the age of 50 from hepatic cirrhosis. Medications included fluticasone nasal spray, ibuprofen, lisinopril, loratadine, metformin SA, and sildenafil.Exam was significant for a very tanned appearing gentleman with several 2–5 mm pink scaly papules, few scattered round-oval superficial erosions, and few sclerotic pink patches on the dorsums of both hands. Labs revealed the patient to be HIV and HCV negative, but with increased iron saturation of 60% with a ferritin of 790. HFE gene analysis showed the patient to be homozygous for H63D mutation. Woods' Lamp fluorescence of his urine showed amber coloring, corresponding to urine fractionated porphyrins that were elevated. The patient's blisters were diagnosed as acquired Porphyria Cutanea Tarda (PCT), secondary to Hereditary Hemochromatosis (HH). The patient was referred to dermatology, hematology, genetics, hepatology, and mental health for alcohol abstinence.

IMPACT: This case illustrates the power of observation and need for continued curiosity. This patient presented routinely, but his concern ended up being life-changing. At a symposium, it was briefly mentioned that patients with hep C could acquire PCT, which can result in increased iron and tanned skin. My patient did not have hep C. When I saw my patient was tanned in October, I linked the diagnoses of HH and PCT together. This ultimately had a huge impact on my patient.

DISCUSSION: PCT affects 1 in 25,000 individuals in the US. PCT is caused by reduced activity of uroporphyrinogen decarboxylase (UROD) in the heme biosynthetic pathway. PCT results in failure to break down porphyrins which are transported from liver to skin, causing blisters on sun-exposed areas. Increased iron increases susceptibility to PCT by reducing UROD activity. This patient has the rarest genotype of HH, as <1% are homozygous for the H63D mutation. Other risk factors include alcohol use, HCV, HIV, estrogen exposure and smoking. This patient was taking NSAIDs and metformin, also linked with pseudoporphyria. The key in distinguishing pseudoporphyria from PCT lies in urine testing, which came back positive in this patient.

ACROMEGALY: A MASQUERADE Daniel J. Hindman; James H. Miller. Johns Hopkins, Baltimore, MD. (Control ID #2707073)

LEARNING OBJECTIVE #1: Diagnose acromegaly early in its clinical course.

LEARNING OBJECTIVE #2: Recognize the role of non-medical staff members in facilitating diagnosis.

CASE: A 31-year-old Hispanic female with a history of carpal tunnel syndrome presented with 3 months of unilateral, throbbing headaches accompanied by nausea, emesis, and photophobia. She had no prior personal or family history of migraines. Her medical history was notable for bilateral carpal tunnel syndrome (CTS) diagnosed 3 years prior, though she had symptoms for over 7 years. Her CTS was attributed to her work in food preparation at a restaurant. She had sequential carpal tunnel release in the year prior to her visit, with improved CTS symptoms. At the time of presentation to our clinic, her neurologic exam was unremarkable. She was prescribed a triptan with plans for close follow-up. At follow-up, she noted progression of her headaches, which were now waking her from sleep, and no response to medication. She also noted that her rings no longer fit and her shoe size had increased. Upon asking about changes in her appearance, her medical interpreter interjected that she had trouble recognizing the patient, despite having worked with her previously. The patient denied any visual changes or menstrual irregularities. Physical exam was notable for prominent supraorbital ridges, a broad nasal bridge, normal visual fields, and wide, doughy hands and feet without edema. Lab testing revealed an elevated insulin-like growth factor-1 level, 2.7 SD above the median value for her gender. MRI demonstrated a left pituitary macroadenoma. She was evaluated by Endocrinology and Neurosurgery, and had a transphenoidal resection of her adenoma.

IMPACT: Acromegaly is an easily missed diagnosis and can masquerade behind non-specific symptoms in a primary care setting. We suggest considering the diagnosis of acromegaly earlier in patients with bilateral CTS, especially when other factors predisposing to CTS are absent.

DISCUSSION: Acromegaly is a rare condition with an incidence of 3–4 cases per million persons per year. The disease course is slow and progressive. The vast majority of acromegaly cases are caused by pituitary adenomas. There is often a delay in diagnosis, with an average delay of 7–10 years from initial symptoms. The diagnosis is further confounded by the relatively non-specific symptoms at initial presentation. Classically, acromegaly is associated with the late findings, including enlarged hands and feet, coarsened facial features, and bitemporal hemianopsia. Early symptoms are more non-specific and include headaches (60–80% of cases), bilateral carpal tunnel syndrome, arthropathy, fatigue and obstructive sleep apnea. In the case of our patient, she lacked continuity with one provider who may have noticed her changing physical appearance. Notably, it was a non-medical staff member who had previously translated for the patient at visits with other providers who assisted in providing history to help make the diagnosis.

ACUPUNCTURE-INDUCED-PNEUMOTHORAX Anjanet Perez-Colon[1]; Leslie L. Seijo[2]; Mariana Mercader[2]; Ana I. Velazquez[2]. [1]Icahn School of Medicine at Mount Sinai Beth Israel, New York, NY; [2]Mount Sinai Beth Israel, New York, NY. (Control ID #2707573)

LEARNING OBJECTIVE #1: Common and serious complication of alternative medicine.

CASE: 36y/o non-smoker woman with hypothyroidism presented with 6 days of dyspnea. Days before she had acupuncture for neck pain; where needles were placed below the base of the skull, lower neck and in the shoulder above the spine of the scapula. Immediately after the procedure she started to feel shortness of breath but didn't seek medical attention until developed concomitant chest tightness and left-sided pain with radiation to the left arm. Vital signs were: temperature 98.6 °F, heart rate 58 beats per minute, respiratory rate 13 per minute, blood pressure 99/63 mmHg and oxygen saturation 90–94% at room air. Physical exam was significant for patient speaking in full sentences and decrease breath sounds at the apex of the left lung. An arterial blood gas revealed a pH of 7.37, Pco2 of 51 mm Hg, and Po2 of 89 mm Hg on room air. A chest x-ray showed a small to moderate 25% left pneumothorax with small basilar component, small left basal pleural effusion and midline trachea. The patient was placed on supplemental oxygen nasal cannula and underwent bedside pigtail catheter placement. Air leak stopped the next day and pigtail catheter was removed. Given patient's good clinical response she was discharged home. No complications reported up to this moment.

IMPACT: Given the popularity of alternative medicine physicians must be aware of complications. Although acupuncture is considered relatively safe, and a study found that physicians have positive attitudes toward acupuncture as a therapeutic method, is important to be aware of common and serious complications. Knowledge of anatomy and depth of insertion of the needle is crucial to prevent complications. A chest x-ray and supplemental oxygen should not be delayed in a patient presenting with dyspnea after acupuncture since pneumothorax is a potentially life-threatening complication.

DISCUSSION: Is believed that acupuncture was developed in China hundreds of years ago and to the present continues to play an important role in China's medical system. It has spread to other countries and it uses include treatment of chronic pain. Although mechanisms are not clear, fine needles serve as instruments of "healing". Complications of the procedure include delay of diagnosis due to treatment of pain, inoculation of infections, nerve damage, trauma, retained needle, and puncture of body cavities with associated complications such as pneumothorax. Iatrogenic pneumothorax after acupuncture is believed to be an underreported common complication, and actually, the lung is the most common organ injured after the procedure. The clinical course of iatrogenic pneumothorax after acupuncture ranges from spontaneously resolved to fatal acupuncture induced pneumothorax. Incidence can be higher in patients with underlying lung disease such as COPD. Treatment of pneumothorax depends on the severity and includes supplemental oxygen, aspiration, chest tube or video-assisted thoracoscopic surgery.

ACUTE ENCEPHALOPATHY RESULTING FROM IFOSFAMIDE TOXICITY Jennifer Schwenk. George Washington University, Washington, DC. (Control ID #2689488)

LEARNING OBJECTIVE #1: Recognize the importance of researching common side effects of chemotherapy treatments so they can be promptly managed

LEARNING OBJECTIVE #2: Diagnose the side effects of chemotherapy regimens in an efficient manner while avoiding the "shotgun" approach

CASE: Ms. P was a 59-year-old woman with history of diabetes, hypertension, and diffuse large B-cell lymphoma, who presented with abdominal pain and vomiting. She had received three different combination chemotherapies, but her disease progressed. Computed tomography (CT) scan revealed a large abdominal mass compressing her duodenum. She received fourth line chemotherapy with rituximab, ifosfamide, carboplatin, and etoposide. The next day, she had confusion, which progressed to lethargy, and then stupor. Chemotherapy infusion was stopped. Relevant labs included leukocytes 13.64 mg/dl and normal values for arterial blood gas, electrolytes, glucose, liver panel, thyroid-stimulating hormone, B12, folate, ammonia, lactate dehydrogenase, and urinalysis. Blood and urine cultures had no growth. A CT scan of the brain had no acute changes, and bedside EEG showed evidence of diffuse encephalopathy

without seizure activity. On neurologic exam, she opened her eyes to stimuli but did not follow commands. Corneal and gag reflexes were normal. Pupils were equal and reactive, and she withdrew to pain. All reflexes were 2+. Remaining physical exam was unremarkable. The care team discussed initiation of methylene blue for ifosfamide toxicity, but it was ultimately deferred due to improvements in mentation. During a period of 24 h, the patient gradually recovered, and was back to her previous baseline, alert and conversant, at 36 hours.

IMPACT: This case reminded me to thoroughly review the side effects of the chemotherapy regimens being used while caring for oncology patients. I will use a more targeted and research-driven approach to diagnose complications based on the primary diagnosis and treatment regimen, rather than employing a wide-ranging search that may be appropriate for other medical inpatients.

DISCUSSION: Caring for oncology patients on the medical ward presents unique challenges for internal medicine residents and hospitalists. It is especially important to familiarize ourselves with the most common side effects of our patients' chemotherapy. Ifosfamide is an alkylating agent that is used in chemotherapy regimens to treat sarcomas, lymphomas, and other malignancies. Common side effects include hemorrhagic cystitis, nephropathy, cytopenias, and neurotoxicity. The incidence of ifosfamide-induced encephalopathy has been estimated to range between 20–60%. Mental status changes in a patient receiving ifosfamide should prompt the clinician to discontinue the therapy immediately and order EEG monitoring to evaluate for status epilepticus. A "shotgun" approach to evaluate all causes of altered mental status is likely not necessary in this setting, and most patients will improve within 48–72 hours of discontinuation of the medication.

ACUTE HEART FAILURE- TERMINAL EVENT IN THROMBOTIC THROMBOCYTOPENIC PURPURA vimalkumar R. patel[1]; abdulwahab Hritani[2]; rupesh prasad[1]; Federico Sanchez[2]. [1]Aurora HealthCare, Milwaukee, WI; [2]Aurora Healthcare, Milwaukee, WI. (Control ID #2706233)

LEARNING OBJECTIVE #1: Diagnose TTP in absence of the classic PENTAD (fever, thrombocytopenia, microangiopathic hemolytic anemia, elevated creatinine, and neurologic symptoms).

LEARNING OBJECTIVE #2: Distinguishing between anemia and thrombocytopenia caused by autoimmune overlap syndrome and thrombotic thrombocytopenic purpura.

CASE: A 72-year-old female with a past medical history of primary biliary cirrhosis, autoimmune hepatitis, scleroderma, and lymphoplasmacytic vasculitis presented to the hospital with one-week complaint of weakness, headache and nausea. Her physical examination was unremarkable. Her labs showed a hemoglobin of 7 (down from 13), platelets of 22 (down from 364), INR of 2 and a Cr of 0.6. The patient received 2 units of blood, and was started on Methyprednisone along with IV immunoglobulin for the suspicion of autoimmune overlap syndrome. On day 2, she was found to have elevated serum proteins, IgG 5760, for which bone marrow biopsy was planned to exclude lymphoplasmacytic lymphoma. The patient had negative Coombs test which may be from chronic steroids for primary biliary cirrhosis.On hospital day 3, the patient developed chest pain, diaphoresis and hypoxia requiring high flow oxygen, her troponin levels rose to 13.2 ng/ml. she was diagnosed with non ST segment elevation myocardial infarction and a subsequent echocardiogram showed moderate left ventricular hypertrophy, severely decreased left ventricular systolic function, severe mitral valve regurgitation with reduced ejection fraction to 15%. Cardiology was consulted but given the patient health status no acute interventions were performed. By hospital day 4, she had developed acute hypoxic respiratory failure that required intubation. The patient continued to do worse and passed away on the same day. Her ADAMTS 13 came back after her death with levels < 5%. Autopsy report was consistent with TTP and showed diffuse platelet thrombi in the coronary arteries.

IMPACT: This case illustrates the dire need to recognize the signs and symptoms of patients with TTP even in absence of the classic PENTAD of TTP. Also, fact that it is very important to rule out TTP in patient with other confounding diagnosis especially patients with other autoimmune disease, which may present in similar fashion. This case will help other physicians recognize acute heart failure as one of the presenting complaints of TTP. This case demonstrates that the untreated TTP can be detrimental and the autopsy report from this patient will add to the literature as the pathology report demonstrate the classic presentation of TTP.

DISCUSSION: This case signifies the potential for misdiagnosis of TTP in light of patients having other autoimmune disease that may cause hemolytic anemia and thrombocytopenia. Additionally, this case demonstrates that acute heart failure is rare but fatal complication in patients with TTP. Also, providers must realize the pentad of TTP is present in < 20% of cases. Recognition of this syndrome is critical to initiate appropriate therapy to reduce mortality.

ACUTE HEPATITIS WITH MIXED PATTERN IN THE SETTING OF PRIMARY EPSTEIN-BARR VIRUS (EBV) INFECTION IN A 43-YEAR-OLD WOMAN

Liliya Benchetrit[1]; Lovemore Makusha[1]; Andrew Silverman[1]; Sonia Taneja[1]; Alexander Pine[1, 2]. [1]Yale University School of Medicine, New Haven, CT; [2]Yale New Haven Hospital, New Haven, CT. (Control ID #2706920)

LEARNING OBJECTIVE #1: Recognize EBV infection as a primary cause of acute hepatitis

CASE: A 43-year-old woman with no history of liver disease presented with 4 weeks of malaise, nasal congestion, and fevers for which she was taking 4–5 g acetaminophen (APAP) daily. Two days prior she began taking amoxicillin for presumed sinusitis. She had previously tolerated the drug as prophylaxis for dental procedures. She denied sore throat, alcohol use, and sick contacts. She was afebrile. Physical examination was remarkable for small tender cervical lymph nodes and diffusely tender abdomen. White cell count was normal with 22% neutrophils and 71% lymphocytes. Hemoglobin was 11 mg/dl. Blood and urine cultures were without growth. Liver enzymes revealed ALP 745 U/L, ALT 688 U/L, and AST 573 U/L. Total bilirubin was 1.6 mg/dL and INR was 1.1. The testing for hepatitides A, B, and C was negative. The APAP level was 4 mcg/mL (normal). The PCR testing for respiratory syncytial virus, influenza A and B, parainfluenza, and adenovirus was negative. The right upper quadrant ultrasound was negative for cholelithiasis, cholecystitis, and biliary dilatation. A CT of the abdomen and pelvis revealed periportal edema. Autoimmune tests for AMA, ANA, smooth muscle, liver-kidney microsomal, and mitochondrial antibodies were negative. Subsequent cytomegalovirus (CMV) PCR was negative. EBV PCR was positive with the viral load of 3,829 copies/mL. The EBV viral capsid antigen (VCA) IgM was positive while VCA IgG and EBV nuclear antigen IgG were negative. Monospot was positive. Liver biopsy revealed portal, lobular, and sinusoidal lymphocytes with EBV. Liver enzymes improved over 6 days with

supportive care but ALP remained elevated (AST 47, ALT 165, ALP 612), which prompted treatment with ursodiol.

IMPACT: Although EBV is a less common cause of acute hepatitis, it should be included on the differential and tested for in all patients presenting with nonspecific symptoms such as profound fatigue, fever, and cervical lymphadenopathy as it may be underdiagnosed.

DISCUSSION: EBV is an often overlooked cause of acute hepatitis. A patient with no prior liver disease presented with a prolonged course of constitutional symptoms, and was found to have a mixed pattern of hepatocellular injury and cholestasis with AST and ALT nearly 20-fold above the upper limit of normal (ULN), and ALP 5-fold ULN. The finding of lymphocytosis and exclusion of hepatitides prompted testing for CMV and EBV. EBV serologies and a liver biopsy confirmed EBV hepatitis. The mechanism of cholestasis in the setting of EBV-related liver injury is due to cytokine-induced disruption and subsequent stagnation of bile flow within the sinusoidal and canalicular transport systems (1). Our case highlights the importance of suspecting acute hepatitis as a possible presenting feature of an EBV infection, and the importance of testing for an EBV infection. Reference 1) Shaukat A, et al. Hepatol Res. 2005;33(1):24–29.

ACUTE ISONIAZID TOXICITY: AN UNCOMMON CAUSE OF METABOLIC ACIDOSIS REQUIRING A UNIQUE TREATMENT

Brian Hom[1]; Bradley A. Moore[2]. [1]Northeast Ohio Medical University, Fairview Park, OH; [2]Summa Akron City Hospital, Akron, OH. (Control ID #2702365)

LEARNING OBJECTIVE #1: Recognize the clinical features and unique treatment of acute isoniazid (INH) toxicity.

CASE: A 33-year-old Nepalese male being treated for latent tuberculosis (TB) with INH, presented with vomiting and depressed mental status. In the ED, he suffered from a generalized tonic-clonic seizure that was aborted with IV lorazepam. The family expressed concern that the patient had intentionally overdosed by taking multiple days worth of INH. His vitals were significant for mild tachycardia, but otherwise were within normal limits. He appeared post-ictal and lethargic, but responsive on physical exam. He was assigned a Glasgow Coma Scale score of 12 out of 15 (eye opening to voice, groaning, purposeful movement). Initial labs revealed a serum pH of 7.1, anion gap 32, lactic acid 28 mmol/L, WBC 19.2 × 103 per mL, potassium 3.1, glucose 178 mg/dL and creatinine 1.48. The CK level was normal at 297 U/L. Hepatic function studies were normal. EKG showed sinus rhythm with a QTc of 435. Serum ethanol and acetaminophen levels were unremarkable. Chest x-ray and CT head were unremarkable. He was initially treated with 100 mg of pyridoxine, 40 mEq KCL, and normal saline. He was admitted and treated with an additional 2 g of IV pyridoxine and Lactated Ringer's solution. The INH was held. Over the next 48 hours, the patient's mental status returned to normal, his labs normalized, and he experienced no further seizures. Once his encephalopathy resolved he admitted to taking a one-month supply of INH. He was transferred for inpatient psychiatric care.

IMPACT: This case differentiates chronic INH toxicity, which is commonly recognized by medical students and clinicians to present as peripheral neuropathy and hepatotoxicity, from acute INH toxicity. It also familiarizes clinicians with the high dosage of pyridoxine used as an antidote.

DISCUSSION: A presentation of altered mental status, seizures, coma, and metabolic acidosis should raise clinical suspicion of acute INH toxicity, especially in those with a history of TB. Acute INH toxicity depletes pyridoxine stores, which is critical in forming the inhibitory neurotransmitter GABA. GABA deficiency can lead to severe seizures. Recognition of acute INH toxicity is crucial as the seizures are frequently non-responsive to benzodiazepines alone, which potentiate the effects of available GABA. Both benzodiazepines and high dose pyridoxine (one gram per gram of INH ingested up to 5 g) should be given. Though INH toxicity is a relatively uncommon cause of metabolic acidosis and seizures, this case serves to remind clinicians to remain vigilant and to consider INH toxicity in the differential diagnosis. Making the correct diagnosis is imperative, as the high dosage of pyridoxine needed for effective treatment may be life saving.

ACUTE MYOCARDIAL INFARCTION FOLLOWING INITIATION OF ATRA + ARSENIC FOR TREATMENT OF ACUTE PROMYELOCYTIC LEUKEMIA Ryan Bober. Weill Cornell Medical College, New York City, NY. (Control ID #2702798)

LEARNING OBJECTIVE #1: Review complications of APL therapy, including differentiation syndrome

LEARNING OBJECTIVE #2: Recognize other rare complications of APL therapy including cardiac sequelae

CASE: An 83 y/o female p/w HTN, mild aortic regurgitation, fatigue was found to be pancytopenic. Marrow biopsy was consistent with acute promyelocytic leukemia (APL). Initial therapy was all-trans retinoic acid (ATRA) therapy with prophylactic dexamethasone for prevention of differentiation syndrome (DS). She required transfusions for coagulopathy. On day two, chest x-ray revealed new bilateral patchy opacities and pulmonary edema concerning for DS. Twelve hours after dose escalation of steroids and initiation of arsenic trioxide (ATO), she required oxygen by facemask and received furosemide and meropenem for presumed pulmonary edema and multi-lobar pneumonia. Repeat EKG was consistent with a non-ST myocardial infarction pattern. Troponin was 4.43, and she later died.

IMPACT: This case illustrates that ATRA + ATO may not be as benign as once thought with documented cases of myocardial insults increasingly common. It is important for clinicians to recognize the potential for cardiac ischemia early and expand the differential beyond pulmonary edema, pneumonia, and differentiation syndrome given the potential lethality of the complication, particularly for patients in DIC. Furthermore, this case demonstrates the increased thrombotic risk of therapy, even in patients with few traditional cardiac risk factors.

DISCUSSION: APL is a form of acute myeloid leukemia (AML) that develops from a retinoic-acid receptor translocation, accounting for 5–20% of cases of AML. Initial therapy is ATRA with ATO. ATRA induces differentiation of the atypical promyelocytes into mature neutrophils. The addition of ATO adds a synergistic apoptotic effect and has improved remission rates. A significant complication of treatment is DS, characterized by fever, pulmonary opacities, and hypoxemia thought to result from promyelocyte inflammatory cytokine release. Other major complications of therapy include coagulopathy, hyperleukocytosis, and QT prolongation (from ATO). To date, there are limited case reports of myocardial infarction in patients initiated on these therapies. Differentiation syndrome has only been reported to be associated with acute MI in two case reports, both of which were after at least 10 days post therapy in patients with no known cardiac risk factors. Furthermore, the risk was attributed to ATRA monotherapy. This is among the first reported cases with rapid development of myocardial injury following initiation of ATRA and arsenic in this time frame. Further research is needed to elucidate the pathophysiologic role behind the increased thrombotic risk of ATRA, and whether ATO compounds that risk to patients in need of urgent APL therapy. Physicians must be cognizant of the risk of these rarer complications of therapy.

ACUTE PANCREATITIS AND HYPERTHERMIA: AN UNUSUAL CASE OF RHABDOMYOLYSIS

Richard H. Zou; Joseph S. Bednash. University of Pittsburgh, Pittsburgh, PA. (Control ID #2706577)

LEARNING OBJECTIVE #1: Describe the differential diagnosis, evaluation, and medical management of non-traumatic rhabdomyolysis

CASE: A 45 year-old male with a history of hypertension and back pain presented with one day of sudden-onset epigastric pain with radiation to his back. He denied fevers, chills, or recent illness. He had no history of pancreatitis, gallstones, or alcoholism. He was initially afebrile with stable vital signs. His exam revealed mild abdominal distension with epigastric tenderness without rebound or guarding. Initial labs were remarkable for WBC 24.7 with 82% neutrophils, amylase 1162 U/L, lipase 7846 U/L, TBili 0.7 mg/dL, and CPK 3153 IU/L. CT abdomen revealed extensive peripancreatic fluid and fat stranding without evidence of necrosis. He received aggressive fluid resuscitation, pancreatic rest, and antibiotic therapy. Over the ensuing days, he became persistently febrile between 101–106 F and was subsequently intubated due to hypoxemic respiratory failure secondary to hypervolemia. His CPK rose to a peak level of 90627 IU/L. There was no evidence of compartment syndrome. Multiple family members confirmed that the patient did not use alcohol, illicit drugs, or nutritional supplements. His medications included longstanding atorvastatin and hydrochlorothiazide; both were held at admission. There was no recent exertional activity. Serologic testing for ANA, anti-Jo-1 antibody, anticardiolipin, and antiphospholipid were negative. He developed severe oliguria with peak creatinine of 6.9 mg/dL, and was started on daily hemodialysis. CPK and creatinine returned to baseline, and he was extubated on day 19 of admission.

IMPACT: There are several reports associating acute pancreatitis with non-traumatic rhabdomyolysis managed conservatively. This case highlights an association between acute pancreatitis-induced systemic inflammation and persistent hyperthermia with rhabdomyolysis and acute renal failure, successfully managed with aggressive fluid resuscitation and hemodialysis.

DISCUSSION: Non-traumatic rhabdomyolysis can be a life-threatening condition associated with elevated CPK, electrolyte derangements, and acute renal failure. Common etiologies include marked physical exertion, medications, infections, thermal extremes, toxins, and rheumatologic disorders. Drug-drug interactions, especially with statins, macrolides, gemfibrozil, or cyclosporine, should be assessed. Bodybuilders should be inquired about nutritional supplementation. It is important to rule out acute compartment syndrome and thyroid disorders, as both are reversible causes. Medical management of non-traumatic rhabdomyolysis focuses on aggressive fluid resuscitation, correction of electrolyte abnormalities, and reversal of underling etiologies. Urine alkalinization with bicarbonate has been suggested to minimize myoglobin breakdown into nephrotoxic metabolites, although with unproven benefit. Heme pigment-induced acute kidney injury with subsequent renal failure warrant hemodialysis or continuous hemofiltration.

ACUTE STEMI IN THE SETTING OF LEFT VENTRICULAR THROMBUS

Joan Bosco; Stephen Z. Peeke; Patricia Dharapak. Mount Sinai Beth Israel, New York, NY. (Control ID #2693520)

LEARNING OBJECTIVE #1: Consider an embolic source as a cause of myocardial infarction (MI), even in patients without atrial fibrillation.

LEARNING OBJECTIVE #2: Recognize the importance of vigilance in the days after a left ventricular (LV) thrombus is diagnosed.

CASE: A 43 year-old man with history of alcohol abuse presented with progressive shortness of breath. He was found with severe pneumonia and subsequently developed cardiac arrest. Initial EKG suggested anteroseptal infarct, age undetermined; troponin was elevated with a peak of 0.188 ng/mL (normal <0.031 ng/mL). A left heart catheterization (LHC) revealed non-obstructive coronary artery disease and increased LV end diastolic pressure. A transthoracic echocardiogram (TTE) showed severely reduced global LV systolic function, an ejection fraction (EF) of 10%, and LV dilatation with suggestion of a thrombus. The patient was aggressively diuresed, started on enoxaparin and continued on aspirin with high-dose statin. On hospital day 10, he developed crushing substernal chest pain and diaphoresis, and became hypotensive to 60/40 mm Hg. EKG showed new inferior lead ST segment elevation. An emergent LHC found 100% occlusion of the posterolateral branch of the right coronary artery; troponin peaked at 26.3 ng/mL. After successful balloon angioplasty, the patient was bridged to and discharged on warfarin as well as aggressive medical management. Repeat TTE 7 months later showed an improved EF of 40 and no LV thrombus.

IMPACT: We describe an uncommon cause of ST elevation myocardial infarction (STEMI), suspected secondary to embolization of an LV thrombus. Our case demonstrates the importance of considering an embolic etiology of MI, especially in the setting of a known LV thrombus, and of remaining vigilant in the days after an LV thrombus is diagnosed.

DISCUSSION: Studies show enoxaparin to be effective in resolving LV thrombi, with a mean treatment duration of 13 days. In our patient, enoxaparin was initiated just 2 days prior to his MI. The literature notes that most systemic emboli occur within the first weeks of thrombus discovery. Therefore, close observation is recommended during this period given the continued risk of embolization and MI even with timely initiation of anticoagulation. This case also highlights an uncommon but life-threatening event. In one study of 'first' MIs, 2.9% were due to embolism, most commonly in the setting of atrial fibrillation. This distinction is important because, while the 30-day mortality rate for those with MI from embolism is similar to other MI patients, the 5-year all-cause and cardiac death rates are significantly higher. An embolic source of MI should be considered even in patients without atrial fibrillation, especially if the patient has known cardiomyopathy, lacks cardiac risk factors or has had a prior LHC showing non-obstructive disease. Early identification of thrombus and rapid initiation of anticoagulation can be life-saving.

ADENOVIRUS-ASSOCIATED ASCENDING FLACCID PARALYSIS AND RECURRENT FEVER IN A LONG TERM HIV PATIENT

Joseph R. Ida; Ying Ting Lau; Fady A. Ibrahim; Janet R. Zolli; Joseph Conigliaro. Hofstra Northwell Health, Manhasset, NY. (Control ID #2706304)

LEARNING OBJECTIVE #1: To include adenovirus and poliovirus (from OPV reactivation) in the differential diagnosis when evaluating immunocompromised patients with ascending flaccid paralysis, polymyelitis and fever of unknown origin.

CASE: G.L. is a 48 year old female with past medical history of HIV infection (diagnosed more than 20 years ago, on HAART, CD4 count was 167 two months prior to admission, no detectable HIV viral load) and cervical intraepithelial lesion of undetermined significance, who presented with progressive, ascending upper and lower proximal muscle weakness, fever and night sweats over the past five months, to the extent that she was unable to walk and became bedbound. Patient continued to have fevers up to 103 F throughout hospitalization. She was

evaluated by ID, Neurology, Rheumatology, Psychiatry and Hematology for a full work up of her unexplained weakness and fever, including negative findings in various tests (CT & MRI head, MRI cervical/thoracic/lumbar spine, CT & MRI of abdomen and pelvis, lumbar puncture, JC virus, lyme, CMV, West Nile virus IgM, Toxoplasmosis IgM, Cryptococcus, HSV 1 &2, parvovirus IgM, Chlamydia, Gonorrhea, Syphilis, blood/urine/spinal fluid culture, drug screen, ANA, RF, antibodies for Myasthenia Gravis, EMG, echocardiogram, muscle biopsy and bone marrow biopsy). Patient was diagnosed with HIV-induced myopathy and discharged home with physical therapy. During a post-discharge outpatient visit 6 weeks later, her clinical condition deteriorated and she had respiratory muscle weakness. This prompted a literature search with emphasis on ascending paralysis in an HIV patient. Citations were found on polymyelitis from reactivation of Poliovirus from oral polio vaccine. Polio titer was checked and confirmed immunity. A literature search for other causes of flaccid paralysis showed adenovirus may be a causative agent. Adenovirus PCR (stool specimen) was checked by NYS Virology Lab and confirmed positive adenovirus (subtype is pending at this time), in the absence of gastrointestinal symptoms. IVIG was suggested for treatment of adenovirus-associated ascending flaccid paralysis.

IMPACT: With early initiation of HAART, there is an increasing population of long term immunocompromised HIV patients. These patients are susceptible to rare viral infections with atypical presentations. This case broadens the differential diagnoses to include poliovirus and adenovirus when evaluating flaccid paralysis in this population, despite presenting in a Polio-free era.

DISCUSSION: We learned that with review of medical records, collaboration with other specialties, literature search and maintenance of board differentials, a correct diagnosis of adenovirus-associated ascending flaccid paralysis in an HIV patient was made.

ADULT-ONSET STILL DISEASE COMPLICATED BY MACROPHAGE ACTIVATION SYNDROME

Elizabeth Meyer[1]; Maya Appley[1]; Benjamin Bailey[1]; Catherine Jones[2]. [1]Tulane University, New Orleans, LA; [2]Tulane University SOM, New Orleans, LA. (Control ID #2705715)

LEARNING OBJECTIVE #1: Recognize adult onset Still disease as a cause of fever of unknown origin

LEARNING OBJECTIVE #2: Identify adult onset Still disease and its known complications

CASE: A 23-year-old Honduran man presented with 2 weeks of fevers and myalgias, with associated sore throat, pleurisy, and non-productive cough. Prior to symptom onset, he was healthy, with no significant family history, recent travel, sexual contacts, new medication or environment exposures. On presentation, he was ill-appearing, febrile, tachycardic and tachypneic. Bibasilar crackles, hepatomegaly and an evanescent salmon colored rash on the anterior chest were noted. Laboratory studies revealed WBC 34,000, 93% segs, 3% bands, Hgb 10.6, platelets 120,000, normal electrolytes, alkaline phosphatase 163, ferritin >15,000, ESR 105, CRP 34, triglycerides 488, fibrinogen > 700, normal CK and TSH, negative HIV, hepatitis panel, ANA, RF, ENA, CCP, RPR, T-spot, Influenza, Strep, Mono, urinalysis, urine, respiratory and blood cultures. CT was suggestive of an interstitial lung disease process. Echocardiogram showed an ejection fraction of 20–25%. Cardiac MRI revealed myocarditis. IL-6 was elevated to 94 and IL-2 was normal. He was diagnosed with adult-onset Still disease (AOSD). Additionally, bone marrow biopsy revealed few scattered hemophagocytes, suggesting macrophage activation syndrome (MAS) complicating AOSD.

IMPACT: Fever may be due to any number of infectious and non-infectious causes. When multi-organ dysfunction is present, fever is likely due to a systemic illness and can include rheumatologic diseases.

DISCUSSION: Recognition of AOSD as a cause of fever of unknown origin and its complications is vital to the internist. AOSD is a clinical diagnosis. The most sensitive, specific and widely used classification system is the Yamaguchi criteria. Diagnosis requires the presence of five or more criteria, of which at least two must be major criteria. Major criteria include intermittent fever ≥39 °C for 1 week, arthralgias or arthritis for 2 weeks, characteristic evanescent rash, and WBC ≥10,000 with neutrophils ≥80%. Minor criteria include pharyngitis or sore throat, lymphadenopathy, hepatomegaly or splenomegaly, liver enzyme abnormalities and negative RF and ANA. Exclusion criteria include absence of infection, malignancy or inflammatory diseases. Exceptionally high serum ferritin levels are also a common feature of both AOSD and MAS. This case is notable for demonstrating multiple rare, life-threatening complications of AOSD, including MAS, parenchymal lung involvement and myocarditis. While patients with milder disease generally respond to NSAIDS or steroids, treatment for severe disease is not well-defined. Treatment typically involves high-dose steroids with adjunctive immunosuppressive therapy. In patients with MAS, only case reports exist to guide treatment. Continued research into targeted treatment is critically needed to improve outcomes.

ADVANCED THERAPY FOR HIGH CLINICAL SUSPICION PULMONARY EMBOLISM

Tushina Jain[1]; Hind Rafei[2]; Yunus Raza[1]. [1]George Washington University, Washington, DC; [2]George Washington University Hospital, Arlington, VA. (Control ID #2707078)

LEARNING OBJECTIVE #1: Recognize signs of massive pulmonary embolism (PE)

LEARNING OBJECTIVE #2: Consider advanced therapy early in suspected cases

CASE: A 74-year-old man, with chronic kidney disease and multiple prior left ankle surgeries with hardware, presented with three days of left ankle pain and shortness of breath. His physical exam revealed hypotension, hypoxia, and respiratory distress. Laboratory workup showed initially normal platelet counts that decreased significantly throughout the hospital stay as well as *Staphylococcus aureus* bacteremia. Imaging of the left ankle showed extensive deep venous thrombosis (DVT) and likely osteomyelitis. A ventilation-perfusion (V/Q) scan showed low probability for PE. A transthoracic echocardiogram showed new, severe right heart strain with normal left ventricular (LV) function. The patient received pressor support, antibiotics for presumed septic shock due to osteomyelitis and infected hardware, and heparin infusion for the DVT. A few days after initial presentation, the diagnosis of massive PE was contemplated due to continued deterioration and the clinical findings. Intravascular ultrasound (IVUS) was used to evaluate the pulmonary arteries (PA). IVUS of the proximal main PA did not reveal an embolus; however, the mean PA pressures were markedly elevated, 50 mm Hg. Pigtail catheters with tissue-plasminogen activator (t-PA) were placed in the main PA. After 16 h of therapy, the catheters were removed. The patient had worsening hypotension again and suffered multiple pulseless electrical activity arrests resulting in death.

IMPACT: The patient's initial diagnosis was sepsis, and possible obstructive shock due to massive PE was overlooked given the V/Q scan result. However, the patient had multiple concerning signs: hypoxia, DVT, and new right heart strain. High clinical probability with a low-probability V/Q scan is indeterminate,

with the chance of PE ranging from 6 to 88%. With high clinical suspicion, PE should remain on the differential, especially in critically ill patients when advanced therapy may provide early hemodynamic improvement.

DISCUSSION: Systemic fibrinolysis is the most studied advanced therapy for massive or submassive PE, defined as PE with hemodynamic instability or right ventricular dysfunction, respectively. With the risk of intracranial hemorrhage though, there is growing interest in targeted fibrinolysis. A recent study of intra-catheter t-PA in 150 patients with massive or submassive PE showed reduction in both RV/LV diameter and mean PA systolic pressure at 48 h. In contrast to the patients in this study, our patient did not have a proximal PE confirmed on IVUS. However, given his elevated PA pressures, high clinical suspicion, and risk of perioperative mortality with such high right heart strain, intra-catheter TPA was administered. Further research is needed to better define the role of targeted TPA in acute PE. This case highlights the importance of weighing risks and benefits in complex patients and early consideration of advanced therapy.

AFOP'S FABLE Saamia Faruqui[1]; Jessica Berman[1]; Irene Grundy[2]. [1]Tulane University, New Orleans, LA; [2]Veterans Affairs/Tulane University SOM, New Orleans, LA. (Control ID #2705780)

LEARNING OBJECTIVE #1: Recognize hilar masses other than malignancy

LEARNING OBJECTIVE #2: Understand a rare interstitial pneumonia pattern

CASE: A 66-year-old woman with rheumatoid arthritis, COPD, and HTN presents with worsening oral pain and ulcers following a dental cleaning. She denied any chest pain or dyspnea. Home medications included methotrexate, prednisone, anti-hypertensive medications and inhalers. She had a fever of 100.5 °F with normal heart rate and blood pressure. Physical exam demonstrated a normal cardiopulmonary and a 3-cm oral ulceration inside her lower lip. Chest x-ray showed left perihilar fullness and opacity. A chest CT showed a new left hilar mass - not present on a previous CT done three months prior (routine lung cancer screening). The new mass was concerning for malignancy versus infection. Ceftriaxone and azithromycin were started; acyclovir was started for presumed HSV oral infection. Blood cultures and sputum cultures were negative. On day three of admit, she developed left sided pleuritic chest pain, respiratory distress, and hypoxemia responsive to oxygen. Fever persisted and physical exam was significant for left lower lobe crackles. Pulmonology performed a bronchoscopy and pathology showed acute fibrinous and organizing pneumonia in the setting of connective tissue disease. Pulmonology recommended a 4-week course of prednisone. On the higher dose of prednisone, her symptoms improved and she weaned from oxygen. She followed up in Pulmonology clinic and is on prednisone daily with plans to transition to mycophenolate.

IMPACT: With an increase in availability and use of CT scans, hilar masses may be easily discovered. An internist should consider other causes than malignancy. This case is an example of an alternative diagnosis.

DISCUSSION: This case highlights an unusual pulmonary complication associated with rheumatic disease. Acute Fibrinous and Organizing Pneumonia (AFOP) was defined in 2002 as a possible histologic variant from the already established cryptogenic organizing pneumonia (COP) and eosinophilic pneumonia (EP). The dominant histopathological finding was the presence of "fibrin balls," or intra-alveolar fibrin in a patchy distribution without hyaline membranes. The majority of cases of AFOP are idiopathic; however there may be an association with rheumatic diseases such as SLE and undifferentiated connective tissue disease. Other similar entities such as COP and EP have been associated with rheumatic diseases. Previously documented treatments for AFOP have included steroids, antibiotics, and cyclophosphamide. In one study, a good clinical response was observed with mycophenolate and corticosteroids. Mycophenolate can preserve lung function in connective tissue disease related interstitial lung diseases, making it a good treatment option for those with rheumatic disease. AFOP, while rare, has a seemingly high mortality rate (up to 50%) and should considered for any patient with rheumatic disease and pulmonary complaints.

ALL THAT FLUSHES IS NOT MENOPAUSE: HOW TO FLESH OUT FLUSHING Pooja Mehra; Rachel H. Kon. University of Virginia, Charlottesville, VA. (Control ID #2706100)

LEARNING OBJECTIVE #1: Generate a differential diagnosis for flushing in an adult and order appropriate testing.

LEARNING OBJECTIVE #2: Recognize symptoms of carcinoid syndrome.

CASE: A 59-year old female presented with flushing and sweating for 1 year with 30 episodes per day of suddenly feeling hot and sweating over her neck and face. She had intermittent diarrhea. A trial of paroxetine to treat presumed vasomotor symptoms provided no relief. She had been on HRT since TAH/BSO 20 years ago, but this was stopped 2 years. Past medical history included chronic back pain on narcotics, recurrent pancreatitis, hypertension, and hypothyroidism. She was on a fentanyl patch, HCTZ, metoprolol, and levothyroxine. Examination confirmed diaphoresis. TSH was normal. One month later, she was still having more than 30 flushing episodes per day. Urine 24 h 5-HIAA was normal. MRI to evaluate abdominal pain showed several bibasilar pulmonary nodules. Biopsy revealed spindle cell carcinoid. Chromogranin A level and Octreoscan were both normal. EGD and colonoscopy did not find GI carcinoid. Since she remained severely symptomatic, octreotide was started by Oncology despite the negative serologic and secretory workup. Flushing decreased to 3 episodes per day and nodules decreased slightly in size.

IMPACT: Knowing the sensitivity of the screening test can help determine if further workup is needed. When the urine 5-HIAA test returned normal, carcinoid syndrome was felt to be unlikely. However, she had a high enough pretest probability due to typical symptoms to pursue the diagnosis.

DISCUSSION: The evaluation of a patient with flushing starts with a detailed history and physical exam, including a flushing diary. Specific questions should include presence of diarrhea, headache, palpitations, wheezing, shortness of breath, or urticaria; correlation with fever or blood pressure change; and triggers (diet, alcohol, or strong emotion). The differential can be broken into two parts: autonomic versus vasodilation. Autonomic mediated flushing includes thermoregulatory flushing as seen in fevers and exercise, post-menopausal hot flashes, emotional flushing, and flushing caused by certain neurologic disorders. Vasodilator mediated flushing includes medication side effect (vasodilators, nicotinic acid, steroids, hormonal therapy, and narcotics). Further workup should include urine 5-HIAA for carcinoid syndrome; histamine, prostaglandin D2, and tryptase for systemic mastocytosis; and fractionated metanephrines for pheochromocytoma as these are the most common systemic causes of flushing. If negative, then referral to Endocrinology for workup of rare causes is necessary. This patient had a seronegative, non-secreting carcinoid tumor and her symptoms were likely related to this, owing to decrease in flushing with octreotide. Sensitivity of the urine 5-HIAA test is 90% for carcinoid syndrome, but bronchial carcinoids can produce severe flushing through release of vasoactive peptides that will not be detected in the urine 5-HIAA test.

ALLOPURINOL-INDUCED DRESS SYNDROME WITH CHOLESTASIS Preeyanka R. Sundar[1]; Amani F. Sargios[2]. [1]Berkshire Medical Center, Assonet, MA; [2]Berkshire medical center, Wappingers falls, NY. (Control ID #2681581)

LEARNING OBJECTIVE #1: Recognizing signs, symptoms, and understanding the pathophysiology of DRESS syndrome (DS)

LEARNING OBJECTIVE #2: Recognize diagnostic modalities for DS

CASE: 54 year old male with past medical history of gout, asthma, status post gastric bypass graft presented after 3 days of fever, chills, and subcutaneous abscess of his right foot. Admitted for necrotizing fasciitis complicated by sepsis, AKI with creatinine of 4, and hemodynamic instability that required below knee amputation of his right leg, he post operatively developed acute gout flare of his right knee and was prescribed colchicine. Weeks after discharge he presented with gout flair with hemoglobin of 6.8, complicated by an episode of hematemesis. EGD was performed which revealed a 3 cm bleeding marginal ulcer and he had pre-renal azotemia in the setting of acute blood loss. He was started on allopurinol with tapering dose of prednisone by his rheumatologist. One month later, he complained of 4 days chills, swollen tongue with oral cavity and posterior wall pharynx raised flat-topped lesions with difficulty swallowing, and morbiliform, infiltrated erythematous skin eruption began on his face and spread to his chest over 24 hrs with scrotal tenderness and swelling. Negative Nikolski sign. Allopurinol was stopped, but the rash continued to spread, which necessitated admission. Labs showed ALP 881, AST 70, ALT 201, ESR 80 mm/hr, with eosinophilia of 0.9 K/uL, CMV IgG was elevated at 72 although Herpes Virus 6 DNA PCR was less than 500 copies/mL. CT abdomen and pelvis showed biliary sludge without evidence of acute cholecystitis, dilatation of proximal common bile duct of 12 mm, and distally CBD measured 9 mm. Skin biopsy confirmed DRESS demonstratin spongiosis with microvesicles overlying perivascular lymphohistiocytic infiltrates with eosinophils. Treatment with methylprednisone 60 mg Q6h tapered to oral dose of prednisone over 6 weeks showed improvement of rash, systemic symptoms, and lab results.

IMPACT: Drug-Reaction with Eosinophilia and Systemic Symptoms (DRESS) also known as Drug-Induced Hypersensitivity Syndrome (DIHS) is a rare, severe cutaneous adverse reaction, first introduced by Bocquet in 1996. Several common drugs may induce DS including anti-epileptics, antibiotics, NSAIDs, allopurinol, sulfonamides, carbamazepine, biologics and phenobarbital.

DISCUSSION: DS/DIHS begins 2–6 weeks after drug initiation and is characterized by fever, morbilliform-type or maculopapular rash, lymphadenopathy, eosinophilia, with or without leukocyte abnormalities, with internal organ involvement in the form of acute kidney failure with elevated creatinine, liver toxicity characterized by transaminitis with no obstruction. A type IV late hypersensitivity reaction, DS evidences of interaction between immune system, the offending drug, and reactivation of HHV-6, CMV, and EBV. Incidence is between 1:1,000, and 1:10,000 patients, mortality rate up to 10%. Corticosteroid-resistant DRESS is treated with IVIG, valganciclovir, cyclosporine, and immunosuppressants.

AMBULATORY BLOOD PRESSURE MONITORING: SHOULD WE BE DOING THIS MORE FOR OUR PATIENTS? Galina S. Tan. Cambridge Health Alliance, SOMERVILLE, MA. (Control ID #2702266)

LEARNING OBJECTIVE #1: Use a patient case to illustrate a common clinical conundrum related to management of hypertension and white coat hypertension

LEARNING OBJECTIVE #2: Review the rationale and evidence behind ambulatory blood pressure monitoring (ABPM)

CASE: 50 year old female in primary care clinic for hypertension follow up. Past medical history includes resistant hypertension, type 2 diabetes, and obesity. Closely followed over the past year for poorly controlled hypertension, with a negative workup for secondary hypertension. She is compliant on diet and 3 antihypertensives, and checks her blood pressure regularly at home. She is unhappy with the number of pills she has to take, and notes that her clinic blood pressure readings are always much higher than her home blood pressure readings. Clinic BP: 164/96 at the time of visit (no signs/symptoms of hypertensive crisis). BP range 122-170/80-102 over the past year. Home BP: 120 s/70s every morning before breakfast and medications, over the past few months per patient's logbook.

IMPACT: Questions from case: Why the discordance in clinic vs. home BP readings? Could it be due to bad technique, false home blood pressure recordings, white coat hypertension? Would ambulatory blood pressure monitoring (ABPM) be useful in this patient's case and help change management? ABPM is often cited on the medical board exams and clinical guidelines as being an important diagnostic tool in hypertension, yet it is seldom done in practice. What exactly is the rationale and evidence behind this recommendation?

DISCUSSION: This case was presented at Cambridge Health Alliance's (CHA) Medicine grand rounds, which involved a thorough review of the background and literature behind ABPM as well as discussions with cardiologists and members of the hypertension task force at CHA. - ABPM gives an unparalleled breadth of patient blood pressure data outside the artificial clinic setting, and has also been shown to be better predictors of longterm cardiovascular outcomes compared to clinic blood pressure readings. While this gives it potential to be a great tool for diagnosing/managing HTN, it is highly unpractical given the current limitations of insurance coverage, contract quality metrics, and logistical barriers. - It is also important to remember the important goal of improving meaningful patient outcomes, not just treating the numbers (BP readings), when managing hypertension. ABPM may lead clinicians to be biased towards treating the numbers. - The most obvious benefit of ABPM is in identifying patients with white coat hypertension and thus leading to less prescription of unnecessary antihypertensive medications. However, it is interesting to note that there is increasing data suggesting that white coat hypertension is not as benign as previously thought. - Incremental benefit of ABPM over home blood pressure monitoring (HBPM) seems small, so it is unlikely that we are doing patients a huge disservice by not offering ABPM as long as we use a standardized approach to following home BP readings.

AMIOADARONE-INDUCED THYROTOXICOSIS Elizabeth Meyer; Kristin Bateman. Tulane University, New Orleans, LA. (Control ID #2705804)

LEARNING OBJECTIVE #1: Identify thyroiditis as cause of fever.

LEARNING OBJECTIVE #2: Recognize amiodarone as a cause of thyroiditis.

CASE: A 53-year-old woman with history of cardiac sarcoidosis (EF 25–30%) complicated by ventricular tachycardia on chronic prednisone and amiodarone presented with a three-week history of fever and chest pain. She had a temperature of 38.8 degrees celsius, sinus tachycardia, and a non-palpable thyroid. Cardiac exam revealed a regular rate and rhythm. Pulmonary exam was clear to auscultation. Pertinent labs included normal WBC, elevated ESR and CRP, markedly decreased TSH with elevated free T4 and rT3. ECG showed sinus tachycardia with premature ventricular contractions. Extensive infectious and non-infectious

work-up was completed and negative, including lumbar punctures, chest CT angiography, CT abdomen and pelvis, stool studies and blood, urine and stool cultures. Thyroid ultrasound showed a heterogeneous echogenic thyroid. Thyroid uptake scan showed diffuse decreased uptake consistent with thyroiditis. She was diagnosed with destructive thyroiditis due to amiodarone use.

IMPACT: Fever without a source is commonly encountered by the internist. Initial work-up is directed towards infection, venous thromboembolism, malignancy, and autoimmune. If initial testing is non-revealing, noninfectious inflammatory diseases, such as thyroiditis should be considered.

DISCUSSION: Painless thyroiditis is autoimmune-mediated or after exposure to certain drugs, such as amiodarone. Manifestations of amiodarone-induced thyrotoxicosis can be missed due to beta-blocking activity minimizing many adrenergic manifestations; common signs are arrhythmias, ischemic heart disease or heart failure exacerbation, weight loss, restlessness or fever. Amiodarone-induced thyrotoxicosis is categorized as type 1 or 2. Type 1 is caused by active production of excessive thyroid hormone and associated with an underlying thyroid abnormality/disease. Thyroid Doppler shows an enlarged gland with increased vascularity; scanning with 99mTc-sestamibi shows normal to increased thyroid uptake. Proptosis and serum TSI are diagnostic of type 1. Treatment includes methimazole and perchlorate, which further blocks iodine uptake. Type 2 is the result of drug-induced lysosomal activation leading to destructive thyroiditis. Incidence rises as cumulative amiodarone dosage increases. Thyroid Doppler shows a normal sized gland without increased vascularity; scanning with 99mTc-sestamibi reveals no thyroid uptake. Discontinuation of amiodarone will not have an acute effect because of its storage and prolonged half-life (100 days). However, serum levels of interleukin-6 are usually quite elevated; thus patients are treated with a prednisone taper. Though amiodarone can have tremendous beneficial effect, it requires constant vigilance. Current recommendations include checking thyroid function tests prior to commencing amiodarone and monitoring every six months.

AN (INBORN) ERROR IN THE DIAGNOSIS: AN UNUSUAL PRESENTATION OF ALTERED MENTAL STATUS Poorvi Desai; Kellee Oller; Cuc Mai. University of South Florida, Tampa, FL. (Control ID #2706869)

LEARNING OBJECTIVE #1: Recognize that inborn errors of vitamin B12 metabolism can present initially in young adults.

LEARNING OBJECTIVE #2: Assess for disorders of cobalamin metabolism in young adults with macrocytic anemia and altered mental status despite normal B12 levels.

CASE: A 22 year-old woman with known mild cognitive delay attributed to infant hypoxia presented with progressive cognitive decline and regressive behavior. She lived independently until 8 months prior to hospitalization when she was diagnosed with pernicious anemia and hypothyroidism. Despite cyanocobalamin and levothyroxine adherence, her symptoms worsened to forgetting activites of daily living. Upon admission she was oriented only to person. Physical exam was remarkable for delayed speech, wide-based gait, atrophic glossitis, and a witnessed episode of brief cyanosis with emesis. Initial laboratory studies revealed macrocytosis with mean corpuscular volume of 135 femtoliters. Peripheral smear demonstrated hypersegmented neutrophils. RBC folate, cobalamin, and methylmalonic acid levels were unremarkable, but homocysteine was elevated at 124 umol/L. Extensive altered mental status workup was then undertaken. MRI brain showed confluent increased T2 and FLAIR signals in the periventricular white matter disproportionate to age. Electroencephalogram revealed moderate diffuse encephalopathy. Urine drug screen, TSH, whole spine MRI, HIV, CSF studies, and malignancy testing were unremarkable. Lastly, genetics evaluation was obtained. Serum oganic acid testing returned with low-normal plasma methionine and elevated free homocysteine. Homocysteinuria NextGen sequencing revealed two MTRR gene mutations known to cause Cobalamin E (CblE) deficiency. Hydroxocobalamin and betaine were begun, which aided in improvement, though she continued to require 24 h care.

IMPACT: This case adds to the literature of rare cases of young adults who present with inborn errors of cobalamin metabolism, contributing to the differential for altered mental status. Additionally, it provides a diagnostic strategy for internists who may otherwise make the easy mistake of anchoring onto the presumptive diagnosis of vitamin B12 deficiency in a patient with macrocyctic anemia and neurologic changes.

DISCUSSION: CblE Deficiency, an autosomal recessive disease of impaired methionine synthase, comprises less than 5% of disorders of intracellular cobalamin metabolism. The median age of presentation is 4 weeks old, but internists should be aware that patients can present atypically as adolescents or young adults. Not all states have incorporated it into newborn screening, and results may differ by laboratory technique. Our case highlights that with a clinical suspicion of vitamin B12 deficiency despite adequate supplementation, internists should consider screening for intracellular disorders of cobalamin metabolism. Treatment is focused on betaine and hydroxocobalamin, a precursor to cyanocobalamin, and prognosis for patients with late-onset varies after initiation of appropriate therapy.

AN ATYPICAL CASE OF AKI: WHEN CRYOGLOBULINS GO COLD Hani Rashid[1]; Phuong T. Nguyen[2]; Roberto Collazo-Maldonado[1]; Anas Saleh[2]. [1]Methodist Dallas Medical Center, Dallas, TX; [2]Medical City of Fort Worth, Fort Worth, TX. (Control ID #2688224)

LEARNING OBJECTIVE #1: Diagnose atypical causes of acute kidney injury

LEARNING OBJECTIVE #2: Recognize relationship between Sjogren's syndrome and cryoglobulinemia

CASE: A 30 year old Hispanic female with no past medical history presented with one week history of progressive dyspnea, lower extremity edema, orthopnea and nocturnal cough. She denied associated chest pain, nausea, or diaphoresis. Significant findings on physical examination were hypertension, bibasilar crackles and lower extremity pitting edema to the knees. Chest radiograph revealed bilateral pleural effusions and CT angiography was negative for pulmonary embolism. Echocardiography and abdominal ultrasound were unremarkable. Laboratory data revealed a creatinine of 1.3 mg/dL, as well as nephrotic range proteinuria (4.7 grams protein per 24 h period). The patient was started on intravenous furosemide in an attempt to overcome her volume overload, but this treatment failed and renal function continued to worsen. Autoimmune evaluation demonstrated positive anti-SSA antibody and rheumatoid factor with undetectable serum complement component C4. Kidney biopsy confirmed the diagnosis of Sjogren's syndrome-associated mixed cryoglobulinemic membranoproliferative glomerulonephritis. The patient completed a course of plasmapheresis, and was begun on therapy with rituximab and steroids. While she initially achieved remission following treatment, she has since had one relapse that was successfully treated with a course of cyclophosphamide.

IMPACT: Acute kidney injury is too often categorized as either pre-renal azotemia or acute tubular necrosis. This case emphasized that interpretation of

certain lab findings (e.g. an elevated creatinine) requires critical evaluation of potential etiologies. Specifically, this case illustrated the importance of maintaining a high degree of suspicion for cryoglobulinemia in patients with acute kidney injury and findings suggestive of rheumatologic disease.

DISCUSSION: Cryoglobulinemia is characterized by the presence of immunoglobulins that reversibly precipitate at low temperatures. This may result in a clinical syndrome of systemic inflammation and tissue damage commonly affecting kidneys and skin caused by cryoglobulin-containing immune complex deposition and complement activation. Patients with type II (mixed) cryoglobulinemia have rheumatoid factors associated with chronic inflammatory states such as SLE, Sjogren's syndrome, and viral infections. An internist must be able to recognize when acute kidney injury may be a manifestation of a rare underlying disease process, especially in young patients with no known contributing factors. Cryoglobulinemia is a rare disease entity that can result in devastating organ damage, including membranoproliferative glomerulonephritis. Patients with cryoglobulinemia are usually diagnosed in the inpatient setting, and often respond to immunosuppressive regimens.

AN ELUSIVE DIAGNOSIS REVEALED BY AUTOPSY Saroja Bangaru[2]; Amanda Strickland[3]; Stephen Dickson[2]; Nainesh Shah[1]. [1]UT Southwestern, Dallas, TX; [2]University of Texas Southwestern, Dallas, TX; [3]University of Texas Southwestern Medical Center, Dallas, TX. (Control ID #2700935)

LEARNING OBJECTIVE #1: Recognize HLH and its association with HHV-8

LEARNING OBJECTIVE #2: Appreciate the role of autopsy in postmortem diagnosis

CASE: A 45-year-old man with a history of AIDS (CD4 34) who recently restarted antiretroviral therapy after prolonged noncompliance presented with fever (40C) and diarrhea and was admitted for septic shock. His lab work was notable for hemoglobin 7.9, leukocyte count 3.6, platelets 126, and ferritin 2500. Infectious work-up including bacterial, fungal, and acid fast bacilli blood cultures; sputum, urine, and stool studies; and cytomegalovirus PCR was negative. He improved initially with fluids, empiric antibiotics, and steroids but his shock recurred two weeks later and was associated with rapidly progressive somnolence and transfusion-dependent cytopenias. A more extensive work-up was negative for EBV, disseminated HSV, parvovirus, HHV6, tuberculosis, disseminated histoplasmosis, cryptococcus, brucellosis, and bartonella. Computed tomography of chest, abdomen, and pelvis revealed hepatosplenomegaly and diffuse lymphadenopathy. He was started on empiric treatment for disseminated mycobacterium avium-intracellulare. Hemophagocytic lymphohistiocytosis (HLH) was considered given persistent fever, splenomegaly, low fibrinogen (106 mg/dL), high ferritin (7125 ng/mL), and severely elevated IL-2 receptor level (18,890 pg/mL (normal = <1033). Bone marrow biopsy did not show hemophagocytosis but was unable to rule out HLH, so high-dose dexamethasone was initiated to treat HLH. The patient did not improve, though, and his family elected for comfort care. He died two days later. Postmortem exam via autopsy revealed profound hemophagocytosis in the bone marrow, spleen and lymph nodes, affirming a diagnosis of HLH. It also revealed pulmonary Kaposi's sarcoma (KS) with scattered HHV-8 positive cells. HHV-8 serum PCR resulted 210,000 DNA copies/mL. The postmortem diagnosis was HLH secondary to HHV-8 and associated KS in the setting of advanced AIDS.

IMPACT: This case brings to attention HLH, a rare hematologic diagnosis that should be on the internist's early differential for a decompensating patient with poorly controlled AIDS. This patient's diagnosis adds to only a few reported cases of HHV8-associated HLH in the HIV population.

DISCUSSION: In HIV/AIDS patients, HLH is usually driven by an underlying infection or malignancy. The mainstay of management of secondary HLH is treatment of the underlying cause, but patients with HHV-8-associated HLH have benefited from steroids and chemotherapy. Autopsy rates have declined more than 50 percent over 4 decades, but in our case, HHV-8 positivity, KS, and HLH were all postmortem diagnoses, illustrating the power of autopsy to provide diagnoses that are complex and so, can evade clinical evaluation. Thus it maintains value in modern clinical medicine. As providers of end of life care and in an effort to advance medical knowledge, it is imperative for internists to discuss autopsy with patients' families when appropriate.

AN ESSENTIAL VITAMIN FOR EFFECTIVE HEMATOPOIESIS: A SIMPLE CURE FOR BONE MARROW FAILURE Adrienne N. Poon[1]; Hind Rafei[2]; William B. Ershler[3]. [1]George Washington School of Medicine and Health Sciences, Clifton, NJ; [2]George Washington University Hospital, Arlington, VA; [3]Institute for Advanced Studies in Aging, Falls Church, VA. (Control ID #2706959)

LEARNING OBJECTIVE #1: Diagnose pancytopenia as a presentation of severe vitamin B12 deficiency

LEARNING OBJECTIVE #2: Recognize indications of B12 screening and repletion

CASE: A 47 year old female with a history of carcinoid gastric tumor and anemia presented with a month of progressive generalized weakness, dizziness, fatigue, and 20 lb weight. She was transfused for symptomatic anemia a year prior. Medications included ferrous sulfate tablets. Vital signs were unremarkable. Examination was notable for a petechial rash on bilateral upper and lower extremities. Labs included: WBC 2,480/mm^3 with ANC 1,413; hemoglobin 6.1 g/dL with MCV 100.6 fL, RDW 39%, and 4/100 nucleated RBCs; platelets 67,000/mm^3; Tbili 3.6 mg/dL; AST 62 U/L; ALT 28 U/L; iron 88 ug/dL, TIBC 167 ug/d, and iron saturation 53%. Folate was normal at 14 ng/mL, however vitamin B12 was severely low at 54 pg/mL with a high methylmalonic acid of 2,700 nmol/L. She had high gastric parietal cell antibody of 80.3 U though intrinsic factor blocking antibody was negative. Parvovirus antibody and JAK2V617F were also negative. Peripheral blood smear revealed pancytopenia, occasional hypersegmented neutrophils, oval macrocytes and fragmented erythroid cells. Bone marrow biopsy to showed hypercellular marrow with trilineage hematopoiesis and megaloblastosis consistent with megaloblastic anemia. Flow cytometry was normal. CT abdomen was notable for splenomegaly. She was diagnosed with pernicious anemia and treated with 1000 mcg of intramuscular vitamin B12 for 7 days with improvement in her hemoglobin to 9.8 g/dL, MCV to 99.4 fL, RDW to 32%, and nucleated RBC to 2/100 WBCs. Tbili as marker of indirect bilirubin for intramedullary hemolysis from ineffective erythropoiesis improved to 2.6 mg/dL. She will continue intramuscular vitamin B12 indefinitely.

IMPACT: Screening B12 in the setting of macrocytic anemia is relatively low cost compared to more extensive and invasive evaluation often warranted in undiagnosed severe B12 deficiency as in this case. Early repletion of vitamin B12 leads to rapid reversal of symptoms, improvement in erythropoiesis, and prevents progression to severe disease.

DISCUSSION: Vitamin B12 deficiency is a reversible cause of bone marrow failure and a demyelinating nervous system disorder. Thus, early detection and

prompt treatment is essential. The severity of ineffective erythropoiesis that results also causes ineffective myelo and megakaryocytopoiesis as well, leading to the presentation of pancytopenia similar to this case. The presentation might be complicated by the presence of splenomegaly that mimics acute leukemia and mislead diagnosis. Ineffective erythropoiesis in the hypercellular bone marrow likely led to premature release of nucleated red blood cells that overwhelmed the spleen's ability to clear, which may have accounted for the splenomegaly. In this case, the presence of macrocytic anemia, anti-parietal cell antibodies, low B12, elevated MMA, bilirubin, and megaloblastosis on biopsy were suggestive of megaloblastic anemia.

AN INDECISIVE THYROID Kyle V. Keinath[1]; Jason Unger[1]; Joan B. Ritter[2]. [1]Walter Reed National Military Medical Center, Washington, DC; [2]Walter Reed National Military Medical Center, Bethesda, MD. (Control ID #2706247)

LEARNING OBJECTIVE #1: Tailoring management and assessment of thyroid conditions.

LEARNING OBJECTIVE #2: Recognize shifts in disease states in patients with thyroid diseases.

CASE: A 55 year old female presented to clinic with insomnia, frequent waking, feeling warm, and palpitations. She has a history of Hashimoto's Thyroiditis, diagnosed in 1997 with a Radiolabeled Iodine Uptake scan (RAIU) of 0 and positive Thyroperoxidase antibodies (TPO Abs), treated with 125mcg Synthroid. Physical exam proved a 2 cm small goiter. Blood work revealed a TSH <0.005 U/ml and free Thyroxine of 2.02 μg/ml. Synthroid was sequentially decreased. Serial labs revealed free Thyroxine (1.88, 1.96, 1.77 μg/ml) and decreased TSH (<0.005, 0.006, 0.007 U/ml). Further tests revealed a Thyroptropin Receptor Ab of 4.6 and a Thyroid Stimulating IgGs of 167%. RAIU revealed 18% uptake at 4 hours, 45% uptake at 24 hours. The pinhole images show homogeneous trapping without focal areas of accumulation, consistent with Graves Disease. She was treated with Methimazole 20 mg daily. She returned two months later with easy fatigue. Labs showed TPO Ab of 93 IU/ml, Thyroglobulin Ab of <1.0 IU/ml, Thyroxine of 0.88 μg/ml, and TSH of 4.830 U/ml. Methimazole was held, serial labs continued to be hypothyroidic, 25mcg Synthroid was instituted on which the patient remains.

IMPACT: We were unaware of the possibilty of shifting pathologies. In surviellance of my patients, we have been more proactive in lab work monitoring. In treating patients, we no longer immediately associate symptoms with Synthroid. This case adds to the literature in the nature of the stability of the patient treatment prior to acquiring Grave's Disease, the longest of researched cases, in addition to episodic nature of hyperthyroidism.

DISCUSSION: Hypothyroidism affects 1–2% of the global population[1]. The most common cause of iodine replete hypothyroidism is Hashimoto's Thyroiditis. In rare instances patients being treated for Hashimoto's Thyroiditis can develop Grave's Disease, the leading cause of hyperthyroidism[2]. It is theorized there is a paradigm shift in auto-antibodies occurs creating a conversion to Grave's Disease[3]. The case is an atypical pattern of thyroid disease. Complicating the clinical picture is the initial prolonged stability, a stable nineteen year clinical course. This case highlights the importance of not solely attributing thyroid changes to improper medication dosages, and to always consider that individuals with a history of hypothyroidism may actually have developed hyperthyroidism pathophysiology. [1] Vanderpump MPJ. The epidemiology of thyroid diseases. In: Braverman LE,Utiger RD, editors. Werner and Ingbar's The Thyroid: A Fundamental and Clinical Text. 9th edn. Philadelphia: JB Lippincott-Raven; 2005. p. 398–496. [2] Canaris GJ, Manowitz NR, Mayor G, et al. The Colorado thyroid disease prevalence study. Arch Intern Med 2000;160:526–34. [3] Furqan S, Haque N, Islam N: Conversion of autoimmune hypothyroidism to hyperthyroidism. BMC Research Notes 2014, 7:489.

AN INFECTIOUS HEMORRHAGE Yekaterina Kim; Phillip D. Zhang; Daniel Landau; Lewis A. Eisen. Montefiore Medical Center, Bronx, NY. (Control ID #2703732)

LEARNING OBJECTIVE #1: Recognize the differential diagnosis of intracerebral hemorrhage (ICH)

LEARNING OBJECTIVE #2: Recognize that herpes encephalitis can be complicated by ICH

CASE: A 72 year-old woman with a history of cerebral aneurysm clipping, seizures and hypertension presented with headache, confusion and lethargy for two weeks. She was febrile to 104 F, hypertensive and tachycardic. The patient was disoriented and had nuchal rigidity. CT head on admission was normal. Cerebrospinal fluid revealed total protein 72 mg/dL, glucose 79 mg/dL, red blood cells 1979/mm^3, and white blood cells 58/mm^3 with lymphocyte predominance. Polymerase chain reaction was positive for HSV-1. The patient was started on intravenous acyclovir. One week later, she had worsening confusion with new left sided hemiparesis. Repeat imaging revealed an acute right frontotemporal hemorrhage with mass effect on the right lateral ventricle and midline shift. CT angiogram ruled out any aneurysm or evidence of arteritis. Patient underwent supportive care and remained stable in the intensive care unit with slowly improving neurologic status.

IMPACT: Typical causes of ICH include hypertension, brain masses and vascular malformations. However, clinicians should also be aware of less common causes of ICH, such as HSV encephalitis.

DISCUSSION: Intracerebral hemorrhage (ICH) is the second most common type of stroke, trailing only ischemic stroke in frequency. Common causes include hypertension, cerebral amyloid angiopathy (CAA), brain tumors, and blood vessel abnormalities. Approximately 80% of cases of ICH are considered primary which include arterial hypertension and CAA. Cerebral hemorrhage associated with herpes simplex encephalitis (HSE) - a type of secondary ICH - is uncommon, with only several cases reported. HSE is the most common cause of fatal sporadic encephalitis in the United States, accounting for approximately 10–20% of annual cases of viral encephalitis. The temporal and frontal lobes are the most commonly affected areas in HSE. A common pathological feature is necrotizing infiltrate with foci of small hemorrhages. Mortality associated with HSE is 20–30% in treated patients and can reach up to 70% in the untreated patient. A rare complication of HSE is large territory ICH. It has been suggested that HSV induces small vessel vasculitis of the brain causing endothelial damage, followed by rupture of small vessels and formation of hematoma. Even after standard therapy with IV acyclovir, risk of hemorrhage continues to exist within one to two weeks of presentation. The role of neurosurgical intervention such as decompressive craniectomy remains unclear. Case reports demonstrate similar outcomes in patients who underwent neurosurgical intervention versus those who received supportive management. In patients with HSV encephalitis, when there is lack of clinical improvement or worsening of initial symptoms, clinicians should have a high index of suspicion for ICH.

AN OMINOUS CAUSE OF FACIAL PAIN AND NUMBNESS Layal S. Sayegh[2]; Dan Hunt[1]. [1]Emory University, Atlanta, Uganda; [2]Emory School of Medicine, Atlanta, GA. (Control ID #2697974)

LEARNING OBJECTIVE #1: Recognize features of fungal sinusitis.
CASE: A 30 year-old woman presented with three weeks of progressive right facial pain and headache. She described a constant burning, throbbing headache over the right frontal and peri-orbital region accompanied by right facial numbness, blurred vision in the right eye, photophobia and phonophobia. Other associated symptoms included fatigue and malaise. Percocet, Tylenol 3, Lortab or carbamazepine did not relieve her symptoms and she had been on a three-week course of azithromycin without improvement. Her temperature was 36.2, blood pressure was 114/72, heart rate was 58, respiratory rate was 16 and oxygen saturation was 100%. She had mild proptosis of the right eye; extraocular movements were intact with pain on movement of the right eye and photophobia of the right eye. Facial movements were symmetric bilaterally, but she had decreased sensation to light touch in all distributions of the right trigeminal nerve. Laboratory evaluation revealed white blood cell count 6500 and negative HIV antigen/antibody testing. CT revealed complete opacification of the right sphenoid sinus and mucosal thickening in the right posterior ethmoid and left sphenoid sinuses, consistent with acute on chronic fungal sinusitis. MRI was consistent with the CT findings with the addition of involvement of the right Meckel's cave and foramen ovale, suggestive of chronic fungal sinusitis with a possible invasive component. Tissue sampling revealed necrotic material with fungal elements. We initiated ampicillin/sulbactam to treat presumed co-existent bacterial sinusitis along with isavocanazonium/isavoconazole. Treatment resulted in improvement of her trigeminal neuropathy and returned home on long-term oral isavuconazonium. Cultures eventually grew *Schizophyllum commune*.
IMPACT: This young woman's course has been a reminder that significant neurologic findings in patients presenting with localized headache warrant neuroimaging and that imaging suggestive of possible fungal sinusitis should lead to multidisciplinary intervention.
DISCUSSION: Headache and facial pain is a commonly encountered problem for practicing internists. This case was suggestive of a trigeminal neuropathy. Common etiologies of trigeminal neuropathy include; trigeminal neuralgia, postherpetic neuralgia, acute herpes zoster, and post-traumatic trigeminal neuropathy. However, in this case MRI confirmed the presence of sinusitis consistent with fungal etiology and also showed direct extension to the foramen ovale along the V3 branch of the trigeminal nerve. This finding was consistent with her presenting symptoms and sensory findings on exam. Acute invasive fungal rhinosinusitis requires immediate evaluation by an otolaryngologist. Direct endoscopic visualization of the sinuses confirmed fungal sinusitis, allowed extensive debridement of the involved sinuses, and led to systemic antifungal therapy. *Schizophillum commune* is an under-recognized cause of bronchopulmonary disease and sinusitis.

AN ORDINARY FINDING COULD BE A CLUE TO THE SOLUTION Yuji Nishihara; Ryuichi Sada; Makito Yaegashi. Kameda Medical Center, Kamogawa, Japan. (Control ID #2700333)

LEARNING OBJECTIVE #1: Although an infection of a simple liver cyst is extremely rare, it could happen after endoscopic retrograde cholangiopancreatography (ERCP).
CASE: A 85-year-old man with a history of choledocholithiasis, cerebral infarction, and rheumatoid arthritis was transferred to our emergency center with a two-day history of high grade fever and difficulty in movement accompanied with fever, chill, and fatigue. He had no abdominal pain. About one year ago, he underwent ERCP and choledocholithotomy. At that time, he was found to have a simple liver cyst with the diameter of 60 mm. His regular medication included prednisolone 5 mg, bucillamine 300 mg, and furosemide 40 mg. On admission, he was hypotensive with his blood pressure of 80/40 mmHg, and his pulse rate of 90 beats per min. Although his physical examination was unremarkable, his laboratory data showed acute kidney injury, and elevated inflammatory markers with normal hepatic and biliary enzymes. His abdominal CT with contrast showed choledocholithiasis and intrahepatic bile duct dilatation, but his liver cyst revealed no sign of infection. We diagnosed acute cholangitis, and treated with piperacillin/tazobactam and endoscopic biliary drainage. Both his blood culture and his bile culture were positive for *Raoultella ornithinolytica*. He recovered from the septic shock rapidly, but his high grade fever persisted despite continuous drainage and appropriate antimicrobial coverage to susceptible organisms. His repeated work-up for the fever was unrevealing. His Abdominal ultrasound revealed no change in the existing liver cyst. On the day 6 of admission, his MRI showed an enlarged liver cyst with the diameter of 92 mm containing pus. After percutaneous transhepatic puncture, his condition improved dramatically.
IMPACT: To date, no case of simple liver cyst infection after ERCP was reported. This is the first case report of the matter. This is important, since it is really difficult to recognize the infection of simple liver cyst with few subjective symptoms. Identification of the infection might lead to the percutaneous drainage.
DISCUSSION: Simple cysts are found in up to 5% of the population. They develop congenitally from aberrant intrahepatic bile ducts, and don't communicate with the biliary tree. In this case, MRI revealed no connection of the cyst with bile ducts. In the patients of autosomal dominant polycystic kidney disease (ADPKD), liver cyst infection (LCI) usually causes abdominal pain and fever. In one report, sepsis developed in 75% of LCI episodes in ADPKD patients and the mortality was 25%. Since the rapid enlargement with pus in the cyst occurred just after the ERCP, the cyst infection could be caused by the ERCP. Negative culture of the pus might be due to preceding antibiotics. When a patient with simple liver cysts has a persistent fever after ERCP, we should investigate the existence of cyst infection.

AN OUNCE OF PREVENTION: A CASE OF A WOMAN AT RISK Adaugo Amobi. Massachusetts General Hospital, Brookline, MA. (Control ID #2704145)

LEARNING OBJECTIVE #1: Initiate PrEP treatment and monitoring.
LEARNING OBJECTIVE #2: Explain the available data on PrEP use in women.
CASE: Ms. V is a 29 yo F IV drug user presenting for her annual wellness visit. She has no complaints. Review of systems is negative. Social history is significant for sexual activity with 3 different male partners within the past month who are also IV drug users. She uses condoms infrequently. She injects heroin every other day and has shared needles twice in the past 2 months. Screening labs show she is HIV and HCV negative.
IMPACT: I learned how to counsel my patients about PrEP.
DISCUSSION: All patients with high risk of contracting HIV should be considered for pre-exposure prophylaxis (PrEP). This includes men who have

sex with men (MSM) with no or inconsistent use of condoms, high numbers of sexual partners, or recent bacterial STI; heterosexual women with inconsistent or no condom use with sexual partners who are at substantial risk of HIV infection (MSM or IV drug users) and IV drug users who share injection equipment or have recently been in drug treatment program. The Partners-PrEP trial examined use of PrEP in heterosexual serodiscordant couples and found 71% efficacy of tenofivir in women compared to placebo. Subsequent studies including FEM-PrEP and VICE compared the use of tenfovir alone and tenofovir-emtricitabine in reproductive age women. FEM-PrEP and VOICE trials did not show a definitive reduction in HIV incidence; post-hoc analysis suggests that this is likely explained by poor adherence. Less than 40% of women in all study arms of the two trials were adherent to the medication, qualitative analyses have identified participant beliefs and attitudes as a major cause. Based on the totality of data available on PrEP, the CDC and WHO recommend PrEP for women at high risk of contracting HIV. PrEP treatment consists of one combination pill daily of tenofovir disoproxil fumarate 300 mg and emtricitabine 200 mg (coformulated as Truvada). Patients with GFR <60 mL/min/1.73 m2 should not be given PrEP given the risk of renal dysfunction associated with tenofovir disoproxil fumarate. HBV serologies, pregnancy status and risk of osteoporosis should be evaluated before starting treatment as these may affect the decision to initiate treatment. Truvada is classified by the FDA as a Pregnancy Category B medication with no known fetal risks in humans. Patients should be willing to take the medication regularly and counseled about other risk reduction behaviors. Drug monitoring of PrEP consists of HIV and STD testing every 3 months and renal function monitoring at least every 6 months. Common side effects of PrEP treatment include nausea, diarrhea, fatigue, dizziness, headache, insomnia, depression, and rash. Patients initiated on PrEP should have ongoing evaluation about the need to continue prophylaxis at least annually. General internists should feel comfortable initiating PrEP treatment for all patients who are at high risk of becoming infected with HIV.

AN UN"COMMON" CAUSE OF BLEEDING Amanda Bisset; Ryan Satovsky. Tulane University Health Sciences Center, New Orleans, LA. (Control ID #2703798)

LEARNING OBJECTIVE #1: Review a diagnostic approach to bleeding disorders

LEARNING OBJECTIVE #2: Discuss a rare cause of coagulation disorders

CASE: A 27-year-old man presented with a painful left hand for 1 day. He recently had abdominal bruising after a fall at work the week prior. He reported that he and his brother had hemophilia with a factor IX deficiency. He used the last of a 3-factor prothrombin complex concentrate (II, IX, X) medication that he borrowed from his brother. Blood pressure was 99/55 and heart rate was 69. His left hand had diffuse swelling with tenderness to palpation and blue colored bruising to the dorsal side. Ecchymosis was noted on the right lower quadrant of the abdomen. Initial labs showed a prolonged PT, PTT and an elevated INR, hemoglobin of 12.2, and platelets of 184. Thrombin Time was 18.3 (14–21), with normal fibrinogen and negative D-dimer. He received 1 dose of factor IX. On the first night, he developed pain and bleeding in his right jaw - bleeding of the buccal mucosa, with swelling that extended into the right side of his jaw and neck. A CT of the soft tissue of the neck showed an uncompromised airway. Anticoagulation toxicity, DIC, liver disease, and vitamin K deficiency were ruled out. A mixing study demonstrated normalization of the PT, indicative of a factor deficiency as opposed to an inhibitor. Fibrinogen, Factor II, V, VIII, IX, X levels were drawn. The factor II level was undetectable, diagnostic of factor II (prothrombin) deficiency. Hematology was consulted. A 4-factor prothrombin complex concentrate (II, VII, IX, X) was administered along with Aminocaproic Acid. His bruising, bleeding and swelling improved. His hemoglobin remained stable and he was discharged with follow up in a hemophilia clinic.

IMPACT: To delineate bleeding disorders, knowledge of clot formation can assist the internist in interpreting the initial laboratory evaluation that includes a complete blood count with platelet count, peripheral blood smear, prothrombin time, and partial thromboplastin time.

DISCUSSION: The PT measures factors of the extrinsic and common pathways while PTT measures the factors of the intrinsic and common pathways. Our patient presented with non-traumatic soft tissue bleeding and a reported history of Hemophilia B. While his clinical presentation was consistent with Hemophilia, his labs did not support the diagnosis. Factor IX is a factor of the intrinsic pathway. Thus, Hemophilia B (Factor IX deficiency), has a prolonged aPTT, but not a prolonged PT. Prolongation of both the aPTT and PT is indicative of a defect in the common final pathway, which includes factors I (fibrinogen), II (prothrombin), V, and X. Our patient had an inherited prothrombin deficiency. This is a rare, autosomal recessive disorder, affecting about 1 in 2,000,000. Our case highlights the importance of a timely and accurate diagnosis of a bleeding disorder. Had our patient continued to receive only factor IX replacement, he may have continued to bleed, potentially leading to morbidity or mortality.

AN UNCHARACTERISTIC PRESENTATION OF ESSENTIAL THROMBOCYTHEMIA Nathan Wong; Victoria Heasley. Pennsylvania State University, Hershey, PA. (Control ID #2687658)

LEARNING OBJECTIVE #1: Recognize how arterial thrombi can be attributed to myeloproliferative disorders (MPDs) versus antiphospholipid syndrome (APS).

LEARNING OBJECTIVE #2: Stratify essential thrombocythemia (ET) patients into low, intermediate, and high risk for thrombotic events.

CASE: 42-year-old man with a past medical history of gout on allopurinol presented with acute right upper quadrant discomfort, left flank pain, and gross hematuria. He was found to have celiac, superior mesenteric, hepatic, and splenic artery thrombi with bilateral pulmonary emboli. Differential diagnosis includes hypercoagulable state versus malignancy versus thromboembolism. Deep venous thromboembolism with a patent foramen ovale were ruled out. CT imaging revealed numerous paraesophageal lymph nodes, which were biopsied and found to contain no malignant cells. A hypercoagulable workup including Factor V Leiden, Prothrombin G20210A mutation, anti-β2-glycoprotein and anti-cardiolipin antibodies were found to be negative. Anti-thrombin III deficiency and lupus anticoagulant (LA) antibody were false positives since these tests were performed while on a heparin drip. With a mildly elevated platelet count and normal red and white cell counts throughout his hospital course, a JAK2 V617F mutation test was sent. He was stabilized on IV heparin drip, transitioned to enoxaparin, and discharged on warfarin as empiric anticoagulation. Once his JAK2 V617F mutation was found weeks after being discharged, a diagnosis of ET was made.

IMPACT: Arterial thrombotic events are typically attributed to APS and MPDs. Given the unknown etiology of his arterial thrombi and no evidence of malignancy, empiric anticoagulation with warfarin was thought to

sufficiently prevent further thrombus formation during his continued workup. However, ET treatment is based on antiplatelet medications such as aspirin and hydroxyurea; warfarin is not recommended. Caution should be taken before prescribing medication for an unknown hypercoagulable state.

DISCUSSION: ET is a MPD associated with arterial thrombi. ET patients can be stratified into low, intermediate, or high risk for thrombosis depending on independent risk factors for thrombosis including age >60 years, history of thrombosis, presence of cardiovascular risk factors (diabetes, hypertension, smoking), and presence of JAK2 V617F mutation. Using this model, low, intermediate, and high risk categories had a 1.03 percent/year, 2.35 percent/year, and 3.56 percent/year risk of thrombosis, respectively. Our patient was <60 years old, had a history of thrombosis, no cardiovascular risk factors, and a JAK2 V617F mutation which places him at high risk for thrombosis. In patients treated with hydroxyurea with a goal platelet count below 600,000, the thrombotic rate was 3.6% compared to a rate of 24% in those treated without hydroxyurea. While hydroxyurea reduces platelet count and prevents thrombotic events in ET patients, care should be taken in younger patients since it is unknown if the drug increases the risk leukemia.

AN UNCOMMON CAUSE OF ANNULAR RASH Ana I. Velazquez[1]; Mariana Mercader[1]; Anjanet Perez-Colon[1]; Geeta Varghese[2]. [1]Mount Sinai Beth Israel, New York, NY; [2]Mount Sinai Beth Israel, First Avenue at 16th Street, NY. (Control ID #2707134)

LEARNING OBJECTIVE #1: Diagnose annular skin lesions.

LEARNING OBJECTIVE #2: Distinguish the differential diagnosis of annular skin lesions.

CASE: 68y/o male with treated Hepatitis C, atrial fibrillation, and + PPD was evaluated at our primary care clinic. The patient was born in Puerto Rico; he is a former IV drug abuser, and current smoker. No significant family history. Patient described nonpruritic skin lesions, which developed on his face and arms approximately 3 years prior. He denied fevers, night sweats, weight loss, or cough. No ill contacts or recent travel. Physical exam revealed multiple annular plaques, up to 5 cm in diameter, involving his face and a 7x10cm lesion on his right forearm. Lesions had raised erythematous borders, central clearing and atrophy. Patient was referred to dermatology and skin biopsies showed inflammation and fibrosis suggestive of granulomatous dermatitis. Given his 40-pack year smoking history a chest CT was obtained which revealed multiple calcified nodules diffusely involving both lung fields. Given these results and his history of + PPD, he completed a course of isoniazid for latent tuberculosis and PUVA treatment without improvement in lesions. Bacterial, fungal and AFB sputum cultures were negative. Lung nodule biopsy revealed noncaseating granulomas with negative AFB and fungal staining. Genprobe analysis showed Mycobacterium avium complex (MAC) for which he was started on rifampin, ethambutol, and azithromycin. Skin cultures and biopsy were performed given concern of disseminated MAC, however AFB and fungal skin cultures were negative. The second biopsy revealed interstitial infiltrate of histiocytes with surrounding connective tissue, elastic tissue loss, and fragmented elastic fibers within the cytoplasm of multinucleated giant cells with negative AFB, Fite, and PAS stains. Skin biopsy was diagnostic for elastolytic annular giant cell granuloma (EAGCG).

IMPACT: EAGCG is a rare granulomatous skin disease with unclear pathogenesis that has been mainly associated with UV-exposure and autoimmune diseases, such as diabetes and hypothyroidism. It has also been described in association with hematologic malignancies, as leukemias and lymphomas. While a causal or direct association is difficult to prove, to our knowledge this is the first case of EAGCG with concomitant MAC infection.

DISCUSSION: Among patients with granulomatous skin lesions it is vital to rule out common causes as granuloma annulare, necrobiosis lipoidica, and sarcoidosis among others. Particularly important in immunocompromised patients or those from endemic areas, as our patient, is considering tuberculoid and nontuberculoid infections, as potential etiology of rash. A good history, exam, and adequate testing including biopsy, specific stainings and cultures can differentiate and guide management. Particularly on EAGCG the presence of classic findings as centrifugal growth and photodistribution are key to diagnosis. Similarly, the presence of specific findings as elastophagocytosis on histopathology is confirmatory.

AN UNCOMMON CAUSE OF LACTIC ACIDOSIS Cecil A. Rambarat; Krista N. Larson; Mark Hankins; Dominique Broutin; Denise C. Schain. University of Florida, Gainesville, FL. (Control ID #2704109)

LEARNING OBJECTIVE #1: Recognize thiamine deficiency as a rare cause of unexplained lactic acidosis.

LEARNING OBJECTIVE #2: Recognize that chronic diarrhea can be a risk factor for thiamine deficiency.

CASE: A 66-year-old African American female presented to the emergency department (ED) with a 3-day history of progressively worsening diarrhea, emesis and malaise. Past medical history was notable for HIV which was well managed chronically on dolutegravir, lamivudine and stavudine and end stage renal disease for which a kidney transplant was performed one year prior. Physical examination revealed an afebrile, hypotensive and tachycardic female with hyperactive bowel sounds. Initial laboratory tests revealed an arterial blood gas pH and sodium bicarbonate of 6.99 and 12 mmol/L respectively, a creatinine level of 2.8 mg/dL, an anion gap of 18 and a lactic acid level of 2.9 mmol/L. On admission the patient was fluid resuscitated and placed on a continuous bicarbonate infusion which resulted in an improvement in her vital signs and correction of her arterial blood pH and sodium bicarbonate levels. After a thorough infectious work-up returned negative, the patient was initiated on loperamide for her diarrhea. Lactic acid levels continued to increase from 2.9 mmol/L to 6.9 mmol/L after 2-days of stable vital signs prompting further diagnostic studies. An abdominal CT scan was obtained which showed a normal appearing gastrointestinal tract and stavudine was discontinued. Despite this, lactic acid levels continued to increase to a maximum value of 8.2 mmol/L. At this point a thiamine level was obtained which was noted to be low at 48 nmol/L. Thiamine replacement was initiated which resulted in gradual resolution of the lactic acidosis by the time of discharge 3-days later. The patient was discharged on a HAART regimen which did not include stavudine.

IMPACT: This case serves to increase awareness of a potential lethal complication of thiamine deficiency in addition to highlighting a risk factor, chronic diarrhea, for thiamine deficiency. In practice, patients who experience chronic diarrhea as a medication side effect should be monitored and treated for thiamine deficiency.

DISCUSSION: This case illustrates two uncommon causes for lactic acidosis. One of these is medication side-effects. Antiretroviral drugs in particular have been implicated in cases of elevated lactic acid levels which usually takes weeks to resolve after the discontinuation of the causative agent. An even more rare cause of lactic acidosis is thiamine deficiency. Lactic acidosis due to thiamine

deficiency is caused by dysregulation of enzymes involved in aerobic carbohydrate metabolism and can be quickly corrected with thiamine supplementation. In our patient, the use of sirolimus led to chronic diarrhea which resulted in thiamine deficiency, causing elevated lactic acid levels which was quickly corrected with thiamine supplementation. Thiamine deficiency and medication side effect should be considered in otherwise unexplained cases of lactic acidosis.

AN UNCOMMON CAUSE OF SYNCOPE Islande Joseph[1]; Grant Jester[2]; De-Vaughn Williams[2]; Margaret C. Lo[3]. [1]Univeristy of Florida, Gainesville, FL; [2]University of Florida, Gainesville, FL; [3]University of Florida College of Medicine, Gainesville, FL. (Control ID #2705858)

LEARNING OBJECTIVE #1: Recognize the congenital development of cor triatriatum

LEARNING OBJECTIVE #2: Evaluate and manage cor triatriatum

CASE: A 48 years-old female with self-reported leaky valve syndrome and recurrent syncopal events presented with acute left vision loss after another syncopal fall. Patient had no recollection of any symptoms and only recalls waking up on the floor. Patient reported no prior workup for her recurrent syncope. Exam revealed decreased vision and superficial ulceration of left eye. Cardiac exam was normal without murmurs, gallops, JVD, or leg edema. Neurologic exam revealed no focal deficits. Outside MRI brain showed no acute intracranial hemorrhage or infarcts. Carotid US showed no arterial stenosis. CT sinus showed no fracture. Upon admission, Ophthalmology found no eye pathology to explain visual symptoms which since resolved. Additional syncope workup during admission was negative for serial troponins, telemetry, and EKG with normal QTc. TTE later uncovered an obstructing patent membrane in the left atrium but normal EF and pulmonary arterial pressure. This solidified a diagnosis of cor triatriatum which explained her recurrent syncope. Arrangements were made for TEE and cardiology clinic follow-up.

IMPACT: This case adds to the limited literature of cor triatriatum as a rare yet viable cause of syncope. This rare congenital cardiac anomaly is characterized by ventricular inflow obstruction due to abnormal septation within the atrium resulting in three atrial chambers subdivided by a thin membrane. It represents 0.1–0.4% of all congenital cardiac anomalies and may be associated with up to 50% of other cardiac defects i.e. atrial septal defect, patent foramen ovale. It is often mistaken for mitral stenosis or constrictive pericarditis. Suspect this diagnosis in young patients with recurrent cardiac symptoms but no other cardiovascular diseases.

DISCUSSION: The time course for manifestation of cor triatriatum depends on the degree of obstruction between the bisected atrial chambers of the abnormal atrium and the size of the communicating orifice. Earlier and more severe presentations occur in smaller communicating orifices. Patients may remain asymptomatic until the third decade of life or later, as true for our patient. The late onset of symptoms results from progressive increase in pulmonary artery pressure. Several anatomical variants of this anomaly exist and depending on the variant and degree of obstruction, syncope (as in this case), cyanosis, heart failure and sudden cardiac arrest have been reported. Thus, multimodal diagnostic modalities are vital for characterization and differentiation of anatomical variance. Although no treatment best practices are established for cor triatriatum, anticoagulation, balloon dilation or surgical correction of the membrane have been proposed depending on the anatomical variant. Females must be caution on the risk of pregnancy. Early diagnosis is important since surgical correction is curative

AN UNCOMMON CAUSE OF SYNCOPE - GET THE GIST?
Shradha A. Kulkarni. Baylor College of Medicine, Houston, TX. (Control ID #2707642)

LEARNING OBJECTIVE #1: Syncope has many varied etiologies, ranging from cardiogenic to neurologic phenomena. We present a case of a gastrointestinal (GI) tumor causing anemia and subsequent syncope in a patient with no clinical evidence of GI bleeding.

CASE: A 79-year-old Filipino female with sick sinus syndrome status-post pacemaker placement, atrial fibrillation on anticoagulation, history of a stroke with no residual deficits, and coronary artery disease presented to the hospital with a syncopal episode. Physical examination showed hemodynamic stability, negative orthostatic vital signs, and normal neurologic and cardiovascular findings. Electrocardiogram, computed tomography (CT) and CT angiography of the head and neck, bilateral carotid ultrasound, and pacemaker interrogation were unremarkable. Laboratory studies were significant for hemoglobin of 5.8 g/dL. Hemoglobin one month prior to presentation was 8.0 g/dL; an anemia work-up had not been performed previously. The patient denied abdominal pain, nausea, vomiting, melena, or hematochezia. She had never undergone a screening colonoscopy and denied a family history of GI malignancy. Upon further laboratory evaluation, ferritin was found to be less than 20 ng/mL, concerning for iron-deficiency anemia. Despite a discordant clinical history, in order to evaluate for a possible source of bleeding, upper and lower endoscopies were performed. Esophagogastroduodenoscopy (EGD) revealed a 3–4 cm oozing gastric mass. Biopsy confirmed gastrointestinal stromal tumor. CT imaging completed for staging purposes showed liver nodules suspicious for metastases, indicating likely stage IV cancer. The patient was deemed a poor surgical candidate given her co-morbidities and age, and treatment was initiated with imatinib.

IMPACT: This case demonstrates the importance of maintaining a broad differential when evaluating syncope, a common reason for admission to the hospital. It also demonstrates the need to investigate all abnormal laboratory values and consider further work up if warranted. In this patient, the only manifestation of stage IV GIST was syncope due to anemia, which was particularly unexpected in the absence of overt GI bleeding.

DISCUSSION: Gastrointestinal stromal tumors (GIST) are a rare and clinically diverse set of mesenchymal tumors of the GI tract, comprising only 1% of primary GI malignancies. Approximately one half of these tumors are located in the stomach and are primarily identified by histopathological staining of a mucosal biopsy. GIST shows no gender predominance and has a median age at diagnosis of sixty years. The highest incidence rates are seen in regions of East Asia, though interestingly, the only known identifiable risk factor is an association with neurofibromatosis type I.

AN UNCOMMON ETIOLOGY OF DYSURIA, HEMATURIA AND FLANK PAIN IN A YOUNG WOMAN Lauren N. Smith[1]; Oanh K. Nguyen[2]. [1]UT Southwestern, Dallas, TX; [2]UT Southwestern Medical Center, Dallas, TX. (Control ID #2699328)

LEARNING OBJECTIVE #1: Understand the diagnostic utility of hydronephrosis in diagnosing urolithiasis

LEARNING OBJECTIVE #2: Recognize arteriovenous malformation of the renal artery as an uncommon etiology of hematuria, flank pain and hydronephrosis

CASE: A healthy 32 year old woman presented to the emergency department (ED) with one week of dysuria, hematuria and flank pain and no fevers, chills,

frequency, or vaginal discharge. Previous evaluation at an outside facility was notable for right hydronephrosis on computerized tomography (CT) of her abdomen. She was treated with intravenous fluids and analgesics for a presumed diagnosis of urolithiasis with recurrence of symptoms one day after ED discharge. Ciprofloxacin was added for potential superimposed urinary tract infection. She returned to our ED for re-evaluation due to persistent symptoms despite medical therapy for several days. Physical examination was notable for normal and stable vital signs with a blood pressure of 132/83 mmHg and the presence of right costovertebral angle tenderness. Laboratory examination showed blood urea nitrogen 10 mg/dL, serum creatinine 0.85 mg/dL, and hemoglobin 10.4 g/dL with mean corpuscular volume 90.5 fL. Urinalysis showed red, turbid urine with 41+ RBCs/hpf, 3–5 WBC/hpf and no nitrites. Urine culture was unremarkable. A repeat CT abdomen demonstrated right hydronephrosis and a previously unobserved soft tissue attenuation in the proximal right ureter extending into mid-ureter. Cystoscopy with ureteral stent placement and biopsy showed no evidence of malignancy. Persistent intermittent post-procedure bleeding raised concern for an arteriovenous malformation (AVM). Subsequent CT angiogram showed a 1 cm pseudoaneurysm within the right kidney supplied by a branch of the right renal artery, consistent with an AVM. The patient underwent successful AVM embolization with complete resolution of symptoms.

IMPACT: Although urolithiasis is the most common cause of dysuria, hematuria, flank pain and hydronephrosis, vascular etiologies such as AVM should also be considered in individuals in whom malignancy has been excluded.

DISCUSSION: The presence of unilateral hydronephrosis in ED patients with dysuria and flank pain is modestly predictive of urolithiasis, with a likelihood ratio (LR) of 5.0 [1]. The presence of both hydronephrosis *and* hematuria is typically highly predictive of urolithiasis, with a LR of 20.1 [2]. Nonetheless, alternative diagnoses should be considered when symptoms are refractory to therapy. Renal AVMs are rare, with an estimated incidence of 0.04%. The vast majority (~75%) are acquired due to trauma or procedures. Presenting symptoms include hematuria, flank pain and hypertension. Diagnosis can be delayed by several weeks in the absence of a high index of suspicion. The mainstay of therapy is endovascular embolization, with resolution of symptoms in 60% of patients.

AN UNCOMMON PRESENTATION OF STREPTOCOCCUS PNEUMONIAE

Anish Vani; Man Hsuan M. Su; Patrick M. Cocks. NYU School of Medicine, New York, NY. (Control ID #2672030)

LEARNING OBJECTIVE #1: Describe the mechanism of septic arthritis

LEARNING OBJECTIVE #2: Recognize the epidemiology, risk factors, and prognosis of patients with septic arthritis caused by *Streptococcus pneumoniae*

CASE: A 43 year-old man with a history of Hodgkin's Lymphoma, treated with chemotherapy and radiation, complicated by avascular necrosis requiring bilateral hip replacements, and myelodysplastic syndrome requiring a splenectomy and stem cell transplant, presented with one month of productive cough, two days of myalgias, and acute on chronic bilateral shoulder and hip pain. On presentation to our institution, he was found to have profound leukocytosis with neutrophilia and bandemia and a computed tomography of the chest suggestive of a multi-lobar pneumonia. His physical exam was remarkable for a high fever, rigors, diminished breath sounds at the lung bases, and decreased range of motion in his right lower extremity due to right hip pain. He was treated empirically with intravenous vancomycin and piperacillin-tazobactam. Blood cultures grew pan-sensitive *S. pneumoniae* and his antibiotics were narrowed to intravenous ceftriaxone. His hospital course was complicated by persistent leukocytosis, fevers, and right hip pain. Magnetic resonance imaging and a gallium nuclear scan were performed, which suggested infection of his right hip. He underwent an arthrocentesis followed by a right hip wash out without prosthesis removal. He was discharged home on an extended course of antibiotics with resolution of his leukocytosis, fevers, and right hip pain.

IMPACT: Our case highlights a relatively uncommon phenomenon, which is septic arthritis caused by *S. pneumoniae*. Clinicians should be aware of predisposing factors that place patients at risk for developing a joint infection from this organism.

DISCUSSION: Septic arthritis occurs via bacterial invasion of the synovial membrane, most commonly by hematogenous spread, leading to an acute inflammatory response involving synovial membrane hyperplasia, local cytokine production, and cartilage destruction. Several studies report a widely disparate prevalence of septic arthritis caused by *S. pneumoniae*, with most studies reporting a low single digit prevalence. While relatively uncommon, *S. pneumoniae* arthritis should be considered in patients with extra-articular infections, such as pneumonia or meningitis, and predisposing factors, which include alcoholism, rheumatoid arthritis, immunosuppression, splenectomy, preexisting joint disease, or patients with prosthetic joints. Prosthetic joints pose a fifteen-time greater risk of infection by providing a surface for *S. pneumoniae* to multiply and form biofilms to defend against circulating leukocytes, complement, and antibiotics. Good functional outcome is seen in the majority of patients treated with appropriate antibiotic therapy and surgical intervention, and often patients with prostheses do not require removal.

AN UNDERLYING OUTLET

Stephen Z. Peeke. Mount Sinai Beth Israel, New York, NY. (Control ID #2707442)

LEARNING OBJECTIVE #1: Recognize the need for clinical reassessment after initial diagnosis

LEARNING OBJECTIVE #2: Diagnosis Effort-Induced Venous Thrombosis

CASE: A 27 year old right-handed male presented with bilateral forearm swelling. Six days prior the patient participated in a vigorous exercise session consisting of pull-ups and jumping rope. Swelling and stiffness of his forearms worsened over the week with associated weakness and cramps. Later, at an urgent care clinic, he was found to have a creatine kinase of 34,394 U/L and was sent to the ED. He had been diagnosed with thoracic outlet syndrome of his right arm 6 years ago while playing for his college baseball team. The diagnosis was made clinically without imaging and was successfully treated with rest and physical therapy. On exam there was non-pitting edema of the bilateral forearms from wrist to elbow, right minimally more than left without erythema or lacerations. He denied any shortness of breath or change in urination. The patient was treated with IV fluids to prevent rhabdomyolysis-induced kidney injury. His creatinine remained normal and his CK trended down. While hospitalized the patient's right forearm became noticeably more swollen than his left; the rate of IV fluids was decreased due to concern for developing compartment syndrome. An ultrasound of the upper extremities was performed and revealed multiple deep vein thromboses of the right subclavian and axillary veins. Imaging of the left arm was normal and the patient was started on IV heparin. A CT angiogram of the chest was negative for pulmonary embolism. The patient declined inpatient surgery and was transitioned to rivaroxaban for discharge.

IMPACT: Physicians should be wary of early closure after initial diagnosis. Through careful clinical monitoring, including oft-overlooked daily physical

exams, an underlying diagnosis was suspected and pursued. This case also adds to the expanding literature on exercise-induced rhabdomyolysis as the same demographic is also at risk for exercise induced thrombosis of the upper extremities.

DISCUSSION: While upper extremity DVT is rare overall[1], the diagnosis has become more common as rates of instrumentation have escalated. This is the secondary form; most primary cases are due to underlying malignancy[2] or the Paget-Schroetter Syndrome. Our patient presented with exercise-induced rhabdomyolysis, an entity increasing in frequency especially among the young and physically active[3]. This same group is at risk for effort-induced venous thrombosis which often occurs in the dominant arm due to repetitive strenuous activities[4]. The pathogenesis involves repeated microtrauma to the subclavian vein and upstream vasculature from nearby anatomical structures which cause inflammation, fibrosis, and intimal hyperplasia. Compartment syndrome is a known complication of rhabdomyolysis and impaired venous drainage may increase this risk. While the initial diagnosis seemed obvious, this case highlights the need for continuous reassessment.

AN UNEXPECTED CAUSE OF SEVERE HYPOCALCEMIA IN A PATIENT WITH METASTATIC CANCER Anne Linker[1]; Arjun Suri[1]; Jessica Beaman[2]. [1]UCSF, San Francisco, CA; [2]San Francisco VA Medical Center, San Francisco, CA. (Control ID #2706125)

LEARNING OBJECTIVE #1: Diagnose prolonged hypocalcemia in a patient treated with denosumab

LEARNING OBJECTIVE #2: Recognize risk factors for prolonged hypocalcemia in patients receiving denosumab

CASE: A 63 year old woman with stage IV cervical cancer (metastases to lung and bone) presents with subacute cough, fever, and malaise/fatigue. ROS is positive for pleuritic chest pain, nausea, vomiting, hip pain, and paresthesias in her hands. Medications included opiates and denosumab monthly (for 8 months). Her last denosumab injection was one month prior. She was afebrile with mild tachycardia. Exam was non-focal, without perioral numbness or Chvostek's sign. She had a mild leukocytosis and stable anemia. Ionized calcium was 0.73 mg/dL, phosphorus was 1.0 mg/dL, PTH was 545.7 pg/mL and 25-hydroxy vitamin D was 4.6 ng/mL (prior to denosumab it was 11.9 ng/mL). Imaging showed progression of her intrathoracic disease. With aggressive IV repletion of calcium and phosphorus her fatigue and paresthesias improved. Her serum calcium and phosphorus levels were initially refractory to repletion, but then slowly approached normal. Given the progression of disease and her goals of care, the patient transitioned to home hospice with plan for aggressive daily oral calcium, vitamin D and phosphorus repletion.

IMPACT: This case should empower non-oncology providers (PCPs, inpatient teams) to intervene if vitamin D and calcium levels are not being monitored in patients on denosumab, or if patients are vitamin D deficient before or during denosumab therapy. As a result of her condition, our patient was worried about initiating hospice care because of fear that her symptoms would recur, and we were concerned that electrolyte abnormalities might contribute to an earlier death.

DISCUSSION: Denosumab is a humanized monoclonal antibody that inhibits osteoclast-mediated resorption of bone. The FDA approved denosumab for the prevention of skeletal-related events (SREs) in patients with bone metastases from solid tumors. It can decrease the incidence of and delay the time to SREs. Hypocalcemia is a recognized toxicity of denosumab, though previously it was thought to be rare. As more patients receive denosumab for this indication, the incidence of this toxicity is increasing. In one of the largest series of such patients, Autio et al. found an incidence of 15% of severe hypocalcemia in patients with metastatic cancer treated with denosumab. Median time to calcium nadir from administration was 25 days, and median time to recovery was 17 days. Some patients required repeated hospitalizations and were severely symptomatic. Risk factors for developing severe hypocalcemia included vitamin D deficiency prior to initiation of therapy, increased disease burden, and corrected calcium levels in the low normal range prior to initiation of therapy. Autio, K. A. et al. Severe Hypocalcemia Associated With Denosumab in Metastatic Castration-Resistant Prostate Cancer: Risk Factors and Precautions for Treating Physicians. Clin. Genitourin. Cancer 13, e305-e309 (2015).

AN UNUSUAL BUT EASILY TREATABLE CAUSE OF SEVERE ABDOMINAL PAIN Emily Unger[1, 2]; Shirin Karimi[2, 1]; Priyank Jain[2, 1]. [1]Harvard Medical School, Somerville, MA; [2]Cambridge Health Alliance, Cambrdige, MA. (Control ID #2704802)

LEARNING OBJECTIVE #1: Distinguish abdominal wall pain from intra-abdominal causes of pain

LEARNING OBJECTIVE #2: Diagnose Anterior Cutaneous Nerve Entrapment Syndrome

CASE: Ms. C is a 53 year-old female with obesity, diabetes, asymptomatic ventral hernia, peripheral neuropathy, and a 2 week history of cardiac catheterization, who presented to the hospital with severe abdominal pain that began 2 days after the procedure. Pain was present in the right lower quadrant and right groin, close to the catheterization site. Patient described the pain as stabbing and constant, less when lying down, and worse with any movement or standing. Patient needed a walking aid due to the pain. Other GI or GU review of symptoms were negative. Ms. C was admitted for pain control and further diagnostic workup including a CT of abdomen/pelvis, Doppler of femoral vessels, MRI of Lumbar spine, and CBC/CMP/UA. Results were nondiagnostic and her pain persisted. On hospital day 3, a more detailed physical exam revealed that patient's pain was localized to a 2 cm sized area in the RLQ of her abdomen and this small area had reduced sensation to temperature and was numb. Patient had a positive Carnett's sign. The groin was non-tender. Ms C's physical examination suggested neuropathic pain of the abdominal wall, specifically Anterior Cutaneous Nerve Entrapment Syndrome (ACNES) as a probable diagnosis. She consented for diagnostic trial of local anesthetic injection in the abdominal wall. 2 min after the injection, her pain was barely noticeable and she was walking unaided. She was diagnosed with ACNES and discharged pain free.

IMPACT: When working up severe abdominal pain, our diagnostic reasoning focuses mainly on intra-abdominal causes of pain. However, with a careful history and exam it is important to differentiate abdominal wall pain from more serious causes of intra-abdominal pain. This differentiation can save a patient from a stressful, expensive and potentially risky work-up, and get them lasting pain relief as quickly as possible.

DISCUSSION: Ms. C's duration of severe abdominal pain, hospital stay, and numerous tests were avoidable. The first step in recognizing this diagnosis is distinguishing abdominal wall pain from intra-abdominal causes of pain. An abdominal wall etiology is highly suggestive if pain is relieved when lying down and worse when standing up; worse with tensing the abdominal muscles (Carnett's sign); and absence of other neuro/GI/GU symptoms. ACNES is a

cause of abdominal wall pain and may be responsible for 2% of patients presenting to the ED with abdominal pain. Abdominal wall pain is caused by the compression of abdominal cutaneous nerves within the rectus sheath and abdominal fascia. Patients have a discrete trigger point lateral to the Abdominus Rectus muscles. Diagnosis and treatment are the same: injection of point of maximal tenderness with Lidocaine and steroids. After injection, a patient with ACNES should have rapid pain relief.

AN UNUSUAL CASE OF ALTERED MENTAL STATUS IN A PATIENT WITH HIV John Chiosi[1]; David Mushatt[2]. [1]Tulane University, New Orleans, LA; [2]Tulane University, New, LA. (Control ID #2705896)

LEARNING OBJECTIVE #1: Recognize a cause of altered mental status in immunocompromised patients

LEARNING OBJECTIVE #2: Diagnose and treat CNS histoplasmosis.

CASE: A 43 year-old woman from central Louisiana with untreated HIV presented for 1 week of general malaise with 1 day of new-onset confusion. She became increasingly altered, requiring intubation. She was started on empiric antibiotics. Initial laboratory studies revealed a CD4 count of 7 cells/μL and HIV-1 RNA viral load of 640,000 copies/μL. Initial CSF studies: WBC 0, glucose 62, total protein 22, cryptococcal antigen negative. Despite antibiotics, she was persistently febrile and developed tonic-clonic seizures. CT head revealed diffuse cerebral edema. On day 4, a peripheral smear revealed PMNs with intracellular yeast. Serum histoplasma antigen was collected and she was started on liposomal amphotericin B. On day 10, the serum histoplasma antigen was positive, and later the CSF histoplasma antigen collected on admit resulted as positive. She developed septic shock requiring vasopressors, acute renal failure, and coagulopathy with bleeding from her mouth. A biopsy of oral mucosa revealed intracellular organisms on PAS and GMS stains consistent with histoplasmosis. An endotracheal aspirate revealed intracellular yeast forms. During the hospitalization, her mental status improved. Repeat CT head showed improvement of cerebral edema. Her coagulopathy and renal failure resolved.

IMPACT: CNS involvement can be seen in patients with disseminated histoplasmosis; however, histoplasmosis is not a commonly suspected agent in AIDS patients presenting with CNS disease.

DISCUSSION: Histoplasma capsulatum is a fungus endemic to regions of the Ohio and Mississippi River valleys, and extends throughout the Midwest, Southeast, and South Central US. Disseminated histoplasmosis is often seen as an opportunistic infection in AIDS patients in these regions. Disseminated histoplasmosis occurs in approximately 1 in 2000 patients with acute infection, and 5-10% of these cases can develop CNS disease. Our severely immunocompromised patient likely acquired pulmonary histoplasmosis where she lived in central Louisiana, which is moderately endemic for H. capsulatum. Immunocompromised patients may present with advanced disease causing obtundation, coagulopathy, shock, and organ failure. Diagnosis of CNS infection should be suspected in patients with disseminated histoplasmosis accompanied by altered mental status, abnormal CSF and/or abnormal findings on brain imaging. CSF antigen or anti-Histoplasma antibodies in the CSF can confirm diagnosis. Despite treatment with amphotericin B, mortality is close to 50% in these patients. The relapse rate of CNS histoplasmosis after amphotericin B is up to 50% after cessation of therapy. Current therapy involves induction with liposomal amphotericin B for 4–6 weeks followed by itraconazole for at least 1 year to prevent relapse.

AN UNUSUAL CASE OF CONFUSION AND WEAKNESS Nathalie Kolandjian[2]; Sujata Bhushan[1]. [1]Dallas VA Medical Center, Dallas,, TX; [2]UT Southwestern, Dallas, TX. (Control ID #2692948)

LEARNING OBJECTIVE #1: Recognize the clinical features of Creutzfeldt-Jakob Disease.

LEARNING OBJECTIVE #2: Distinguish Creutzfeldt-Jakob Disease from other neurodegenerative disorders.

CASE: A 74 year old male presented with non-syncopal falls and new lower extremity weakness. He denied recent travel, hunting or consumption of wild game or beef. CT head was negative for stroke. Several weeks later, he was re-admitted with worsening confusion and agitation. Exam showed lower extremity muscle wasting with hyperreflexia and diffuse fasciculations. EMG revealed severe peripheral neuropathy and CT neck showed myelomalacia. He became progressively less verbal and developed difficulty ambulating. MRI brain showed non-specific signs of inflammation. EEG showed diffuse slowing. The patient was discharged with the diagnosis of severe neurodegenerative dementia. One week later, the patient was re-admitted. He had become completely bedbound; unable to speak or follow commands, only opening his eyes and withdrawing from pain. Exam showed rigidity of all four extremities, bilateral positive Babinski's sign and diffuse fasciculations. He later developed myoclonic facial jerks. Repeat EEG showed a triphasic wave pattern. MRI showed T2 enhancement of the temporal lobe. Infectious and autoimmune CSF studies were negative. CSF results for Creutzfeld-Jacob protein 14-3-3 and RT-QuIC were positive. CSF T-tau protein level was elevated at 16092 pg/ml supporting the diagnosis of Sporadic Creutzfeld-Jacob Disease (CJD).

IMPACT: The clinical course of CJD can mimic many other diseases. This case illustrates the importance of maintaining a broad differential for patients with new-onset altered mental status with focal neurologic changes.

DISCUSSION: CJD is a human prion disease that is universally fatal with a median survival of 7–8 months. It causes rapid deterioration of cognitive and motor function. Initial psychiatric symptoms include memory impairment, anxiety, depression and sleep disturbances. Multiple brain systems are affected causing ataxia, and bradykinesia. Corticospinal Tract dysfunction causes hyperreflexia, spasticity and extensor plantar responses. Peripheral neuropathy can cause fasciculations as seen in ALS. Myoclonus is often seen later in the disease and patients in terminal stages often progress to akinetic-mutism. Typical MRI findings include increased T2 and Flair signal intensity in the putamen and head of caudate. These findings are often misinterpreted given the rarity of the condition. Characteristic EEG findings are of periodic synchronous biphasic or triphasic sharp wave complexes (PSWC). CSF specific biomarkers include protein 14-3-3, total tau protein and neuron specific enolase which act as surrogate markers for neuronal damage. Prion conversion assays like real-time quaking induced conversion (RT-QuIC) are highly sensitive and specific, however definitive diagnosis requires pathological examination of brain tissue.

AN UNUSUAL CASE OF DIARRHEA MISDIAGNOSED AS ULCERATIVE COLITIS Elizabeth Sprague[2]; Alina Brener[1]; Adam Schiro[2]; Shira Ronen[2]; Mohan Dhariwal[2]; Laura Michaelis[2]. [1]MCW, Milwaukee, WI; [2]Medical College of Wisconsin, Milwaukee, WI. (Control ID #2692350)

LEARNING OBJECTIVE #1: Recognize the clinical and pathologic features of Langerhans cell histiocytosis

LEARNING OBJECTIVE #2: Describe treatment strategies in Langerhans cell histiocytosis

CASE: A 67 year-old female with history of type II diabetes and hypertension presented with abdominal pain and diarrhea. The patient was diagnosed with UC one year prior after presenting with similar symptoms at which time a colonoscopy showed pan-colitis with biopsies revealing chronic inflammation. She was started on sulfasalazine but did not improve despite multiple courses of systemic steroids and repeated hospital admissions. She was admitted to our medical service with persistent diarrhea and dehydration felt to represent steroid-refractory ulcerative colitis. On admission her temperature was 100.3 °F and she had mild diffuse abdominal tenderness. A colonoscopy revealed large, deep ulcers with friability and spontaneous hemorrhage involving the entire colon. Biopsies showed active colitis with crypt architectural distortion consistent with chronic colitis such as UC. However, there was a mucosal and submucosal infiltration of cells characterized by abundant pale eosinophilic cytoplasm. These cells were positive for CD1a and S-100, consistent with a diagnosis of LCH. Sulfasalazine was stopped, and the patient was referred to oncology. She has been initiated on chemotherapy with modest improvement in her symptoms.

IMPACT: Less than 20 cases of LCH with gastrointestinal involvement in adults have been previously reported. As such, treatment for these patients is based upon case reports and small case series. In addition, new research shows that LCH is associated with a mutation in the BRAF gene, which is the specific target of a new molecular therapy, Vemurafenib. While it is only approved for use in late stage melanoma, case reports using this medication for LCH have been promising. Correct diagnosis of this disease may allow for targeted therapy in the near future.

DISCUSSION: LCH is a rare infiltrative disorder of myeloid dendritic cells with a childhood incidence of 3–5 per million and adult incidence estimated at 1–2 per million. The disease can affect any organ system, and can present with either single or multi-organ involvement. Most commonly, it presents in the bones with lytic lesions and bone pain, though is also commonly seen in skin, lymph nodes, or lungs, which present as rash, lymphadenopathy, and cough respectively. In its more severe form, LCH affects multiple organs; involvement of the liver, spleen, or bone marrow denotes a worse prognosis. No prospective trials have been conducted in adults so treatment is targeted to the involved organ and includes surgery, radiation, and/or chemotherapy. This case represents an unusual presentation of LCH involving the gastrointestinal tract and highlights the need to consider alternative diagnoses in patients with UC who are not responding to high-dose steroid therapy.

AN UNUSUAL CASE OF DIZZINESS Cody R. Gomez; Cynthia Woods; Hetendra Makanbhai. Methodist Dallas Medical Center, Dallas, TX. (Control ID #2703945)

LEARNING OBJECTIVE #1: Diagnose vertebral artery dissection by careful evaluation of patient history and appropriate diagnostic imaging

CASE: A 30 year old Hispanic female presented to the ER with a chief complaint of new onset dizziness. The patient denied pre-existing medical conditions, and prior to the dizziness had reported neck pain and headache starting several weeks ago. She had sought the aid of a chiropractor utilizing manipulation. Upon evaluation in the emergency room the patient was noted to have neck pain, an unremarkable head CT, and leukocytosis. Intact strength on exam. Left sided ataxia with no appreciable right sided ataxia noted. No papilledema noted. Multiple infarcts were identified on MRI - infarction involving both cerebellar (predominantly left) hemispheres, vermis, right occipital lobe and posterior thalamus. ECHO demonstrated a PFO. Bilateral doppler US of her lower extremities negative for DVT. Neurosurgery was consulted. A diagnostic cerebral arteriogram was performed, which yielded the diagnosis of bilateral vertebral artery dissection (significant stenosis limiting flow/dissection on right, and less than 70% stenosis/dissection on left). Given the history and symptom onset, it is believed that the manipulation was the likely etiology in her bilateral dissection and subsequent stroke. The patient was evaluated by PT/OT, placed on dual anti-platelet therapy, and discharged to follow up with outpatient repeat angiogram.

IMPACT: Death related to vertebral artery dissection and its subsequent complications may be as high as 10%[1]. Given the degree of mortality, it is important to remain vigilant in the search for a vertebral artery dissection when clinical suspicion is high. This case highlights the importance of a thorough history when evaluating patients with vague or nonspecific complaints. This case is fairly unique in that dissection of vertebral arteries (especially bilaterally related to trauma) is considered rare - such a diagnosis has been associated with automobile and sports injuries as well as iatrogenic causes in literature[2].

DISCUSSION: The frequency of this type of vascular event, in association with manipulation, occurs in 1 in 15,846,381 - other sources suggest 1 in 20,000. While imaging modalities such as magnetic resonance angiography are useful in evaluating multiple neurological conditions, it may not be able to detect such a dissection[3]. Digital subtraction arteriography should be considered[2]. Reference: 1. Nagurney, John et al. Unusual Visual Symptoms in a Patient with Bilateral Vertebral Artery Dissection: A Case Report. The Journal of Emergency Medicine. 2006. Volume 31. No. 2. pp 169–171. 2. Galtes, Ignasi et al. Traumatic bilateral vertebral artery dissection. Forensic Science International. Volume 214. Issue 1. 2012. e12-15. 3. Preul et al. Bilateral Vertebral Artery Dissection After Chiropractic Maneuver. Clinical Neuroradiology. 2010. Volume 20. Issue 4. pp 255–259.

AN UNUSUAL CASE OF HYDRONEPHROSIS DUE TO PERITONEAL CARCINOMATOSIS FROM METASTATIC PROSTATE ADENOCARCINOMA Corey R. O'Brien[1]; Christopher Sciria[1]; Kevin Ikuta[1]; Daniel G. Federman[2]. [1]Yale New Haven Hospital, New Haven, CT; [2]West Haven VA Medical Center, West Haven, CT. (Control ID #2702728)

LEARNING OBJECTIVE #1: Build upon the limited literature describing metastatic prostate cancer as a cause of peritoneal carcinomatosis

CASE: An 87 year-old man presented with a rise in creatinine (Cr) in the setting of bilateral hydronephrosis. His medical history was notable for DM2, CKD (baseline Cr 1.5 mg/dl), and prostate cancer (diagnosed 18 years prior, s/p external beam radiation). He initially presented to urology with a 1 month history of painless gross hematuria. CT scan showed bilateral hydronephrosis. Upon cystoscopy there was an abnormal prostate and right hydroureter; a foley catheter was placed. At that time Cr was 2.2.mg/dl; one week later Cr was 2.6 mg/dl, at which point he presented to the ED. Pertinent positives included hematuria and recent GU instrumentation. Pertinent negatives were dysuria and suprapubic pain. Medications were HCTZ, metformin, and oxycodone. He had no family history of renal disease. He had a 50 pack-year smoking history (quit >25 yrs ago) and was a retired salesman with no occupational exposures. A focused physical exam demonstrated an elderly male with no CVA tenderness and a foley catheter draining clear yellow urine. Laboratory studies showed a wbc 7.4 k/cmm, Cr 2.6 mg/dl (baseline 1.5), A1c 6.9 mg/dl, PSA 50 ng/ml, FEUrea 46%, urinalysis: 32 wbc's, 12 rbc's, 3+ LE, neg nitrite. A non contrast CT showed: worsening

bilateral hydronephrosis; peritoneal carcinomatosis; and pelvic bony metastases. He then underwent a peritoneal biopsy, which based on immunostains showed that tumor cells were scattered positive for PSA and PSAP; findings were consistent with metastatic adenocarcinoma of prostatic origin.

IMPACT: Prostate cancer is the 2nd most common cancer in men and one of the leading causes of cancer death. Prostate cancer typically metastasizes to the bone, lung, and liver (Bubendorf 2000 et al.). Peritoneal carcinomatosis is a cancer of the peritoneum, typically arises from metastasis from colon or ovarian cancer, and rarely presents as primary mesothelioma. There are only a few case reports describing metastatic prostate cancer leading to peritoneal carcinomatosis. To our knowledge, none describe peritoneal carcinomatosis as the presenting manifestation of a very late recurring prostate cancer. This case builds upon the limited literature describing prostate cancer as a cause of peritoneal carcinomatosis. Because the patient declined ADT (androgen deprivation therapy) we describe the natural history of peritoneal carcinomatosis secondary to prostate cancer.

DISCUSSION: We suspect that this patient had hydronephrosis and gross hematuria due to peritoneal carcinomatosis enveloping the genitourinary tract. Peritoneal carcinomatosis is often difficult to appreciate on CT and was likely present, although undetectable, on initial CT scan. Peritoneal biopsy was positive for prostate cancer. After multidisciplinary family meetings the patient decided to pursue comfort measures and declined ADT, palliative chemotherapy, and percutaneous nephrostomy tubes.

AN UNUSUAL CASE OF WEIGHT LOSS IN A 69 year OLD MAN

Emily Poppens; Mikhail Akbashev. Emory University, Atlanta, GA. (Control ID #2702034)

LEARNING OBJECTIVE #1: Recognize temporal arteritis as cause of unintentional weight loss

LEARNING OBJECTIVE #2: Identify atypical presentations of temporal arteritis

CASE: A 69 year old African American man presented with tachycardia and fever in the setting of subacute weight loss, fatigue, intermittent fevers and night sweats. He had a history of coronary artery disease, congestive heart failure, diabetes mellitus, depression, dementia and emphysema. Recent evaluations by his primary care physician included routine laboratory testing, esopho-gastro-duodenoscopy, colonoscopy, chest, abdominal and pelvic computed tomography scans that were unrevealing for a cause of his weight loss. His admission exam was pertinent for a cachectic man with bitemporal wasting and weight of 66 kilograms, a decline from 87 kilograms 2.5 years prior. Blood pressure was 108/53, heart rate 140 which improved to 110 with fluids, and he had a lone temperature to 39.4 Celsius. Initial laboratory evaluation revealed stable values from his baseline on the comprehensive chemistry and complete blood count. Electrocardiogram and chest x-ray had no pertinent changes. Upon further review of systems he noted left sided headache and symmetric pain in his hips and shoulders. He denied visual changes, jaw claudication and scalp tenderness. An erythrocyte sedimentation was extremely elevated at 111. Rheumatology was consulted for concern of temporal arteritis and polymyalgia rheumatica. Temporal artery biopsy revealed partially healed temporal arteritis. Ophthalmology did not find any evidence of ocular involvement. He was started on steroids for polymyalgia rheumatica and temporal arteritis. At follow-up with his primary care physician two months later, he reported improvement in headaches, shoulder and hip pain, and improved appetite without further weight loss.

IMPACT: This case highlights the importance of considering vasculitis as a source of unintentional weight loss.

DISCUSSION: Unintentional weight loss in older adults is a problem commonly encountered by the general internist and is associated with increased morbidity and mortality. While not the most common cause, rheumatologic etiologies account for 7% of unintentional weight loss in this population and can be easily missed. While the typical presentation of temporal arteritis is characterized by continuous temporal headache unresponsive to analgesics, jaw claudication and visual changes, it can also present with constitutional symptoms of fatigue, weight loss and night sweats or as a fever of unknown origin like our patient experienced. 40–60% of patients with temporal arteritis, including our patient, also have polymyalgia rheumatica, another rheumatic condition characterized by muscle pain and stiffness in the neck, shoulders and hips. A thorough rheumatologic review of systems and the initial work-up for weight loss, with an erythrocyte sedimentation rate, led to this cannot miss diagnosis.

AN UNUSUAL CAUSE OF CHEST PAIN AND SHORTNESS OF BREATH IN A YOUNG FEMALE Nurilign A. Bulcha; Fojas Antonio. Montefiore Medical Center, Bronx, NY. (Control ID #2707562)

LEARNING OBJECTIVE #1: Diagnose large B-cell lymphoma in a young female.

LEARNING OBJECTIVE #2: Recognize cardiac tamponade as a complication of large B-cell lymphoma

CASE: A 31 year old female presented with two weeks of shortness of breath and chest pain. Heart rate was 111 beats per minute. Blood pressure was 115/80 mm Hg. She had engorged neck veins, distant heart sounds and bilateral leg edema. Laboratory tests revealed a white blood cell count of 9,000 and hemoglobin of 12.8 g/dl. Transaminases were mildly elevated. Alkaline phosphatase, bilirubin and LDH were normal. A CT scan of the chest revealed a large pericardial effusion and an anterior mediastinal mass measuring 10.4 × 7.1 × 7.1 cm. An Echo revealed a large pericardial effusion with diastolic right ventricular collapse. Patient underwent emergent pericardiocentesis and 700 ml of hemorrhagic fluid was removed. A CT guided core biopsy revealed large B-cell lymphoma CD 20+ phenotype. Chemotherapy with R-EPOCH was started and patient has completed 3 cycles.

IMPACT: Early recognition and prompt treatment of Non Hodgkin's Lymphoma can dramatically improve patient outcomes and avoid often fatal consequences.

DISCUSSION: Diffuse large B cell lymphoma is the most common type of Non- Hodgkin's lymphoma and accounts for about 30% of all newly diagnosed NHL. It is more common in men older than 65. Patients usually present with a rapidly enlarging mass in the neck, mediastinum or abdomen with compressive symptoms. Patients may also have fever, weight loss and night sweats (B- symptoms). Up to half of the cases may not have elevated serum LDH. The most common site of extra -nodal involvement is the GI tract. Cardiac metastases may be found in 18 percent of patients of NHL. It often occurs late in the course of disease. Consequences of cardiac involvement include heart failure, arrhythmias or cardiac tamponade as in our patient. Early cardiac involvement in malignant lymphoma with cardiac tamponade is very rare especially in a young female. Cardiac tamponade is a consequence of accumulation of fluid in the pericardial space compressing the heart and causing diastolic dysfunction. Right ventricular collapse may be noted especially in the presence of hypovolemic conditions such as hemorrhage or over diuresis. Common etiologies include tumors, infections particularly tuberculosis and trauma. Acute cardiac tamponade occurring within min is life threatening and requires emergent fluid removal. Clinical findings include

hypotension/shock, engorged neck veins, distant heart sounds and pulsus paradoxus. Echocardiography and CT/MRI imaging are diagnostic. Pericardial fluid analysis may be helpful but pericardial window biopsy has better yield in determining etiology. In our case, the gender and age of the patient as well as early cardiac involvement with tamponade make the presentation of NHL very unusual. A thorough clinical evaluation is vital to make an early diagnosis especially in cases of cardiac metastasis and prevent lethal outcomes.

AN UNUSUAL DVT THREATENS LIFE AND LIMB

Sharanya Rajendra[1]; Sophia Paraschos[2]; Beth Ann Brubaker[2]. [1]University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, NC; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC. (Control ID #2692444)

LEARNING OBJECTIVE #1: Recognize hypovolemic shock and compartment syndrome as sequelae of phlegmasia cerulea dolens

CASE: A 34 year-old-man with bipolar disorder, diabetes mellitus type 1, multiple sclerosis, and DVT status post IVC filter 10 years ago, presented unresponsive in PEA arrest. ROSC was achieved after CPR and intubation. With an FiO2 of 100%, his arterial blood gas showed a pH of 6.86, pCO2 of 29 mm Hg, and bicarbonate of 5.2 mmol/L. Other notable chemistries included a lactate of >16 mmol/L, creatinine of 3.19 mg/dL, and creatinine kinase of 2,117 U/L that increased to 12,145 U/L after 24 h. He was anuric and started on emergent dialysis. Evaluation for cardiogenic, neurogenic, and septic shock was unrevealing. He had painful lower extremities that were edematous, cool and without palpable pulses. Dopplers revealed acute DVTs in the right and left common femoral veins and right popliteal vein. CT chest showed a new IVC thrombus superior to and abutting the apex of his IVC filter. His bilateral lower extremity compartment pressures were 70–90 mm Hg. He was diagnosed with phlegmasia cerulea dolens, a heparin drip was started, and he underwent emergent bilateral lower extremity fasciotomies with pharmacomechanical thrombectomies of the IVC, popliteal, femoral, common femoral, external and internal iliac veins. His fasciotomy sites were closed with skin grafts, and he was started on warfarin. He regained full neurovascular function of his legs. Hypercoagulability studies and investigations for malignancy were negative.

IMPACT: The most common precipitants for phlegmasia cerulea dolens (PCD) are malignancy and hypercoagulable states, especially antiphospholipid syndrome, although neither were ever identified in this patient. The most likely etiology of PCD in this case was propagation of clot from his IVC filter. It has been reported that 3-30% of patients with an IVC filter develop a new, obstructive thrombosis, thought to be due to the filter itself.

DISCUSSION: PCD is a rare, but dangerous consequence of DVT caused by venous obstruction of the major deep veins and collateral veins. The elevated venous hydrostatic pressures cause as much as 6–10 L of fluid to extravasate into the interstitium of the extremities in a matter of days. This can lead to acute compartment syndrome, venous gangrene, and rhabdomyolysis, as well as hypovolemic shock and cardiac arrest. Additionally, the high compartment pressures collapse arterial vessels, resulting in hypoperfusion and lactic acidosis, as described in the above case. The overall mortality from PCD is 20–40%, and among survivors there is a 12–50% amputation rate. PCD is a rapidly progressive and highly morbid condition that should be considered in any patient presenting with new onset leg pain, edema, and cyanosis. Complications including compartment syndrome, hypovolemic shock, and death can be avoided with timely diagnosis and thrombolysis. The condition should prompt investigation for underlying malignancy and hypercoagulable conditions.

AN UNUSUAL PRESENTATION OF HYPERTHYROIDISM Lei Lynn; Sripooja Satya; Kathryn Stigliano; Farida Izzi. George Washington University, Washington, DC. (Control ID #2703052)

LEARNING OBJECTIVE #1: Recognize rare cardiovascular and hepatic complications associated with hyperthyroidism.

CASE: A 49 year-old, previously healthy woman was sent from clinic for workup of a three-month history of symmetric lower extremity swelling and new-onset jaundice. She also endorsed generalized malaise, diffuse pruritus, and a 50 lb weight loss. Physical exam revealed scleral icterus, mild thyromegaly without palpable nodules, non-tender but distended abdomen, and 2+ pitting edema in bilateral lower extremities. Labs revealed anemia, thrombocytopenia, hyperbilirubinemia (Tbili 9 mg/dL) and low TSH (<0.015 mcIU/mL) with elevated T3 (19.7 pg/mL) and T4 (>6.99 ng/dL). Additionally, both TPO and TSI were elevated and thyroid ultrasound showed hypervascularity consistent with Grave's disease. Abdominal CT revealed hepatic steatosis and cirrhosis, which was confirmed on biopsy. Furthermore, echo showed dilated left and right atria and moderate pulmonary hypertension. Both lower extremity swelling and hyperbilirubinemia resolved after treatment with methimazole.

IMPACT: This case was unique in that this hyperthyroid patient presented with jaundice and evidence of cardiac decompensation in the setting of newly discovered pulmonary hypertension. The final diagnosis of Grave's disease was a reminder to always consider endocrine diseases in the differential.

DISCUSSION: Grave's disease is the most common cause of hyperthyroidism in iodine sufficient regions. Intrahepatic cholestasis seen on biopsy of our patient can be associated with Grave's disease. Jaundice in the setting of Grave's disease can develop either in a healthy patient or those with autoimmune liver disease, with variable manifestations ranging from hepatic congestion to gross hepatic decompensation. Treatment for Grave's disease is complicated in the setting of cholestasis given the hepatic side effects of thionamide drugs: methimazole can cause cholestasis and propylthiouracil can cause hepatocellular damage. However, when jaundice is associated with Grave's disease, methimazole has been found to be effective in treating hyperthyroidism and alleviate cholestasis. Hyperthyroidism has long been associated with cardiovascular sequelae such as tachycardia, hyperdynamic circulation, and decreased exercise capacity. Echo in our patient revealed dilated cardiomyopathy, which has been associated with Grave's disease in some cases. The proposed mechanism may be autoimmune in nature given the presence of TSH receptors in cardiomyopathy. Pulmonary hypertension is another uncommon complication. Our patient's lower extremity edema is likely the consequence of right heart insufficiency in the setting of pulmonary hypertension, which when associated with hyperthyroidism, can be reversible with proper treatment of hyperthyroidism. Thus, recognizing atypical presentations of hyperthyroidism is important in prompt diagnosis and effective treatment.

AN UNUSUAL REACTION TO A COMMON ANTIBIOTIC Ang Xu; David J. Hyman; Anoop Agrawal; Anthony wiseman; Justin Arunthamakun; Bhavish Manwani; Lee Lu. Baylor College of Medicine, Houston, TX. (Control ID #2707455)

LEARNING OBJECTIVE #1: To recognize the clinical features of drug induced AIN

CASE: Patient is a 67-year-old male with a history of well-controlled type 2 diabetes mellitus, hypertension, who was hospitalized a month prior for

Methicillin-sensitive Staphylococcus aureus and Group B Streptococcus bacteremia discharged on 2 g IV cefazolin q8h for 6 weeks who presented primarily for abdominal pain and distension. Since discharge patient had progressive nausea/ vomiting with inability to keep down any food. Notably, two weeks after patient was discharged with home IV cefazolin, patient's creatinine increased from a baseline of 1.3 mg/dL to 2.3 mg/dL. On physical exam vitals were stable. No jaundice was noted. Abdominal exam showed a distended abdomen that was diffusely tender to palpation with fluid waves. Extremities showed bilateral 2+ pitting edema up to the thighs. The rest of the physical exam was unremarkable. Patient had a normal leukocyte count; the differential was notable for eosinophilia (7.0%). Patient had elevated blood urea nitrogen (56 mg/dl) and elevated creatinine (1.8 mg/dL). Urine analysis showed 3+ protein, 2+ blood, 19 WBC and eosinophiluria. 24-hour urine analysis revealed 7.95 g of protein. Patient's PT, INR and PTT were elevated to 32.3, 3.1 and 49.8 s respectively. Given that the time course of the acute kidney injury coincided with the use of cefazolin, cefazolin was thought to likely be the culprit and was discontinued; steroids were started. Patient's coagulopathy resolved during hospitalization. Patient's serum creatinine improved from a high of 2.6 mg/dL to 1.9 mg/dL within 2 weeks of discharge. Patients proteinuria improved from 7.95 g to 142 mg within two months of discharge.

IMPACT: This is a case of a common antibiotic (Cefazolin) causing two rare reactions. Many drugs can cause AIN however only a select few have been known to cause AIN with nephrotic range proteinuria, the most well-established being NSAIDs. Additionally, in this patient, the cefazolin also caused an acute coagulopathy, which is a rarely reported side effect of cefazolin. To the best of our knowledge, cefazolin has not been reported in the literature to cause AIN with nephrotic range proteinuria.

DISCUSSION: Acute interstitial nephritis is primarily iatrogenic. AIN is classically thought to have a triad of rash, eosinophiluria and fever however more common signs are microhematuria and sterile pyuria. Treatment of drug induced AIN consists primarily of discontinuing the offending agent and supportive care. Steroids are often used however the evidence is mixed with some studies showing benefits. It is important for clinicians to recognize the clinical features of AIN especially if new medications coincide with the signs and symptoms of AIN.

ANAPHYLAXIS AS AN ADVERSE REACTION TO EMERGENCY CONTRACEPTION Victoria Menashy[1]; Ann Prokofieva[1]; Rebecca Mazurkiewicz[1]; Ronit Herzog[2]. [1]Lenox Hill Hospital, New York, NY; [2]New York University, New York, NY. (Control ID #2688200)

LEARNING OBJECTIVE #1: Oral contraceptives and emergency contraception such as levonorgestrel are commonly used forms of birth control among women. Ninety-nine percent of sexually active American women aged 15 to 44 have used a contraceptive method, with an increase use progressively over the years from 2002 to the present. However, to our knowledge, there are no reports of anaphylaxis to date. We report a case of acute systemic anaphylaxis to oral levonorgestrel. The case demonstrates the potential for severe allergic reaction to this commonly used emergency contraception.

CASE: A 38 year old female with past medica lhistory of depression presented with generalized skin pruritis and a rash, along with a sensation of swelling in her throat that started fifteen min after taking oral levonorgestrel at an urgent care facility. An epinephrine injection was administered, but it did not help her symptoms. Upon admission to the emergency room, the patient felt dizzy, short of breath and had acute urticaria. On physical examination, she was noticed to have tachycardia to 102, while the rest of her vitals were stable. The patient had uvula angioedema, no facial swelling and her lungs were clear. Blood testing with a cell blood count was normal. Her symptoms were alleviated by dexamethasone, diphenhydramine and famotidine intravenously. The patient had a similar episode of hives and anaphylaxis to the oral contraceptive, norethindrone-estradiol two years ago. Pertinent family history is notable for anaphylaxis to a bee sting in her father. Home medication includes sertraline for depression, which she has been taking for years. No other new medications were taken at this time. Patient denies eating any new foods, insect bites or exposure to any new chemicals. The patient denies alcohol, tobacco or illicit drug use. The review of systems was otherwise negative.

IMPACT: The patient's acute anaphylaxis was likely induced by the progesterone. Further studies are needed to evaluate the safety profile of this contraceptive and the predicting risk factors to the development of a systemic reaction.

DISCUSSION: The patient's acute anaphylaxis was likely induced by the progesterone. The patient did not eat anything before the levonorgestrel, therefore eliminating food related allergic conditions. Although she is on sertraline, this is not a new medication; thereby drug allergies may be excluded. The patient has no recent infections or chronic medical conditions that may be potential counfounding factors. There is one case report of acute urticaria following implantation of levonorgestrel and another report of autoimmune progesterone dermatitis 24 hours after insertion of levonorgestrel. The importance of reporting this case is to raise awareness of rare side effects of contraceptive pills. As a general practitioner, it is important while prescribing birth control medications to be aware of even the side effects of commonly taken medications.

ANCHORING ON THE NOSE Justin S. Louie. Kaiser Permanente San Francisco, Berkeley, CA. (Control ID #2692560)

LEARNING OBJECTIVE #1: Recognizing granulomatosis with polyangiitis as an uncommon, but clinically important disease, necessitating high clinical suspicion and rapid diagnosis

LEARNING OBJECTIVE #2: Reminder to avoid anchoring bias, especially when working in a multidisciplinary environment

CASE: A 70 year old male with type 2 diabetes and hypothyroidism was directly admitted to the hospital with a diagnosis of acute bacterial sinusitis, refractory to outpatient antibiotics. He originally had right sided facial pain, with full opacification of the right sinuses on CT. Care was managed by a multidisciplinary team including medicine, infectious disease, ophthalmology, and head and neck surgery (HNS). Treatment continued with IV antibiotics, but symptom progression prompted surgical evaluation with discovery of necrotic tissue. He ultimately required ICU admission, and 2 further debridements with removal of necrotic tissue. Unfortunately, his cultures were persistently negative. He was eventually discharged with additional antibiotics and follow up. Soon after discharge, his wife noticed he was tripping over his feet. Examination revealed right foot drop and he was referred to rheumatology. Labs returned with elevated PR3-ANCA (cANCA) and negative MPO-ANCA (pANCA), and he was diagnosed with granulomatosis with polyangiitis(GPA). He was treated with steroids and rituximab, with resolution of his nasal and neurologic symptoms.

IMPACT: This case is a classic presentation of GPA, masked by a pre-existing diagnosis of sinusitis. It illustrates the dramatic and morbid course of the disease, while also reinforcing the importance of avoiding anchoring bias by maintaining wide differentials and revisiting diagnoses when cases do not progress as expected. Earlier consideration of rheumatologic disease and other

vasculopathies, may have allowed the patient to avoid multiple surgical procedures and decrease the risk of developing long term complications.

DISCUSSION: Granulomatosis with polyangiitis is a systemic small and medium vessel vasculitis, mediated via autoimmune attack by abnormal antibodies, PR3 directed cANCA in 80–90% of cases. Early presentation is nonspecific, though rhinitis is a frequent initial complaint. Manifestations commonly involve multiple organ systems, and damage to the lungs and kidneys can be fatal. Before modern treatments, the average survival was five months, with 2-year mortality over 90%. There are multiple classification algorithms; however, in clinical practice, biopsy data in conjunction with clinical findings is the most definitive method of diagnosis. Presumptive diagnosis can be made in high probability situations with consistent clinical findings and positive serology. This allowance is made, because prompt diagnosis is important to permit initiation of immunosuppressive therapy which may be life-saving and organ sparing. GPA should be suspected in patients with upper and lower respiratory disease who develop consistent systemic symptoms and are poorly responsive to non-immunosuppressive treatments.

ANCHORS AWAY: ANCHORING BIAS, CONFIRMATION BIAS, AND PULMONARY EMBOLI Derek C. Mazique. NewYork-Presbyterian/Weill Cornell Medical College, New York City, NY. (Control ID #2700921)

LEARNING OBJECTIVE #1: Understand the reported failure rates of enoxaparin in medically ill hospitalized patients

LEARNING OBJECTIVE #2: Recognize anchoring bias and confirmation bias in the treatment of pulmonary embolism

CASE: HPI: Patient AD is a 75-year-old man with a PMH of CLL for years, on no treatment -Approx. 3 days of dyspnea, productive cough, subjective fever, and diarrhea -In the ED, VS T 37, RR 24, BP 138/79, HR 97, 97% on 4 L NC; uncomfortable appearing, tachypneic, but no other findings, and in no distress -Positive *L. pneumophila* antigen (urine) and rhinovirus PCR -Chest x-ray negative for acute pulmonary finding, EKG with RBBB unchanged from prior, troponin negative ×1 -Treated with azithromycin and oxygen, on prophylactic enoxaparin A Progression: On day 20, patient became acutely hypoxic with new tachypnea and tachycardia during ambulation, requiring escalation of O2 to 4 L -On exam, patient uncomfortable appearing, but otherwise similar to prior days of hospitalization -Given patient's continuous decline over weeks, patient considered to likely have subacute worsening of his already-established diagnosis -Bacterial superinfection strongly considered given narrow *Legionella* coverage and risk factors, despite lack of new infectious symptoms -ACS considered, but unlikely, given lack of cardiac risk factors, typical angina symptoms, or significant EKG changes -PE considered given CLL, worsening hypoxia, and new tachypnea but since on prophylactic enoxaparin, not pursued initially -Primary team broadened antibiotics and attributed presentation to worsening *Legionella* -With detrioration, CT Chest done next day with contrast revealed bilateral saddle emboli

IMPACT: −Treatment failure is a common complication of enoxaparin in medically co-morbid hospitalized patients -Confirmatory and anchoring bias can affect the diagnosis and prompt treatment of pulmonary emboli

DISCUSSION: −In research of hospitalized medically-ill patients, treatment failure with enoxaparin was approximately 3-5% -Among interests reporting 669 diagnostic errors, the most common missed diagnosis involved pulmonary emboli (26, 4.5% of total) -Cognitive errors arise when non-analytical reasoning (Type 1 processes) uses biases and heuristics to override analytical reasoning (Type 2 processes) i.e. based on objective clinical information -Among IM residents, anchoring and confirmation biases accounted for 87 and 48% of cognitive errors, respectively -Anchoring Bias: Anchoring on the diagnosis of worsening *Legionella* pneumonia or bacterial superinfection due to presence of prophylaxis, despite history of malignancy and new clinical change -Confirmation Bias: Pursuing diagnosis of infection (confirmation) despite lack of infectious symptoms, rather than pursuing other possibilities -Pulmonary emboli, given their often atypical presentation and risk for misdiagnosis, might be at elevated risk for cognitive bias and medical error -More research is needed for formal didactics on cognitive bias and recalibrating Type 1 processes in the setting of pulmonary embolism

ANEMIA AND HYPOTHYROIDISM; STOP THE THYROID INSANITY Arwa M. Elsheikh[2]; Yazan Samhouri[1]; James Bingham[1]; manuel matos[1]. [1]Rochester Regional Health/Unity Hospital, Rochester, NY; [2]Unity Hospital, Rochester, NY. (Control ID #2706731)

LEARNING OBJECTIVE #1: Be aware of the association between hypothyroidisim and anemia.

LEARNING OBJECTIVE #2: Recognize hypothyroidism per se as a cause of otherwise unexplained severe macrocytic anemia.

CASE: A 22-year-old lady with history of primary hypothyroidism presented to the emergency with worsening fatigue and dizziness over one week, associated with exertional dyspnea. She denied any blood loss, constipation or cold intolerance. She was off levothyroxine for over seven years due to non compliance. On physical exam: BP 85/50 mmHg, HR 111 bpm, BMI 24.1, she had bilateral conjunctival pallor, ejection systolic murmur, delayed relaxation phase of tendon reflexes and neck exam showed no palpable thyroid. Her Labs showed HB 3.6 gm/dl, HCT 11.8%, MCV 105.4, TSH 524.38 uIU/ml, FT4 0.2 (0.9-1.8 ng/dl) and T3 42.8 (60–180 ng/dl). She was admitted as a case of severe anemia and hypothyroidism. Further work up for the anemia showed normal iron studies, normal B12 and methyl malonic acid, normal folic acid and her hemolytic work up (T. bilirubin, Haptoglobin, corrected reticulocyte count, LDH) was negative. She received total of four units of PRBCs during her hospitalization. She did not meet the criteria for myxedema coma diagnosis and was started on oral levothyroxine replacement. Her anemia was attributed to severe chronic hypothyroidism by exclusion. Her symptoms improved over the next two days, her hemoglobin was 8.1 g/dl, she was discharged to follow up with endocrinology.

IMPACT: This case highlight the importance of recognizing hypothyroidism as a cause of anemia and the assessment of thyroid function as a part of workup of anemia of unknown etiology. Hypothyroidism can cause various types of anemia and comprehensive workup is essential to identify the underlying etiology and direct management. This case also adds to the sparse literature that reported severe macrocytic anemia secondary to hypothyroidism per se in the absence of vitamin B12 and folic acid deficiency.

DISCUSSION: Anemia is reported in 20–60% of the patients with hypothyroidism (overt and subclinical). Anemia in hypothyroidism is characteristically normochromic normocytic related to inhibition of erythroid colony development, reduction in oxygen distribution to tissues and low erythroprotein level in the absence of thyroid hormones. Normalization of hemoglobin level occur with replacement of thyroid hormone. Iron deficiency resulting from iron malabsorption and menorrhagia is the second common cause. Macrocytic anemia can occur secondary to vitamin B12 deficiency (pernicious anemia) or rarely to hypothyroidism per se. Association between the degree of severity

of the anemia and the severity of hypothyroidism has been a controversial issue and in our patient the severity of anemia and the macrocytosis can be explained by the long standing untreated hypothyroidism. Clinician should be aware of the association between anemia and hypothyroidism and suspicious for hypothyroidism should be raised in all cases of anemia of unclear etiology.

ANOTHER AMIODARONE SIDE EFFECT! A RARE CASE OF AMIODARONE INDUCED SIADH Katherine A. Markelz; Shakil Shaikh. Baystate Medical Center, Springfield, MA. (Control ID #2707138)

LEARNING OBJECTIVE #1: Identify amiodarone as a rare etiology for medication induced SIADH

LEARNING OBJECTIVE #2: Recognize the dose-dependent relationship between amiodarone and SIADH

CASE: A 72 year old male with a past medical history of biventricular heart failure and hypothyroidism presented to our facility with a four day history of progressive dyspnea. Upon arrival he was in atrial fibrillation with rapid ventricular rate in the setting of acute constrictive effusive pericarditis. Despite optimal medical treatment and pericardiocentesis, his heart rate remained elevated and irregular. Rhythm control was pursued with Amiodarone at 400 mg every 8 hours. The first day following amiodarone initiation, our patient developed abrupt hyponatremia, from 136 to 128. By day two, his sodium fell to 123. Urine studies revealed: sodium 49 and osmolality 336. Serum osmolality was 279. Despite fluid restriction, liberal salt intake, and euvolemic clinical state, sodium remained low. Further workup showed renin 12.2, TSH 9.12 (16.05 on admission), Free T4: 1.26, aldosterone 21.3, and morning cortisol: 28.1. The only acute change preceding the hyponatremia was addition of amiodarone. Despite rate and rhythm control, with our leading suspicion for amiodarone induced SIADH, amiodarone was discontinued. Sodium level resolved three days after his last high loading dose of amiodarone. He eventually restarted amiodarone on a reduced loading dose of 400 mg twice daily and was discharged on maintenance dose amiodarone, with stability in his sodium levels.

IMPACT: Our case illustrates the importance of monitoring sodium levels for patients on amiodarone therapy. It also raises questions regarding the optimal dosing for safety and efficacy of amiodarone therapy.

DISCUSSION: SIADH is a major cause of hyponatremia. Characteristic findings include high urine osmolality and high urine sodium in the absence of hypoadrenalism and hypothyroidism, as seen in our patient. While malignancy, and central nervous system disorders are common etiologies, drugs have also been described. Since 1996, there have been 12 cases reporting amiodarone induced SIADH.While the exact mechanism is unknown, possible theories include enhanced secretion of ADH, increased sensitivity of the aquaporin-2 channels to ADH, and channel modulation in renal or neural tissue. Prior case studies describe a a temporal and dose-dependent relationship between amiodarone and drug induced SIADH. Two of the aforementioned cases describe hyponatremia as early as three days from initial loading dose, with resolution after dose reduction. Seven of the cases had resolution of hyponatremia within 7 days of discontinuation of amiodarone. Our patient developed SIADH one day after he received a full loading dose of amiodarone, yet his sodium remained stable on a reduced loading and maintenance dose. This suggests that dose reduction may treat and possibly prevent amiodarone induced SIADH. While amiodarone induced SIADH is very rare, clinicians should be aware of this potentially serious complication.

ANTIACID OR ANTIRENAL - A CASE OF OMEPRAZOLE INDUCED ACUTE INTERSTITIAL NEPHRITIS Nosheen Sarwar; Hani Erian; Steven Lamontagne. Berkshires Medical Center, Pittsfield, MA. (Control ID #2690491)

LEARNING OBJECTIVE #1: To recognize proton pump inhibitors (PPIs) as a potential cause of acute intersitial nephritis (AIN).

CASE: An 82-year-old female with a past medical history significant for hypertension, hypothyroidism and degenerative joint disease presented to our institution with progressive fatigue, anorexia and confusion over the last 4 weeks. She also reported decreased urine output for the last 2 weeks. Her home medications included lisinopril, nifedipine, ibuprofen as needed, gabapentin, levothyroxine, and omeprazole - which had been started few weeks prior to presentation for nonspecific stomach discomfort. In the ER, she was found to be bradycardic with a heart rate of 50 and was given atropine. Her labs showed severe acute kidney injury with serum creatinine of 9.6 mg/dl (from baseline creatinine of 0.8 mg/dl), and severe hyperkalemia with potassium 6.9 mEq/l. Given symptomatic hyperkalemia (bradycardia) and presumed uremic encephalopathy she underwent emergent hemodialysis on the day of presentation. Diagnostic evaluation for her AKI included an unremarkable renal ultrasound and urinalysis showing significant eosinophilia without any cellular casts. Renal ultrasound showed heterogenous renal parenchyma consistent with medical renal disease. Renal biopsy was performed and showed an extensive interstitial infiltrate composed of plasma cells, lymphocytes and neutrophils consistent with severe interstitial nephritis. Given the temporal association of the start of omeprazole therapy and the patient's proven AIN, this medication was presumed to be causal and was discontinued. Treatment with prednisone (tapered over 2 weeks) was initiated. She continued to require hemodialysis for one week, but eventually had renal recovery and became dialysis-independent with a creatinine that progressively improved to 1.6 mg/dl over the following weeks.

IMPACT: Given the high prevalence of PPI use in the general population, physicians should be aware of and closely monitor for renal complications of these medications.

DISCUSSION: PPIs are one of the most commonly prescribed drugs worldwide, and as such deserve close scrutiny for potential adverse effects. AIN is a hypersensitivity immune reaction involving the renal interstitium. PPI use has been associated with the development of AIN, as well as chronic kidney disease. Case series have shown similar incidence in male and female patients. The average time between exposure and development of AIN is highly variable, ranging from 1 week to several months. Diagnosis of PPI induced AIN is complex due to concomitant use of other AIN causing agents including antibiotics and nonsteroidal anti-inflammatory drugs. Patients may present with fever, loin pain, nausea or signs/symptoms of uremia. Inactive urinary sediment in the absence of significant hematuria or proteinuria should make one suspect AIN. Keeping a high index of suspicion, timely stoppage of the potential offending agent and steroids are the mainstay of treatment.

ANTICOAGULANT THERAPY LEADING TO HEMOTHORAX OF THE MAJOR FISSURE Julie Worthington[1]; Charis Whitney[1]; Nisha Hariharan[2]; Sravanthi Ennala[1]. [1]Pinnacle Health System, Hummelstown, PA; [2]Pennsylvania State University College of Medicine, Hershey, PA. (Control ID #2706317)

LEARNING OBJECTIVE #1: Diagnosing and treating a hemothorax in the major fissure.

CASE: An 89-year-old male presented with hemoptysis and dyspnea. Two weeks prior, the patient received diagnosis of new-onset asymptomatic paroxysmal atrial fibrillation and was started on rivaroxaban. The day prior to admission, he took 1 aspirin for back pain then developed hemoptysis and dyspnea. Initially, the patient was tachypneic with an oxygen saturation of 97% on continuous positive airway pressure with fraction of inspired oxygen of 35%. Laboratory values were within normal limits. A chest X-ray revealed a newly developed 11 centimeter left upper lobe mass-like density. Computed tomography of the chest showed an 11 centimeter soft tissue density in the left upper lobe along the left major fissure. Interventional radiology performed thoracentesis and drained only minimal fluid containing red blood cells and no microorganisms. Cardiothoracic surgery evaluated the patient and performed video-assisted thoracoscopy and evacuation of the hematoma, confirming presence of the hematoma along the left pleural fissure.

IMPACT: In patients with atrial fibrillation, the prevention of thromboembolic events using novel oral anticoagulants, including rivaroxaban, has become increasingly popular. While intracranial and gastrointestinal bleeding have been reported, pulmonary bleeding and spontaneous hemothorax are infrequently reported complications of rivaroxaban use.

DISCUSSION: This case demonstrated that using aspirin only one time while on rivaroxaban may result in a spontaneous hemothorax. This presentation was unusual in that the hemothorax was contained in the left pleural major fissure. Since rivaroxaban has become popular as an oral anticoagulant, both patients and providers need to be aware that spontaneous hemothorax is a risk.

AORTIC DISSECTION PRESENTING AS AORTIC REGURGITATION LEADING TO CHF Anirudh Penumetcha; Aditya Sood; Raju Penumetcha; Luis Afonso. Wayne State University, Farmington Hills, MI. (Control ID #2707552)

LEARNING OBJECTIVE #1: Recognize thoracic aortic dissection as part of the differential diagnosis of new onset CHF and/or aortic regurgitation.

LEARNING OBJECTIVE #2: Diagnose ascending thoracic aortic dissection with negative CTA.

CASE: A 59-year-old gentleman with PMHx significant for HTN presented to our ED complaining of one month onset of progressively worsening dyspnea, orthopnea and worsening bilateral LE edema. He also complained of intermittent substernal non-radiating chest pressure that started one day prior. Admitted to being non compliant with medications and PCP follow up. On ROS he denied any dizziness, syncopal episodes, pleuritic chest pain, lateralized weakness or numbness. He did not have history connective tissue diseases, tobacco use, prior MI, HLD or DM. Vitals were significant for BP 180–210 s/100 s, HR 70s, RR 16, Tmax 36.6 C and 100% O2sat on RA. Cardiac exam was significant for S3 gallop, 2/6 diastolic murmur heard best at the left sternal border and negative for JVD. On labs creatinine 1.37 (unknown baseline), BNP 2,595, troponin (peaked at 0.131), albumin 3.2, Hb 15.2. CXR showed no acute abnormalities. Subsequent TTE showed systolic (EF 30–35%) and grade II diastolic heart failure. In addition severe aortic valve regurgitation and a non mobile echogenic mass was noted at the aortic root consistent with atherosclerotic plaque vs dissection. Subsequently a CTA of the thorax, abdomen and pelvis were done and negative for aortic aneurysm/dissection or intramural hematoma. To further evaluate the aortic regurgitation patient underwent a TEE that showed findings consistent with a focal dissection of the ascending and root aorta (Type 2 De Bakey) with avulsion of the AV cusps and severe aortic regurgitation. CT Surgery was immediately brought on board and patient underwent subsequent aortic root replacement and aortic valve repair.

IMPACT: Aortic dissection presenting with heart failure symptoms and aortic regurgitation is documented but uncommon. In addition, this case emphasizes the importance of TEE in the diagnosis of aortic dissection due to a negative CTA.

DISCUSSION: Aortic dissection is an emergency that if undiagnosed or untreated has high mortality rates (>80% in 2 weeks). It is crucial for clinicians to consider aortic dissection in a patient presenting with new onset HF with aortic regurgitation. Roughly only 6% of aortic dissections present with acute CHF [1]. Although CTA is the most commonly obtained diagnostic test to diagnose aortic dissection, in our case it did not aid in the diagnosis. TEE is another test that should be obtained if CTA is inconclusive and clinical suspicion is high. It has a sensitivity of 99 and specificity of 98% in diagnosing aortic dissection [2]. 1. Evangelista, Arturo, et al. “Role of Transoesophageal Echocardiography in the Diagnosis of Acute Aortic Syndrome.” 2. Ali, Usman, et al. “Painless aortic dissection presenting with congestive heart failure.” British Journal of Medical Practitioners 4.1 (2011).

APPROACH TO ANXIETY AS A BARRIER TO VENTILATOR WEANING IN THE ICU Dheepa R. Sekar; Kaylee J. Shepherd; Sonja Bartolome. UT Southwestern, Dallas, TX. (Control ID #2702989)

LEARNING OBJECTIVE #1: Recognize anxiety and post intensive care syndrome in the process of ventilator weaning

LEARNING OBJECTIVE #2: Manage anxiety during ventilator weaning with the paradoxical use of oral benzodiazepines

CASE: The patient is a 65 year old woman with metastatic breast cancer treated with chemotherapy and radiation and left hemidiaphragm paralysis who was admitted to the intensive care unit with pneumonia, hypercapnic respiratory failure requiring intubation and septic shock. The evening after the patient was extubated, she was re-intubated due to tachycardia and recurrent hypercapnea. Tracheostomy was performed to aid with ventilator weaning. She initially tolerated tracheostomy collar for 3–5 h at a time, but would request ventilator support due to fatigue and was noted to be hypertensive with systolic blood pressure >160 mmHg during these trials. Considering anxiety as a factor, Lorazepam was offered to the patient prior to her ventilator weaning trials. On the second day of Lorazepam use, the patient tolerated tracheostomy collar during all waking hours, and her systolic blood pressure during trials soon stabilized. Although she tolerated more frequent and longer sessions of physical therapy, she was discharged to a skilled nursing facility, as she required pressure support at night.

IMPACT: Management of patients in the ICU has a predominant focus on the details of physiology and cardiopulmonary status. However, treatment success requires appreciation of the patient as a whole, including psychosocial factors. In this case, the patient’s anxiety was the primary barrier to ventilator weaning and subsequent ICU discharge. Recognition of the patient’s anxiety allowed appropriate treatment and successful improvement in ventilator status.

DISCUSSION: Post-critical care syndrome has been described in critical care patients and involves physical and psychosocial impairment, including anxiety and acute stress response. In fact, anxiety is one of the most common psychiatric challenges for ventilated patients. It is also thought that memories of the experience contribute to a feeling of lack of control. In this patient, the major barrier to ventilator weaning was not physiologic but rather psychosocial, namely, related to her anxiety. The anxiety led to prematurely shortened tracheostomy collar trials, prolonging her stay in the ICU. Although it may

seem paradoxical to use benzodiazepines in ventilator weaning, they were used in this particular case to treat the patient's anxiety, allowing her to progress in her ventilator weaning. She was judiciously given Lorazepam in small oral doses and at longer time intervals, and her oxygen saturation was maintained during the daytime. Once her anxiety was addressed, the patient improved more quickly, allowing sooner discharge from ICU.

AT WIT'S END: UNRAVELING AN UNEXPECTED CAUSE OF DELIRIUM Carlos A. Lopez[2]; Erik Kockenmeister[1, 2]; Vinita Gupta[1, 2]. [1]Northwell Health, New Hyde Park, NY; [2]Northwell Health, Manhasset, NY. (Control ID #2706618)

LEARNING OBJECTIVE #1: Recognize the clinical features of cefepime-induced encephalopathy (CIE) while distinguishing it from other common causes of delirium

CASE: A 75-year old woman with osteoarthritis treated with a left knee replacement presented to her primary doctor with worsening left knee pain. She was sent to the emergency room when her CBC showed a platelet count of 33 k and an absolute neutrophil count of 320, which were subsequently found to be due to acute myeloid leukemia. Arthrocentesis of the knee showed hemoarthrosis without evidence of infection or crystallopathy. After developing neutropenic fevers without a clear source of infection, she was started on cefepime. She started induction chemotherapy with decitabine the next day. Two days after starting induction, she developed progressively worsening hypoactive delirium, lethargy, disorientation, slurred speech, dysphagia, and tachypnea; symptoms persisted even after completing induction. An MRI was negative for leptomeningeal disease, ischemic stroke, or hemorrhage. Serial ABGs showed normal pH, pCO2 and pO2 levels. Mild hypercalcemia (ionized calcium 1.47 mmol/L) was noted, which when treated failed to resolve her encephalopathy. Ammonia levels were normal; both hepatic function and renal function were normal. She was started on lactulose for constipation, though mental status failed to improve despite having regular soft bowel movements. Serial lumbar punctures were negative for malignant cells or infection. A video EEG showed moderate diffuse nonspecific slowing without epileptiform abnormalities. Opiates and patient's home oxybutynin and cyclobenzaprine were held without improvement. Despite normal renal function (baseline creatinine clearance of 93 mL/min), cefepime was switched to meropenem due to concern for CIE. The patient's encephalopathy, tachypnea, and dysphagia markedly improved, returning to baseline over the next 24 hours.

IMPACT: The work up for encephalopathy in a hospitalized patient should always include a review of less common adverse effects of a patient's medications. This can simplify the work up and avoid delays in diagnosis.

DISCUSSION: This case shows that CIE can go unrecognized when competing etiologies are present. It can present with delirium, myoclonus, hallucinations or seizures. It is particularly important to suspect CIE in patients with seizures prior to initiating anti-epileptics, as symptoms typically resolve within 48 hours of stopping cefepime. The proposed mechanism for CIE is through an increase in excitatory neurotransmission by inhibiting the release of GABA from nerve terminals. Retrospective cohort studies of patients with hematological malignancies show that patients with renal dysfunction are at greater risk of developing CIE, even when properly dosed; this is thought to be due to an increase in blood–brain permeability due to the effects of accumulated organic acids. However, as our case shows, having normal renal function is not completely protective against CIE.

ATRIAL FIBRILLATION IN A PATIENT WITH AN ACCESSORY PATHWAY Andrew Silverman; Sonia Taneja; Liliya Benchetrit; Lovemore Makusha; Robert L. McNamara; Alexander Pine. Yale School of Medicine, New Haven, CT. (Control ID #2702843)

LEARNING OBJECTIVE #1: Recognize confounding electrocardiographic (ECG) features and appropriate treatment of Wolff-Parkinson-White (WPW)/atrial fibrillation (AF) syndrome.

CASE: A 24-year-old man with a history of unspecified arrhythmia presented with palpitations and chest pain. Initial ECG revealed irregular tachycardia with varying QRS width: 150–200 bpm for narrow complexes and 300 bpm for wide complexes. Several wide QRS complexes in the lateral leads showed a slurred upstroke phase. Due to an interpretation of the rhythm as ventricular tachycardia (VT), the patient was given two rounds of amiodarone 150 mg IV without effect. He was then cardioverted with 100 J, synchronized. The post-cardioversion ECG revealed sinus tachycardia with a pre-excitation pattern of positive delta waves in the anterolateral leads (I, aVL, V2-6) and negative delta waves in inferior leads (III, aVF). The patient remained in sinus rhythm and underwent successful ablation of a right posteroseptal accessory pathway. Subsequent ECG showed upright T waves in leads I, aVL, and V2-6, large inverted T waves in leads III and aVF, and no delta waves. The troponin level peaked at 0.53, and was undetectable within 12 hours. The patient was discharged after 3 days in stable condition.

IMPACT: This case serves as an important reminder that rapid AF (rAF) in the presence of an accessory pathway may present with confounding ECG features, potentially leading to incorrect diagnoses and treatments that may be life-threatening. Despite 10–30% prevalence of rAF in the presence of an accessory pathway and the relative awareness of WPW syndrome among general internal medicine providers, the clinical recognition of WPW may be hindered in the presence of rAF.

DISCUSSION: The patient's first ECG reflected an irregular chaotic WCT, partly because of abnormal depolarization along the accessory pathway. It was also apparent that some impulses were conducted through the AV node, as evidenced by narrow QRS complexes without the delta wave (capture beats). Since impulses travel through both the AV node and accessory pathway, treatment with AV nodal blockers (e.g., adenosine, calcium channel blockers, beta blockers, and possibly amiodarone) is contraindicated, as atrial impulses would preferentially conduct through the accessory pathway. This can cause the rhythm to degenerate into ventricular fibrillation. Thus the key to recognition of WPW/AF syndrome is irregular WCT with QRS of varying morphology with sustained rates exceeding 200 bpm. While this rhythm can be difficult to differentiate from polymorphic VT, the immediate treatment for both is cardioversion. The definitive treatment for WPW/AF syndrome is radiofrequency ablation. Following ablation, peaked T waves may appear in leads where the delta wave was most noticeable, with concordant polarity. In the context of small and transient cardiac enzyme elevation, such an abnormality is a classic post-ablation memory T wave pattern and is considered evidence of a successful ablation.

ATTEMPTED SUICIDE WITH CRUSHED ROSARY PEAS: ABRUS PRECATORIUS Alena Perez-Majul[2]; Andrew Zabel[2]; Amelia Todd[1]; John Andrew O'Connor[1]. [1]St. Vincent Hospital, Indianapolis, IN; [2]Marion University, Indianapolis, IN. (Control ID #2707603)

LEARNING OBJECTIVE #1: Recognize the clinical features of abrin ingestion

CASE: A 32-year-old male with a past medical history of bipolar disorder presented to the emergency department with a two day history of nausea, vomiting, and diarrhea. He reported approximately 10 episodes of vomiting and 40–50 episodes of diarrhea in the past two days. His blood pressure and heart rate were elevated on admission. He reported loose, watery bowel movements with hematochezia and colicky abdominal pain. He denied any fevers, chills, dyspnea, cough, sick contacts, changes in medications or diet, or recent travel. He also denied a family history of inflammatory bowel or autoimmune disorders. A complete blood count revealed an elevated white count of 24.5. An abdominal CT scan showed pancolitis. Although the patient initially denied suicidal ideation or depression, he later admitted to intentionally ingesting 100 crushed rosary peas (abrus precatorius) in a suicide attempt two days prior to admission. With supportive care, his vomiting and diarrhea improved within three days.

IMPACT: Cases of abrin toxin ingestion are uncommon in North America but have high fatality rates. This case expands on the literature as another example of management of abrin toxin ingestion without fatality. No antidote exists for the toxin, so the ability to recognize clinical symptoms and understand successful symptom management is vital to patient outcomes.

DISCUSSION: Abrin, a toxin similar to ricin, comes from the seeds of the arbus precatorius tree (rosary pea) which is commonly found in tropical areas. Abrin contains a toxalbumin which is a AB subunit protein toxin and is obtained from the seeds of Abrus precatorius. Abrin is highly toxic, with an estimated human fatal dose of 0.1-1 microgram/kg, and commonly causes death after accidental ingestion in children. Toxalbumins inhibit protein synthesis and cause cell death by binding and penetrating cell membranes through endocytosis. Symptoms generally begin within a few hours and include persistent vomiting, diarrhea, and abdominal pain, with associated hypokalemia, which our patient developed during his hospital course. Systemic injury may appear as late as 1–5 days after ingestion as the cumulative effects of inhibition of protein synthesis mount. Elevated serum LFTs and creatinine levels may be seen, indicating hepatorenal failure. If death occurs, it is generally 3 to 5 days after ingestion. Our patient ordered 100 rosary peas from a major online retailer, ground them in coffee grinder, and mixed the powder into a protein shake, which he then ingested two days prior to admission. This dose is several magnitudes higher than the toxic dose suggested by the literature so it is fortunate that the patient did not suffer hepatorenal failure, as observed in some cases of smaller ingestion. His gastrointestinal distress began within 3–4 h, first with vomiting followed by persistent diarrhea.

ATTENTION TO DETAIL: EXAMINING A CASE OF CHRONIC DIARRHEA AND A BLEEDING DIATHESIS Anna L. Dill[1]; Andre N. Sofair[1]; Reginald Severe[2]. [1]Yale Internal Medicine-Primary Care, New Haven, CT; [2]Yale School of Medicine, New Haven, CT. (Control ID #2706309)

LEARNING OBJECTIVE #1: Recognize signs and symptoms of multiple myeloma and systemic amyloidosis.

LEARNING OBJECTIVE #2: Recognize cognitive bias and systems limitations in decision making.

CASE: A 55-year old man presented with 4 months of daily diarrhea, right upper quadrant pain, weight loss, and orthostatic hypotension. He was previously healthy, originally from Mexico and had been living in the area for 5 years. He was employed as a mechanic and had no toxic habits. He had been hospitalized 2 times already for the same complaints. During his first presentation, 2 months prior, he had labs notable for an anemia and isolated elevated alkaline phosphatase. A CT scan of the abdomen showed stranding around the terminal ileum but otherwise normal. He underwent an infectious workup for his diarrhea that was normal. He had a colonoscopy that showed normal mucosa and negative pathology. He was discharged to home. He returned 3 days later with bloody diarrhea. A CTA showed a hematoma in the colon. He underwent colonoscopy that showed ulcer at prior bx site. Hematology was consulted and workup showed platelet function abnormality, low fibrinogen levels, and low alpha-2-antiplasmin suggestive of abnormal fibrinolysis. He was discharged to home. For his 3rd presentation, the total duration of complaints was 4 months. His ROS was now notable for paresthesias in hands/feet and a 50 pound weight loss. His PE was significant for a firm slightly enlarged liver and no splenomegaly. He had had diminished sensation in bilateral hands and feet. His labs were unchanged from prior. He had an EKG, which was notable for low voltage. Given neuropathy, hypotension, weight loss, and bleeding diathesis he was evaluated for a monoclonal gammopathy and his initial serum SPEP and IFE did not show evidence of monoclonal protein. However, his UPEP and urine IFE were positive for free lambda light chain. A bone marrow bx showed 20% involvement of plasma cells, consistent with multiple myeloma. Given low voltage of EKG and firm liver on exam, there was concern for systemic amyloid and he underwent rectal and fat pad biopsies that were negative for amyloid. Bone marrow biopsy was also negative for amyloid. Eventually, a liver biopsy was obtained which confirmed the diagnosis of AL amyloid associated with multiple myeloma.

IMPACT: This case heightend my awareness to cognitive bias. Our patient encountered numerous providers and I relied on earlier assessments (anchoring). Furthermore, his presentation did not fully “fit” with a primary GI diagnosis, but the decision making process was terminated prior to me exploring these aspects (premature closure).

DISCUSSION: The case highlights the diagnosis of amyloidosis as well as systems/cognitive challenges. Regarding the diagnosis, our case displayed that a high degree of suspicion is necessary. Furthermore, our patient did not speak English. We believe this could have contributed to a less in-depth HPI that was carried forward. Early workup was anchored on GI symptoms, which may have led to a delay in diagnosis.

ATYPICAL PRESENTATION OF AL AMYLOIDOSIS Munit Singh; Daniyal Ansari; Anupama Paranandi. Saint Mary’s Hospital, Cartersville, GA. (Control ID #2706352)

LEARNING OBJECTIVE #1: To obtain clinical insight about the atypical signs and symptoms of AL amyloidosis

CASE: A51-year-old female with no significant past medical history initially presented with dyspnea and chest pain. On exam, she was noted to have mild respiratory distress, oxygen saturations of 89% on room air, trace lower extremity edema bilaterally and a normal cardiac exam. ACS was ruled out. Brain natriuretic peptide was 592 pg/ml suggestive of heart failure. A transthoracic echocardiogram showed an ejection fraction of 60-65% with moderate evidence of left ventricular hypertrophy. The discharge diagnosis was acute hypoxic respiratory failure secondary to new onset diastolic heart failure. She was readmitted a month later with complaints of bright red blood per rectum, worsened dyspnea and bilateral lower extremity edema refractory to prescribed diuretic treatments. Despite the bleed, the hemoglobin remained at her baseline. Troponin peaked at 1.23. Repeat transthoracic echocardiogram showed worsening of the ejection fraction and severe concentric hypertrophy suggestive of an infiltrative process. Cardiac catheterization was negative for significant coronary

artery disease and demonstrated a restrictive physiology. Cardiac MRI was indicative of cardiac amyloidosis. Tc-99 m pyrophosphate scan confirmed immunoglobulin light chain (AL) amyloidosis. The gastrointestinal bleed prompted a duodenal biopsy, which showed abundant amyloid deposition. Due to the association of AL amyloidosis with plasma cell dyscrasias, a bone marrow biopsy was pursued, which confirmed multiple myeloma with secondary amyloidosis. A 24-hour urine protein electrophoresis showed a discreet band present in the beta region, identified as free lambda light chain consistent with multiple myeloma. The patient is currently being treated with systemic chemotherapy with cyclophosphamide, bortezomib, and dexamethasone.

IMPACT: Amyloidosis is the deposition of abnormal protein that affects multiple organ systems with diverse clinical manifestations. The incidence in the United States is about 6–10 cases per million persons. Amyloidosis has many distinct subtypes with primary (AL) being the most common. It can have unusual presentations and can rarely be associated with multiple myeloma.

DISCUSSION: Amyloidosis is a clinical disorder due to the deposition of extracellular and/or intracellular amyloid fibrils resulting in alteration in the normal function of tissues. There are several forms of amyloidosis, however, AL (primary) is the most common, which is the deposition of abnormal protein composed of immunoglobulin light chain fragments. Typically, AL amyloidosis involves heavy proteinuria, edema, hepatosplenomegaly, and cardiomyopathy. However, our patient only presented with intermittent lower extremity edema, restrictive cardiomyopathy, and subtle gastrointestinal bleed. A subset of patients have atypical presentation and rarely (0.4%) develop multiple myeloma, which was found to be the case in our patient.

ATYPICAL PRESENTATION OF CARDIAC SYNCOPE Mo Shirur[2]; Hassan Alsabbak[1]; Kais Zakharia[1]; Cynthia R. Piko[1]. [1]Beaumont Hospital - Dearborn, Dearborn, MI; [2]Wayne State University - School of Medicine, Detroit, MI. (Control ID #2702526)

LEARNING OBJECTIVE #1: Diagnosing atypical presentation of cardiac syncope.

CASE: 72-year-old female with past medical history of hypertension, CKD stage 3, COPD, Diabetes Mellitus Type 2, Crohn's disease, hypothyroidism, CAD status post drug-eluting stent (DES) placement in distal and proximal LAD artery, and two DES in mid-circumflex artery presented for syncopal episode. She stated that while watching TV, felt dizzy and tried to stand, but fell. The episode lasted 10 min followed by slurring speech, nausea, and heaves. The patient denied shortness of breath, palpitations, chest pain, tingling, or numbness. She has a history of vasovagal syncope during defecation. Her physical exam was negative, is an active smoker, but denied alcohol or illicit drug use. The patient's EKG showed left axis deviation and incomplete RBBB. Echocardiogram had no abnormalities and 60% ejection fraction. CT revealed mild decreased density in right basal ganglia and left thalamus; most likely age indeterminate chronic ischemic changes. MRI was negative for acute infarction and confirmed CT findings. CTA of neck showed <50% stenosis of right carotid and 50–90% stenosis of left carotid. These findings were not ruled as etiology of syncope and patient was set to follow up with vascular surgery as outpatient. Days later, patient had another similar episode while sitting on her chair. A tilted table test showed presyncope with drop in BP, but no loss of consciousness. She was positive for Vasodepressor response and was implanted with a loop recorder. The patient returned for a third syncopal episode, and this time, the loop recorder showed complete heart block. She was put on a permanent pacemaker and eventually discharged.

IMPACT: The case shows importance of conscientiousness towards patients with cardiac histories. Our patient had extensive history of CAD and although she presented with symptoms of vasovagal syncope (prodromal signs of dizziness and lightheadedness, post syncopal signs of nausea), in reality, it was a cardiac cause.

DISCUSSION: Syncope is a spontaneously self-limited syndrome where there is transient loss of consciousness (LOC) due to brief period of inadequate cerebral flow. The LOC causes loss of postural tone and eventual collapse. Causes of syncope are grouped into four categories: Neurally-mediated reflex (vasovagal), orthostatic, cardiac, structural cardiopulmonary disease. According to literature, classic prodromal signs such as lightheadedness, sweating, palpitations, nausea, visual blurring, and pallor occur in vasovagal syncope. In patients without these symptoms, the likely etiology could be cardiac, especially when there is an extensive CAD history. Our case was atypical because our patient did in fact have prodromal symptoms and her EKG did not point towards a heart block. It was not until we placed a loop recorder that we found complete heart block as the cause of her syncope.

ATYPICAL PRESENTATION OF SJOGREN'S SYNDROME Kathryn J. Spavento. NY Presbyterian- Brooklyn Methodist Hospital, Brooklyn, NY. (Control ID #2705908)

LEARNING OBJECTIVE #1: To recognize and diagnose an atypical presentation of Sjogren's Syndrome

CASE: A 74-year-old female with a history of hypertension, hypothyroidism, GERD and diverticulosis presented with a chief complaint of right upper abdominal pain. She reported a 3-week history of abdominal pain that was intermittent, dull and had no association with food. Symptoms were exacerbated in the supine position and improved while upright. Additionally, she had nightly fevers and unintentional weight loss of 15 pounds in 1 month and paranesthesia's of the 4th and 5th digits bilaterally. Her medications included cholecalciferol 10,000 units, levothyroxine 88mcg, valsartan 320 mg, amlodipine 10 mg, pantoprazole 40 mg, for which she adhered too daily. She lived at home by herself and was able to perform all her activities of daily living. She denied any use of alcohol or recreational drugs and she did not smoke cigarettes. Family history was noncontributory. On physical exam, she was pleasant and appeared to be of her stated age. The remainder of her exam was unremarkable with the exception of right upper quadrant pain on deep palpation. A complete evaluation was undertaken with a complete blood count which revealed a mildly elevated white blood cell count at 10.4 K/uL, Hb of 10.6 g/dl and normal platelet count of 160 K/uL. CT chest with contrast showed bilateral subsegmental atelectasis and abdomen and pelvic images were only suggestive of diverticulosis coli. There were no signs of mesenteric ischemia, pancreatitis, cholelithiasis nor bowel perforation. X-ray hands showed age-related changes and no fractures. A search for collagen vascular etiology as the cause of her symptoms ensued. Results of the C-reactive protein was 126 mg/L and an erythroctye sedimentation rate of 98MM/HR. She also had a positive rheumatoid factor of 22.4 and Anti- SSA antibody. Sjogren's syndrome was diagnosed and she was managed supportively

IMPACT: Sjogren's commonly presents as SICCA syndrome and manifests as dry eyes and dry mouth. This case was atypical and forces the clinician to be open minded and consider other differentials when evaluation any case. For me, it further reinforced the concept that vasculitides may present as a myriad of complaints. The astute clinician should have a broad range of differentials and continually analyze every aspect of the patient's presentation to prevent delay in diagnosis and treatment.

DISCUSSION: Sjogren's syndrome can affect people of any age, but symptoms usually appear in older women. (American College of Rheumatology). In the typical presentation known as SICCA syndrome, patients will notice dryness of mucous membranes in addition to enlarged salivary glands. The ability to recognize the other atypical presentation as a vasculitis, which was our diagnosis, is imperative.

ATYPICAL PRESENTATIONS OF BRAF-MUTANT COLORECTAL CANCER: CASE REPORT AND LITERATURE REVIEW Yoshito Nishimura. Okayama University Hospital, Okayama, Japan. (Control ID #2672049)

LEARNING OBJECTIVE #1: Recognize unilateral arm swelling as a potential symptom of axillary lymph node metastasis.

LEARNING OBJECTIVE #2: Assess colorectal cancer patients with biomarker testing to provide the best treatment options.

CASE: A 68-year-old female presented with left arm swelling. Four months prior to the presentation, she noticed a mass in her left axilla. A month prior, she visited an nearby clinic and was referred to our hospital. Her past medical history was unremarkable. Physical examination revealed left supraclavicular and axillary lymphadenopathy. CT scan confirmed generalized lymphadenopathy and irregular wall thickening of the transverse colon. A lymph node biopsy revealed signet ring cell adenocarcinoma. Colonoscopy showed a lesion in the transverse colon. The biopsy of the lesion demonstrated well differentiated tubular adenocarcinoma. The results of genetic analysis with wild-type KRAS, high-level microsatellite instability (MSI-H) and BRAF V600E mutation in both tissues led us to the diagnosis of BRAF-mutant metastatic colorectal cancer. After referral to gastroenterological surgeon, she went through neoadjuvant chemotherapy and transverse colectomy. Four months after the diagnosis, she was referred to another hospital to be a candidate of anti-PD-L1 antibody clinical trial.

IMPACT: The case illustrates two points that can change our daily practice. The first is importance performing full HEENT examination to colorectal cancer patients. The axillary lymph node metastasis with colorectal cancer may be a hallmark of poor prognosis due to BRAF V600E mutation. The second is a need of biomarker testing to every colorectal cancer patient because patterns of biomarker expression change treatment strategies.

DISCUSSION: Patients with BRAF-mutant CRC have poor prognosis with median survival of only 10 months as compared to 35 months for those without the mutation. Axillary lymph node involvement is a unique pattern of metastasis of BRAF-mutant CRC with only nine cases reported to date. Unilateral arm swelling may be a hallmark of malignancy implicating lymphatic congestion. It is important to recognize axillary lymphadenopathy is a potential sign of BRAF-mutant CRC. Because of aggressive clinical course with BRAF-mutant CRC it is imperative to have approproate therapeutic strategies. Recent trials have indicated BRAF inhibitors are not as effective to BRAF-mutant CRC as they are to BRAF-mutant melanoma. Triple targeted inhibitor combinations with BRAF + EGFR + MEK inhibitors has shown promising data in a clinical trial. Anti-PD-L1 inhibitors such as nivolumab have been used in clinical trials for BRAF-mutant CRC. Because PD-1 and PD-L1 are known to be upregulated in MSI-H CRC that are correlated with BRAF mutation, patients with these mutations are considered to be good candidates. Our case illustrates the need to perform both full physical examinations and thorough biomarker testing to reach the diagnosis and provide the best treatment options that patients will be most likely to respond.

AUTOIMMUNE HYPOPHYSITIS PRESENTING AS ADRENAL INSUFFICIENCY AND CENTRAL DIABETES INSIPIDUS Aviva Cohn[1]; Gargi Patel[2]; Vijay Bhat[3]; Payal Dave[3]. [1]Rutgers RWJMS, Highland Park, NJ; [2]Rutgers Robert Wood Johnson, Piscataway, NJ; [3]Rutgers Robert Wood Johnson Medical School, North Brunswick, NJ. (Control ID #2706609)

LEARNING OBJECTIVE #1: Recognize autoimmune hypophysitis as a cause of secondary adrenal insufficiency and central diabetes insipidus.

CASE: A 30-year-old female with a past medical history of diet-controlled diabetes mellitus type II presented to the ED with three weeks of nausea, vomiting, and diarrhea. On admission, laboratory evaluation revealed a sodium concentration of 172. Review of systems was positive for generalized malaise, fevers, galactorrhea, as well as a 40-pound weight loss. Her severe hypernatremia was associated with impaired thirst, and urine studies revealed low urine osmolality, raising concern for central diabetes insipidus. Further workup for a central process revealed a low TSH, LH, FSH, ACTH, and Somatomedin C as well as mildly elevated Prolactin. Given the low ACTH, a Cosyntropin stimulation test was performed which showed a pre-cosyntropin cortisol of 3 and post stimulation cortisol of 12, confirming a secondary cause for her adrenal insufficiency. She was started on stress dose steroids and DDAVP for treatment of adrenal insufficiency and diabetes insipidus respectively. A subsequent brain MRI revealed a pituitary mass, explaining her secondary endocrinopathies as well as her galactorrhea and headaches. Biopsy of the pituitary mass showed pathology consistent with lymphocytic hypophysitis. On post-hospital follow-up, her sodium concentration normalized with DDAVP, her nausea/vomiting improved with stress dose steroids, and her TSH normalized with replacement therapy.

IMPACT: In patients with hypernatremia due to central diabetes insipidus, look for secondary adrenal insufficiency. Furthermore, if workup of secondary adrenal insufficiency reveals a mass, this may not always be due to an adenoma, and lymphocytic infiltration of pituitary gland should be considered.

DISCUSSION: Lymphocytic or autoimmune hypophysitis typically presents in females, usually postpartum, who have other autoimmune disorders. In addition, patients with a pituitary mass from lymphocytic hypophysitis often present with headache or visual symptoms. In cases such as ours, the primary symptoms were not necessarily concerning for a large pituitary mass, however laboratory findings were consistent with a central cause for her symptoms. In a patient who presents with suspected central diabetes insipidus and adrenal insufficiency, it is imperative to consider lymphocytic hypophysitis as a rare but known cause for both of these disease processes. Recognizing that lymphocytic hypophysitis can present as a spectrum of different disease processes can aid in appropriate management, including biopsy for diagnosis, steroid administration, and hormone replacement.

AXIAL GOUT: A CRYSTAL CLEAR CAUSE FOR BACK PAIN Matthew F. Hartman[1]; Joan Addington-White[3]; David Feldstein[2]. [1]University of Wisconsin, Madison, WI; [2]University of Wisconsin School of Medicine and Public Health, Madison, WI; [3]University of Wisconsin-Madison, Madison, WI. (Control ID #2702197)

LEARNING OBJECTIVE #1: Recognize axial gout as an unusual presentation of a common condition

LEARNING OBJECTIVE #2: Recognize the potential neurologic complications of undiagnosed axial gout

CASE: A 74-year-old woman with uncontrolled hypertension and gout presented to the emergency room with low back pain of three-days duration. She denied preceding trauma or recent procedures. Physical exam revealed

tenderness to palpation of the right upper gluteal region without overlying skin changes. There were no focal neurological deficits of the lower extremities, and initial labs were unrevealing. Plain radiograph of the pelvis revealed only a subtle lucency near the right sacroiliac joint. The patient was diagnosed with lumbago and discharge from the ED was in process when she spiked a fever to 101.9 F. Standard infectious work up ensued and was remarkable only for elevated ESR to 110. Because back/gluteal pain continued to be her only localizing symptom, an MRI was obtained showing enhancement of the right sacroiliac and L4-5 facet joints. The patient was admitted on broad spectrum antibiotics due to concern for septic arthritis. On hospital day two, she developed left wrist, MCP, and ankle pain with tenderness and swelling on exam raising suspicion for polyarticular gout. Serum uric acid was 12.7 mg/dL and fluid studies from wrist and ankle arthrocenteses revealed monosodium urate crystals. Antibiotics were replaced with high dose methylprednisolone yielding a dramatic improvement in all symptoms within hours, further supporting a diagnosis of polyarticular gout with axial involvement.

IMPACT: In caring for this patient, I have come to appreciate the various manifestations of gout and the serious implications of spinal involvement.

DISCUSSION: Back pain secondary to axial gout is often overlooked for several reasons including lack of distinctive symptoms, similarities to infection in presentation, and a lack of awareness by general physicians and radiologists. Axial gout most often presents with isolated back pain, but can also masquerade as infection due to the presence of fever, leukocytosis, and elevated inflammatory markers. Despite a recent cross-sectional study identifying axial involvement in 17 of 48 subjects (35%) with uncontrolled gout, clinicians are often unaware of low back pain as a manifestation of gout. Furthermore, undiagnosed axial gout leads to dramatic complications due to the development of tophi in the axial skeleton which can lead to spinal stenosis, lumbar radiculopathy, spondylolisthesis, spinal cord compression, and cauda equina syndrome. This makes it imperative that the astute clinician maintain a high index of suspicion for axial gout in cases such as this. Even a short, uncontrolled period of time in the disease process can lead to devastating neurological deficits.

BACTEREMIA: A NOBLE SOURCE Zorawar Singh; Heidi Gunderson. Henry Ford Hospital, Detroit, MI. (Control ID #2706043)

LEARNING OBJECTIVE #1: Recognize unusual sources of bacteremia

LEARNING OBJECTIVE #2: Educate patients on the use of insulin needles

CASE: 57 year old African American male with a PMHx of well-controlled Type-2 DM, on Lantus, presented to the hospital with fevers, chills, and lethargy with abdominal pain and nausea for 2 days duration. He stated that he was in overall good health and denied any sick contacts, cough, sputum production, chest pain, palpitations or shortness of breath. Physical examination was essentially unremarkable except for a group of small painless and pruritic excoriations along the lower half of his abdomen. They were 1–2 mm in size, red in color, and slightly raised, patient stated that they had been there for a little more than 2 weeks. Patient was found to have a temperature of 39.4 deg C, and a heart rate of 115, with a leukocytosis of 17,000. He was admitted for further septic workup. Subsequent blood cultures were positive for MRSA on 2 bottles and he was started on IV antibiotics for bacteremia without any obvious source. Echo was negative for endocarditis. On further questioning, patient stated that he had a remote history of IV drug abuse but quit over 15 years ago and he denied any recent use. He denied any cuts or bruises on his body, and denied recent dental procedures. When asked about his excoriations on his abdomen, he stated that is the location of his insulin shots. Upon further questioning about his insulin needles it was found that the patient was reusing them to inject himself because he was unable to afford more. It was deemed that his insulin needles were the source of his bacteremia. Patient then completed treatment for MRSA bacteremia and his labs improved and he was discharged home.

IMPACT: Most cases of bacteremia we see in Detroit are from IV drug abusers or skin and soft tissue infections. In this case, this gentleman was unable to afford new needles and tried to save costs by reusing the old supplies he already had in order to continue to receive his medication. It really changed my thinking because there are many other sources of bacteremia which us physicians usually do not think about right away that may potentially lead to detrimental effects on the human body.

DISCUSSION: IV drug abuse is a major worldwide epidemic that affects hundreds of thousands of people and their families. Working in downtown Detroit, we encounter many patients on a daily basis who come in with bacteremia and develop endocarditis or other devastating diseases causing them to be bed bound for the rest of their lives. Physicians have to realize that there are many other ways of becoming bacteremic other than IV drug users. We also need to learn the cost effectiveness of our therapies. Diabetic supplies can be very expensive for some patients and we need to realize the consequences of this. We should also take time to educate out patients and explain the detrimental effects of reusing medical supplies that are only meant for a single use.

BAD POTT LUCK Lylla Ngo; Richard Jennings; Steve Urban; Roger D. Smalligan. Texas Tech Univ HSC-Amarillo, Amarillo, TX. (Control ID #2704324)

LEARNING OBJECTIVE #1: Detect reactivation TB infection of the bone or spine

LEARNING OBJECTIVE #2: Broaden the differential diagnosis if response to treatment of working diagnosis is failing

CASE: A 46yo Vietnamese man (in USA for 2 years) presented with intermittent low grade fever and progressively worsening left lower back pain with left leg radiculopathy. MRI of the spine revealed extensive osteomyelitis involving L1 and L2, epidural abscess and left psoas abscess. CRP was 7.7 and ESR was 123. Patient underwent incision and drainage and laminectomy. Standard broad spectrum IV antibiotics were started for osteomyelitis/diskitis. He continued to spike fevers daily. Pathology came back with granulomatous inflammation, and AFB stains of specimen were positive. He later grew pansensitive Mycobacterium tuberculosis. HIV and PPD were negative. CXR was clear. Within 24 hours of changing to antituberculous therapy the patient defervesced. His back pain and left leg radiculopathy improved remarkably with the help of physical therapy over the ensuing days and weeks. A thorough history disclosed that the patient may have had primary TB at age 7 and was treated with herbal medicine. The patient's wife passed away a few months prior to his illness due to unclear causes.

IMPACT: The diagnosis of Pott disease is frequently delayed in the United States due to the subacute course of the disease and the relatively low incidence of extrapulmonary TB. Early diagnosis is a major factor in determining the outcome of the disease. TB should be considered in the immigrant population when appropriate,

DISCUSSION: Tuberculosis (TB) is one of the world's deadliest diseases; there were 1.5 million TB-related deaths worldwide in 2014. Although pulmonary TB is most common, and initial infections are often self-limited,

reactivation disease leads to the most classic presentation with cough, fever, night sweats and weight loss. Reactivation usually occurs in the setting of malnutrition, advancing age, HIV infection, renal failure, TNF blocking agent use and other immune compromising conditions. Studies have shown that psychological stress can severely impair the immune system by blocking TNF which plays a major role in tuberculosis suppression; thus, we speculate our patient's stressful situation due to his spouse's death might have played a role in his disease. Extrapulmonary TB also represents reactivation disease, and tuberculous spondylitis or Pott disease is the most common form of skeletal TB. When two adjacent vertebrae are involved (usually in the thoracic or lumbar spine) there can be vertebral collapse and kyphosis. This can cause cord compression and paraplegia. Fortunately, our patient had a good outcome with fairly prompt diagnosis and treatment. Treatment is standard 4 drug regimen (INH, rifampin, ethambutol and pyrazinamide) for 2 months, followed by 4mo of INH/rifampin. Despite a negative PPD or interferon gamma release assay test, clinicians need to keep a high index of suspicion for TB in immigrants from endemic regions.

BAKING SODA TETANY — TOXICITY OF A HALF-BAKED REMEDY

Micah Eades; Christopher Lu; Arjmand Mufti. University of Texas Southwestern, Dallas, TX. (Control ID #2703805)

LEARNING OBJECTIVE #1: Recognize alkalemia, due to respiratory alkalosis (pulmonary edema) and sodium bicarbonate use in the setting of renal failure, as a cause of symptomatic hypocalcemia

LEARNING OBJECTIVE #2: Avoid seemingly harmless yet unnecessary treatments

CASE: A 57-year-old male with a history of alcoholic cirrhosis status post liver transplant and chronic kidney disease (CKD) due to perioperative kidney injury was admitted with involuntary spasms of his face and extremities and dyspnea on exertion. He was in excellent health until one month prior when he underwent Mohs procedure for basal cell carcinoma. He was given prophylactic antibiotics, but soon developed hypovolemic acute kidney injury and severe metabolic acidosis from *Clostridium difficile* diarrhea. He was prescribed oral vancomycin for *C. difficile* diarrhea, one teaspoon of baking soda twice daily for three days for metabolic acidosis, and instructed to stop furosemide. He presented nine days later with the above spasms, which were worse with activity, and improved but still present with rest. The dyspnea on exertion reduced his exercise tolerance to 300 yards, whereas he was previously able to walk miles. The diarrhea had resolved, but he was still using baking soda. His respiratory rate was 23 and he had gained 8 pounds. Physical exam demonstrated spontaneous, involuntary contractions of perioral facial muscles and extremities. Chvostek's and Trousseau's signs were positive. Lab tests revealed Na 137, Cl 111, CO2 25 (mmol/L), creatinine 1.6 (baseline 2.2), Ca 8.8, ionized Ca 4.2 (mg/dL), albumin 3.5 g/dL. A chest X-ray showed bilateral pleural effusions and pulmonary vascular congestion. He was treated with IV calcium, magnesium, and furosemide. Tetany and dyspnea resolved and he was discharged with strict orders to discontinue baking soda.

IMPACT: Sodium bicarbonate use and pulmonary edema are often underappreciated processes of hypocalcemia. Also, the temptation of seemingly harmless treatments must be weighed against potentially disastrous consequences.

DISCUSSION: This case highlights an unusual presentation of sodium bicarbonate toxicity. A teaspoon of baking soda contains 59 mEq of bicarbonate, whereas oral sodium bicarbonate tablets contain only 7.7 mEq each. In this case, bicarbonate clearance was reduced due to chronic renal impairment resulting in metabolic alkalosis. In addition, acute volume overload in the setting of high sodium intake, and the resultant pulmonary edema, led to a concomitant respiratory alkalosis. The ensuing alkalemia increased calcium binding to albumin, reduced ionized calcium, and led to tetany. While metabolic alkalosis lowers calcium more significantly than respiratory alkalosis, tetany is more commonly noted with the latter. Were prophylactic antibiotics for Mohs procedures really necessary? A 2008 American Academy of Dermatology Advisory Statement asserted "we do not recommend antibiotic prophylaxis for prevention of total joint prosthesis infection with Mohs micrographic surgery, even in high-risk patients".

BALANCING THE RISKS THAT ARE IN PLAIN SIGHT - VISION SPARING SURGERY DURING ACUTE CORONARY SYNDROME

Phillip S. Hamilton[1]; Thomas R. Radomski[2]. [1]UPMC, Pittsburgh, PA; [2]University of Pittsburgh School of Medicine, Pittsburgh, PA. (Control ID #2706604)

LEARNING OBJECTIVE #1: Review the differential diagnosis of an orbital mass.

LEARNING OBJECTIVE #2: Outline current guidelines and knowledge regarding emergent surgery during acute coronary syndrome.

CASE: A 60-year-old woman with type 1 diabetes presented with 1 week of progressive monocular vision loss. Her physical exam was notable for complete left-sided vision loss and ophthalmoplegia. A brain MRI showed a mass-like enhancement involving the bilateral intraconal spaces with edema of the left optic nerve. Ophthalmology planned to perform an emergent left orbitotomy with biopsy, however, shortly after admission the patient developed burning sub-sternal chest pain. An EKG showed nonspecific ST depressions in leads I, V5, and V6 and cardiac biomarkers were normal. On hospital day 2, the patient developed recurrent chest pain and a repeat troponin was elevated to 3.64 ng/ml. She was started on a heparin drip for non-ST elevation myocardial infarction (NSTEMI). A left heart catheterization was deferred due to rising creatinine. Orbitotomy with orbital mass biopsy was deferred until hospital day 4, ultimately leading to a diagnosis of follicular B cell lymphoma.

IMPACT: ACC/AHA pre-operative risk stratification guidelines do not expressly address blindness. This case required us to extrapolate from existing guidelines to decide whether to emergently operate in the context of her vision loss and ongoing NSTEMI, thus enhancing our thinking regarding pre-operative risk stratification.

DISCUSSION: General Internists commonly perform pre-operative cardiac risk stratification for non-cardiac surgery. An initial step of pre-operative risk stratification is to determine the urgency of the surgical procedure. According to ACC/AHA guidelines, emergent surgery is defined as surgery required within 6 hours to avoid loss of life or limb. Blindness, while highly debilitating, is not expressly addressed by current ACC/AHA guidelines. Our decision whether or not to proceed with emergent surgery in the context of her NSTEMI was driven largely by our differential diagnosis for her orbital mass. Our differential diagnosis focused on both benign and malignant tumors such as a cavernous hemangioma or lymphoma, but also included inflammatory processes such as sarcoidosis, and infectious processes such as mucormycosis. We did not suspect the patient was experiencing a rapidly progressive process that would affect her preserved right-sided vision, therefore, we opted to delay surgery. In patients with Acute Coronary Syndrome (ACS) including NSTEMI, current guidelines recommend delaying elective surgery to treat

the ACS prior to proceeding to the operating room. For patients who undergo bare metal stent placement, this necessitates at least 30 days of dual antiplatelet therapy prior to surgery. Patients with drug eluting stents should have at least 3 months of dual antiplatelet therapy. To our knowledge, the medical literature lacks outcomes based studies of patients with ACS who undergo emergent operations.

BAZEX SYNDROME Kiyoshi Shikino; Tsutomu Mito; Yusuke Hirota; Masatomi Ikusaka. Chiba University Hospital, Chiba, Japan. (Control ID #2700947)

LEARNING OBJECTIVE #1: Diagnose Bazex syndrome when skin findings are resistant to conventional treatments including steroids

LEARNING OBJECTIVE #2: Recognize clinical features of Bazex syndrome

CASE: An 84-year-old man presented with a 2-month history of skin lesions on the hands, feet, ears, and nose. The cutaneous lesions were well-limited but painful. Eight weeks of treatment with clobetasol cream was unsuccessful. He also reported dysphagia, odynophagia, and weight loss (8 kg/ 3 months). He had a smoking history of 3 packs/day for 60 years. Examination revealed symmetric hyperkeratotic plaques on the distal hands and feet. Fingernails were yellow and proximally detached. Violaceous desquamation of the ears and nose was noted. Electronic laryngoscopy revealed a paralyzed right true vocal cord and right arytenoid, with a large submucosal mass in the right false vocal cord and right arytenoids. Computed tomography revealed a mass in the right parapharyngeal space and enlarged right cervical lymph nodes. Microscopic examination of fine-needle aspirate from the mass showed poorly differentiated squamous cell carcinoma. Bazex syndrome was diagnosed based on typical cutaneous findings and associated poorly differentiated laryngeal squamous cell carcinoma (tumor stage 4a, lymph-node stage 2c, no distant metastasis). Radiation therapy for 3 weeks cleared the skin condition associated with tumor regression. There was no recurrence at 6 months.

IMPACT: How did this case change your thinking? I learned two important facts in this case. 1. Although Bazex syndrome can mimic a number of conditions, particularly psoriasis and chilblains, the cutaneous manifestations are resistant to conventional steroids, suggesting Bazex syndrome. 2. Cutaneous manifestations of Bazex syndrome may precede the diagnosis of malignancy. Cutaneous manifestations can indicate underlying upper aerodigestive tract malignancy.

DISCUSSION: Bazex syndrome (acrokeratosis paraneoplastica) is an obligatory paraneoplastic syndrome frequently associated with squamous cell carcinomas of the upper aerodigestive tract. An association with bladder, breast, and gynecological cancers has been reported. The pathophysiology is thought to represent a cross-reaction between specific types of tumor and cutaneous antigens. It is characterized by symmetrical desquamative erythema with bluish or violet discoloration, onychodystrophy, or keratoderma. Lesions are typically located on the fingers, toes, ears, and nose. The skin findings are resistant to conventional treatments including steroids and can serve as a good indicator for general physicians. Improvement occurs after primary tumor treatment (91%). Although cutaneous lesions usually precede the diagnosis of cancer, underlying malignancy is diagnosed at the same time or after the development of cutaneous features. The differential diagnosis includes psoriasis.

BENIGN INTRACTABLE HYPERCALCEMIA Babusai Rapaka; Stacy Higgins. Emory University, Atlanta, GA. (Control ID #2706775)

LEARNING OBJECTIVE #1: Review pathophysiology and management of humoral hypercalcemia

LEARNING OBJECTIVE #2: Learn presentation and epidemiology of ameloblastoma

CASE: 72yo woman presents with 2 weeks of fatigue, constipation, jaw and abdominal pain. PMH: biopsy proven benign ameloblastoma (AB) diagnosed 1 year ago managed with analgesics. EXAM: HR 110 BPM, BP 144/ 102 mmHg, T 36.9 C, and RR 16/min; 10x7cm hard, tender mass on her right mandible, with left shifted tongue and inability to close her mouth; oriented x3, with 2+ reflexes throughout. LABS: creatinine 0.8, calcium 14.3 (ULN 10.3), albumin 4.0, PTH of 5.0 (normal 12–88), and EKG with normal PR, QRS, and QT intervals. Jaw CT: 8x7x13cm mandibular mass. Hypercalcemia therapy was initiated with IV fluids and calcitonin with initial improvment, but the hypercalcemia persisted. Bisphosphonates were forgone due to risk of jaw osteonecrosis in setting of possible resection. With negative malignancy work-up and uncontrolled hypercalcemia, malignant hypercalcemia from AB was reconsidered. PTHrP was normal and repeat biopsy revealed benign AB. After resection, hypercalcemia and clinical symptoms resolved within 24 hours without further therapy.

IMPACT: The presence of intractable hypercalcemia often triggers concern for malignancy. Rarely, humoral hypercalcemia occurs with benign tumors, but there are only a handful of cases in the literature reported with AB. This case taught us that a systemic approach to the workup with a strong emphasis on pathophysiology eventually led to the diagnosis.

DISCUSSION: The most common etiologies of hypercalcemia are primary hyperparathyroidism and hypercalcemia of malignancy. In 30% of malignancy cases, hypercalcemia occurs due to skeletal metastases or indirectly via production of a humoral factor (most commonly PTHrP) from the tumor increasing osteoclastic bone resorption. But PTHrP assays are insensitive and normal values cannot rule out humoral hypercalcemia. More reliable is suppression of endogenous PTH with hypercalcemia and low calcitriol indicating exogenous production. Humoral hypercalcemia presents as severe hypercalcemia and is treated in a multifactorial approach. Volume expansion with normal saline increases renal calcium excretion and reduces symptoms secondary to dehydration. Calcitonin with zoledronic acid or pamidronate further reduces serum calcium by osteoclast inhibition. Calcitonin aids in immediate reduction of serum calcium while bisphosphonates take 48–72 h to take effect, stabilizing the patient for definitive therapy. AB is a rare tumor arising from remnants of dental lamina, the developmental organ of enamel, and most commonly affects the mandible causing reactive bone formation and jaw enlargement. It is most common in ages 30–40 with no gender or race predilection. It is extremely rare for AB to cause hypercalcemia and typically signals malignant transformation. Mechanisms of humoral hypercalcemia in AB are not well understood but the most effective therapy remains symptomatic treatment and tumor resection.

BETWEEN A STENT AND A HARD PLACE Eesha Khan; Asad H. Khan; Ahmad Turk; Jaime Hernandez Montfort. Baystate Medical Center, Springfield, MA. (Control ID #2707347)

LEARNING OBJECTIVE #1: Discuss the management of post-myocardial infarction cardiogenic shock with ventricular-assist devices

CASE: An 80 year old male who presented with symptomatic high degree atrioventricular block received a dual-chamber pacemaker. Prior to pacemaker placement, an exercise stress test to assess chronotropic incompetence showed ST segment depressions without angina. Baseline transthoracic echocardiogram (TTE) showed preserved ejection fraction (EF) with inferolateral wall motion abnormalities, suggestive of an old myocardial infarction. One day after pacemaker placement, the patient became confused, hypotensive and was found to have elevated cardiac biomarkers. This clinical picture indicated a silent non-ST elevation myocardial infarction complicated by cardiogenic shock. Repeat TTE showed severe biventricular systolic dysfunction (EF of 15%). Initial treatment with milrinone showed no improvement and he subsequently underwent coronary angiography which showed 99% stenosis of proximal left anterior descending artery (LAD) and 90% stenosis of proximal left circumflex artery (LCX). Given persistent shock, an IABP was also placed. Being a very high risk candidate for a coronary artery bypass, the choice was between pursuing palliative care after IABP removal versus a high-risk protected percutaneous coronary intervention (PCI). A multi-disciplinary decision was made to pursue the latter. He underwent a high-risk PCI of the LAD and LCX under Impella support. He was then successfully weaned off the Impella CP in the next 48 hours, with prompt resolution of cardiogenic shock and improvement in EF to 20-25%.

IMPACT: Our case highlights the value of a multidisciplinary team approach in the management of complex cases in which tMCS is not a 'one-size-fits-all' solution and an innovative approach may be potentially life-saving

DISCUSSION: Temporary mechanical support (tMCS) such as intra-aortic balloon pumps (IABPs) and Impella devices provide hemodynamic support to patients across the cardiogenic shock spectrum. Traditionally, IABPs have been the most commonly used form of percutaneous VADs used during high-risk PCIs. Innovations in the arena of VADs have revolutionized the management of post-MI cardiogenic shock, with a particular focus on revascularization and myocardial recovery. When used in the setting of a protected PCI, the Impella CP provides greater mechanical support than an IABP or the Impella 2.5. In the case above, the transition from intra-aortic balloon pump (IABP) to microaxial flow pump (Impella CP) was used successfully in sequence in a patient with post-myocardial infarction (MI) cardiogenic shock. The strategy to place an Impella as a bridge to recovery saved a patient who may not have survived without revascularization.

BIOTIN INTERFERENCE WITH LABORATORY TESTING RESUTING IN MISDIAGNOSIS Murali K. Duggirala. Mayo Clinic, Rochester, MN. (Control ID #2695478)

LEARNING OBJECTIVE #1: Recognize the biotin interaction with thyroid function testing

CASE: Patient is an 82 year old with hypertension and mild chronic renal insufficiency. Routine blood testing during an annual examination showed low TSH - 0.09 (0.3 - 4.2 mIU/L); normal Free T4 - 1.6 (0.9 - 1.7 ng/dL); elevated Total T3 - 272 (80–200 ng/dL); Thyrotropin receptor antibodies were elevated at 30 (0–1.75 IU/L). She denied any symptoms suggestive of hyperthyroidism and was recommended a recheck of her thyroid function in three months. However, she was lost to follow up but returned one year later for an annual physical examination. Again, she denied any symptoms suggestive of thyroid disease. Repeat blood tests again showed low TSH - 0.1 (0.3–4.2 mIU/L); normal Free T4 - 1.3 (0.9–1.7 ng/dL); elevated Free T3 - 15.2 (2.8–4.4 pg/mL). Thyroid scan with uptake showed a slight decrease of RAI of 7.4% (8–29%). She then saw an endocrinologist, who recommended rechecking the Thyroid function testing after discontinuation of oral biotin supplementation. Ten days after discontinuation, her thyroid function tests including Thyrotropin receptor antibodies were normal. TSH - 1.8 (0.3–4.2 mIU/L); Free T4 - 1.1 (0.9–1.7 ng/dL); Free T3 - 2.8 (2.8–4.4 pg/mL); Thyrotropin receptor antibodies < 1 (0–1.75 IU/L).

IMPACT: The initial laboratory testing was suggestive of hyperthyroidism, possibly grave's disease. However, her thyroid uptake with scan was normal and the patient did not have any symptoms suggestive of hyperthyroidism. It is important to consider a laboratory error when test results do not match with the clinical picture. Further investigation concluded that this is a case of interference of biotin with thyroid laboratory assays.

DISCUSSION: Biotin is a water-soluble B vitamin also called vitamin B-7. For adults, a 30 μg/day is considered adequate. This vitamin is present in a variety of foods and can also synthesized by gut bacteria. People use this as supplement to improve nails, hairs etc. Over the counter biotin formulations usually contain 1,000 IU - 5,000 IU. Ingestion of these supplements result in high biotin concentration in the patients' serum causing interferece with immunoassays. These immunoassays rely on biotin streptavidin interaction and depending the type of assay used, biotin can cause a false increase or decrease in the test result. It can also cause a false positive Thyrotropin receptor antibodies. These labratory abnormalities can lead to unnecessary downstream testing (our patient received Thyroid scan with uptake testing) and even treatments resulting in harm to patients. It important to check with patients about biotin use prior to test ordering, and especially when lab results don't match the clinical picture. Once the biotin supplementation is discontinued, it may take upto two days for the TSH and thyroid hormone levels to normalize and upto one week for the thyrotropin receptor antibodies.

BLEEDING AND CANCER - WHEN ITS NOT JUST LOCAL

Venu M. Ganipisetti[1]; Pratyusha Bollimunta[2]. [1]Miami Valley Hospital, Evanston, IL; [2]Presence Saint Francis Hospital, Evanston, IL. (Control ID #2706586)

LEARNING OBJECTIVE #1: Recognize the importance of considering Disseminated intravascular coagulation (DIC) as potential cause of bleeding in cancer patients.

LEARNING OBJECTIVE #2: DIC in prostate cancer is a poor prognostic sign and may be a manifestation of advanced disease.

CASE: A 65-year-old African-American male presented with complaints of gross hematuria and fatigue for 1 week. He has history of hormone sensitive Prostate cancer with diffuse bony and liver metastases and receiving Eligard and Casodex without having achieved remission yet. He was not on any antiplatelet or anticoagulants. On admission, his hemoglobin was 6.9 with hematocrit of 20.7. His other labs suggested elevated INR of 2.1 and low platelet count of 110,000. No platelet clumping and schistiocytes were noted in peripheral smear. Liver and renal function were within normal range. Further work up was ordered, showing elevated D-dimer levels > 10, fibrinogen level of 117 (192–405 MG/DL), thrombin time of 30 sec (0–24 sec) consistent with onging Disseminated intravascular coagulation (DIC). PSA level was 134. He had no bleeding elsewhere. He was treated with continuous bladder irrigation and transfusion of fresh frozen plasma and packed red blood cells. By day 2, his coagulation parameters normalized as well as platelet count, thrombin time and fibrinogen levels. Hematuria resolved with stable hemoglobin levels and catheter was removed eventually.

IMPACT: Bleeding in prostate cancer patients may represent serious underlying conditions as DIC. Early diagnosis and confirmation with prompt focused laboratory testing may avoid life threatening complications. Physicians should not ignore subtle signs such as low platelet or abnormal coagulation profile in cancer patients and should pursue necessary work up, when appropriate.

DISCUSSION: Disseminated intravascular coagulation (DIC) is an acquired coagulation disorder which may represent a serious underlying systemic disorder. Solid and hematological malignancies are sometimes associated with DIC. In Prostate cancer patients, it usually develops in advanced metastatic prostate cancer or after biopsy of primary or metastatic site due to release of thromboplastic substances. DIC in prostate cancer is considered a poor prognostic sign. Treatment is primarily supportive and aggressive treatment of prostate cancer itself with anti-androgen therapy and chemotherapy in resistant cases. High doses of oral Ketoconozole (anti-androgen mechanism) have been tried in severe life-threatening bleeding situations with success.

BLEEDING IN A BROKEN HEART: A RARE CASE OF IMMUNE THROMBOCYTOPENIA AND TAKOTSUBO CARDIOMYOPATHY
Asad H. Khan[2]; Eesha Khan[1]. [1]Baystate Medical Center, Springfield, MA; [2]Baystate Medical Centre, Broad Brook, CT. (Control ID #2707585)

LEARNING OBJECTIVE #1: Identify various testing modalities for the diagnosis of acute thrombocytopenia

LEARNING OBJECTIVE #2: Recognize that adalimubab can cause severe thrombocytopenia

CASE: A 63 year old male with past medical history significant for Crohn's, history of deep venous thrombosis and severe chronic obstructive pulmonary disease presented with hypercarbic respiratory failure. An electrocardiogram showed diffuse T-wave inversions and subsequent cardiac catheterization showed clean coronaries. An echocardiogram revealed a large apical thrombus with severe left ventricular systolic dysfunction and hypokinesis. A diagnosis of Takotsubo (stress-induced) cardiomyopathy was made and the patient was started on a heparin drip for treatment of the thrombus. Two days after initiation of anticoagulation, the patient had an episode of bleeding, hemolysis on labs and a drop in platelets from 242,000 to 47,000. A '4-T's' score for heparin-induced thrombocytopenia (HIT) was found to be high. Heparin was discontinued and given the significant risk posed by the apical thrombus, anticoagulation was continued with argatroban. HIT workup was initiated. There was no evidence of disseminated intravascular coagulation; coagulation studies were normal. A peripheral smear showed schistocytes and evidence of microangiopathic hemolytic anemia. Platelet count continued to drop to a nadir of 12,000. The patient was started on plasmapheresis and intravenous methylprednisolone. Interestingly, the HIT antibody returned negative. It was thought that the patient may have thrombotic thrombocytopenic purpura (TTP) and the patient was switched back to heparin. With steroids and daily plasmapheresis, the patient's platelet count normalized to 152,000 within a week. The patient clinically improved with no further episodes of bleeding. Further intrigue ensued when the ADAMTS13 results were negative for TTP. At the time, we discovered a case report where adalimumab had caused a TTP-like phenomenon, which the patient had taken for several years for Crohn's disease and adalimumab was discontinued.

IMPACT: The importance of a through review of medications and their potential side effects should be emphasized, especially in complex patients with unusual presentations of common conditions. This case contributes to the existing literature by being one of only a handful of cases where adalimumab can cause life-threatening thrombocytopenia.

DISCUSSION: This case highlights the importance of continuing anticoagulation in a patient with a left ventricular thrombus and thrombocytopenia. It is also one of the rare instances reported in literature where adalimumab is associated with severe thrombocytopenia, with all other causes having been excluded. Anti-TNF-α drugs are used for induction and maintenance of remission in patients with Crohn's disease. Thrombocytopenia is an uncommon side effect of treatment, but one that should be periodically monitored, especially in instances of increased physiological stress.

BONES, GROANS, AND HEPATITIS PRONE: THE SUBTLE SIGNS AND SYMPTOMS OF AUTOIMMUNE HEPATITIS
Rishika Chugh[2]; Kimberly R. Cavaliere[3]; Sanjana Luther[2]; Sheira Schlair[1]. [1]Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY; [2]Montefiore Medical Center, Bronx, NY; [3]Montefiore Medical Center, New York, NY. (Control ID #2705934)

LEARNING OBJECTIVE #1: Appropriately assess for autoimmune hepatitis when incidental liver test abnormalities are seen.

LEARNING OBJECTIVE #2: Distinguish between type 1 and type 2 autoimmune hepatitis.

CASE: A 30-year old previously healthy female developed fatigue, progressive alopecia, and arthralgias involving the right knee, wrist, fingers and elbow. Liver tests incidentally showed aspartate transaminase (AST) of 47 and alanine transaminase (ALT) of 69. Hepatitis serologies and joint imaging were negative. On further review, the patient was noted to have had a mildly elevated ALT of 48 two years prior. A right upper quadrant sonogram showed mild coarsening of the liver echotexture. Liver/kidney microsomal IgG antibody (anti-LKM-1) was elevated to 56.5. Anti-smooth muscle antibody (ASMA), anti-mitochondrial antibody, and antinuclear antibody (ANA) were all negative, and immunoglobulins were normal. Liver biopsy revealed moderately active chronic hepatitis consistent with autoimmune hepatitis. Treatment with azathioprine and prednisone was started, and her symptoms and liver tests improved.

IMPACT: This case demonstrates the nonspecific presentation and subtle lab abnormalities of autoimmune hepatitis. It prompts one to pursue the workup for autoimmune hepatitis even when non-gastrointestinal symptoms are seen in a patient with the appropriate demographic profile.

DISCUSSION: Fatigue, abdominal pain and nausea are well-known symptoms of autoimmune hepatitis; however, extra-hepatic manifestations can also be seen as the presenting sign. In fact, 10–60% of patients with autoimmune hepatitis may have joint pain. The presence of other autoimmune disorders should also heighten the concern for autoimmune hepatitis and may allow for differentiation between the two types. Only type 2 autoimmune hepatitis is associated with polyglandular autoimmune syndrome, which includes a constellation of endocrine glandular insufficiencies such as alopecia, vitiligo, type 1 diabetes mellitus, and hypothyroidism. Laboratory abnormalities are usually the first to suggest chronic liver disease. Classic, or type 1, autoimmune hepatitis may present with AST and ALT elevation in the thousands; however both type 1 and type 2 can present with any liver test abnormality including a cholestasis or infiltrative pattern. Auto-antibodies provide further assistance. ANA and ASMA are positive in type 1, whereas anti-LKM-1 and antibody to

liver cytosol are positive in type 2. Despite the above-mentioned findings, diagnosis is difficult and liver biopsy is necessary. One clinical prediction rule includes ANA titers, LKM titers, immunoglobulin levels, liver histology, and the exclusion of viral hepatitis. A score of six or above is noted to have a sensitivity of 88 and specificity of 97%. Inconsistent symptoms in young patients, especially healthy females, should prompt internists to pursue an autoimmune diagnosis. However, this case highlights a morbid and likely underdiagnosed autoimmune disease in the setting of very mild abnormalities in liver tests.

BOWEL BYPASS SYNDROME/BOWEL -ASSOCIATED DERMATOSIS ARTHRITIS SYNDROME -A RELAPSING AND RARE COMPLICATION OF GASTRIC BYPASS SURGERY Swathi Vallabhaneni. Brookwood Baptist Health System, Birmingham, AL. (Control ID #2707593)

LEARNING OBJECTIVE #1: Although this syndrome is rare inoccurrence the constellation of symptoms especially in patients with a remote history of Bowel surgeries should prompt the physician in early recognition and diagnosis and treatment, avoiding myriad of investigations and diagnostic tests

CASE: Bowel bypass syndrome, also known as bowel-associated dermatitis arthritis syndrome, has been described after a range of intestinal bypass procedures. This syndrome is an extremely rare complication of gastric bypass surgeries done in 1960- 1970s for Morbid obesity. Approximately 20 percent of those patients who underwent these surgeries developed serum sickness like syndrome. We report an interesting case of bowel-associated dermatitis arthritis syndrome that developed many years after this procedure in a 50-year-old woman presenting with polyarthralgias, fevers, ulcerating lesions and pustules on the upper and lower limbs, with protein malabsorption and severe Vit D and Vit A deficiency. Before the development of these symptoms she was morbidly obese and underwent verified banded gastroplasty with duodenal switch. A skin biopsy taken from the left shin showed superficial to mid-dermal neutrophilic dermatosis, consistent with bowel-associated dermatitis arthritis syndrome. The patient had multiple relapses even though she is on corticosteroids and antibiotics. This case may illustrate another possible complication following bariatric surgery. The significant time period between the initial surgery and the development of bowel-associated dermatitis arthritis syndrome may mean that more cases of this condition will continue to emerge.

IMPACT: Although this syndrome is rare inoccurrence the constellation of symptoms especially in patients with a remote history of Bowel surgeries should prompt the physician in early recognition and diagnosis and treatment, avoiding myriad of investigations and diagnostic tests

DISCUSSION: ●The Jejuno-Ileostomy procedure done to reduce obesity in the mid 1980s was succeeded by other sophisticated procedures and the picture of the bowel bypass or arthritis-dermatitis syndrome has become rare. ●However, Our case shows that this syndrome can appear many years after bypass surgery and as long as people live with their blind loops, it is important to think of the possibility of a bowel bypass syndrome when we see patients with arthritis, vasculitis and a history of surgical treatment for obesity. ●Also as depicted in our patients case, this is a relapsing condition with multiple failed Prednisone and Antibiotic therapies and ultimately needing surgical restoration of the normal bowel anatomy ●Although rare in occurrence the constellation of symptoms especially in patients with a remote history of Bowel surgeries should prompt the physician in early recognition and diagnosis and treatment, avoiding myriad of investigations and diagnostic tests.

BREAKDOWN ON THE MAT: A RARE CASE OF EARLY ADULT-ONSET DERMATOMYOSITIS Monica Lee[2, 1]; Mark Hall[1]; Ritik Tiwari[1]. [1]UT Health Sciences Center at San Antonio, San Antonio, TX; [2]South Texas Veterans Health Care System, San Antonio, TX. (Control ID #2692481)

LEARNING OBJECTIVE #1: Differentiate early dermatomyositis from rhabdomyolysis.

LEARNING OBJECTIVE #2: Identify extra-muscular manifestations of dermatomyositis.

CASE: An 18 year-old man presented with two months of progressive weakness and dysphagia. He was previously active in high school wrestling and weightlifting but is now unable to participate in either due to the weakness. He was recently treated for rhabdomyolysis at an outside facility and encouraged to continue aggressive oral hydration. Exam was notable for sinus tachycardia without chest pain, reduced strength in hip and elbow flexion without palpable tenderness, and tea-colored urine. He had an extensive non-pruritic rash involving the face, torso, and hands. Labs revealed a troponin of 0.30, myoglobin elevated to greater than 1,000, and creatine kinase at 21,825. Both electrocardiogram and echocardiogram were unremarkable for acute pathology. While video swallow fluoroscopy revealed severe pharyngeal dysphagia, no cause could be identified by esophagogastroduodenoscopy. Rheumatology was consulted and with their assistance a muscle biopsy was performed. Findings were consistent with dermatomyositis. The patient was first started on high dose steroids but due to only a modest response, intravenous immunoglobulin was initiated. This young man further improved and was discharged home to the care of his parents but required a percutaneous endoscopic gastronomy tube due to his continued dysphagia. It is unknown if he has since recovered enough to resume his previously active lifestyle.

IMPACT: When faced with suspected rhabdomyolysis and acute extra-muscular symptoms, the internist should broaden their differential to include dermatomyositis. Awareness of these extra-muscular manifestations can heighten clinical suspicion for DM, prevent misdiagnosis, and help expedite appropriate treatment.

DISCUSSION: Dermatomyositis (DM) is part of a group of rare idiopathic Inflammatory myopathies associated with proximal muscle weakness and is differentiated by a violaceous, photosensitive rash classically appearing on the face, chest, and hands. Though DM is often considered a disease of older age with peak incidence at ages 50–59, a juvenile form also exists but is notably less common (1–10 versus 1–3.2 cases per million annually). DM can present with a variety of extra-muscular symptoms such as dysphagia, pulmonary, and cardiac involvement. Swallowing may be disrupted by involvement of the striated muscles in the oropharynx causing dysphagia and possible aspiration. Cardiac involvement, though rare, includes myocarditis, conduction abnormalities, arrhythmias, and even increased risk for myocardial infarction. Before the development of extensive cutaneous involvement, early DM may be difficult to distinguish from rhabdomyolysis as both classically involve weakness and elevated creatine kinases. Because of this, it is prudent to include DM in the differential of those with suspected rhabdomyolysis and extra-muscular symptoms, leading to faster treatment and recovery.

BREAKING THE MOLD: METASTATIC CERVICAL CANCER INITIALLY DIAGNOSED AS PULMONARY HISTOPLASMOSIS

Casey N. McQuade[2]; Amar Kohli[1]. [1]UPMC, Mars, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2687792)

LEARNING OBJECTIVE #1: Recognize framing bias, anchoring bias, and confirmation bias, and how they affected the clinical reasoning in this clinical case.

CASE: A 33 year-old previously healthy woman presents to the hospital with a worsening chronic cough accompanied by a 15-pound unintentional weight loss. In the past month, she developed dyspnea with minimal exertion and required a blood transfusion for "low hemoglobin." Initial outpatient workup revealed positive Histoplasma IgM antibodies and a CT scan with pulmonary nodules. The patient resides in central Pennsylvania and denies trips to the Ohio River valley. Physical examination revealed coarse crackles and an oxygen saturation of 93%. Admission labs showed WBC 9.6, Hb 7.3 g/dL (MCV 71.2, RDW 26.6), Platelets 753, Fe 5 ug/dL, ferritin 116, TIBC 245, Fe saturation 5%. Fourth generation HIV testing was negative. Chest x-ray on admission showed diffuse, patchy airspace disease. She also reports menorrhagia preceding her respiratory symptoms. Given the high suspicion for fungal disease, treatment with itraconazole was initiated. Repeat CT chest showed bilateral, innumerable pulmonary nodules and lymphangitic carcinomatosis. Transbronchial biopsy revealed nests of poorly differentiated non-small cell carcinoma. CT abdomen showed a large cervical mass with subsequent biopsy positive for invasive cervical adenocarcinoma. All bronchial specimens and cultures were negative for fungal organisms, itraconazole was discontinued, and the patient established follow up with Oncology.

IMPACT: This case changed my practice by serving as a reminder of the how errors in clinical reasoning can delay making an important diagnosis.

DISCUSSION: The diagnosis of pulmonary histoplasmosis was considered so seriously for this patient that treatment with itraconazole was initiated prior to confirmatory tests being ordered. The diagnosis of metastatic cervical cancer was delayed because of substantial cognitive biases. Framing bias occurs when the way facts are presented influences how they are interpreted. This case was initially framed as "chronic productive cough with positive Histoplasma serologies." If instead the summary were "unintentional weight loss, menorrhagia, and worsening pulmonary symptoms," cancer may have been considered earlier. Anchoring occurs when the first piece of information reviewed influences subsequent actions. Providers focused on the patient's chief complaint of worsening cough, when menorrhagia causing severe anemia was equally important. Finally, confirmation bias is the tendency to favor new information supporting an initial theory. A diagnosis of pulmonary histoplasmosis may seem validated by news of a positive Histoplasma IgM antibody, CT scan with nodules, and treatment with itraconazole, when none of these are truly confirmatory. In this patient, all three of these biases delayed the diagnosis of metastatic cancer.

BREATHLESS: A CASE OF CENTRAL NEUROGENIC HYPERVENTILATION Elisa Walsh[1]; Robert Montgomery[2]. [1]Harvard Medical School, Brookline, MA; [2]Beth Israel Deaconess Medical Center, Boston, MA. (Control ID #2672310)

LEARNING OBJECTIVE #1: Recognize the signs suggesting a neurologic cause of dyspnea.

LEARNING OBJECTIVE #2: Understand the pathophysiology of central neurogenic hyperventilation.

CASE: A 73 year-old man with a remote history of lung cancer and recent hip replacement presents with one month of dyspnea. Family members note that he gradually developed a regular, rapid deep breathing pattern that interferes with his ability to speak in full sentences and persists even during sleep. On exam, the patient is not in distress despite a respiratory rate of 30 breaths per minute. He is afebrile and his oxygen saturation is normal. Cardiopulmonary exam is unremarkable. There is no lower extremity edema and no lymphadenopathy. Strength is intact. There is hyperreflexia of the left lower extremity and tongue deviation to the right. An EKG is unremarkable. Cross-sectional imaging of the thorax reveals no abnormalities. His initial arterial blood gas on room air is: pH 7.53, pCO2 15, PO2 108, HCO3 14. MRI of the brain is obtained, which reveals areas of signal abnormality in the right subinsular white matter, right basal ganglia and thalamus tracking into the corticospinal tract. Biopsy of the brain reveals diffuse large B-cell lymphoma. He is started on methotrexate and intravenous bicarbonate which results in normalization of his breathing pattern.

IMPACT: We report a rare case of true central hyperventilation secondary to an infiltrating brain tumor. Dyspnea is one of the most common patient complaints encountered in internal medicine. Prompt recognition of the atypical findings in neurogenic hyperventilation can avoid delays in definitive treatment.

DISCUSSION: One of the most helpful diagnostic tools in evaluation of dyspnea is the *arterial blood gas* (*ABG*). In this case, the ABG reveals a chronic primary respiratory alkalosis with maximal metabolic compensation with normal oxygen content and normal A-a gradient on room air. This indicates inappropriately high minute ventilation beyond metabolic needs, suggesting a disorder of respiratory control. Hyperventilation that persists during sleep, low arterial PaCO2, high arterial PaO2, and high arterial pH in the absence of drugs or metabolic cause is diagnostic for *central neurogenic hyperventilation* (*CNH*). CNH is characterized by deep, rapid breaths at a rate of at least 25 breaths per minute. The majority of adult patients with CNH have infiltrative tumors affecting the pons and medulla. The mechanism remains poorly understood, but is thought to arise from physical interruption of negative feedback circuits controlling respiration, or direct chemoreceptor stimulation by local inflammation caused by tumor. Patients can remain conscious if the reticular activating system is spared. However, most patients will progress to coma within two to three months after onset of CNH. Increasing irregularity of the respiratory rate often indicates impending coma. There is no accepted treatment for CNH, but interventions include opioids, mechanical ventilation, and treatment of the underlying tumor.

BRONCHOSCOPY SHOULD BE CONSIDERED EARLY DURING THE EVALUATION OF CAVITARY PNEUMONIA EVEN IN YOUNG AND PREVIOUSLY HEALTHY PATIENTS. Fady Salama[2]; Rahul Nair[1]; Maheshkumar Desai[1]; Theodore Casper[1]. [1]Montefiore Medical Center, Wakefield Campus, New York, NY; [2]Montefiore Medical Center- Wakefield Campus, Bronx, NY. (Control ID #2704430)

LEARNING OBJECTIVE #1: Recognize that unresponsiveness to antimicrobial therapy in patients with risk factors for aspergillosis should raise the suspicion for chronic necrotizing or cavitary pulmonary aspergillosis and bronchoscopy should be considered early for diagnosis.

CASE: A 35 year old African American male taxi driver active smoker with a history of childhood asthma, presented with cough of two weeks duration not responding to outpatient antimicrobial therapy. He also reported fever, night sweats, and unintentional weight loss in the preceding weeks. In the hospital, he was initially treated with broad spectrum antibiotics for multi-lobar pneumonia and placed on airborne isolation for possible pulmonary tuberculosis. CT chest revealed bilateral upper lobes cavities with a thick-walled cavitary lesion and an air-fluid level in the right upper lobe, areas of interstitial infiltrates, and mediastinal lymphadenopathy. Three sputum acid fast bacilli were negative. Aspergillus galactomannan and D glucan were negative.

Despite treatment, he remained febrile, leading to bronchoscopy for further diagnostic evaluation. Bronchoscopy required intubation because of hypoxic respiratory failure, and post procedure ICU stay for stabilization and careful extubation. Bronchoscopic biopsies from the cavitary region revealed Aspergillus invasion and necrotization with non-caseating granulomatous changes in the involved lung parenchyma. AFB and other pathogens were negative and there were no vasculitic changes in the biopsy specimen. Infectious Disease and Pulmonary consults recommended that the patient be treated with antifungal therapy for one year with active clinical follow-up and monitoring. The patient was discharged to outpatient follow-up on continuous home oxygen and bronchodilators.

IMPACT: Chronic pulmonary aspergillosis can have substantial impact on quality of life and can affect even previously young healthy patients. Early diagnosis improves outcome. Suspected patients should be tested for the presence of IgG antibodies to Asperigillus. Bronchoscopy and chest CT should be considered early for diagnosis and better prognosis.

DISCUSSION: Chronic cavitary or necrotizing pulmonary aspergillosis are uncommon and potentially severe diseases. Patients usually have had evidence of prior pulmonary damage or disease, even including mild intermittent asthma. Typically, chronic cavitary or necrotizing pulmonary aspergillosis is not diagnosed until later in the clinical course, as most patients have similar initial presentations to pneumonia or tuberculosis and are only diagnosed when they fail to respond to therapy. Unresponsiveness to anti-microbial therapy in patients with risk factors for aspergillosis should raise the suspicion for chronic necrotizing or cavitary pulmonary aspergillosis and bronchoscopy should be considered for better evaluation. Early diagnosis and early treatment can prevent further lung parenchymal destruction and improve clinical outcomes, including survivorship.

BRUCELLOSIS A CHEESY INFECTION Riya Joseph[1]; leigh K. hunter[2]. [1]Methodist Hospitals of Dallas, Dallas, TX; [2]methodist dallas medical center, Dallas, TX. (Control ID #2680489)

LEARNING OBJECTIVE #1: Recognize an infectious disease that affects <1/100,000 Americans

CASE: An 80 y/o Hispanic man with past medical history of COPD, ascending aortic aneurysm s/p graft repair 10/06, and biventricular pacemaker implantation 4/16 due to third-degree heart block presented with dyspnea, productive cough, orthopnea and fever to 103 F in 5/16. Examination revealed III/VI diastolic murmur, pulmonary rales, peripheral edema and increased O2 requirement. CXR showed bibasilar infiltrates so blood cultures were submitted and therapy with vancomycin, piperacillin/tazobactam, and azithromycin was initiated for presumed HCAP. Despite diuresis and antibiotic therapy, the patient's symptoms did not improve. Cultures subsequently grew Brucella melitensis at 4 days. Patient recently traveled to Mexico from 11/15-4/16 where he consumed unpasteurized cheese. Brucella IgG was positive and IgM negative suggesting the infection had been present for some time. Treatment with doxycycline, rifampin, and gentamicin was begun and a TEE was ordered which demonstrated markedly worsened aortic insufficiency (AI) compared with TTE 4/16, bicuspid valve, mild aortic stenosis, pseudoaneurysm with leaflet perforation, graft dehiscence and paravalvular abscess. Suspected infective endocarditis (IE) was confirmed and his antibiotic regimen was expanded to doxycycline, rifampin, gentamicin, and trimethoprim/sulfamethoxazole. The patient was transferred for cardiothoracic surgery to replace the infected valve and graft. Post-operatively, the patient had multiple complications and expired approximately 1 month post-op.

IMPACT: Brucellosis is caused by Gram negative, non-spore forming, intracellular coccobacilli. The most common mode of transmission is eating unpasteurized milk products. Mortality rates for brucellosis are usually between 1-5 and endocarditis accounts for more than 80% of these deaths. Endocarditis is an uncommon presentation of Brucella infections, which can present immediately or many years after onset of symptoms. As internists, we see patients with CHF and COPD exacerbations almost every day. Since these patients present with the same pattern of symptoms, it is imperative that a complete history is obtained on every patient and the differential diagnosis is broad. Most likely the patient had infection of the graft and IE causing the third degree heart block 1 month prior to the presentation with fever, severe AI and positive blood cultures. No blood cultures were done on that admission. Had the diagnosis been made then, would the outcome have been different?

DISCUSSION: Brucellosis is a rare infection and Brucella endocarditis even more rare. As noted by our case, it is a disease that can have devastating results if not diagnosed and treated in a timely manner. It is important for hospitalists and other primary care providers, especially those practicing in highly diverse cities with travel to endemic areas, to take a complete history and consider uncommon causes of common disease processes.

BUPROPION AS A CAUSE OF SIADH Corey Tapper; Erica Grabscheid. Mount Sinai Beth Israel, BROOKLYN, NY. (Control ID #2706781)

LEARNING OBJECTIVE #1: Recognize CNS-acting agents as rare causes of SIADH

CASE: An 85-year old male presented with a five-day history of generalized weakness and fatigue. The patient reported insomnia and dry cough. He denied fever, dyspnea, nausea, headaches, muscle spasms, and seizures. The patient's medical history included atrial fibrillation, hyperlipidemia, and Alzheimer's Disease. His chronic medications included memantine, donepezil, simvastatin, and warfarin. Two months prior to presentation, bupropion was started for depression. There were no other recent medication changes. The patient had been taking all medications as prescribed. The patient's vital signs were within normal limits. On neurologic exam, the patient was oriented only to self. Otherwise, the exam was unremarkable. Notably, at his baseline, the patient was oriented to person and place. Laboratory results showed serum sodium of 125 mmol/L (normal 135–144), serum osmolality of 265 mOsm/kg (normal 280–296), white blood cell count of 6.5 K/μL, AM cortisol of 24.47 μg/dL (normal 4–22), TSH of 6.588 μIU/mL (normal 0.55–4.78), free thyroxine of 1.25 ng/dL, uric acid of 2.1 mg/dL, urine osmolality of 463 mOsm/kg, and urine sodium of 170 mmol/L (normal 30–90). Chest radiograph showed no consolidations. The urine legionella antigen was negative. Computed tomography of the head showed mild diffuse cortical atrophy. Two years prior, the patient's sodium was 133 mmol/L. This patient was found to have euvolemic hypo-osmolar hyponatremia, consistent with SIADH. A challenge with isotonic fluids was attempted. The sodium did not improve. Bupropion was discontinued, and a fluid restriction was instituted. Over the next three days, sodium levels returned to the previous baseline and symptoms improved. Other causes of hyponatremia were ruled out, including pneumonia, glucocorticoid deficiency and overt hypothyroidism. There were no signs of malignancy. Throughout this presentation, the patient's memantine and donepezil were continued. Both of these medications could have contributed to the patient's mild chronic hyponatremia.

However, they were not likely the cause of the current SIADH given the patient's clinical improvement following bupropion discontinuation.

IMPACT: This case is noteworthy as it potentially shows a widening array of CNS-acting agents that can cause SIADH, although further investigation is necessary.

DISCUSSION: Hyponatremia is a well-established adverse effect of antidepressants, namely SSRI's and TCA's. However, there are only four published case reports of SIADH secondary to bupropion. Due to elevated ADH levels, there is a lowered capacity to excrete dilute urine. Extracellular fluids are retained, leading to a hypo-osmolar state. Physiologically, bupropion acts by inhibiting neuronal re-uptake of dopamine and norepinephrine. It is thought that serotonin may play a role in regulating ADH secretion. However, as bupropion does not act significantly on serotonin, the causal mechanism for bupropion-induced SIADH is not known.

BURKITT LYMPHOMA PRESENTING AS UNILATERAL PLEURAL EFFUSION IN A PATIENT WITH HIV INFECTION: AN INTERESTING ENCOUNTER. Talal Asif; Badar Hasan. University of Missouri, Kansas City, Mission, KS. (Control ID #2703195)

LEARNING OBJECTIVE #1: To create a differential diagnosis for unilateral pleural effusions in patients with human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS).

LEARNING OBJECTIVE #2: To recognize that Burkitt lymphoma (BL) is an exceedingly aggressive B cell non-Hodgkin lymphoma (NHL) known to affect patients with high CD4 counts (>200/μL).

CASE: A 40 years old female with a past history of HIV and AIDS, currently on antiretroviral therapy (ART) with Genvoya, presented to primary care clinic with the complaint of dyspnea on less than normal exertion. Patient reported compliance with her ART and last CD4 count acquired two weeks earlier was 311 cells/μL with undetectable viral load. Physical examination was unremarkable. Chest x-ray was obtained which showed a small right pleural effusion and right lower lobe opacities. Patient's lactic acid dehydrogenase was elevated at 919 U/L. With infection high on the differential, patient was hospitalized with the working diagnosis of Pneumocystis pneumonia and started on trimethoprim-sulfamethoxazole. Bronchoalveolar lavage was performed and was negative for Gomori-methenamine silver staining, acid fast bacilli and Gram staining. On day 3, patient developed hypoxemia. Computed tomographic (CT) scan of chest was obtained which showed diffuse right lung heterogeneous opacities and moderate right pleural effusion. Left lung was clear. There was no evidence of lymphadenopathy. Thoracentesis was done and 1 liter of pleural fluid was drained. Pleural fluid analysis showed an exudative picture and a white cell count of 44123 with 100% mononuclear cells. On day 5, patient's hypoxemia worsened again. CT chest was repeated which showed massive right pleural effusion with complete right lung compressive atelectasis. There was new demonstration of hilar, mediastinal and bilateral axillary lymphadenopathy. Ultrasound guided core biopsy of right axillary lymph node was obtained which showed CD10 positive monoclonal lymphocytes with high mitotic rate, 100% Ki-67 index, starry sky macrophages negative for BCL-2 and BCL-6, consistent with BL. Flow cytometry of pleural fluid showed CD10 positive cells as well. Patient was started on chemotherapy with improvement in her pleural effusion.

IMPACT: Given its rising incidence and propensity to evolve in patients with normal CD4 counts, it is important to consider BL when encountered with patients who have no clear cause for rapidly accumulating pleural effusions. This case also aims to raise awareness of the diagnostic challenges that pleural effusions present in patients with HIV.

DISCUSSION: Patients with HIV/AIDS are at an increased risk of development of lymphoma. BL in this subset of patients often presents with disease involving the lymph nodes, bone marrow and central nervous system. Extranodal involvement is typically a late manifestation. Unilateral pleural effusion as in this instance is an unusual mode of presentation for BL. This occurrence is also an attestation to its aggressive nature.

BUTTERFLY-SHAPED PONTINE LESION WITH NON-MASS-FORMING B-CELL LYMPHOMA: A CASE SERIES Naoki Kanda; Ayako Kumabe; Yu Yamamoto; Shuji Hatakeyama; Masami Matsumura. Jichi Medical University Hospital, Tochigi, Japan. (Control ID #2690900)

LEARNING OBJECTIVE #1: Recognize the significance of symmetrical hyperintense lesions in the pons on T2-weighted imaging

LEARNING OBJECTIVE #2: Assess non-mass-forming lymphoma when a butterfly-shaped pontine lesion is observed

CASE: [Patient 1] An 86-year-old Japanese woman was admitted with a 2-week history of fever and pitting edema of the extremity. Laboratory data showed a platelet count of $8.0 \times 10^6/\mu L$, a lactate dehydrogenase level of 836 U/L, and a soluble interleukin-2 receptor level of 5,360 U/mL. Physical and radiographic evaluation revealed no lymphadenopathy. Despite the absence of neurological symptoms, brain magnetic resonance imaging (MRI) demonstrated a butterfly-shaped hyperintense lesion in the central parts of the pons on T2-weighted and diffusion-weighted imaging. Random skin biopsy specimens showed atypical lymphocytes strongly positive for CD20 within the lumina of capillaries. She was thus diagnosed with intravascular large B-cell lymphoma. [Patient 2] A 26-year-old woman presented with a 3-month history of night sweats and 1-month history of fever. Physical exam and imaging studies showed isolated massive splenomegaly without adenopathy. There was no neurological abnormality, but brain MRI presented a symmetrical pontine lesion similar to that observed in patient 1. Biopsy specimens of the bone marrow, skin, and liver yielded no pathologic findings. A diagnostic splenectomy was performed and the histological analysis revealed a splenic diffuse red pulp small B-cell lymphoma. [Patient 3] An 82-year-old man was referred to our division due to prolonged fever lasting more than 3 weeks with dyspnea, leukopenia, and thrombocytopenia. He had no lymphadenopathy and neurological symptoms. Brain MRI showed a symmetrical lesion in the pons similar to the other cases. A bone marrow biopsy showed CD20-positive atypical lymphocytes, which were strongly suggestive of B-cell lymphoma.

IMPACT: We may perform a more aggressive histological exam including invasive surgical procedures to diagnose lymphoma if asymptomatic symmetrical pontine lesions on MRI are found in patients with suspected lymphoma without lymphadenopathy.

DISCUSSION: Diagnosis of non-mass-forming lymphoma is challenging because of the difficulty in obtaining histological evidence. Spleen or liver biopsy can be used for diagnosis; however, a dilemma between the diagnostic yield and the risk of the procedure exists. There have been a few reports describing the symmetrical pontine lesion complicated with systemic lymphoma, mainly intravascular large B-cell lymphoma. The lesion may represent a tumor cell infiltration into the vessels of the pons producing venous congestion. In cases with suspected lymphoma without lymphadenopathy, the asymptomatic butterfly-shaped lesion in the pons might indicate the presence of an unusual type of lymphoma requiring aggressive procedures to diagnose.

CANAGLIFLOZIN MAY CAUSE EUGLYCEMIC DIABETIC KETOACIDOSIS IN PATIENTS WITH TYPE 2 DIABETES MELLITUS WITHOUT COEXISTING FACTORS Ryuta Suzuki. Kameda General Hospital, Kamogawa, Japan. (Control ID #2700813)

LEARNING OBJECTIVE #1: Diagnose euglycemic diabetic ketoacidosis in patients with type 2 diabetes mellitus (T2D) without coexisting factors

CASE: A 62-year-old woman with hypertension and non-insulin dependent T2D presented to our hospital with a six-day history of nausea, vomiting, and anorexia. She has been taking 100 mg of canagliflozin, a sodium-glucose cotransporter-2 (SGLT2) inhibitor, for six months, together with pioglitazone 7.5 mg and metformin 1500 mg. On presentation, she was afebrile and breathing normally, but was tachycardic to 112 beats per minute. She did not have signs of dehydration including dry mouth and decreased skin turgor. However, her arterial blood gas revealed a significant anion gap acidosis (pH 7.139, pCO_2 9.6 mmHg, HCO_3 3.1 mmol/L, anion gap 35). Her glucose was 192 mg/dL, suggesting euglycemic diabetic ketoacidosis (DKA) caused by canagliflozin. She was admitted to our hospital and started on a continuous intravenous insulin infusion at a rate of 0.1 unit/kg/hour, which led to a resolution of the anion gap acidosis and improvement in her symptoms on the following day. On the fifth hospital day, her symptoms resolved completely, and the insulin infusion was replaced with subcutaneous basal-bolus insulin. After her glucose levels became stable, she was discharged to home on the tenth hospital day.

IMPACT: This case suggests that patients with T2D treated with SGLT2 inhibitors have a potential risk of euglycemic DKA, even if they do not have coexisting factors.

DISCUSSION: DKA in patients with T2D treated with canagliflozin has been reported in previous studies. Canagliflozin-induced DKA is relatively less common in patients with T2D than in patients with type 1 diabetes (T1D): incidence of less than 0.1% in T2D, but 4.3–6.0% in T1D [1,2]. Erondu et al. reported that most of the patients with T2D who developed DKA while taking an SGLT2 inhibitor had coexisting factors for ketoacidosis: post-gastric cancer surgery, pancreatic cancer, pancreatitis, and/or insulin-dependent diabetes [1]. This case, however, had none of these coexisting factors. SGLT2 inhibitors are a new class of oral hypoglycemic agents approved by the Food and Drug Administration in 2013. Since its approval, they have been widely used for patients with T2D across the globe. SGLT2 inhibitors are likely to be even more widely used in the coming years, and hence further caution for ketoacidosis - euglycemic or hyperglycemic - is necessary in patients treated with SGLT2 inhibitors. [1] Erondu N, Desai M, Ways K, and Meininger G. Diabetic ketoacidosis and related events in the canagliflozin Type 2 diabetes clinical program. Diabetes Care 2015; 38:1680–6. [2] Peters AL, Henry RR, ThakkarP, TongC, and Alba M. Diabetic ketoacidosis with canagliflozin, a sodium-glucose cotransporter 2 inhibitor, in patients with Type 1 diabetes. Diabetes Care 2016; 39:532–8.

CARBON MONOXIDE POISONING - A SILENT MENACE Jordon Holt; Carmen Vesbianu. Oklahoma University, Tulsa, Jenks, OK. (Control ID #2706119)

LEARNING OBJECTIVE #1: Diagnose carbon monoxide poisoning in the chronic setting

LEARNING OBJECTIVE #2: Point out that carbon monoxide exposure is an under-recognized occupational hazard.

CASE: A 55-year-old man with a history of sleep apnea and benign prostatic hyperplasia presented with complaints of dizziness. He described sudden onset repeated episodes of a "sinking feeling," lasting for few seconds while flying alone in his personal aircraft. He consulted his primary care physician the next day and reported similar symptoms that continued outside the plane as well as headache, dull neck pain, fatigue, and tinnitus. He denied loss of consciousness, nausea, ataxia, chest pain, or palpitations. On physical exam, blood pressure was 133/86 supine and 137/86 standing, heart rate 78, oxygen saturation 96% on room air. He had a regular heart rhythm, no murmurs, no carotid bruit.. Neurovestibular examination was normal. Patient denied ever smoking or alcohol abuse. He was compliant with the routine airplane inspections required by the Federal Aviation Administration. Over the next four months, he continued to experience similar symptoms while flying that persisted during days when he was not operating the aircraft. To address the etiology of the dizziness, he underwent a cardiac and neurovestibular work-up. A 48-hour Holter monitor was consistent with occasional premature ventricular complexes and an echocardiogram showed normal left and right ventricular function and no valvulopathy. Audiogram and brain MRI results were normal. The diagnosis was revealed four months later when a carbon monoxide leak was detected in the patient's aircraft. In retrospect, he remembered having more persistent and severe symptoms the first two days after a flight. He fully recovered after the leak was repaired.

IMPACT: The full extent of carbon monoxide poisoning in aviation is not known; we believe this could be an under-recognized occupational health risk factor. Our case illustrates how the failure to identify the link between the patient's symptoms and his work environment led to an expensive work-up and delay in explaining the etiology of his complaints. Perhaps the most severe consequence of this missed diagnosis is that the patient was discharged to the same environment of the original exposure.

DISCUSSION: The symptoms of chronic carbon monoxide poisoning are vague and nonspecific making it difficult for physicians to recognize cases of low-level exposure. Patients with mild intoxication present with headache, dizziness, and nausea and often are misdiagnosed with an acute viral disease. Nevertheless, it is vital for medical professionals to identify the signs of carbon monoxide poisoning in a timely manner and minimize further harm. Prolonged, short-term exposure can lead to delayed neurological and cardiac sequelae including memory loss, personality changes, movement disorders and myocardial injury.

CARDIAC ARREST AFTER ADMINISTRATION OF INTRAVENOUS AMIODARONE IN WOLFF - PARKINSON - WHITE SYNDROME: A CHANGE IN PERSPECTIVE Mahesh A. Chandrasekhar[2]; Zuyue Wang[1]; guastavo guadalini[2]. [1]Medstar Heart and Vascular Institute, Washington, DC; [2]Medstar Washington Hospital Center, Washington, DC. (Control ID #2702900)

LEARNING OBJECTIVE #1: To address a serious harm associated with administration of intravenous amiodarone in atrial fibrillation and WPW syndrome.

LEARNING OBJECTIVE #2: To review appropriate diagnosis and treatment of atrial fibrillation WPW syndrome.

CASE: A 63-year-old African American Woman presented to emergency room with chest pressure and palpitations. A baseline electrocardiogram showed atrial fibrillation with WPW syndrome. Patient was given intravenous amiodarone as a means to convert the patient to a sinus rhythm. Following this administration, the patient went to ventricular fibrillation requiring intubation and defibrillation. The patient was transferred to a tertiary care hospital,

stabilized in the cardiac critical care unit, and underwent catheter ablation of the accessory pathway.

IMPACT: This cases addresses the controversies of appropriate, acute medical management of these patients. The 2011 AHA guidelines for the treatment of patients with atrial fibrillation and WPW suggest that hemodynamically stable patients should be cardioverted either via direct current cardioversion. In addition to procainamide and ibutilide, was amiodarone was an AHA Class II B recommendation for the treatment. Amiodarone is a class III antiarrhythmic and a commonly used drug for rhythm control in this atrial fibrillation. No properly conducted trials of amiodarone, with or without comparison to procainamide, exist to justify the use of this medication in this patient population. Several authors published these concerns and have helped reimagine current guidelines such that, as the 2015 guidelines for the management of adult patients with supraventricular tachycardia amiodarone is now a class III recommendation against use in this patient population.

DISCUSSION: There is a paucity of evidence showing safety or efficacy in regard to AF WPW patients receiving amiodarone, and several case reports and case series note a pathophysiologically plausible significant harm. Though medical literature has removed amiodarone as first-line medication to convert atrial fibrillation in WPW patients, recommendations may not go far enough in regard to dissuading its use. Procainamide and ibutilide would be appropriate in the above clinical scenario. Working to change these guidelines may help guide providers avoid amiodarone administration in this population and decrease the rate of conversion to ventricular arrhythmia.

CARDIAC ARREST DURING RAPID PACING IN A PATIENT WITH AORTIC STENOSIS (AS) AND CARDIAC AMYLOIDOSIS UNDERGOING TRANSCATHETER AORTIC VALVE REPLACEMENT (TAVR). Shubha Deep Roy; Siva Sagar Taduru; Shariq Shamim; Paramdeep S. Baweja. University of Missouri Kansas City, Kansas City, MO. (Control ID #2706990)

LEARNING OBJECTIVE #1: Recognize a potentially fatal outcome in patients with AS and cardiac amyloidosis undergoing TAVR.

CASE: A 77 year old male with a history of coronary artery disease (CAD), combined heart failure and severe AS presented with progressive “slowing down” for 6 months. Physical exam revealed a late peaking grade 3/6 systolic ejection murmur in aortic area with slow and delayed carotid upstroke. JVP and pulmonary exam was normal. Transthoracic echocardiography showed paradoxical low flow, low gradient AS. Transesophageal echo (TEE) showed aortic valve area of 0.7 cm2 and severe biventricular hypertrophy. Endomyocardial biopsy was consistent with cardiac amyloidosis and was sent for subtyping. Cardiac MRI showed diffuse late gadolinium enhancement (LGE) transmurally in basal segments suggestive of ATTR amyloidosis. He was considered to be at a high risk for surgical aortic valve replacement (SAVR) due to his comorbidities and severe ventricular hypertrophy but at an acceptable risk for TAVR. A pre-procedural coronary angiogram showed stable CAD. He underwent placement of a 26 mm Sapien valve via a transfemoral approach. Left ventricular end diastolic pressure (LVEDP) was elevated. During rapid pacing for initial balloon aortic valvuloplasty he had a precipitous drop in blood pressure requiring inotropic support. Then immediately after repeat rapid pacing during valve deployment, he developed cardiac arrest with pulseless electrical activity requiring ACLS. Intraoperative TEE, coronary angiography, and ascending aortography did not show any mechanical complication.

IMPACT: This case shows that rapid pacing during TAVR in patients with AS and cardiac amyloidosis with restrictive physiology can have potentially fatal outcomes. It is important to be aware of these complications as they can help in deciding the management of similar patients with AS and amyloidosis.

DISCUSSION: Coexistence of degenerative aortic stenosis (AS) and wild type-transthyretin related cardiac amyloidosis (wt-ATTR) has been suggested to be a potentially dangerous condition in patients undergoing SAVR or TAVR based on autopsy data. Currently, there is limited data on safety of rapid pacing during TAVR in patients with cardiac amyloidosis. Rapid ventricular pacing at a rate of 140 to 220 beats per minute is required for balloon valvuloplasty and implantation of balloon-expandable aortic valve prosthesis during TAVR. Rapid pacing in the setting of restrictive filling pattern, as evidenced by an elevated LVEDP, can potentially lead to hemodynamic collapse and cardiac arrest. This can happen due to a sudden reduction in coronary perfusion pressure (CPP) which is the difference between the end-diastolic aortic pressure and LVEDP. As LVEDP rises, CPP falls which can cause sudden cardiac dysfunction. Another possible explanation of cardiac arrest could be due to unmasking of arrhythmia in patients with amyloidosis with conduction system involvement.

CARDIAC SARCOIDOSIS: A DIAGNOSTIC CHALLENGE

Monil Shah; B. Corbett Walsh; Nathan Teich; Benjamin Milgrom. New York University Langone Medical Center, New York, NY. (Control ID #2706817)

LEARNING OBJECTIVE #1: Diagnose cardiac sarcoidosis (CS) in a patient with complete heart block

LEARNING OBJECTIVE #2: Management of cardiac sarcoidosis

CASE: A 53-year-old female with no prior medical history presented to the ED with a few days of weakness. Initial ECG revealed sinus rhythm with complete heart block and junctional escape rhythm at a rate of 35 bpm. Patient was not on atrioventricular nodal blocking medications. Transthoracic echocardiogram showed normal bi-ventricular size/function without valvular disease. Laboratory workup including Lyme antibodies was unrevealing. Diagnosis of CS was considered and a cardiac MRI (CMR) was performed however, failed to definitively demonstrate late gadolinium enhancement suggestive of fibrosis. Positron emission tomography (PET) imaging was unavailable at the time. CT of the chest demonstrated bilateral hilar lymphadenopathy highly suggestive of sarcoidosis. A transvenous pacemaker was placed and an endobronchial ultrasound guided lymph node biopsy was performed which demonstrated non-caseating granulomas consistent with sarcoidosis. Given biopsy proven extra-cardiac sarcoidosis in combination with complete heart block without alternative explanation, a diagnosis of CS was established. Prednisone therapy was initiated and a dual chamber implantable cardioverter-defibrillator (ICD) was placed. Patient was discharged on oral steroids and planned for PET scan as an outpatient.

IMPACT: Diagnosing CS in patient who presents with complete heart block whose cardiac imaging fails to demonstrate cardiac involvement is challenging. Internists should be aware that a negative CMR, despite high sensitivity, does not exclude cardiac involvement of sarcoidosis. A high index of suspicion should be maintained to pursue evidence of extra-cardiac involvement. If confirmed, the management changes significantly since an ICD should be considered instead of pacemaker along with need for immunosuppression.

DISCUSSION: Cardiac involvement is seen in 5% of patients with sarcoidosis and presents with high-grade AV block, ventricular tachyarrhythmia, left ventricular dysfunction or heart failure. Chest imaging (X-ray or CT) is abnormal in 85-95% of patients. PET and/or CMR are imaging modalities of choice with

PET having higher sensitivity compared to CMR based on multiple studies (87% vs 75%). Endomyocardial biopsy (EMB) can be considered if extra cardiac targets are not available for biopsy; however, the sensitivity is low (25%) due to focal cardiac involvement. The American College of Cardiology recommends ICD implantation for primary prevention of sudden cardiac death in all patients with cardiac sarcoidosis due to high incidence of ventricular arrhythmias. Recovery of AV block following immunosuppression has been demonstrated in small studies however; predicting which patient population would recover their native conduction still remains an active area of investigation.

CARDIAC TAMPONADE SECONDARY TO PURULENT PERICARDITIS IN A PATIENT WITH LUDWIG'S ANGINA AND LEMIERRE'S SYNDROME Karishma Samtani; Katelyn Booher. Wright State University, Dayton, OH. (Control ID #2707252)

LEARNING OBJECTIVE #1: Recognize the clinical features of purulent pericarditis and it's complications.
LEARNING OBJECTIVE #2: Assess for cardiac tamponade in patients with shortness of breath and signs of pericarditis.
CASE: A 51-year-male with non-contributory past medical history presented to the emergency department with five days of right-sided cheek and neck swelling with pain. Magnetic resonance imaging (MRI) head and neck were negative for drainable fluid collection, and the patient was discharged home with antibiotics. He improved however returned in four days with new shortness of breath and dizziness. His heart rate was regular but tachycardic at 108 beats per minute, and he was normotensive. Electrocardiogram (ECG) demonstrated sinus tachycardia with diffuse ST elevation and PR depression. A portable chest radiograph showed widened cardiomediastinal silhouette. Computed tomography (CT) and MRI now revealed extensive Ludwig's angina. Incision and drainage was performed followed by intravenous steroids and antibiotics. Emergent echocardiography revealed a large pericardial effusion with right ventricular diastolic collapse consistent with cardiac tamponade. Emergent pericardiocentesis was performed yielding 590 mL of fluid and a pericardial drain was placed. Due to his worsening clinical status, further imaging was obtained and showed progressing infection including infectious thrombus in his right internal jugular vein. He remained in the hospital for further treatment including antibiotics. His pericardial drain was removed without complication or need for further cardiac intervention.
IMPACT: This case is a valuable addition to literature as it demonstrates purulent pericarditis from Ludwig's angina as a rare cause of pericardial effusion and cardiac tamponade requiring emergent intervention and intravenous antibiotics. This case prompts further learning to recognize cardiac tamponade seconary to purulent pericarditis, a rare and fatal condition.
DISCUSSION: Purulent pericarditis accounts for less than one percent of cases of pericarditis. The incidence of cardiac tamponade secondary to purulent pericarditis is unclear and reportedly ranges from 42 to 77%. This rare entity will generally present as a febrile illness, and possibly with signs of sepsis and hemodynamic instability. Our patient presented with severe odontogenic infection, and subsequently shortness of breath and dizziness. If left untreated it is fatal and therefore early recognition and aggressive treatment is essential. As many as 85% of patients with purulent pericarditis who have received comprehensive therapy will survive with good long-term outcomes. Physicians must recognize rare causes of cardiac tamponade, a life-threatening condition, such as purulent pericarditis due to Ludwig's angina.

CARDIO-RENAL SYNDROME: RAPID PROGRESSION OF CHRONIC KIDNEY DISEASE IN A CARDIOTHORACIC SURGEON Mia Williams; Hsu Chi. University of California San Francisco, San Francisco, CA. (Control ID #2706180)

LEARNING OBJECTIVE #1: Recognize patterns of CKD development in HTN & T2DM
LEARNING OBJECTIVE #2: Understand unique causes of secondary FSGS
CASE: 74 year old African American (AA) male with a history of HTN, T2DM, and BPH presented to Renal Clinic for evaluation of worsening CKD. Five years prior, CKD III was diagnosed and felt likely due to obesity. In 2016 he was found to have an elevated creatinine of 2.51 mg/dl. Given concern that his ARB was the cause it was stopped and he was referred to Nephrology. It was felt that his presentation was most consistent with hypertensive nephrosclerosis; however his Endocrinologst felt it was secondary to FSGS. Given lack of improvement he was referred to UCSF for a second opinion. Regarding possible etiologies of his worsened CKD, his T2DM was first diagnosed two years prior with a HbA1c <7% without evidence of neuropathy or retinopathy. His long term HTN medications were: amlodipine, valsartan and HCTZ. His BPs were well controlled. He endorsed a family history of CKD. At initial evaluation he denied a history of a UTI, dysuria, hematuria but noted some urinary frequency and light froth to urine. He denied edema, change in appetite or energy, pruritus or fatigue. He had intentional weight loss. He had no significant NSAID use. None of his medications were associated with renal disease. Pr:Cr Ratios had increased from 2.49 in 2012 to 3.3 in 2016. His SPEP/UPEP was negative 2012. Physical exam was only significant for obesity. His subsequent work-up was significant for a creatinine of 3.1 mg/dl (GFR 22), Pr: Cr Ratio of 5.27. His work-up was negative for other etiologies of CKD. Given the rapid progression of his disease, a renal biopsy was pursued and demonstrated FSGS. Given the family history of CKD he was sent for APO-L1 testing which was negative. His FSGS was felt to be secondary to obesity rather than hereditary. With continued weight loss and restarting his ARB his creatinine and Pr:CR improved to 2.55 mg/dl (GFR 28) and 2.59.
IMPACT: This case highlighted an approach to assessing patients for CKD and being aware that rapid progression as in this patient is atypical. Specifically I learned that while diabetic nephropathy may present with this degree of proteinuria, hypertensive nephrosclerosis does not. As research and this patient's case demonstrated, weight loss and ACE-I can improve renal function and protein excretion in obesity related FSGS.
DISCUSSION: Compared to patients with T2DM, hypertensive nephrosclerosis rarely presents with nephrotic range proteinuria. Furthermore the absence of diabetic retinopathy does not exclude the development of diabetic nephropathy. FSGS is typically considered inCKD with nephrotic range proteinuria and should be approached by ruling out secondary etiologies. Regarding primary etiologies, there is evidence for APO-L1 as an underlying genetic susceptibility for FSGS. Deleterious mutations in these genes are more prevalent in AAs and provide another etiology in this population. Thus biopsy should be critically advocated for when appropriate.

CARE MANAGEMENT: A SOLUTION FOR HIGH-RISK PATIENTS? (IMPROVING THE CARE OF HIGH-RISK PATIENTS WITH CARE MANAGEMENT) Elizabeth Park[1]; Lee S. Shearer[2]; Paul Lu[3]. [1]New York Presbyterian Hospital, New York, NY; [2]Weill Cornell Medical College, New York, NY; [3]Hospital for University of Pennsylvania, Philadelphia, PA. (Control ID #2702184)

LEARNING OBJECTIVE #1: Recognize high-risk patients as candidates for Care Management.

LEARNING OBJECTIVE #2: Apply Care Management as a tool to improve care coordination, health outcomes, and reduce cost.

CASE: A 75 year old man with Parkinson's Disease Dementia with chronic urinary retention and indwelling suprapubic catheter established care at our outpatient clinic after frequent Emergency Department (ED) visits. His past medical history included Hypertension. Social history was pertinent for living at home with his elderly wife. On initial visit, patient had no complaints. Vitals were notable for sinus bradycardia and physical exam was consistent with Parkinsonian features, with a suprapubic catheter in place. Review of his previous hospital visits showed 8 ED visits in the past year. At this point, a referral was made to Care Management (CM). His hospital visits are summarized below. 11/2014: Admission for Urinary Tract Infection (UTI) 01/2015: Admission for UTI 01/2015: ED visit for Foley complication 02/2015: Admission for UTI 02/2015: ED visit for Foley complication 04/2015: ED visit for Foley complication 05/2015: ED visit for Foley complication 06/2015: ED visit for medication non-compliance 06/2015: Established care and CM introduced 08/2015: Admission for UTI 09/2015: Admission for UTI 06/2016: Admission for UTI

IMPACT: Patients with frequent hospital visits are an example of high-risk patients who may benefit from CM. CM is a tool to help patients coordinate care outside of the office and may serve as a resource to reduce hospital visits, improve health outcomes, and reduce overall cost.

DISCUSSION: High-need, high cost (HNHC) patients are a heterogeneous group of patients that utilize a disproportionate amount of US health care cost. HNHC patients often deal with multiple medical conditions, complex social needs, and poorly coordinated care which contribute to the high cost of care. For example, the most expensive 5% of Medicaid enrollees accounted for nearly half of the total expenditures of all Medicaid enrollees in 2009–2011. Care Management typically comprises of an interdisciplinary team of primary care physicians, sub-specialists, nurses, and social workers, who collaborate to deliver patient-centered and cost-efficient care. Specific interventions include: patient education, medication reconciliation, coordination of care, adjunct social services, counseling, and hospital discharge planning. The literature has shown conflicting data on the effect of CM with inconsistent benefits on outcomes such as mortality, use of primary or secondary care, and cost. This may reflect individualized models of CM employed, with some more successful than others. However, as with our patient, we found CM to be helpful in reducing hospital visits from 8 visits in the year prior to CM down to 3 visits in the subsequent year. CM is one potential tool which may be applied to high-risk patients to improve care coordination, overall health, and cost-effectiveness.

CASE STUDY OF A LIFE THREATENING NEMATODE Sheba E. John. Presence St Francis Hospital, Evanston, IL. (Control ID #2704361)

LEARNING OBJECTIVE #1: Recognize clinical presentation of strongyloides hyperinfection

LEARNING OBJECTIVE #2: Assess the importance of parasitic screening before immunosupressant therapy

CASE: A 58-year-old male was brought to the ED after being found lying on the floor at his apartment. At presentation, patient was confused and failed to recollect the course of events leading to the fall however he reported feeling fatigued and having non-bloody diarrhea. He had significant weight loss over the past 6 months. His past medical history included Crohn's disease for 40 years which was treated initially with infliximab and eventually switched to vedolizumab in the last 8 months. He also underwent two bowel resections in the past for lysis of adhesions. Patient was born in Chicago and had no significant travel history. On examination, he appeared cachectic, blood pressure was 92/58 mmHg, pulse rate of 96 beats/min, temperature of 96 F and was saturating well on room air. Decreased breath sounds and crackles were noted on right chest. Initial blood tests showed leukocytosis, elevated lactate and chest X-ray revealed heterogeneous infiltrates throughout right lung field. Patient was started on broad spectrum antibiotics and fluid resuscitation for severe sepsis secondary to pneumonia. Blood cultures, influenza test, streptococcal and legionella urine antigen testing were all negative. Despite antibiotic treatment, chest X-ray showed worsening infiltrates and opacities on the right side and he started having episodes of non-bloody diarrhea. CT of chest showed dense consolidation throughout the right lung and ground glass opacities at left upper lung. While studying the bronchoscopy cytology, a very rare and interesting finding was revealed in the form of rhabdtitiform larvae of strongyloides. Patient also tested positive for strongyloides antibody which further confirmed the diagnosis and he was started on Ivermectin. He showed significant improvement with treatment and started feeding well without further episodes of diarrhea.

IMPACT: Strongyloides hyperinfection can be prevented by early detection and treatment of asymptomatic chronic infections. A comprehensive screening program should be considered routinely to detect any latent infections before the start of chemotherapy, immunosuppression and steroid therapy.

DISCUSSION: Strongyloides Stercoralis is a soil transmitted intestinal nematode. Its unique ability to replicate in the human host permits cycles of autoinfection, leading to chronic disease that can last for several decades. However, in patients receiving long-term corticosteroid therapy, hyper infection can occur resulting in high mortality rates (up to 87%). Bacteremia develops due to disruption of mucosal barrier by larva, and sepsis complicate the clinical course. Eosinophilia is uncommon in disseminated cases. So even in the absence of eosinophilia, clinical symptoms of diarrhea and pulmonary findings should raise suspicion of strongyloides hyper-infection in immunosuppressed individuals as seen in this case.

CASE STUDY: AGGRESSIVE SIGNET RING CELL GASTRIC ADENOCARCINOMA IN A YOUNG MAN Lauren Choi; Nardos Temesgen. George Washington University, Washington, DC. (Control ID #2689863)

LEARNING OBJECTIVE #1: The incidence of signet ring cell gastric adenocarcinoma is a rising, particularly among younger, otherwise healthy patients.

LEARNING OBJECTIVE #2: Signet cell gastric cancer can initially present as an infiltrative bone marrow process with severe cytopenias.

CASE: A 26 year old previously healthy man presented to the George Washington University Emergency room with 3 days of pre-syncope and significant weakness. He endorsed recurrent epistaxis, fevers and chills. His vital signs were remarkable for tachycardia and fever. He was remarkably pale, with dry mucous membranes. Serum studies showed a hemaglobin concentration of 4.0 g/dL and a platelet count of 96×10^3 cells/microliter. Twenty days prior, his hemaglobin concentration was 13.9 g/dL and platelet count was 163×10^3 cells/microliter. His prothrombin time was elevated, with an international normalized ratio of 1.48. His serum alkaline phosphatase was also elevated at 305 international units per liter. A peripheral smear showed myelophthisic disease with teardrop cells, schistocytes, polychromasia, and many nucleated red blood cells. A CT demonstrated mediastinal, bilateral hilar,

abdominal and retroperitoneal lymphadenopathy, suggestive of lymphoma. A lymph node biopsy atypical hyperchromatic cells with a signet-ring like appearance. It was CK20 positive, CK7 negative, TTF-1 negative, and CDX-2 showed focal weak reactivity, suggesting a GI primary cancer. Gastric biopsy confirmed gastric signet ring cell carcinoma. He was offered palliative chemotherapy with Oxaliplatin, Mitomycin, Doxorubicin, Capecitabine. Unfortunately, he passed away after 4 months of treatment.

IMPACT: Over the last 30 years, the incidence of gastric carcinoma has been declining worldwide, but the incidence of diffuse-type carcinoma, especially signet ring cell carcinoma, has been increasing. Because of these changing trends, internists must be more vigilant about diagnosing signet ring cell carcinoma, as this form is found in younger patients who do not have any risk factors.

DISCUSSION: Our patient is a previously healthy 26 year old man who presented with severe, symptomatic anemia. He was eventually diagnosed with signet ring cell gastric carcinoma with bone marrow infiltration. Signet ring cell gastric adenocarcinoma has a higher rate of bone marrow metastasis compared to other forms of gastric adenocarcinoma. Once bone marrow metastasis occurs, the mortality rate is very high. The average life expectancy is 44 days from the time of documented bone marrow involvement. This case is significant for two reasons. First of all, it highlights the importance of a broad differential diagnosis when evaluating a patient with severe, symptomatic anemia. Second of all, the incidence of signet ring cell gastric adenocarcinoma is rising, particularly among young, otherwise-healthy patients.

CAT FANCIER'S PNEUMONIA: A CASE OF PASTEURELLA MULTOCIDA PNEUMONIA Neelesh Rastogi[1]; Jacqueline Hirsch[1]; Craig Tenner[2]. [1]New York University School of Medicine, New York, NY; [2]VA New York Harbor Healthcare System, New York, NY. (Control ID #2692987)

LEARNING OBJECTIVE #1: Describe a rare presentation of *Pasteurella multocida* pneumonia without history of cat bite

CASE: An 84 year old male with a history of HTN, HLD, BPH, PVD, extensive smoking presented to the ER with small volume hemoptysis of 1 day duration. He reported having a cough productive of scant amounts of clear/yellow phlegm for a few weeks prior to developing hemoptysis. Review of systems was only notable for fatigue. He emigrated from Puerto Rico in the 1950s and lives in an apartment with one cat that often sleeps in his bed with him. Exam showed a well-appearing man, afebrile with a HR of 103, RR of 20, BP of 165/92, saturating 94% on ambient room air. Pulmonary exam was notable for dry crackles throughout both lung fields. Hemoglobin was stable without leukocytosis. In the ER, patient underwent CT chest angiography revealing diffuse mediastinal lymphadenopathy, diffuse interstitial lung disease, and a pleural-based infiltrate in the left upper lobe. The diffuse lung disease had been stable since 2006. The patient was admitted and placed on airborne isolation for further workup. Overnight on hospital day 1, the patient spiked a fever and was started on Unasyn to cover for community acquired pneumonia. Sputum acid-fast bacilli smear returned positive x2 and PCR later revealed Mycobacterium avium complex (MAC), thought to be a colonizer. Bacterial sputum cultures grew *Pasteurella multocida*. The patient improved on IV Unasyn for *Pasteurella* and hemoptysis resolved. The patient was discharged from the hospital on hospital day 9 with a plan to complete a 14-day course of antibiotics.

IMPACT: This case broadened our differential when an immunocompetent patient presents with fevers and hemoptysis and also shed light on a rare presentation of *Pasteurella multocida* infection.

DISCUSSION: *Pasteurella multocida*, is a gram negative bacilli most abundantly found in the oral cavity of cats. Pasteurella has been transmitted to humans most commonly through animal bites or scratches. Severe infection in previously healthy individuals without occupational exposure or bite/scratch history is thought to be extremely rare. *Pasteurella* pneumonia usually presents with non-specific symptoms, including fever, malaise, dyspnea, pleuritic chest pain, and sometimes hemoptysis. Though our patient's sputum was also positive for MAC, adding an extra layer of challenge in treating him, the acuity of the his illness, sputum findings, improvement on Unaysn all argued for *Pasteurella* Pneumonia as the main culprit of this patient's presentation. Our patient appeared to contract *Pasteurella* pneumonia without direct mucous secretion exposure, presumably only from sharing a bed with his cat. This is an exceedingly rare cause of *Pasteurella* pneumonia, but not completely unheard of. Given the presence of other case reports available of rare, but similar presentations of *Pasteurella* pneumonia in the elderly or those with underlying lung disease, we propose that this disease entity be called "Cat Fancier's Pneumonia".

CAT GOT YOUR TONGUE ? A CASE OF NON-CONVULSIVE STATUS EPILEPTICUS (NCSE) PRESENTING WITH MUTISM

rajan gurunathan[1, 2]; Pamela Lobo[1]; scott segan[1]. [1]SBH Health System, Bronx, NY; [2]CUNY School of Medicine, NY, NY. (Control ID #2707684)

LEARNING OBJECTIVE #1: Recognize the clinical features and diverse symptoms associated with NCSE

CASE: A 44 year old male with a history of drug abuse presented to the ER for evaluation of altered behavior. As per his friends, the patient abruptly began refusing to eat or answer questions several days ago. On arrival he appeared well, but would only open his eyes to acknowledge his interviewer and not answer questions. No further history was available. Physical exam was otherwise unremarkable, and no automatisms or rhythmic movements were noted. Serum chemistry, CBC, ammonia, alcohol level, and urine toxicology were unrevealing, and CT brain was normal. On hospital day 2, an EEG was ordered, and psychiatry and neurology were called. The EEG revealed diffuse rhythmic delta waves with some epileptiform activity intermixed over the left temporal region, suspicious for a diagnosis of NCSE, and the patient was loaded with IV Fosphenytoin. Within a few hours the patient was able to speak a few words, and the next morning he was talking and answering questions. He then reported a history of a similar episode years prior that resolved without treatment. Repeat EEG showed improvement, and the patient remained neurologically intact.

IMPACT: Status epilepticus occurs as a result of neural mechanisms which lead to abnormally prolonged seizures, or from the failure of mechanisms responsible for seizure termination. NCSE is defined as status epilepticus without prominent motor signs, and can be a serious diagnostic challenge that is often under-recognized and misdiagnosed, therefore a high index of suspicion is required to make the diagnosis.

DISCUSSION: NCSE can typically be categorized by an impaired level of consciousness; changes in behavior with automatisms (subconscious movements); and/or alteration in muscle tone resulting in posturing or fine motor twitching. While uncommon when compared with other epileptic syndromes, it has been estimated to affect 3–10% of patients presenting to emergency rooms with altered consciousness or coma, and the subtle nature of its symptoms may make it difficult to recognize. Patients with NCSE can be broken down into 2 main types: those with primary generalized seizures (absence status), and those with complex partial seizures. Symptoms associated with

NCSE are diverse, but can be grouped into “negative symptoms,” such as aphasia, mutism, amnesia, or catatonia; and “postitive symptoms,” such as rhythmic twitching of one or more muscle groups, ocular deviation, or nystagmoid eye-jerking. Over 50% of patients presenting with NCSE will have prior history of seizures, though other risks include recent neurosurgery, coma, sepsis, and benzodiazepine discontinuation. Precipitants include infection, sleep deprivation, excess alcohol intake, withdrawal from anti-epileptic drugs (AED), psychotropic meds, and emotional stress. Prompt recognition and initiation of treatment with benzodiazipines or AED therapy is key, as there is significant risk for neurologic sequelae and mortality.

CAT SCRATCH DISEASE (CSD) - AN ATYPICAL MANIFESTATION WITH VISCERAL ORGAN INVOLVEMENT IN ELDERLY IMMUNOCOMPETENT PATIENT Brian V. Dinh; Olusola Isikalu; Shruti Patel; Sara Keiler. Wright State University, Dayton, OH. (Control ID #2706222)

LEARNING OBJECTIVE #1: Recognize clinical and radiological findings of cat scratch disease involving visceral organs.

CASE: 71-year-old Caucasian male with significant history of hypertension, type 2 diabetes mellitus presented malaise, fatigue, anorexia, subjective fevers, and confusion for 1 week. Physical examination revealed alert and oriented male with unremarkable cardiopulmonary, abdominal, lymph node, and neurologic exam. Skin was notable for 0.5 cm round erythematous papule at the right wrist. Laboratory analysis showed normal complete blood count, urinalysis, and chemistries. C-reactive protein was 82.4 mg/L. Chest radiograph showed questionable infiltrate so moxifloxacin was empirically started for concern of pneumonia. Despite antibiotics, patient was febrile up to 102.9 °F for 3 days, while cultures remained negative. CT imaging showed no acute pulmonary process, but revealed hepatosplenomegaly with numerous nonspecific hypodense hepatosplenic lesions. PET/CT showed increased avidity in right axillary lymph node, supraclavicular area, and diffuse focal splenic uptake. Moxifloxacin was held with subsequent defervescence. Legionella antigen, viral hepatitis, HIV, CMV, monospot and fungal serologies were negative. Further history revealed that the patient had a stray kitten for the previous 6 months and recalls a healing linear cat scratch of the right forearm. Bartonella henslae (*B. henslae*) immunoglobulin G titer were obtained, and azithromycin and rifampin were empirically started for suspected CSD. Titers returned >1:1024, confirming the diagnosis of disseminated CSD.

IMPACT: With the case presented, our practice has been greatly changed to consider a large differential with findings of visceral organ hypodensities on imaging. History taking combined with physical, radiological, and laboratory findings are key in making the correct diagnosis.

DISCUSSION: Rarely, CSD presents with disseminated hepatosplenic lesions identified on imaging. CSD manifests as self-limiting fevers and limited regional granulomatous LAD in 85% of patients, asymmetric axillary LAD in about 46% of patients, and hepatospenic lesions in 2.3% of cases. In young or immunocompromised patients, atypical presentations can include visceral organ, neurological, and ocular involvement with associated encephalopathy, transverse myelitis, Parinaud’s oculoglandular syndrome, or optic neuritis. Biopsy of visceral organ lesions would reveal necrotizing granulomas. Cutaneous involvement occurs 3 to 10 days after inoculation, and LAD arises proximally to inoculation site after 2 weeks. CSD with limited LAD is treated supportively or with azithromycin and rifampin is added for disseminated disease. Interestingly, fluoroquinolones have in vitro activity against *B. henslae* which could explain defervescence with moxifloxacin. In challenging cases with fever of unknown origin and imaging suggesting infection, a detailed history and physical, clinical suspicion, and broad differential to include CSD are key in making the diagnosis.

CATCH ME IF YOU CAN: PULMONARY COCCIDIOIDOMYCOSIS AND NON-TUBERCULOUS MYCOBACTERIUM PRESENTING AS COMMUNITY-ACQUIRED PNEUMONIA Jonathan P. Salud; Robin Klein. Emory University School of Medicine, Atlanta, GA. (Control ID #2705218)

LEARNING OBJECTIVE #1: Recognize that persistent symptoms in the appropriate setting raise concern for an atypical pulmonary infection.

LEARNING OBJECTIVE #2: Review the presentation of atypical pulmonary infections such as coccidioidomycosis.

CASE: A 46 year-old male presents with cough, fever, and fatigue for 7 days. He reported weight loss but no night sweats or hemoptysis. Travel included a trip to California and Arizona 10 days prior to symptom onset, and remote travel to Mexico. He denied animal contact, occupational exposures, or use of hot tubs. After 2 days of symptoms, he was evaluated in clinic and treated with azithromycin without improvement. On admission, he was febrile and hypoxic with temperature of 38.9 °C and saturation of 93%. Exam revealed decreased breath sounds and crackles in the right upper anterior lung field. Laboratories showed WBC 14,300/mcL, total protein 7.6 g/dL and albumin 3.1 g/dL. Imaging showed right upper lobe consolidation and ground glass opacity. Blood cultures, HIV and hepatitis serologies, urine *Histoplasma* and serum *Cryptococcus* antigen were negative. Bronchoscopy showed no endobronchial lesions, cytology was negative, and respiratory viral cultures were negative for influenza, parainfluenza, RSV, HSV, and CMV. He remained febrile with leukocytosis and persistent cough. He was diagnosed with community-acquired pneumonia and treated with moxifloxacin, with gradual symptom resolution. After discharge, respiratory cultures grew 3+ *Coccidioides* species, and serum *Coccidioides* IgM antibody was detected. Sputum and respiratory culture later grew *Mycobacterium avium complex*.

IMPACT: Persistent symptoms in the appropriate setting raise the possibility of certain atypical pulmonary infections. History is the first step to ascertain this, and proved to be key in diagnosing pulmonary coccidioidomycosis and *Mycobacterium avium complex*.

DISCUSSION: Atypical pulmonary infections refer to infections not caused by one of the more traditional bacteria pathogens. *Coccidioides* are spore-forming fungi found in the southwestern US and Mexico that can cause symptoms of fever, cough, weight loss, and marked fatigue. Image findings can resemble that of classic community-acquired pneumonia. Uniquely, recent or active infection is conferred by detection of either IgG or IgM antibodies. Current guidelines advise close observation for these patients if symptoms are mild. *Mycobacterium avium complex* (MAC) is the most common non-tuberculous mycobacterium pathogen in the US. Pulmonary MAC often presents as cavitary disease in older white male smokers, or as nodular/ bronchiectatic disease in nonsmoking older females, but presentation can vary. In this case, recent travel to the southwestern US pointed to *Coccidioides* as a potential etiology, and culture confirmed the diagnosis of pulmonary coccidioidomycosis and MAC. Physicians should be cognizant that persistent pulmonary symptoms in an immunocompetent patient warrant thorough history in order to ascertain the likelihood of an atypical pathogen as the cause.

CAVITARY LESIONS IN THE LUNG WHAT CAN THEY BE

Tehseen Haider; Kezia Ann Sam; Charles Fishman. montefiore medical center, Bronx, NY. (Control ID #2702757)

LEARNING OBJECTIVE #1: Identify different causes of cavitary lung lesions.

LEARNING OBJECTIVE #2: Consider chronic invasive aspergillosis as a cause of cavitary lung lesions in immunocompetent host.

CASE: A 33 year old man (former smoker - 5 pack years) with history of asthma presented with complaints of dry cough and shortness of breath for 3 weeks. He was febrile to 101.7 °F with cachexia and bilateral rales on exam. He had white blood cell count (WBC) of 10.6 k/uL (granulocytes 76%, eosinophils 2%). Initially he was treated with broad spectrum antibiotics for bacterial infection, with no relief. Further workup showed CD4 count of 376 cells/uL, negative HIV, normal ACE level, indeterminate mycobacterium interferon assay, serum aspergillosis galactomannan antigen of 0.084 (reference range <0.5), negative cryptococcal antigen, negative ANCA and negative respiratory bacterial and acid fast bacilli sputum cultures. CT-scan showed chronic parenchymal changes with upper lobe volume loss, fibrosis, and multiloculated cavities. He underwent bronchoscopy, revealing non-necrotizing granulomas and necro-inflammatory tissue with clusters of fungal species suggesting chronic invasive pulmonary aspergillosis (CPA). He was treated with voriconazole with improvement in his symptoms.

IMPACT: Diagnosing CPA can be challenging. Outcome largely depends on early diagnosis and treatment.

DISCUSSION: The differential diagnosis for cavitary lung lesions includes infectious and noninfectious causes. Infectious causes include necrotizing pneumonias, lung abscesses, septic pulmonary emboli, HIV, and fungal, mycobacterial and parasitic infections. Noninfectious causes are Wegner's granulomatosis, sarcoidosis, Langerhans's cell histiocytosis, and others. Usually Aspergillus causes lung disease in immunocompromised host, or in patients with underlying lung disease. CPA is a spectrum of diseases ranging from simple aspergilloma to progressive cavitary aspergillosis. Prevalence varies from <1 case/100,000 in developed countries to 42.9/100,000 in underdeveloped. Inflammatory makers such as CRP and sedimentation rate are very commonly elevated but are not specific. Serum total IgG, IgE, and Aspergillus specific IgG (cardinal test) levels are elevated. Sputum cultures are often positive (10-40%), but negative cultures do not rule out disease. Aspergillus PCR from sputum has high false positive rates due to contamination or colonization. Galactomannan is positive sometimes (38% sensitivity for serum vs 92% for bronchoalveolar lavage), while serum 1–3 beta glucan is unreliable. Ultimately, diagnosis relies on a combination of clinical presentation, imaging, serology, cultures, and underlying risk factors. Treatment includes systemic antifungals, local instillation, and sometimes surgical resection if necessary.

CENTRAL VENOUS CATHETER PLACEMENT A ROUTINE PROCEDURE WITH UNEXPECTED COMPLICATIONS

Rahul Nair; Sangeetha Venugopal; Manoj Karwa. Montefiore Medical Center, Wakefield Campus, New York, NY. (Control ID #2700955)

LEARNING OBJECTIVE #1: Recognize the rare but lethal side effect of heart blocks in central line insertion.

CASE: A 67 year-old woman with history of upper gastrointestinal bleeding and end stage renal disease on hemodialysis was admitted with symptomatic anemia secondary to acute onset of melena. Electrocardiogram (EKG) showed normal sinus rhythm with left axis deviation and pre-existing left bundle branch block (LBBB). She was transferred to the intensive care unit for hemodynamic monitoring. A decision was made to insert a trialysis catheter, as her AV fistula for dialysis access was clotted. The CVC was introduced using the Seldinger technique into the right internal jugular vein. While inserting the guide wire, at about 20–25 cm she started to develop bradycardia to 40s on cardiac monitor. Guide wire was immediately withdrawn and patient went into asystole and became unresponsive. She was revived as per Advanced Cardiac Life Support protocol with return of spontaneous circulation in 40 sec. Post-cardiac arrest EKG revealed normal axis with right bundle branch morphology with slow ventricular escape rhythm at approximately 26/minute and atrio-ventricular dissociation, which did not respond to Atropine requiring emergent trans-venous pacemaker insertion. Repeat panel of cardiac enzymes were normal. Her complete heart block resolved and she returned to baseline cardiac rhythm within twenty four hours.

IMPACT: It is essential to recognize those patients at higher risk of complications such as heart blocks during central line placement. Patients with prior LBBBs are at greatest risk, and carefully reviewing an EKG prior to CVC insertion is crucial. CVC insertions are commonly done without cardiac monitoring. We emphasisize that it is essential to have such procedures done in a monitored environment with careful assessment of telemetry while such procedures take place.

DISCUSSION: In our patient, the transient complete heart block was caused by trauma to the right bundle branch by the guide wire, causing bilateral bundle branch block in the setting of pre-existing LBBB. Eissa et al. described a case akin to our patient, suggesting complete heart block as a potential complication of CVC placement when a contralateral bundle branch is present (1).Additionally, having a patient on cardiac monitoring while the procedure is taking place is vital to quickly identify and reverse such complete heart blocks. Andrews et al. assessed the safest distance for guide wire access in a non-randomized prospective trial. The right IJV distance was the shortest, averaging about 16 cm and it was deemed that 18 cm to be considered as the upper limit for guide wire insertion (2). It pays to be vigilant during guidewire insertion so as not to exceed 18 cm in length. And to always have the patient in a monitored setting with dedicated personnel looking at the cardiac monitor during such procedures to recognize the possibility of complete heart block as a potential complication in patients with pre-existing LBBB.

CHASING THE K

Shakera Syed; Doris Yang; Dipen Khanapara; Colette Knight. Montefiore Medical Center Wakefield Campus, Bronx, NY. (Control ID #2706742)

LEARNING OBJECTIVE #1: Recognize secondary causes of hypertension in the setting of hypokalemia.

LEARNING OBJECTIVE #2: Describe the work-up for diagnosis of primary aldosteronism as a cause of secondary hypertension

CASE: 33-year-old woman with no significant past medical history presented to urgent care complaining of headaches. Blood pressure was 209/122 mm Hg. Physical exam was unrevealing. Therapy was initiated with hydrochlorothiazide 12.5 mg daily and symptoms improved. Three days later blood tests revealed a low serum potassium of 2.5 mEq/l which prompted an urgent referral to the hospital. Upon presentation to the hospital the patient's blood pressure was 173/106 mmHg. Physical examination was unremarkable. Hypokalemia was refractory to medical management. A workup for secondary causes of hypertension showed Plasma cortisol and urine metanephrines were within normal range,

plasma renin activity was suppressed to 0.13 ng/mL/h and plasma aldosterone was elevated to 62 ng/dL. An abdominal CT Scan revealed a right adrenal nodule measuring 2.4 cm × 1.5 cm with characteristics typical for adrenal adenoma. The presentation was suggestive of primary aldosteronism and the patient was treated with spironolactone. On her follow up visit, blood pressure improved significantly and the potassium level was 3.5 mEq/l.

IMPACT: Consider secondary causes of hypertension especially in young patients with associated hypokalemia.

DISCUSSION: Primary hyperaldosteronism(PA) constitutes about 10% of the diagnosis of secondary hypertension. Idiopathic hyperaldosteronism and aldosterone-producing adenomas account for more than 95% of the cases with PA. Patients with hypertension and hypokalemia, regardless of suspected cause (diuretics, incidentaloma), and patients with medically-resistant hypertension, should be considered for screening for primary hyperaldosteronism. Initial screening tests show suppressed Plasma Renin Activity (PRA) and increased Plasma Aldosterone Concentration(PAC) with the PAC/PRA ratio >20 ng/dL per ng/mL/hour. The combination of a PAC above 20 ng/dL and a PAC/PRA ratio above 30 had a sensitivity and specificity of 90 percent for the diagnosis of aldosterone-producing adenoma. These screening tests are not employed in older normokalemic patients with hypertension. Adrenal venous sampling has a high sensitivity and specificity for detecting unilateral aldosterone excess and ideally should be performed prior to surgical resection. In patients with bilateral adrenal hyperplasia or adenomas and in patient who are not surgical candidates, medical management is considered. Spironolactone has been preferred over Eplerenone because of reduced cost, greater efficacy and easy availability. However, Eplerenone causes fewer anti- androgenic side effects.

CHRONIC DIARRHEA AND ZOLLINGER-ELLISON SYNDROME (ZES) : WELL-DOCUMENTED YET RARELY SOLICITED

Archana A. Kulkarni[1]; Pritam Tayshetye[1]; Marcia Mitre[2]. [1]Allegheny Health Network, Pittsburgh, PA; [2]Allegheny Health Netwrok, Pittsburgh, PA. (Control ID #2707675)

LEARNING OBJECTIVE #1: This case signifies considering Zollinger-Ellison syndrome (ZES) as a differential diagnosis of chronic diarrhea

CASE: 75 year-old male with history of Barrett's esophagus on chronic proton-pump inhibitor (PPI) therapy presented to the hospital with nausea, vomiting, diarrhea and dehydration. On further questioning he had chronic diarrhea since the last 45 years and was on PPI therapy for atleast >30 years. On admission to the hospital he was found to have acute kidney injury with elevated creatinine of 3.0 mg/dL (baseline 0.9–1.1 mg/dL) and BUN of 63 mg/dL (baseline 14–18 mg/dL). Stool clostridium difficile toxin was positive and metronidazole 500 mg every 8 hours was initiated. A CT scan of the abdomen demonstrated distension of the stomach with gastric wall thickening. A follow up EGD displayed esophagitis, gastritis and prominent gastric rugae. Subsequent to the EGD findings, a gastrin level was checked which was noted to be 303 after holding the PPI for a >48 hours (normal: <100 pg/mL). This was followed by a secretin stimulation test which confirmed increased gastrin levels to 1716 pg/mL 5 min after secretin injection with reproduction of symptoms of nausea, vomiting and diarrhea. An octreotide scan confirmed somatostatin receptor positive abnormality in the area of the duodenum. The patient subsequently had a repeat CT abdomen and pelvis which noted a 1.4 centimeter thickening in the second portion of the duodenum. A repeat EGD showed Barrett's esophagus and a mass in the second portion of the duodenum which was biopsied and was resulted as benign. A EUS was performed with fine needle aspiration of the mass which was again benign. Patient was resumed on omeprazole daily. With no resolution of symptoms he was then referred for surgical resection and a distal gastrectomy, proximal duodenectomy and resection of duodenal mass was performed. The pathology of resection specimen was consistent with a 1.9 cm well-differentiated, low grade (G1) neuroendocrine tumor. Immunohistochemistry testing was positive for chromogranin and synaptophysin and the mitotic rate was less than 1 per 100 hpf. The TNM staging was T2N0MX. The patient continues to be treated with omeprazole with plans to possibly discontinue it in near future. He has remained symptom free without any diarrhea since the surgery and his gastrin levels have decreased to a normal level of 67 pg/mL.

IMPACT: With delayed diagnosis, complications arise as seen in this case with Barrett's esophagus because of gastric acid hypersecretion.

DISCUSSION: Chronic diarrhea occurs because of multiple mechanisms in ZES. Complete removal of the lesion is the main curative treatment when gastrinomas are sporadic and not a part of MEN1 syndrome. Medical management includes high dose PPIs or somatostatin analogues such as octreotide. Patients without metastatic disease should be offered surgery with curative intent as it has been demonstrated to protect against the possible morbidity and death from metastatic spread.

CHRONIC EOSINOPHILIC PNEUMONIA: A DIAGNOSIS TO CONSIDER IN PATIENTS WHO FAIL TREATMENT OF INFECTIOUS PNEUMONIA Shivani Thanawala; Aron Mednick. New York University School of Medicine, New York, NY. (Control ID #2706987)

LEARNING OBJECTIVE #1: Recognize clinical features of chronic eosinophilic pneumonia

LEARNING OBJECTIVE #2: Diagnose eosinophilic pneumonia when imaging is atypical

CASE: A 42-year-old male with history of hypertension and asthma presented with intermittent cough and progressive dyspnea over eight months. His symptoms were more pronounced in the two months leading to admission, during which time he had outpatient treatment with 5 courses of simultaneous oral antibiotics and steroids. Outpatient CT scan of the chest during this time showed diffuse bilateral ground glass opacities, interpreted as atypical infection and inflammatory changes. His symptoms temporarily improved with therapy; however, he was ultimately admitted due to progression of symptoms. On admission, he reported dyspnea at rest, cough productive of yellow sputum, and 20 lb unintentional weight loss over six months. He denied fevers, recent travel, or smoking. Initial vital signs and exam were normal. Labs were notable for WBC 14,000 with 5% eosinophils (750/μL) and elevated ESR and CRP. A repeat CT of the chest showed airspace consolidations primarily in a central and peribronchovascular distribution, with differential diagnosis including infection, organizing pneumonia, vasculitis, chronic eosinophilic pneumonia (CEP), and neoplasm. Blood cultures, HIV, 1,3 beta-d-glucan, galactomannan, ANA, p-ANCA, and c-ANCA were unremarkable. For tissue diagnosis, patient underwent video-assisted thoracoscopy with wedge resection, complicated by an apical pneumothorax requiring chest tube placement. Pathology showed numerous eosinophils in alveolar airspaces, consistent with CEP. Patient was started on high dose steroids with clinical improvement. He was discharged home with a chest tube and continued steroid treatment.

IMPACT: In future practice, diagnoses other than infection should be considered earlier in patients with a history of atopy who fail multiple courses of outpatient

antibiotics for presumed pneumonia. Furthermore, CEP can be diagnosed with elevated eosinophil count in broncho-alveolar lavage (BAL) fluid. For a patient with peripheral eosinophilia and symptoms consistent with CEP, BAL is the less invasive and more appropriate first diagnostic test over open lung biopsy.

DISCUSSION: This patient's chronic dyspnea and cough, weight loss, lack of improvement with antibiotics, and unrevealing infectious and rheumatologic workup made CEP and cryptogenic organizing penumonia (COP) leading differential diagnoses. The classic radiographic appearance of eosinophilic pneumonia is peripheral upper-lobe ground glass infiltrates, which is seen in approximately two thirds of patients with this disease. About three quarters of patients have peripheral eosinophilia. While imaging of COP may appear similar to CEP, peripheral eosinophilia is not typically present, and open lung biopsy is required to make the diagnosis. This patient's classic symptoms along with peripheral eosinophilia pointed toward a diagnosis of CEP even in the absence of typical radiographic findings.

CHRONIC LYMPHOCYTIC LEUKEMIA: A RARE CAUSE OF THE PATHOLOGICAL FRACTURE OF THE FEMUR Parita Soni; Anand Rai; Vivek Kumar; Nidhi Aggarwal; Taek Yoon; Yizhak Kupfer. Maimonides Medical Center, Brooklyn, NY. (Control ID #2706750)

LEARNING OBJECTIVE #1: Although bony involvement or pathological fracture is very rare to happen in cases of Chronic Lymphocytic Leukemia (CLL), it can sometimes be the initial presentation of the CLL.

LEARNING OBJECTIVE #2: With this case, we emphasize that all the physicians should evaluate for pathological fracture of long bones in patients with CLL complaining of bone/joint pain.

CASE: An 85-year-old Caucasian female with a history of CLL, atrial fibrillation, congestive heart failure and hypertension, presented to the emergency room with shortness of breath. She was diagnosed with CLL 6-years ago and refused therapy. On presentation her temperature was 101.3 F, HR 130/min, RR 32/min, BP 156/67 mmHg and Spa02 80% on room air which improved minimally on BiPAP. She was intubated, admitted to the MICU and was successfully extubated after 2-days. Laboratory work showed WBCs 107 K/UL, hemoglobin 10.4 gm/dl, platelets 149 K/UL, 2+ smudge cells on peripheral smear. On day 3 of hospitalization, she started complaining of severe left knee pain and denied any trauma or fall. On examination it was warm and extremely tender to touch. Arthorcentesis was performed and septic arthritis was ruled out. X-ray and CT scan showed acute pathological fracture of the left distal femur. She was not an operative candidate and thus was treated conservatively with brace and pain control. Her fracture was stabilized with Extension Lock Splint (ELS).

IMPACT: Review of literature suggests that the pathological fracture in patients with CLL are mostly associated with vertebral compression fractures. To our knowledge, this is the first case of pathological fracture of the femur secondary to CLL.

DISCUSSION: Chronic Lymphocytic Leukemia (CLL) is a lymphoproliferative disorder predominantly diagnosed around the age of 50 years. The presentation varies from totally asymptomatic to the eventual development of anemia, thrombocytopenia and infections due to involvement of lymph nodes, spleen and liver. Bony involvement in leukemia is most commonly associated with acute lymphoblastic or acute myeloblastic leukemia. CLL involving bone leading to the pathological fracture is rare (1). Review of literature suggests that the exact pathophysiology of the pathological fracture in CLL is not known but may be secondary to locally released osteoclast stimulating factors. Many times it is associated with Richter's transformation or multiple myeloma which were absent in our case. Prior reports of pathological fracture associated with CLL involved vertebral compression fractures. To our knowledge, this is the first case of pathological fracture of the femur secondary to CLL. We therefore suggest to evaluate for pathological fracture of long bones in patients with CLL complaining of bone/joint pain. References: Langenberg JC, et al. Pathological fractures in a patient with chronic lymphatic leucaemia without disease progression. BMJ Case Rep. 2015 Feb 25;2015;doi: 10.1136/bcr-2014-208118.

CHRONIC MOTHBALL TOXICITY IN SETTING OF CIRRHOSIS Krupa Parikh[1]; Genevieve Bergeron[2]. [1]Cambridge Health Alliance, Somerville, MA; [2]Cambridge Health Alliance, Cambridge, MA. (Control ID #2707480)

LEARNING OBJECTIVE #1: Recognize constellation of clinical findings to suspect Para-dichlorobenzene (PDCB- Mothball) toxicity.

LEARNING OBJECTIVE #2: To address underlying diseases that may precipitate mothball toxicity.

CASE: A 51 year old female with a history of alcoholic cirrhosis, fatty liver disease, autoimmune hepatitis, active alcohol and tobacco use disorder, and depression initially presented with a one month history of ataxia, weakness, blurry vision, and an extensive hyperpigmented, hyperkeratotic rash. During that hospitalization she was treated for hepatic encephalopathy and discharged home. However, the patient returned 1 month later after a fall and with continued progression of prior symptoms. At that time, patient's family provided collateral about her chronic mothball use. Patient had been sucking on mothballs since she was 8 years old for 30 min every evening; there was no increase in the amount of ingestion. She had no prior history of rash or ataxia. On exam, she was found to have extensive hyperkeratotic, hyperpigmented plaques along bilateral hands, forearms, and distal lower extremities. Neurologic evaluation showed mild wide-based gait and difficulty with memory and cognition. MRI Brain showed was normal with no evidence of leukoencephalopathy. Fundoscopic exam was normal. MELD score was 15. Patient discontinued mothball ingestion. There was resolution of rash within one month and normal gait after three months after cessation of mothball ingestion. After 5 months MELD score decreased to 12.

IMPACT: Chronic PDCB toxicity causes reversible neurotoxicity and rash, with studies reporting onset of symptoms 2 months to 6 years after exposure. This patient's 43-year ingestion history is longer than what has previously been reported. The progression of her cirrhosis may have caused her symptoms. PDCB is metabolized by the liver, and cirrhosis decreases the metabolism of PDCB. The relationship between progressive liver disease and mothball toxicity is a novel addition to the literature.

DISCUSSION: Mothballs are a commonly used fumigant and these days are composed of PDCB. Toxicity is usually due to occupational exposure, and toxicity from ingestion is rare. Chronic toxicity affects liver, skin, central and peripheral nervous system. The reversible neurotoxicity from mothball intoxication has been well documented; gait instability is present in almost every case. A hyperkeratotic rash is also a characteristic of chronic toxicity. There are no studies that show how pre-existing liver disease affects PDCB metabolism. Conversely, there are no human studies of how PDCB affects progression of liver disease. Murine models show PDCB causes increased liver weights and centrilobular necrosis. Progressive hepatic disease may precipitate PDCB toxicity. We advocate for further studies to understand the relationship between underlying liver disease and PDCB accumulation.

CLASSICAL HODGKIN'S LYMPHOMA PRESENTING AS ACUTE CHOLANGITIS Janice Jang. New York University School of Medicine, New York, NY. (Control ID #2691417)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of Hodgkin's lymphoma.

CASE: A 54-year-old Hispanic woman presented with 5 days of subjective fevers, jaundice, nausea, vomiting, and right-sided abdominal pain. On presentation, she was febrile with borderline hypotension and tachycardia, abdominal tenderness, and laboratory values notable for leukopenia and transaminitis with direct hyperbilirubinemia. The patient received vancomycin, cefepime, metronizadole, and intravenous fluids per sepsis protocol. She was intubated for an emergent ERCP, which revealed a possible common bile duct stricture for which a stent and cholecystectomy drain were placed. Bile cultures grew *Staphylococcus epidermidis*, *Enterococcus faecalis* and candida, while blood cultures remained negative. Despite antibiotics, the patient remained persistently febrile with worsening hyperbilirubinemia and altered mental status. MRI of the abdomen revealed numerous hyperintense lesions of the liver and MRCP confirmed multiple hepatic lesions. A liver biopsy was performed with pathology revealing Epstein-Barr virus positive mixed inflammatory cells with immunophenotype studies consistent with a diagnosis of classical Hodgkin's lymphoma (HL). She received one dose of doxorubicin and gemcitabine, however, she was unable to tolerate further chemotherapy and died within days after treatment.

IMPACT: This case highlights the importance of maintaining a broad differential diagnosis in a patient with presumed cholangitis and no response to antibiotics. It is important to consider cholangitis as an atypical presentation of HL in order to prevent delays in treatment and diagnosis, as HL has an excellent prognosis when treated early.

DISCUSSION: With an incidence of 2.6 per 100,000 people per year in the United States, Hodgkin's lymphoma is a rare disease. It typically presents with constitutional "B symptoms" such as fevers, night sweats, weight loss, and fatigue, in addition to painless lymphadenopathy. Though liver infiltration is frequently seen in patients with advanced HL, initial presentation with acute cholangitis leading to a diagnosis of HL is rarely seen. As such, the patient's hepatic lesions on the MRI were thought to be most likely foci of abscesses, given her clinical context of septic cholangitis and it was only after the pathology report was released that a hematological malignancy was considered as the underlying illness. Our patient's clinical presentation is attributable to lymphomatous cells infiltrating the liver, causing bile duct necrosis, obstruction and ultimately cholangitis.

CLINICAL DILEMMA IN SLE: MANAGING DIFFUSE ALVEOLAR HEMORRHAGE IN THE SETTING OF DEEP VENOUS THROMBOSIS. Anuhya Kommalapati[1]; Allan-Louie Cruz[2]; Joseph Catlett[2]. [1]Washington Hospital Center, Silver Spring, MD; [2]Washington Hospital Center, Washington, DC. (Control ID #2706551)

LEARNING OBJECTIVE #1: Managing a patient with systemic lupus erythematosus (SLE) and acute deep venous thrombosis (DVT) presenting with hemoptysis while on rivaroxaban.

CASE: We describe a case of a 28-year-old African American male with past medical history of SLE complicated by acute non-provocative lower extremity DVT. He was started on Rivaroxaban 15 mg twice daily. Four days after initiation of Rivaroxaban, the patient presented to our emergency department with the complaints of shortness of breath, cough with bloody sputum. His vital signs on presentation: Temperature: 37 C, Blood Pressure: 118/78 mm Hg, heart rate: 68/min, saturating 92% on ambient air. Physical examination is remarkable for bloody sputum on coughing and tender right lower extremity. Laboratory values on presentation were: hemoglobin 11.4 g/dL, hematocrit 35.5%, WBC 5.9x10^3/mcl, platelet count 350x10^3/mcl, PT 18.7 sec, INR 1.6, PTT 24 sec, antinuclear antibody speckled pattern 1:640, Anti-smith >8 Anti-dsDNA >1:1280 (positive), C4 7 mg/dL, C3 66 mg/dL. Urinalysis showed moderate proteinuria with 1.9gm/24 h. Liver function and basic metabolic panel were within normal limits. Lupus anticoagulant, anticardiolipin antibody and beta-2 glycoprotein 1 IgG and IgM antibodies were negative. Diffuse alveolar hemorrhage (DAH) was diagnosed on bronchoscopy. We had a dilemma about managing the patient's DAH in the setting of DVT. We discontinued rivaroxaban and started the patient on steroids. A retrievable inferior vena cava (IVC) filter was placed. Within five days, the patient recovered from hemoptysis. Eventually steroids were tapered and the patient was discharged home on Mycophenolate mofetil and Enoxaparin. On discharge, emoval of IVC filter was scheduled. Long-term anticoagulation using enoxaparin was recommended.

IMPACT: DAH in SLE is rare but potentially lethal complication. In a patient whose disease is complicated by concomitant DAH and DVT, IVC filter placement is an option and anticoagulation should be initiated as soon as bleeding risk is subsided.

DISCUSSION: Diffuse alveolar hemorrhage is a life threatening clinical manifestation of SLE. It is rare and has been reported in 2–5% of patients with SLE. It is more associated with anti-phospholipid syndrome, and lupus nephritis. Capillary inflammation and subsequent necrosis, and small vessel vasculitis are the main causes of bleeding. Control of SLE using immunosuppressive therapy is the mainstay of treatment. Beside respiratory complications, mortality was predominantly due to thrombotic disease. Thus, it is crucial to initiate anticoagulation as soon as possible especially in our patient who recently had DVT. Because of its rarity, data are lacking on optimal duration of anticoagulation. However, intuitively, long-term anticoagulation will be considered for our patient.

CLINICAL PRESENTATION IS EVERYTHING:CHURG- STRAUSS VASCULITIS (CSV) WITH LIFE THREATENING LIVER HEMORRHAGE. Steven Smith[2]; James Sabetta[2]; Irem Nasir[1]. [1]Greenwich Hospital, Greenwich, NY; [2]Greenwich Hospital, Greenwich, CT. (Control ID #2701750)

LEARNING OBJECTIVE #1: To recognize that liver hemorrhage can develop in CSV.

LEARNING OBJECTIVE #2: To diagnose CSV without a tissue biopsy in emergent cases.

CASE: 60y old female with chronic sinusitis and asthma for 5 years presented with acute L foot drop x1day.Despite multiple courses of steroids and antibiotics,she had multiple sinusitis flares.A sinus biopsy few years prior had severe eosinophilia and inflammatory polyps.She denied fevers,chills,chest pain,shortness of breath,headaches,blurry vision,slurred speech.She felt her abdomen distended,but had no nausea,vomiting,diarrhea,abdominal pain,melena,or hematemesis.She denied coughing,weight loss,and night sweats.There were no sick contacts,recent travel history,or family history of autoimmunity.Vital signs-97.2 F,BP126/

76,HR120,RR14,100% RA.Lungs were clear.Abdomen was soft.No rashes noted.She had 0/5 dorsiflexion of L foot.No other focal deficits.On labs,WBC 27(42% eosinophils),TB0.4, ALT212, AST282, INR1, Cr0.8, and hemoglobin(hgb)9.4,which had decreased from 12.9, 3 days prior.CRP was high at 11.Over the years,her Anti-myeloperoxidase (MPO)Ab had been negative,but now had a high titer of >1:8.CT head was negative.CT chest abdomen pelvis revealed sub-capsular hepatic hematoma with peritoneal hemorrhagic fluid.She was admitted to the ICU for aggressive IVF and stat blood transfusion.A diagnosis of CSV was made and high dose IV solumedrol started.Hgb stabilized at 9–10 within 24 hours.Echo revealed a normal EF75%.MRI/MRA brain had no acute ischemia and no vasculitis.EMG had reduced activations of L peroneal nerve consistent with motor neuropathy.A 6 month course of prednisone with cyclophosphamide was initiated.L foot drop improved.On follow up,WBC normalized to 7,14% eosinophils.Both MPO titer and CRP declined to 0.7 and 0.3,respectively

IMPACT: CSV usually has a good prognosis.It can rarely have a life threatening complication of liver hemorrhage that needs to be managed emergently.IV steroids can be instituted without a tissue biopsy with good effect.

DISCUSSION: CSV,also known as eosinophilic granulomatosis with polyangiitis,is a diffuse vasculitis affecting small and medium sized blood vessels.CSV can affect any organ including lung,kidney,GI tract,brain,nerves,and rarely liver.There is only one other case report of CSV related hepatic hemorrhage.It was fatal.Anti-MPO Ab is associated with 40%CSV cases and its pathogenic role is not well understood.Clinicians should know that CSV can have severe complications including liver hemorrhage and must maintain a low threshold to evaluate acute anemia.There are several CSV diagnostic criteria and is suspected based on clinical findings.There are no lab tests that are specific.Eosinophilia is characteristic.Our patient met 4/6 ACR diagnostic criteria (asthma,eosinophilia >10%,mononeuropathy,and paranasal sinus abnormality).Though a tissue biopsy is encouraged,emergent immunosuppressive treatment can be instituted without a biopsy in life threatening cases.As in our case, steroids can be life saving.

CLONIDINE OVERDOSE IN ADULT. zannat kawsari; Alejandro Lemor; Punya Dahal. Mount sinai St. Luke's/West, NY, NY. (Control ID #2707476)

LEARNING OBJECTIVE #1: Suspect clonidine overdose when a patient displays altered mental status along with other signs similar to opioid intoxication.

LEARNING OBJECTIVE #2: Clonidine intoxication is a serious complication and resembles other causes of overdoses.

CASE: A 38 year-old male with a past medical history of hypertension, ADHD, bipolar disorder and major depression brought himself to the ER stating he overdosed on numerous clonidine pills. Physical examination was remarkable for a lethargic male with Glasgow Coma Scale (GCS) of 5, hypotension (60/40 mmHg), bradycardia (70 bpm), bradypnea (11 breaths/min), and pinpoint pupils. He was intubated for airway protection and given three doses of Naloxone 2 mg and activated charcoal for respiratory depression. Laboratory analysis included finger stick glucose of 90 mg/dL, arterial blood gas showing metabolic acidosis (pH 7.28, PCO2 19, HCO3 14), lactic acid of 9.5 mmol/L and urine toxicology positive for cocaine. EKG confirmed sinus bradycardia (48 bpm) and early repolarization with no ST wave changes. He was admitted to the Intensive Care Unit (ICU) for further monitoring and management. Intubation was maintained for 12 h; blood pressure and heart rate were closely monitored. He was started on IV fluids, but required 4 h of dopamine infusion, as his heart rate was between 46–52 bpm and systolic blood pressure was <100 mmHg. He initially had a low urine output (600 cc in first 12 h), which improved with fluids. After 24 h in the ICU, his mental status improved, GCS recovered to 15, and his lactate and vital signs normalized.

IMPACT: This case made us think that clonidine overdose can be difficult to distinguish from other opioid intoxication and should always be suspected in a suicidal attempt of a patient with history of hypertension.

DISCUSSION: Clonidine is an alpha-2 adrenergic agonist that is used in the treatment of hypertension. Clonidine overdose presents as a classic "toxidrome" with symptoms of decreased mentation, bradycardia, hypotension, respiratory depression and miosis. In addition, altered mental status is seen in these patients. Other cases include miosis, hyporeflexia and hypotonia without mental status changes. These symptoms are difficult to differentiate from opioid intoxication. Our patient presented with depressed mental status alongside the classic toxidrome symptoms. The treatment of clonidine overdose is supportive with particular care of airway, breathing, and circulation. Naloxone can be used in cases of uncertainty, which has been shown to reverse the symptoms. Clonidine can exacerbate the lethargy or coma following alcohol, barbiturates, and other sedative hypnotics ingestion thus it is important to check urine toxicology level.

CLOZAPINE INDUCED MYOCARDITIS: A CASE REPORT

Tanuka Datta; Allen J. Solomon. George Washington University Hospital, Washington, DC. (Control ID #2701369)

LEARNING OBJECTIVE #1: Patients experiencing chest pain while taking Clozapine should be evaluated for potentially fatal cardiovascular side effects of this drug. Mortality rates can approach 25%.

LEARNING OBJECTIVE #2: Myocarditis should be considered for patients presenting as STEMIs in the setting of antipsychotic medication use. ECHO and cardiac angiography are necessary to confirm diagnosis. Beta blockers and ACE inhibitors are associated with improved outcomes.

CASE: A 40 year old Caucasian female with history of schizophrenia, being cared for on the psychiatric unit, was undergoing treatment with Clozapine. 10 days into treatment, she started to experience chest pain, nausea and vomitting. EKG demonstrated new marked ST segment elevations. Labs revealed elevated troponin and CKMB. She was transferred to our cardiac service. Vital signs were stable and physical examination unremarkable. Additional labs showed elevated BNP, ESR and CRP. No upper respiratory viral infection was detected on PCR and chest-xray was unremarkable. Left heart catheterization showed no occlusive coronary artery disease, but revealed reduced left ventricular ejection fraction. Echocardiogram (ECHO) confirmed reduced ejection fraction as well as moderate global hypokinesis. Diagnosis of myocarditis was made and Clozapine stopped. Metoprolol and Lisinopril therapy was initiated. Subsequent ECHO in 4 days revealed fully recovered left ventricular function and no wall motion abnormalities. Cardiac medications were stopped and the patient was transferred back to the psychiatry unit in stable condition.

IMPACT: Association of Clozapine with myocarditis is not well documented in cardiology literature. This case changed our thinking to include a broader differential of drug induced myocarditis when evaluating chest pain. A high rate of mortality is associated with failure to discontinue the medication thus it is important for physicians caring for psychiatric patients to be aware of the presentation of symptoms, diagnostic findings and management of Clozapine induced myocarditis.

DISCUSSION: Our case report highlights a rare yet potentially fatal cardiovascular complication of Clozapine. All chest discomfort while on this medication should be taken seriously. Given our patient's findings of new EKG changes at the time of chest pain, elevation of cardiac markers, and an echocardiogram to support decreased cardiac function in the absence of coronary artery disease confirmed on cardiac catheterization, an etiology of myocarditis was correctly suspected. Other etiologies of myocarditis including viral and autoimmune were less likely. Immediate discontinuation of Clozapine and intiation of cardiac medical therapy during the acute phase of reduced systolic function allowed this patient the best chance for cardiac recovery. The mechanism of Clozapine induced myocarditis has not been well established. Theories encompass everything from geographical preference based on ozone concentrations to genetic predisposition, Ig-E pathways, and elemental deficiencies.

CO-INCIDENCE OF WHEEZE AND MONONEURITIS MULTIPLEX SHOULD NOT PERPLEX Stefanie D. Wade[3]; Erin Little[1]; Jameel Uddeen[2]. [1]Univeristy of Connecticut, Hartford, CT; [2]University of Connecticut, Farmington, CT; [3]University of Connecticut Health Center, West Hartford, CT. (Control ID #2704102)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of eosinophilic granulomatosis with polyangiitis (EGPA)

LEARNING OBJECTIVE #2: Distinguish EGPA from other forms of adult asthma by identifying mononeuritis multiplex (MNM) as a hallmark feature

CASE: A 55-year-old former smoking male with chronic allergic rhinitis and recently diagnosed asthma presented with weakness and paresthesias of his feet and left hand with associated weight loss, fatigue, post-nasal drip, wheeze and cough. He denied rash, hemoptysis, illicit drug abuse, NSAID/ASA use, pets, recent travel, or occupational risks. On presentation pulse was 120 beats/min, respirations 20/min with oxygen sat 93% on room air. Exam showed middle ear effusions, posterior oropharyngeal erythema, sinus tenderness, and expiratory wheeze. Neurologic exam revealed left abductor pollicis brevis and first dorsal interosseous weakness, left foot dorsiflexion motor power 4/5, absent left ankle reflex, and diminished sensation of right hand median distribution, entire left hand, and feet. Laboratory data revealed leukocytosis with 31% eosinophils and absolute eosinophil count of 10.5×10^9/L. Perinuclear antineutrophil anticytoplasmic antibody (P-ANCA) and myeloperoxidase antibody (MPO) were positive. Chest CT scan showed left lower lobe consolidation or infiltrate. On hospital day 2, lower extremity palpable purpura developed and was biopsied revealing leukocytoclastic vasculitis with intra and perivascular inflammatory infiltrates with eosinophils. A diagnosis of EGPA was made. Treatment with methylprednisolone 500 mg daily for 3 days improved strength and paresthesias.

IMPACT: In patients with adult-onset asthma who develop a MNM a diagnosis of EGPA should be considered.

DISCUSSION: EGPA, (formerly Churg-Strauss,) is an eosinophil-rich, necrotizing vasculitis involving small and medium sized vessels affecting many organs. EGPA presents in three step-wise phases: a prodromal phase characterized by atopy, allergic rhinitis and asthma; a remitting eosinophilic phase with peripheral and tissue eosinophilia; and a third phase involving a life-threatening vasculitis that can involve skin, nervous, respiratory, cardiac, and gastrointestinal systems. Hallmark features such as lung involvement and MNM are present in 90 and 75 percent of cases respectively. MNM manifests as motor and sensory deficits in two or more nerve areas and results from inflammation of peripheral nerve vasculature. Diagnosis of EGPA requires asthma, peripheral eosinophilia, and proof of vasculitis. ANCA positivity is seen in 40–60% of cases. Radiographic or clinical surrogates for vasculitis are acceptable; however, histopathology should be obtained if possible which may not always show necrotizing vasculitis or granulomas. Multiple phases of disease and absence of classic features can lead to delayed diagnosis. Patients with poor prognostic features (high five factor score) benefit from immunosuppressive therapy with rituximab or mepolizumab to induce remission and decrease steroid dependence.

COINFECTION WITH TWO DIFFERENT MALARIA SPECIES Edmond Fomunung. UT Southwestern Medical School, Dallas, TX. (Control ID #2687877)

LEARNING OBJECTIVE #1: Recognize the importance of diagnosing mixed species malaria infections

LEARNING OBJECTIVE #2: Assess the implications of malaria infections for patients outside malaria-endemic areas

CASE: A 21-year-old man presented with cyclical fevers, weakness and headache 10 days after returning from Liberia. He was born in Liberia and moved to the Unites States at the age of 12. He travelled to Liberia where he spent 1 week and soon after his return developed objective fevers up to 103 F at home. He presented to an outside hospital where signet ring cells where noted on peripheral smear and he was diagnosed with *plasmodium falciparum*, then transferred to our hospital. On exam, he was awake and alert. Sclerae were anicteric and abdomen was non-tender. His complete blood count was significant for a Hg of 15.3 and platelet count of 51. Serial peripheral smear testing was significant for the presence of two malaria species, *plasmodium falciparum* and *plasmodium ovale*.

IMPACT: The presence of fever in a patient returning from a malaria endemic area should always raise suspicion for malaria and prompt diagnostic testing. It is important, as clinicians, to recognize that coinfection with 2 species, while uncommon, remains possible and will change management. In our patient, serial testing revealed the presence of an additional malaria species beyond what had been initially diagnosed at an outside hospital.

DISCUSSION: Malaria is an acute febrile illness and remains the most common parasitic disease in the world. The populations at highest risk for severe malaria include children under the age of 5, pregnant women and travelers to endemic areas, as with our patient. Severe malaria is defined as the presence of end organ dysfunction and/or high levels of parasitemia. According to the WHO, approximately 3.2 billion people - about half of the world's population - is at risk of malaria. It is transmitted by the bite of the female Anopheles mosquito and caused by the parasite plasmodium of which there are several species, with *plasmodium falciparum* responsible for the most severe disease. Sub Saharan Africa, where *plasmodium falciparum* is most prevalent, bears the brunt of cases and death. *Plasmodium ovale* is notable in that it includes a dormant stage in the liver that can reactivate several years later and cause relapse of infection. With ongoing globalization, a particular group of note is travelers to malaria endemic areas who have never been exposed before, or those returning to these areas after prolonged absence, as they are at higher risk of severe malaria. Coinfection with two different plasmodium species is reported in 5-7% of all cases of malaria. It is important to realize this early as treatment directed at only one species can allow proliferation of the second species. In the case of *plasmodium ovale*, it can remain dormant in the liver for several years; this can cause persistent parasitemia which can later lead to severe malaria. Diagnostic testing and adequate treatment is thus important.

COMMON ABDOMINAL PAIN DUE TO AN UNCOMMON TUMOR.

Takuji Ueno[1]; KAZUKI SHIMIZU[1]; Kaname Uno[1]; Syo Tano[1]; Mayu Ukai[1]; Yasuyuki Kishigami[1]; Hidenori Oguchi[1]; Mitsunori Iwase[2]. [1]TOYOTA Memorial Hospital, Toyota, Japan; [2]TOYOTA Memorial Hostital, Toyota, Japan. (Control ID #2707229)

LEARNING OBJECTIVE #1: Don't you overlook young woman with ascites? Check the cause of the ascites.

LEARNING OBJECTIVE #2: Ultrasonography can help you find the malignancy.

CASE: A 42-year-old woman was admitted to our hospital complaining of lower abdominal pain lasting 3 weeks. She was followed by her previous doctor and refered to our hospital because of continuous symptoms. Her menstrual cycle was regular and she had no irregular genital bleeding. She had neither history of blood transfusion nor any abuse of drug as well as alcohol. She took no medication at all. She had no family history of cancer. She had neither fever nor weight loss through this period. Her vital signs were completely normal. She felt discomfort and slight pain in her lower abdomen, but did not have tenderness point. Ultrasonography revealed a little ascites. In adition, there was no abnormal laboratory findings including urine human chorionic gonadotropin (hCG). Three weeks later, her symptoms had not get improved. She still had no fever and no tenderness in her abdomen. However, abdominal palpation indicated increased ascites. Ultrasonography showed greater ascites with diffused high echoic area, omentum enlargement and dullness at liver surface. Laboratory test was normal, but some tumor markers were elevated. Computed Tomography (CT) showed ascites and swelling omentum. Gastrointestinal and colorectal endoscopy revealed no findings. We collected the ascites by echo guided abdominocentesis and cytodiagnosis was negative. We suspected peritonitis carcinomatosa and performed a diagnostic laparoscopy. Mucous tumors were scattered on ovary, appendix, peritoneum, and omentum. We removed right ovary and its pathological diagnosis was pseudomyxoma peritonei. She is going to be treated with debulking surgery and hyperthermic intraoperative intraperitoneal chemotherapy (HIPEC).

IMPACT: It is important to suspect common disease, but we should keep the possibility of rare diseases on mind. Omentum enlargement described in ultrasonography help us suspect of peritonitis carcinomatosa.

DISCUSSION: Pseudomyxoma peritonei is mucus-producing tumor originating from appendix or ovary and distinctly rare occurring 1 in 1,000,000 people. That has a poor prognosis because its easy to metastasize broadly in abdominal cavity, so early diagnosis is really important. But it is not easy due to nonspecific symptoms. In this case, there were wide variety of differential diagnoses including gastrointestinal and gynecological diseases. The simple ultrasonography may lead us to suspect pseudomyxoma peritonei or other malignancies.

CONFUSING-CALCEMIA: REFRACTORY HYPOCALCEMIA AS ONE OF THE MANY GUISES OF PERNICIOUS ANEMIA

Mary S. Vamenta; Starr Steinhilber. University of Alabama at Birmingham, Birmingham, AL. (Control ID #2705628)

LEARNING OBJECTIVE #1: List causes of hypocalcemia

LEARNING OBJECTIVE #2: Formulate a work up for refractory hypocalcemia

CASE: A 44-year old Caucasian woman with Graves' disease presents with a one year history of refractory hypocalcemia despite oral supplementation following a total thyroidectomy with inadvertent parathyroidectomy. Symptoms include perioral and acral numbness and tingling, tetany of her upper extremities, and new seizures. High dose calcium supplementation yields some resolution of symptoms with prompt readmission. Vitals, physical examination, and general labs are normal except for a positive Trousseau and Chvostek sign and low serum and ionized calcium. Home medications of calcitriol 1 mcg TID and teriparatide daily are continued. Oral calcium carbonate 1800 mg TID is begun and leads to modest improvement in calcium levels. Due to medication compliance, a concern for malabsorption is raised. EGD with duodenal biopsies is negative for any abnormality and anti-tissue transglutaminase antibodies and H. pylori stool antigen are negative. She is iron and vitamin B12 deficient, anti-parietal cell antibody returns elevated at 73.4 (normal <20), intrinsic factor antibody is positive, and gastrin levels are elevated to 1264 pg/mL (normal 13–115 pg/mL). These findings are consistent with pernicious anemia (PA).

IMPACT: There are many case reports on refractory hypocalcemia secondary to a multitude of drugs or diseases; however, little information exists regarding appropriate work up. Based on our literature search, we formulated an approach to refractory hypocalcemia that others can utilize and expand.

DISCUSSION: Complications of total thyroidectomy are iatrogenic parathyroidectomy and transient post-operative hypocalcemia, but oral calcium supplementation often resolves symptoms. Work up of refractory hypocalcemia should be considered in symptomatic patients on appropriate therapy and should begin with medications that affect vitamin D and stomach pH. It is well documented that efavirenz and anti-epileptic drugs can metabolize vitamin D through induction of the P450 system predisposing patients to refractory hypocalcemia. Other uncommon drugs such as foscarnet are powerful chelators of divalent cations (Ca and Mg). More commonly, H^2 blockers and proton pump inhibitors decrease calcium absorption by decreasing acidity in the stomach. When investigation into iatrogenic causes is insufficient, malabsorption must be considered. Bypassing the duodenum and proximal jejunum in Roux-en-Y surgery can cause a 10% rate of calcium deficiency and 51% rate of vitamin D deficiency since 80% of vitamin D absorption occurs at these sites. Mucosal damage in Celiac sprue and Crohn's disease, achlorhydria due to PA, and fat malabsorption are known culprits of calcium and vitamin D malabsorption and must be recognized also. From our patient experience, we propose 1) reviewing all medications affecting vitamin D, calcium, or stomach acidity and 2) considering malabsorption through further history, laboratory studies, and imaging.

CONGENITAL UNILATERAL PULMONARY VEIN ATRESIA IN A YOUNG ADULT

Abhimanyu Chandel; Amanda Duttlinger. Walter Reed National Military Medical Center, Bethesda, MD. (Control ID #2704183)

LEARNING OBJECTIVE #1: Recognize the expected radiographic findings of pulmonary vein atresia.

LEARNING OBJECTIVE #2: Identify the complications and natural history of unilateral pulmonary vein atresia.

CASE: An 18-year-old highly active student at an elite U.S. military academy with a history of prior pneumonia as a child presented to his primary physician with complaints of persistent fevers and productive cough despite multiple courses of outpatient antibiotics. Chest radiographs demonstrated multifocal pneumonia, a shift of the mediastinum to the right with associated right lung volume loss, hyperinflation of the left lung, and prominence of the left pulmonary artery. Subsequent CT scan with IV contrast revealed a smooth left atrium where the right pulmonary veins should enter, right lung hypoplasia,

unilateral right pulmonary edema, and gradual tapering of the right pulmonary arterial system. Dilation of bronchial arteries on the right with a conglomeration of varices in the posterior mediastinum was also present. Based on these findings, unilateral pulmonary vein atresia was suspected and the patient was referred for echocardiogram, pulmonary angiography, and right heart catheterization to further delineate the anatomy and to evaluate for associated congenital cardiac defects. Echocardiogram revealed normal biventricular function without evidence of shunt or other congenital defect. Invasive angiography demonstrated normal position of the right superior and right inferior pulmonary veins adjacent to the left atrium, but without luminal communication with the left atrium. The right lung drained via collateral vessels to the right pulmonary artery; with associated retrograde flow into the main pulmonary artery. Right heart catheterization was remarkable for lack of pulmonary hypertension or shunt. These findings were consistent with the diagnosis of congenital unilateral right pulmonary vein atresia. Upon follow up, the patient resumed physical activity and experienced excellent clinical recovery from the pneumonia which had prompted the initial diagnostic workup. His underdeveloped right pulmonary venous system was deemed to be unsuitable for surgical intervention. Based on current normal pulmonary artery pressures, the patient is felt to be low risk for progression to pulmonary hypertension, but will be followed annually with echocardiography.

IMPACT: This case illustrates a very uncommon cause of recurrent and persistent pneumonia in a young adult caused by congenital disease.

DISCUSSION: In a recent review of the literature, less than 50 cases of isolated pulmonary vein atresia had been reported, with only a few adult cases having been described. Associated congenital heart defects occur in about 1/3 of patients. Most commonly, the condition is identified following recurrent infections in the affected lung. Hemoptysis or hematemesis often occurs due to systemic collateral supply to the affected lung. Pneumonectomy should be considered if pulmonary hypertension or severe recurrent pulmonary infections develop.

CORONARY ARTERY ANEURYSM PRESENTING AS NON-ST ELEVATION MYOCARDIAL INFARCTION Murtaza A. Sundhu[1]; Mehmet Yildiz[1]; Gaurav Kistangari[2, 1]; Emad Nukta[3]. [1]Fairview Hospital/Cleveland Clinic Hospital, Fairview park, OH; [2]Medicine, Cleveland, OH; [3]Fairview Hospital/Cleveland Clinic, Cleveland, OH. (Control ID #2702174)

LEARNING OBJECTIVE #1: Identifying coronary artery aneurysm as a cause of non-ST elevation myocardial infarction.

LEARNING OBJECTIVE #2: Learning the differential diagnoses, management and complications of coronary artery aneurysms.

CASE: 52 year old man with past medical history of migraine, is an active smoker with 40 pack years smoking history and a recovering drug addict (used cocaine, heroin and prescription opioids) who has been sober for 5 years, presented to the hospital with typical chest pain which was sub-sternal in location that radiated to the jaw and left arm and was associated with nausea. Complete blood count and comprehensive metabolic profile were within normal limits. The electrocardiogram showed ST depressions in leads III and AVF. Initial troponin was negative. He was admitted to rule out acute coronary syndrome. Subsequent troponins were elevated and he was diagnosed as non-ST elevation myocardial infarction. He was started on subcutaneous enoxaparin and transferred to coronary care unit. The following day he underwent cardiac catheterization that showed dilated ectatic coronary arteries with aneurysmal dilatation, sluggish flow and several clots especially in left circumflex artery. No intervention was done and he was anticoagulated with intravenous heparin infusion until he was therapeutic with coumadin. His C-reactive protein, sedimentation rate and autoimmune panel were negative as well. Transthoracic echocardiogram was done showing ejection fraction of 35% with anterior and inferoseptal wall dyskinesia. There was no valvular abnormality. He was discharged on aspirin, beta-blocker, angiotensin converting enzyme inhibitor and statin for the medical management of reduced ejection fraction. Coumadin was given for the coronary artery aneurysms.

IMPACT: We do not see coronary artery aneurysm in internal medicine and this case stimulated me to read more about differential diagnosis, management and complication of the coronary artery aneurysms (CAA). There is not enough evidence on the management of CAA and hence cases with CAA should be reported so that medical community can understand more about the disease.

DISCUSSION: Coronary Artery aneurysms (CAA) are rare in general population. The most common causes of CAA include inflammatory disorders such as Kawasaki disease in children, atherosclerosis and cocaine abuse in adults. Our patient had CAA most likely secondary to a combination of cocaine abuse and smoking history and presented with acute myocardial infarction to the hospital. Treatment of CAA is not established; due to the rarity of the condition there is a lack of randomized controlled clinical trials to guide treatment. Surgery or covered stent is used when there is stenosis associated with the aneurysms. For non-obstructing aneurysms, however, medical management alone is appropriate. Untreated CAA even without stenosis can be complicated by arrhythmias, myocardial infarction or sudden death which is most likely from the thrombus formation and embolization due to sluggish blood flow.

CORTISOL SUPPRESSION OF CALCIUM ABSORPTION IS IMPORTANT Brian C. Adams. Virginia Commonwealth University Health System, Richmond, VA. (Control ID #2694195)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of adrenal insufficiency in a person taking oral calcium.

CASE: A 68-year-old with a history of prostate cancer with extensive bony metastases, chronic kidney disease and heart failure presented to clinic with a chief complaint of fatigue and dizziness. He noted vague abdominal pain as well. He was discharged 19 days prior, after presentation with vague abdominal complaints. He was found to have fluid responsive hypotension, and discharged home with a diagnosis of gastroenteritis. While he previously performed all activities of daily living, patient stated he had not yet regained strength after discharge. Multiple falls after discharge were noted in an interval clinic note - found to be orthostatic so anti-hypertensives were de-escalated. His medications included Calcium-Vitamin D 500 mg-200 IU PO BID started the year before, and his last trial of chemotherapy was Abiraterone 1 g daily and Prednisone 5 mg BID which was started the year before and discontinued 4 days before initial hospitalization. In clinic he was found to be hypotensive with a blood pressure of 85/58 mmHg and heart rate of 43 bpm, with orthostasis on standing. Pertinent labs included sodium 136 mmol/L, potassium 5.2 mmol/L and calcium 11.1 mg/dL (most recent albumin 3.4 g/dL, and previous calcium level of 9.4 mg/dL at discharge) and a fall in estimated GFR from 29 to 18 mL/min over 19 days from discharge. The patient was admitted to the Palliative Care service for supportive care. His exam was consistent with consumptive disease and otherwise non-specific. He was given an IV fluid bolus of 1 L normal saline, followed by a rate of 50 cc/hr normal saline. His workup consisted only of a cortisol stimulation test, with a cortisol level of

1.4ug/dL at 0 min and 8.4ug/dL at 60 min post-administration of 0.25 mg cosyntropin IV - which confirmed adrenal insufficiency. Daily steroids were started. Blood pressure was 137/55 mmHg Day 1 of steroids, with further elevation (160/77 mmHg) on Day 2. Concurrently, his calcium level dropped to 9.5 mg/dL Day 2 of steroids. He was discharged with PO steroids and oral calcium was discontinued. At follow-up three days later his blood pressure was 142/66 mmHg, heart rate was 78 bpm, and calcium level was 8.5 mg/dL.

IMPACT: This case changed my thinking regarding the physiology of cortisol. A lesser known physiologic effect of cortisol is its role to suppress calcium absorption from the gut. The simultaneous abrupt withdrawal of steroid tone and ongoing delivery of calcium to the gut led directly to a reversible hypercalcemia.

DISCUSSION: The takeaway from the above case is to consider adrenal insufficiency as a potential cause of hypercalcemia (especially in the setting of oral calcium supplementation.) The current clinical algorithms for hypercalcemia do not include cortisol stimulation testing, however this test should be considered given the high incidence and easy reversibility of adrenal insufficiency.

CORYNEBACTERIA KROPPENSTEDTII: A NOVEL CULPRIT IN RECURRENT BREAST ABSCESSES Tolulope Ogriki; Jignesh Patel; Nidhi Saraiya. Montefiore Medical Center, Bronx, NY. (Control ID #2706064)

LEARNING OBJECTIVE #1: Recognize the clinical significance of *Corynebacterium kroppenstedtii* in breast infections

CASE: A 34 year old obese woman with prolactinoma presented with four days of chills and severe throbbing pain in her right breast. Her temperature was 100.2 °F and pulse was 98 beats per minute. Examination was unremarkable except for right breast peau d'orange appearance, erythema, tenderness and induration. She had leukocytosis of 14,300 cells/μL and sedimentation rate of 57 mm/h. She had been admitted twice for right breast abscess in the prior four weeks and had undergone needle aspiration; cultures grew *Corynebacterium spp*. She received doxycycline for 17 days in total. In this hospitalization, ultrasound showed a multi-loculated abscess and a peri-areolar collection. The abscess was drained and she was started on vancomycin and ampicillin-sulbactam. Fluid cultures grew *Corynebacterium spp*, further speciated to *C. kroppenstedtii*. Six days later, she developed a fever, after being afebrile for days, plus worsening leukocytosis and recurrent breast discharge. Ultrasound revealed a new abscess. Linezolid was initiated after a repeat drainage procedure. She then remained afebrile with decreasing leukocytosis and sedimentation rate.

IMPACT: When breast infections are recurrent, it is critical to have a high index of suspicion for *C. kroppenstedtii*. The lipid-rich breast tissue favors its growth and makes eradication difficult since many commonly used antibiotics are not lipophilic. Selecting a lipophilic antibiotic, such as linezolid, for *C. kroppenstedtii* breast infection can spare the frustration that may be associated with multiple antibiotics, drainage procedures and hospitalizations.

DISCUSSION: *Corynebacterium* species are gram positive, catalase positive bacilli which are usually *considered* contaminants. *C. kroppenstedtii* has emerged a pathogen in cases of granulomatous mastitis and breast abscess likely because of its lipophilic properties with tissue tropism for lipid-rich mammary glands. In the past, identification of this organism was laborious, but newer technologies such as gene sequencing and MALDI-TOF MS has made the diagnosis of *C.kroppenstedtii* easier. Breast infections caused by this organism require prolonged courses of antibiotics, with or without surgery, before cure can be achieved. Of note, a few cases of recurrent breast abscess in patients with prolactinoma have been reported. The most commonly used antimicrobials have been amoxicillin, amoxicillin-clavulanate, cefuroxime, ciprofloxacin, and doxycycline. Of the two main *C. kroppenstedtii* strains found in breast tissue, the ITA 205 strain can be multi-drug resistant to clindamycin, macrolides, and sulfa agents. Additionally, antibiotic sensitivity in vitro may not correlate in vivo due to poor penetration. Hence, lipophilic antibiotics such as ciprofloxacin, doxycycline, and linezolid may be more effective.

COSMETIC INJECTIONS ASSOCIATED WITH HYPERCALCEMIA AND ACUTE KIDNEY INJURY Sania Sultana; Colette Knight. Montefiore Medical Center, Bronx, NY. (Control ID #2707397)

LEARNING OBJECTIVE #1: Physicians have to become aware of potential complications of cosmetic injections which cause life-threatening conditions such as hypercalcemia.

LEARNING OBJECTIVE #2: Clinicians should inform and educate their patients about these practices.

CASE: 55 years old woman with history of Hypertension, CAD s/p MI, CKD and bipolar disorder presented to hospital with dizziness. On presentation, she had hypertensive urgency, BP: 228/127 mmHg which was treated with Labetalol. Routine labs revealed hypercalcemia: Ca:13.7- > 15 mg/dL (8.5–10.5 mg/dl), acute kidney injury: creatinine:1.89- > 3.49(0.5–1.5 mg/dl) and increased ionized Ca:1.63 mmol/L(1.10–1.35 mmol/L). She denied previous history of hypercalcemia, bone pain, abdominal pain, constipation, malignancy or family history of calcium disorder. She had been taking calcium and vitamin D supplements. Further studies revealed low PTH:9.9 pg/mL (10–65 pg/mL), elevated 24-h urine calcium:622 mg/24-h (50–250 mg/24 hr), elevated Vitamin D 1,25 $(OH)_2$:149 (18–72 pg/mL) and elevated ACE level:88 U/L (8–52 U/L). Renal Ultrasound showed bilateral nephrolithiasis. The constellation of findings raised the suspicion for hypercalcemia due to granulomatous disease. A noncontrast CT of thorax, abdomen and pelvis revealed diffuse inhomogeneous density enlarging buttocks and infiltrating subcutaneous fat consistent with prior injection augmentation procedure. On further inquiry, she admitted ~ 10 years ago, she had injections of "saline" to gluteal region for aesthetic enhancement and those were neither performed in a medical setting nor administered by a medically trained professional. Treatment with prednisone 30 mg daily was initiated and resulted in improvement of renal function and calcium level. However, she was not adherent to treatment and has had multiple admissions for relapsing hypercalcemia.

IMPACT: Cosmetic injections for body contouring have been widely increasing. However, granuloma formation associated with life-threatening hypercalcemia can be a major complication of this practice.

DISCUSSION: Hypercalcemia after cosmetic injections should be considered in any patient who has had a history of these procedures. Granulomatous reactions secondary to filling materials are rare complications and usually result from T-cell activation which results in release of cytokines that accelerate granuloma formation. Macrophages residing in granulomas convert 25-OH vitamin D to 1,25-(OH)2 D3 with help of 1α-hydroxylase, leading to hypercalcemia by increase of gut calcium absorption and calcium mobilization from bone. Systemic glucocorticoids inhibit production of calcitriol and suppress pro-inflammatory cytokines. Therapeutic management is usually long term as normocalcemia can be difficult to attain.

CROHN'S IS NOT ALWAYS ABOUT DIARRHEA: A CASE OF CROHN'S DISEASE PRESENTING AS ACUTE PANCREATITIS

waqas nawaz. Geisinger Medical Center, Danville, PA. (Control ID #2674713)

LEARNING OBJECTIVE #1: Recognize high risk of acute pancreatitis in Crohn's disease.

LEARNING OBJECTIVE #2: Recognize acute pancreatitis as an extra-intestinal manifestation of Crohn's disease.

CASE: 25 year old male with no medical history admitted for diffuse abdominal pain for 2 days, and was found to have epigastric tenderness on exam. Labs showed mildly elevated amylase and lipase. CT scan of abdomen showed acute pancreatitis (AP). Abdominal sonogram showed no biliary pathology. Serum triglyceride, calcium, ANA and IgG4 levels were normal. He denied any preceding flu like symptoms, drinking alcohol or taking any medication. He reported constipation with intermittent streaks of blood mixed with stools and 10 pound weight loss over last 7 months. Rectal exam showed anal fissure and ulceration. Sedimentation rate and C-reactive protein were markedly elevated. Pelvic MRI showed grade I perianal fistula. Colonoscopy showed ulcerations in terminal ileum. Histopathology showed active colitis and granulomas in terminal ileum consistent with initial Crohn's disease (CD). He was started on fluid therapy. Treatment for Crohn's disease was not initiated until pancreatitis resolved. He was started on mesalamine as outpatient, one month later.

IMPACT: This case taught me to look for rare etiologies of apparently looking idiopathic pancreatitis.

DISCUSSION: Patient with CD are at 4-fold higher risk of developing AP than general population mostly due to gallstones and medications with incidence of 1.4%. Most patients with CD present with AP within 2 years of diagnosis. However, CD may present for the first time as AP as its extraintestinal manifestation in 0.06% of cases. It tends to be less painful and severe than other causes of pancreatitis. Amylase is mildly elevated in most of cases. Prognosis is the same as in general pancreatitis.Some animal studies have shown evidence of migration of mucin-1 (MUC 1)-specific T cells, which are implicated in pathogenesis of human CD, to pancreas which suggests that pancreatitis might be an extraintestinal manifestation of CD. Pathogenesis involves duodenopancreatic reflux, papillary obstruction due to duodenal inflammation, pancreatic autoantibodies and development of pancreatic granulomas leading to inflammatory pancreatic changes.Management of CD related AP is same as in other cases of AP. However, drugs with harmful effects on the pancreas, like mesalamine, azathioprine, may have to be held as they have been associated with relapse of pancreatitis. Similarly, steroids used for CD may increase risk of necrosis and infection in AP. Although AP is a severe disease with 5% mortality, Crohn's related AP has a benign course with median hospital stay of 3.5 days.

CRYOGLOBULINEMIA: A RARE PRESENTATION OF RENAL FAILURE DUE TO CRYOGLOBULINEMIC VASCULITIS.

Gargi Patel; Abhishek Sarkar; Anand Patel; Manish Patel; Vivien Hsu. Rutgers-RWJ Medical School, New Brunswick, NJ. (Control ID #2702254)

LEARNING OBJECTIVE #1: Recognize mixed cryoglobulinemia as a cause of glomerulonephritis in patients with vague symptoms and no other physical findings for vasculitis.

CASE: Patient is a 63-year-old female with prior history of well-controlled hypertension, who initially presented to the emergency room (ED) with hypertensive urgency and normal laboratory data including renal function. Shortly after, she developed recurrent abdominal pain, and returned to the ED. On presentation, her blood pressure was187/105 and laboratory studies revealed an elevated creatinine of 3.3. She had no other complaints, denying arthralgias, rash, myalgias, fevers, or chills. Prior history was positive for a remote history of malar rash. While hospitalized, her creatinine deteriorated, requiring urgent dialysis. Further workup revealed a negative Hepatitis B and C serologies. Rheumatologic workup revealed a high RF, SS-A, and ANA with very low complement levels, including C3 and C4. The DsDNA was negative. A renal biopsy was consistent with cryoglobulinemic glomerulonephritis. The cryoglobulins returned elevated and immunofixation confirmed type 2 cryoglobulinemia. The patient was treated with pulse dose steroids and plasmapheresis. Subsequently, she received Rituximab with oral steroids. She improved and no longer required dialysis after 3 months from initial presentation, and her steroid was tapered off.

IMPACT: This case illustrates a unique presentation of cryoglobulinemic glomerulonephritis (CGN) in the absence of typical findings associated with CGN, such as palpable purpura, arthalgias, peripheral neuropathy, or hepatitis C infection. Despite her positive serologic profile and remote history of malar rash, she had no rheumatologic findings such as SLE or polyarthritis, and a renal biopsy was required to confirm her diagnosis.

DISCUSSION: The differential diagnosis of renal failure in the setting of low complement levels should include vasculitis due to viral infections (more than half the cases are due to Hepatitis C infection[1]), autoimmune diseases such as SLE and Sjogren's syndrome, as well as lympho-proliferative malignancies. A complete evaluation of any unexplained renal failure generally requires renal biopsy to confirm the diagnosis and guide in the management. Early detection of glomerulonephritis due to cryoglobulinemia was crucial in our case, since the early initiation of steroid and immunosuppressive therapy contributed to her complete recovery of kidney function. Despite the negative viral titers in our patient, we chose Rituximab because of the favorable results with Hepatitis C infection[2][3].References: 1. Schmid H, Braun GS. Chapter 169. Cryoglobulinemia and Cryofibrinogenemia. Fitzpatrick's Dermatology in General Medicine, 8e. New York, NY: McGraw-Hill; 2012. 2. De Vita et al.: A randomized controlled trial of rituximab for the treatment of severe cryoglobulinemic vasculitis. Arthritis & Rheumatism 2012; 64: 843–853.

CULTURAL BARRIERS TO CARE: PRIMARY HYPERPARATHYROIDISM IN A BANGLADESHI IMMIGRANT WITH DEPRESSION

Rebecca Boas[2]; Parimal A. Patel[1]. [1]NewYork-Presbyterian, New York, NY; [2]Weill Cornell Medicine - New York Presbyterian Hospital, NY, NY. (Control ID #2701880)

LEARNING OBJECTIVE #1: Recognize barriers for immigrants in New York City accessing mental health services

LEARNING OBJECTIVE #2: Assess improvement in depression after parathyroidectomy in primary hyperparathyroidism (PHPT)

CASE: 64 years old Bangladeshi woman, diagnosed and treated for depression without improvement presents to establish care. She reports trouble with memory, sad mood, and passive suicidal ideation over the last 3 years. She started escitalopram 5 mg daily, discontinued due to drowsiness. She also complained of chronic abdominal pain and fatigue. No history of kidney stones, polydipsia/polyuria, constipation. No lab work performed previously. Physical exam notable for BMI 20.1, otherwise stable vital signs, thin

appearing. Her thryoid cardio-pulmonary, abdominal and neurological exams were unremarkable. PHQ-9 score of 12. Laboratory data was collected, notable for elevated calcium level (11.7, corrected) and parathyroid hormone (142), leading to the diagnosis of primary hyperparathyroidism (PHPT). Patient's other electrolytes and creatinine were normal. Patient was found to have osteoporosis of the lumbar spine and left femoral neck on bone mineral density testing. The patient met surgical criteria for parathyroid resection. Patient underwent parathyroidectomy. 6 months post-op patient reported improved mood with suicidal ideations resolved.

IMPACT: Bangladeshi immigrants are one of the fastest growing immigrant groups in the US, with NYC having the largest population. Depression is much more widespread than previously thought. South Asians frequently go to primary care physicians (PCP) with vague somatic symptoms. It is important to recognize poor health behaviors in this population and need for early intervention and health promotion. It is essential to screen for depression and treat reversible causes, such as hyperparathyroidism.

DISCUSSION: Healthcare resources for Bangladeshi immigrants, particularly women, has lagged significantly behind the enormous growth in population. Advocates report mental health services are the largest shortfall with limited providers that speak Bengali or understand the Bangladeshi culture. A multitude of other barriers exist including cultural gender norms, financial dependence on their spouses, geographic isolation and poverty. Rates of domestic violence and abuse are high. In the community, 36.5% of this population screen positive for depression, with high rates of self harm, attempted and completed suicide attempts. Mental disorders, depression, and CNS dysfunction are all associated with hypercalcemia and PHPT. Patients meet surgical criteria for parathyroid resection with calcium elevation and bone mineral density scan with osteoporosis. Surgery has been shown to be effective for treatment of depression in PHPT after parathyroidectomy. At 12 months post-op there is a significant decrease in anxiety and depression, with incidence of suicidal ideation reduced to half the level compared to baseline (10.7% vs 22%). Physical and mental health scores also improve.

CURING CANCER WITH COMPASSION? Kristen Kelley[1]; Dominic Nguyen[2]; Sara-Megumi L. Naylor[3]. [1]Internal Medicine Residency Program, David Geffen School of Medicine, Los Angeles, CA; [2]David Geffen School of Medicine, Los Angeles, CA; [3]Division of Primary Care at the VA Greater Los Angeles Healthcare System, Department of Medicine David Geffen School of Medicine at UCLA, Los Angeles, CA. (Control ID #2702451)

LEARNING OBJECTIVE #1: Recognize that people with mental illness die earlier than otherwise similar people without mental illness, largely due to common medical conditions including cancer.

LEARNING OBJECTIVE #2: Acknowledge that physician pessimism, bias, and lack of training contribute to this mortality disparity.

CASE: A 68 year-old male veteran with schizoaffective disorder and tobacco use disorder was brought to the emergency room with worsening paranoid delusions. Recently, he had undergone a chest x-ray as part of a workup for altered mental status and a 3.5 cm opacity was found. A CT scan confirmed a mass compatible with a primary lung neoplasm. He declined any further workup, and in the setting of his grave disability from his mental illness, conservatorship was pursued. His cousin was appointed his conservator. On this current admission, he underwent a biopsy and staging. He was diagnosed with stage 1B non-small cell lung carcinoma. Management options of this potentially curable malignancy, which included surgical resection and radiation, were discussed with his conservator. Ethics was consulted, and the Tumor Board reviewed his case. There was abundant physician pessimism and bias that the patient would not be able to participate in treatment options. Our Ethics team helped clarify and enhance all providers' alignment with ethical principles, including understanding that patient autonomy could not exist at this time. All parties agreed the patient enjoyed an acceptable quality of life, even in the setting of severe mental illness. Management of his schizoaffective disorder and building a trusting doctor-patient relationship were prioritized. He eventually completed radiation therapy.

IMPACT: This vignette illustrates that physician compassion, teamwork, and training can overcome challenges that arise in taking care of patients with severe mental illness and lead to more favorable and just outcomes.

DISCUSSION: A well-documented, persistent mortality gap exists between patients with severe mental illness and otherwise similar people without mental illness. The causes of deaths are largely due to medical conditions like cardiovascular disease and cancer, which internists diagnose and manage daily. It is a common misunderstanding that mental illness itself leads to more deaths. Although there are many reasons for this disparity, physician pessimism, bias, and lack of training contribute. After humbly reflecting on our collective pessimism, we channeled compassion and resilience daily to engage our patient and ourselves in his care. Guidance from consultants and teamwork were crucial. Our lack of training forced us to review and deliberately practice capacity assessment and the ethical principles of beneficence and non-maleficence. We encourage providers to reflect on their own biases and channel compassion to help reduce the mortality gap that exists for patients with severe mental illness.

CURIOUS CASE OF CALCIPHYLAXIS CAUSING CARDIOMYOPATHY Asma Khatoon; Deepthi Chiluvuri; Renuka Chowdhury. Methodist Dallas Medical Center, Dallas, TX. (Control ID #2690740)

LEARNING OBJECTIVE #1: Calciphylaxis is characterized by skin ischemia and necrosis due to calcification of dermal arterioles. It is believed to be part of a continuum of systemic vascular and soft tissue calcification that is common in end-stage renal disease (ESRD). We share a unique case of dystrophic calcification causing restrictive cardiomyopathy.

CASE: A 42 year old Hispanic female presented to our service with complaints of severe chest pain after a mechanical fall. She had known history of diabetic nephropathy, ESRD and cirrhosis. On further evaluation, patient had a loud pericardial friction rub, scattered ulcerated as well as non-ulcerated skin plaques, predominantly on the legs and new onset jaundice. Laboratory data analysis was suggestive of myocardial injury and cholestasis. She had decreased responsiveness on day 3 of hospitalization and found to be in shock which responded well to vasopressors. Patient briefly required ICU monitoring and continuous renal replacement therapy as well. 2D Echocardiogram showed cardiomegaly, trivial pericardial effusion, elevated right ventricular systolic pressure and dilated inferior vena cava concerning for constrictive pericarditis. Left and right heart catheterization was performed which surprisingly revealed restrictive hemodynamics with mean pulmonary artery pressure of 50 mmHg and pulmonary capillary wedge pressure of 35 mmHg along with normal pulmonary vascular resistance and severely elevated mean right atrial pressure of 30 mmHg. Constriction was ruled out. She had normal coronary arteries and normal cardiac output. A wide array of tests ensued to rule out sarcoidosis, hemochromatosis, amyloidosis and direct cancer invasion. She had no prior radiotherapy. Patient had improvement in chest

pain but developed worsening dyspnea. A CT angiogram revealed worsening cardiomegaly and heavy calcium deposition in aorta and all major vessels, as well as the right atrium. Thus dystrophic calcium deposition was deemed to be the cause of her restrictive cardiomyopathy. Hemodialysis was continued as allowed by blood pressure during the hospital stay. She was initiated on intravenous sodium thiosulfate with improvement of the non-ulcerated plaques.

IMPACT: Calciphylaxis in the calves is easily confused with cellulitis in 80% of the patients. However, the mortality rate with non-ulcerated plaques at 6 months is 33 and once ulceration develops mortality increases to 80%!

DISCUSSION: This case illustrates the potentially severe effects of calciphylaxis which is usually an asymptomatic finding in patients with ESRD and renal transplant. Review of literature revealed varying degrees of soft tissue calcification in up to 60% of the patients with ESRD, including blood vessels, lungs, pericardium, myocardium, abdominal wall, even conjunctiva. Although many ESRD patients have vascular calcification, few develop severe clinical manifestations, such as the case described above. Therapy is multifaceted and efforts should be geared more towards prevention.

CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS: MORE THAN JUST SKIN DEEP? Allison Guttmann; Jason F. Wang; Karin M. Warltier. New York University School of Medicine, New York, NY. (Control ID #2679850)

LEARNING OBJECTIVE #1: Review Cutaneous Leukocytoclastic Vasculitis and its association with malignancy

CASE: A 70 year-old man with diabetes presented with a lower extremity rash for two days. Five weeks prior to presentation, he experienced pharyngitis and rhinorrhea, resolving spontaneously. Two weeks later, he began to feel generalized weakness and fatigue. Two days prior to presentation, he had intense pruritus of his feet, and shortly thereafter developed purple lesions on the plantar surfaces, at which point he presented to the hospital. On presentation, physical exam showed multiple tender erythematous and violaceous non-blanchable macules coalescing on his lower extremities and back. Laboratory evaluation was notable for creatinine 1.0mg/dL, c-reactive protein 40mg/L and erythrocyte sedimentation rate 130mm/hr. Anti-nuclear antibody, rheumatoid factor, P-ANCA, C-ANCA, SS-A/SS-B, IgA and cryoglobulin were negative. C3 was normal and C4 was slightly elevated. Infectious evaluation was negative for hepatitis B and C, with an elevated antistreptolysin O. Skin biopsy showed leukocytoclastic vasculitis, though direct immunofluorescence was unavailable. Our patient was diagnosed with Cutaneous Leukocytoclastic Vasculitis (CLV) once other connective tissue disorders were excluded and with reassurance that visceral organs were not affected. This case was likely related to a recent respiratory infection, however underlying malignancy was not excluded. The patient received oral steroids, and was discharged to complete a malignancy work-up.

IMPACT: This case reminds us to consider associations between pathologies. For this patient, it was not sufficient to make the diagnosis of CLV, but we had to appreciate its association with malignancy in order to thoroughly manage this patient.

DISCUSSION: Cutaneous Luekocytoclastic Vasculitis (CLV) is a small vessel vasculitis limited to the skin. The pathophysiology is poorly understood, however it may be due to immune complex deposition and neutrophil migration resulting in the release of free radicals. CLV may be precipitated by infection, malignancy, medication or deemed idiopathic. Patients present with non-pruritic purpura predominantly in dependent areas, and may report constitutional symptoms. Pathologically, lesions appear as neutrophilic infiltration of the small vessels, and direct immunofluorescence reveals immune complex deposition containing C3, IgM, IgA and IgG. The diagnosis is made after excluding other vasculitides with visceral involvement. CLV may be considered a paraneoplastic process due to its association with malignancy. One study showed that 16 of 421 patients with CLV (3.8%) had an underlying malignancy, and the vasculitis appeared an average of 17 days before malignancy was diagnosed. Both solid organ and hematologic malignancies have been implicated, including chronic lymphocytic leukemia, urinary and gastrointestinal malignancies. CLV may also be associated with infections, including HIV, beta-hemolytic streptococcus, and endocarditis.

DECEPTIVE ANTINUCLEAR ANTIBODIES IN A PATIENT WITH HYPOTHYROIDISM, MALAR RASH AND MICROSCOPIC HEMATURIA Matthew Spindler[2]; Mackenzie Naert[2]; Brittany Glassberg[2]; Joseph Truglio[1]. [1]Icahn School of Medicine at Mount Sinai, Maplewood, NJ; [2]Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2706408)

LEARNING OBJECTIVE #1: Assess the clinical significance of a positive antinuclear antibody (ANA) test.

CASE: A 60-year-old woman presents to her primary care provider to establish care. She has a medical history significant for hypothyroidism and hypertension. She takes levothyroxine (100mcg daily) and amlodipine (5mg daily). She reports a history of recurrent urinary tract infections and complains of ongoing dysuria. A urinalysis revealed microscopic hematuria (4–10 RBC's/hpf). A urine culture was negative, urine calcium/creatinine ratio was within normal limits, and a renal ultrasound was normal. The patient denies history of fever, weight loss, fatigue, joint pain/stiffness, weakness, sicca symptoms, oral mucosa ulcers, or Raynaud's phenomenon. She reports a positive family history of systemic lupus erythematosus (SLE) in her twin sister and aunt. On examination, the patient exhibits a malar erythematous rash. An ANA test was positive (1:360). The patient was diagnosed with SLE, started on plaquenil (200 mg daily), and referred to a rheumatologist. Subsequent laboratory tests were negative for anti-dsDNA, anti-Smith, anti-IgA/IgG/IgM, anti-ribonucleoprotein (RNO), anti-SSA, C reactive protein, and positive for anti-thyroidperoxidase (TPO). A subsequent ANA test was <1:40. The initial ANA result was considered a false positive associated with anti-TPO. Urine cytology showed atypical cells and the patient was referred to urology for potential cystoscopy.

IMPACT: The presence of a malar rash, microscopic hematuria, and ANA initially suggested SLE. Subsequent autoimmune workup was unrevealing however, and the repeat ANA was negative. The initial ANA likely resulted from thyroid antibodies.[1] Although an ANA test is often included in the initial workup of patients with signs of SLE (such as microscopic hematuria), other potential causes of ANAs should be considered prior to diagnosing SLE.

DISCUSSION: ANA detection plays an important role in the diagnosis of connective tissue diseases such as SLE. The clinical sensitivity of diagnosing SLE by ANA detection is 91%.[2] However due to the low prevalence of SLE in the general population, most people with ANAs do not have SLE. 13.8% of individuals age 12 years and older have ANAs, but the prevalence of SLE is only 0.24% in patients 17 years and older. ANAs are also present in a large percentage of patients with autoimmune thyroiditis (45%).[1] A recent guideline suggests using ANA testing when there is a strong clinical suspicion of SLE.[3] A separate study analyzed factors associated with SLE development and found

that oral ulcers, anti-dsDNA and renal disease (proteinuria or cellular casts) were independent predictors of developing definite SLE.[4] As our case demonstrates, a positive ANA test may not be clinically significant in a patient with few symptoms of SLE and a known ANA-associated comorbidity. In patients with hypothyroidism, ANA results should be carefully considered given the large ANA positivity in patients with autoimmune thyroiditis.

DEFECATE WITH A LIMPING GAIT! Payal Sen[2]; Uddalak Majumdar[3]; Patrick Rendon[1]. [1]UNM Health Science Center, Albuquerque, NM; [2]University of New Mexico, Albuquerque, IL; [3]Blessing Hospital, Quincy, IL. (Control ID #2692618)

LEARNING OBJECTIVE #1: Recognize Clostridium Difficile as a predisposing infection to Reactive arthritis

LEARNING OBJECTIVE #2: Use corticosteroids judiciously in the treatment of refractory Clostridium difficile related reactive arthritis

CASE: An 84-year-old Caucasian female presented with 3 days of profuse, watery diarrhea and right knee pain. She had been hospitalized for bronchitis a few weeks ago, treated with amoxicillin-clavulanic acid and discharged. There was no history of trauma or travel. Her past medical history included CKD stage IIIa and diverticulosis. She was afebrile and her clinical exam was normal except for dry oral mucosa and minimal swelling of the right knee. She had a normal WBC count, UA and LFTs, but had a GFR of 27 (baseline 45) and creatinine of 1.9 (baseline 1). Stool was positive only for Clostridium difficile (C.Diff) toxin. She was diagnosed with acute kidney injury from C. Diff associated diarrhea and started on IV fluids with oral vancomycin. Her diarrhea and renal function improved but the pain and swelling of her right knee increased and flexion became restricted. Work up showed CRP of 118 mg/dL, and ESR of 18 mm/hr, while X-rays, Rheumatoid Factor, anti-CCP, Anti-Nuclear Antibodies and uric acid were normal. The knee joint was aspirated and showed 12090 leukocytes with 85% PMNs. Gram staining, crystals and eventually cultures were also negative. Methylprednisolone was added and knee symptoms rapidly improved. Patient was discharged on oral prednisone and oral vancomycin for 2 weeks. On follow-up her renal insufficiency, diarrhea and knee pain had resolved. ESR and CRP had decreased to 12.2 mg/dL and 9 mm/hr. respectively.

IMPACT: I have started thinking of extra-gastrointestinal complications of C.Diff infection (CDI) and I also weigh the pros and cons of using corticosteroids in refractory cases.

DISCUSSION: Reactive Arthritis (ReA) is a syndrome of sterile asymmetrical autoimmune oligo-arthritis following infection. Preceding infections are usually Chlamydia, Campylobacter, Shigella, Salmonella, and Yersinia but CDI is distinctly uncommon. Only 50 CDI related ReA cases have been reported since the first case report in 1976. With increasing incidence of CDI, clinicians should expect to see more extra-gastrointestinal morbidity from CDI. CDI associated ReA has been mostly reported in younger people, with positive HLA-B27, with excellent prognosis. Although traditionally NSAIDs have been the first line of treatment, we used corticosteroids to avoid the well-known nephrotoxic effects of NSAIDs, since our patient had acute kidney injury. Even though conventional knowledge is that usage of corticosteroids in patients with CDI have worse outcomes, there is anecdotal evidence of refractory CDI being treated with corticosteroids. A recent study of elderly adults with pneumonia or COPD showed decreased incidence of CDI when treated with steroids. As demonstrated in this case, judicious use of corticosteroids in clinically appropriate situations may decrease morbidity in patients with CDI.

DELAYED POST-HYPOXIC LEUKOENCEPHALOPATHY AFTER APPARENT RECOVERY FROM CO INTOXICATION Jiping Zeng; Christopher J. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #2710533)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of delayed post-hypoxic leukoencephalopathy (DPHL) following CO poisoning.

LEARNING OBJECTIVE #2: Manage DPHL using a team-based approach.

CASE: A 43 year-old man presented with behavioral changes and paranoia. He had a history of depression and methamphetamine abuse and was hospitalized 3 weeks earlier for carbon monoxide (CO) poisoning following a suicidal attempt. He recovered after hyperbaric oxygen therapy and was discharged home on daily fluoxetine and buproprion. According to his family, his symptoms started to worsen 10 days prior to admission. He developed confusion, memory loss, paranoia, and aggressive behaviors. He had no recent head trauma, medication changes, or illicit drug use. Physical exams showed normal vital signs, muscle strength and DTRs. He was alert and oriented. No frontal release signs, tremor, cogwheel rigidity or focal neurologic deficits were noted. He had childish demeanor, labile mood, tangential thought process and poor insight. Lab tests, including CBC, CMP, UA, acetaminophen and salicylate levels, and UDS, were normal. Head CT revealed subtle hypodensity of the bilateral globus pallidus that was similar to the previous MRI. He continued to exhibit impulsivity, distractibility, hyperphagia, and hypersexuality. Brain MRI showed confluent frontal and parietal lobe white matter changes consistent with DPHL. His aggressive and impulsive behaviors required increasing doses of quetiapine, olanzapine, and trazodone. The patient was transferred to a cognition rehabilitation facility for ongoing care.

IMPACT: Internists and hospitalists should be aware of the variable presenting features of DPHL. This syndrome has been recognized for a century and more cases will be diagnosed with the expanding availability of MRI. The prompt recognition of DPHL allows early utilization of supportive care and rehabilitative services.

DISCUSSION: CO poisoning is responsible for up to 40,000 emergency department visits, and DPHL is a common complication that may be encountered by general internists and hospitalists. The incidence of DPHL varies widely in studies from a few percent to two thirds of patients. The findings are diverse, including focal neurologic deficits, motor dysfunction, personality change and psychosis. Various MRI findings, including globus pallidus lesions, white matter changes, and diffuse low-density lesions throughout the brain have been reported. There are no widely accepted criteria for diagnosis of DPHL, however it can be made with appropriate history and by ruling out common causes of acute toxic-metabolic encephalopathy. The management requires coordination of inter-professional teams, including internal medicine, neurology, psychiatry, neuropsychology, speech therapy, nursing, social work and rehabilitation. Although no specific treatment has proven effective, recovery from DPHL after CO poisoning occurs in 50% - 75% of patients within one year follow-up.

DELAYS IN DIAGNOSIS OF NECROTIZING FASCIITIS IN PATIENTS WITH NORMAL CT RESULTS Arthur Ablayev. Capital Health Regional Medical Center, Trenton, NJ. (Control ID #2706372)

LEARNING OBJECTIVE #1: Recognize necrotizing fasciitis when CT is normal.Avoid delays in surgical intervention

CASE: A 55-year-old male presented to the ER complaining of pain and persistent swelling in both legs. Patient denies fever, chills. Past medical history: lower extremity venous stasis, cellulitis, hypertension, alcohol abuse and seizures. Current medications: none. Denies smoking, drug use. Drinks alcohol 3–4 days a week. On physical exam: VS: T 99; POX 94%; RR 24; BP 100/58; HR 111 Patient looks not in acute distress. Examination of head, neck, chest and heart did not show any obvious changes. Lungs: mild basal rales left lung. Lower extremities: +1 edema, chronic venous stasis changes bilaterally. Right leg - no evidence of infection. Left leg - moderate cellulitis, some superficial bullae of the skin. No crepitus. Labs: WBC 11.7; bands 61%; BUN 17; creatinine 0.8mg/dl Doppler: no DVT. Patient was hospitalized, started on vancomycin + cefepime and supportive treatment. Eight hours later: BP 80/54, HR 130, RR 40, Temp 100.2. The pain in left leg worsened. Patient was intubated, got more fluid boluses, started on pressors, transferred to ICU. Repeat labs: WBC 14.4; bands 44%; BUN 56mg/dl; creatinine 2.66mg/dl; LA 4.9mmol/L There was no significant change on physical exam in lower extremities. CT leg showed no evidence of subcutaneous air, abscess. Surgical team was consulted and after reviewing CT, recommended observation. Later, due to worsening of systemic symptoms, repeat consult was requested. The subcutaneous tissue was aspirated at the bed side with a needle and showed murky fluid. At this point, decision was made to take the patient urgently to the operating room. Final diagnosis of necrotizing fasciitis was made in OR. Incision and drainage, debridement of the necrotizing soft tissue infection was done.

IMPACT: This case demonstrated again that necrotizing fasciitis is aggressive and rapidly progressing infection which is difficult to diagnose. CT can delay the diagnosis and treatment. Clinical judgment must be the most important element in diagnosis.

DISCUSSION: Necrotizing fasciitis is characterized with rapid progression, significant tissue destruction, systemic symptoms and high mortality. Early recognition of necrotizing fasciitis is an important and difficult task for any physician. There are some clinical features that can help with diagnosis of Necrotizing Fasciitis: Severe pain that is out of proportion to skin findings; Induration of soft tissue extending beyond the area of visible skin changes; Crepitus on palpation, bullous lesions, and skin necrosis. Negative results on imaging studies should not delay surgical consult and aggressive management when clinical suspicion is high.

DELTA-DELTA GRADIENT TO THE RESCUE: ELEVATED ANION GAP ACIDOSIS WITH A BASIC PH Rachna Rawal; Oluwasayo Adeyemo; Stewart G. Albert. St. Louis University, St. Louis, MO. (Control ID #2705228)

LEARNING OBJECTIVE #1: Utilize delta-delta gradient to explain elevated anion gap acidosis

LEARNING OBJECTIVE #2: Analyze alkalosis in the setting of alcoholic ketoacidosis

CASE: Elevated anion gap acidosis is a common finding after acute alcohol ingestion due to accumulation of keto and lactic acids associated with alcoholic ketogenesis. We report a case of recurrent metabolic acidosis with superimposed metabolic alkalosis that was analyzed using the delta-delta gradient. A 56 year-old man with a medical history of alcoholic pancreatitis was admitted for alcohol withdrawal and non-bilous emesis for three days. Exam was notable for blood pressure of 151/96, conjugate gaze palsy without nystagmus and diffuse abdominal tenderness. Labs were significant for: HCO3 16.6, lactic acid 4.7, beta-hydroxybutyrate 6.95, alcohol level 214, lipase 95, glucose 80, VBG pH 7.51, pCO2 21, pO2 51, base excess mixed venous 17.2. The patient's anion gap was 29 with a delta-delta gradient of 10. During the course of five hospitalizations his anion gap ranged from 24mmol/L to 30mmol/L. He was treated for acute pancreatitis, presumed thiamine deficiency and alcohol withdrawal syndrome. His large anion gap prompted further analysis. The delta-delta gradient of 10 (adjusted for loss of the chloride secondary to vomiting) confirmed a concomitant metabolic alkalosis. A gradient greater than 0 suggests a primary metabolic alkalosis with an anion gap metabolic acidosis.

IMPACT: This patient presented with an elevated anion gap, low bicarbonate and alkalotic pH. Typically, such large anion gaps trigger a search for additional etiologies, which may be misleading especially with an alkalotic pH. In such a setting, the delta-delta gradient can be helpful in determining the various components/etiologies of the patient's acid–base disorder.

DISCUSSION: This patient's alcohol binge drinking combined with chronic malnutrition prevented hepatic gluconeogenesis: the accumulation of NADPH from alcohol consumption prevented the oxidation of lactic to pyruvate. His persistently high alcohol levels caused alcoholic ketoacidosis leading to lactic acidosis with hypoglycemia. His intractable vomiting caused gastric chloride loss and a metabolic alkalosis. An elevated anion gap acidosis with a concomitant alkalosis is explained by the delta-delta gradient due to the combined organic acidosis and intractable vomiting. The patient presented with recurrent episodes of alcoholic keto/lactic alkalosis. It is uncommon to have alcoholic ketoacidosis with a large anion gap in the setting of alkalosis. The delta-delta gradient unmasked the true etiology of his elevated anion gap alcoholic acidosis with hypoglycemia by accounting for the loss of chloride due to vomiting. This case emphasizes the significance of using a less familiar, yet a valuable medical principle, the delta-delta gradient in clinical diagnosis, before ordering additional unnecessary testing.

DEMONSTRATING RESILIENCE AFTER FLEEING PERSECUTION: A MAN TORTURED FOR HIS POLITICAL OPINION IS GRANTED ASYLUM Katherine C. McKenzie[1]; Sarah Kimball[2]; Ryan Handoko[1]; Emmanuella Asabor[1]. [1]Yale School of Medicine, New Haven, CT; [2]Boston University School of Medicine, Boston, MA. (Control ID #2697888)

LEARNING OBJECTIVE #1: Understand fundamentals of the process of seeking asylum in a man tortured because of his political opinion, and the role physicians can play in providing medical forensic evaluations of asylum seekers.

LEARNING OBJECTIVE #2: Assess the characteristics of the man who was granted asylum and the provisions in the asylum program that increased the likelihood that once granted asylum, allowed him to transition to a successful and healthy professional and personal life.

CASE: AN was born in the Democratic Republic of Congo where he was persecuted because of his political beliefs. He was imprisoned in inhumane conditions and interrogated for two weeks, and as a result of his torture developed scars from a burn and cuts with a bayonet. Shortly after being released from detention, he fled to the US. Through a torture survivors program, he found an immigration attorney to represent him, who in turn referred him for a medical forensic evaluation. Shortly after arriving, he also

sought counseling and was treated for depression and post-traumatic stress disorder. He was granted asylum based on persecution due to his political opinion. His medical forensic report contributed to his successful case. His family joined him and he started a job in a surgical supply factory. He learned English and displays no chronic signs of psychological scars. His children are thriving in high school and college.

IMPACT: It has been shown that medical evaluations significantly increase the likelihood that asylum will be granted. (1) This case supports literature that demonstrates that many individuals who emigrate to other countries show remarkable resilience despite their pre-immigration trauma. (2) Physician support of asylum seekers is important is many cases, but additional institutional infrastructure which promotes occupational engagement and family reunification are key to success after asylum is granted.

DISCUSSION: AD experienced severe trauma when he was tortured in his country due to his political opinion. He fled the US and was able to access systems that increased the likelihood of a successful asylum appeal, including an experienced immigration attorney and physicians skilled in gathering evidence to be used effectively in immigration court. In addition, he demonstrated insight by entering counseling for depression and PTSD. After asylum was granted, US asylum policy provided the mechanism to unite him with his family and a torture survivors group provided occupational counseling. His personal resourcefulness, together with these institutional supports, have contributed to his ability to thrive personally and professionally. 1.Lustig SL, et. al. Asylum grant rates following medical evaluations of maltreatment among political asylum applicants in the United States. J Immigr Minor Health. 2008;10(1):7–15) 2.Overland G. Generating theory, biographical accounts and translation: a study of trauma and resilience. International Journal of Social Research Methodology. 2011;14(1):61–75

DENOSUMAB-INDUCED HYPOCALCEMIA Zaid Abdel-Rahman; Sameer K. Avasarala. Henry Ford Health System, Detroit, MI. (Control ID #2701608)

LEARNING OBJECTIVE #1: Recognize the increased use of denosumab and the likelihood of developing hypocalcemia

LEARNING OBJECTIVE #2: Educate patients on the dire necessity of calcium supplements to prevent the morbidity associated with denosumab-induced hypocalcemia

CASE: An 83-year-old male with chronic kidney disease (CKD), early Alzheimer's dementia presents with worsening back pain. Magnetic resonance imaging showed vertebral lesions, labs showed a high prostate-specific antigen (PSA) and he was eventually diagnosed with metastatic prostate cancer based on bone biopsy results. Treatment was initiated with bicalutamide followed by leuprorelin and radiation therapy to the vertebral lesions. Five months after starting therapy, he developed castration resistance and his PSA started to rise so he was started on docetaxel followed by cabazitaxel. He received additional radiotherapy sessions for cauda equine syndrome in addition to a denosumab injection for his bony metastases. Before administering denosumab, his baseline ionized calcium (iCa) was 1.1 mmol/l (1.00 - 1.35 mmol/L) and vitamin D and calcium supplements were prescribed. Six days after the injection he presented to the emergency department with generalized weakness and muscle twitches, his iCa was found to be 0.61 mmol/L requiring an intensive care unit (ICU) admission where he was started on an intravenous calcium drip while his QT intervals were closely monitored. After normalization of his calcium levels, he was switched to oral supplements and discharged on 500 mg of calcium citrate three times daily and 2000 units of vitamin D daily. Twenty eight days after the injection, he presented with similar complaints and his iCa was found to be 0.62 mmol/L. This necessitated another ICU admission for IV calcium replacement and monitoring. He was then discharged on the same supplements as last time with the addition of calcitriol 1 mcg twice daily. His serum calcium levels were followed on outpatient basis by his oncologist. Fifty days after the denosumab injection, he had a third ICU admission for severe hypocalcemia

IMPACT: Many factors played a role in this patient's course, most importantly; he was not taking his calcium and vitamin D supplements thinking that these are just non-essential vitamins rather than a key component of his treatment, in addition to CKD and social factors like not getting prescriptions filled because of transportation issues. Keeping these issues in mind can decrease the burden and morbidity of a preventable complication.

DISCUSSION: Hypocalcemia can be a serious electrolyte abnormality that can result in cardiac arrhythmias, coronary vasospasm and even sudden cardiac death. Denosumab-induced hypocalcemia has an incidence of 2-5 and as the use of denosumab is increasing among cancer and non-cancer patients (e.g., osteoporosis), all physicians should be aware of this adverse effect and should monitor patients by frequently checking their calcium levels before and after treatment and making sure they are taking their supplements as prescribed.

DEPLETE Eileen Hennrikus; Amanda Bryson; Melissa Yacur. Penn State College of Medicine, Hershey, PA. (Control ID #2705435)

LEARNING OBJECTIVE #1: Not only alcoholics suffer from thiamine deficiency. Consider thiamine deficiency in elderly, ill patients who acutely develop altered mental status while hospitalized.

CASE: RG, an 89-year-old male with Parkinsonism, presented to the emergency department with community acquired pneumonia and sepsis. He improved significantly within 24 hours of antibiotic treatment. While NPO for a swallow evaluation, he became hypoglycemic (45 mg/dl) and was started on a D5W infusion. The next morning, he became confused and agitated, developed opthalmoplegia, and subsequently became unresponsive. There was no evidence of recurrent sepsis or acute brain abnormality. He was empirically started on thiamine. Over the next 24 hours, he became responsive and continued to improve back to his baseline mental status. Thiamine level later returned < 7 (normal 8–30 nmol/L).

IMPACT: Wernicke's encephalopathy (WE) is a neuropsychiatric emergency caused by thiamine deficiency and is characterized by ocular disturbances, gait ataxia, and confusion. Physicians commonly prophylactically treat thiamine deficiency in alcoholic patients, but the clinical suspicion in non-alcoholic patients remains low. We suspect that many elderly patients undergo unnecessary procedures such as lumbar punctures, MRI of the head and a multitude of lab tests, when they suffer from a missed, treatable diagnosis of Wernike's encephalopathy.

DISCUSSION: We propose that acutely ill, elderly patients are at risk for thiamine deficiency and its sequela. When well, these patients may have borderline thiamine stores due to poor nutrition, which deplete rapidly when acutely ill due to a hypermetabolic state. Additionally, hospitalization can exacerbate thiamine deficiency, due to decreased oral intake. The administration of dextrose-containing fluids can precipitate Wernike's encephalopathy which can be mistaken for dementia in the elderly. Thiamine deficiency and progression to WE is preventable and treatable. Prompt initiation of

intravenous thiamine is low-risk and is paramount for achieving favorable outcomes in these patients. Physicians should consider thiamine supplementation in elderly, non-alcoholic patients with marginal nutrition who present with or develop “dementia”.

DEVELOPING AN ALGORITHM TO APPROACH PATIENTS WHO REFUSE CARE BUT LACK CAPACITY Maura George[1]; Kevin Wack[2]; Sindhuja Surapaneni[3]; Stephanie Larson[1]. [1]Emory University, Atlanta, GA; [2]Grady Memorial Hospital, Atlanta, GA; [3]Emory University School of Medicine, Atlanta, GA. (Control ID #2708015)

LEARNING OBJECTIVE #1: Articulate the ethical challenges and vulnerability of a patient who refuses treatment but lacks capacity

LEARNING OBJECTIVE #2: Use an innovative algorithm to approach this common but difficult ethics case

CASE: A 57 y/o male with PMH of schizophrenia and HTN is brought to the hospital by the police who found him lying on a sidewalk. There was no reported trauma, and the patient was awake but moaning. In the ED, he describes diffuse body pains but remains too confused to provide more info. His baseline mental status is unknown but 24 hours after admission he has spoken very little and seems unable to understand what is being said to him. Upon evaluation, he repeats “I’m all right” and “I’m ok;” however, when providers attempt to examine him, says “Leave me alone!” There is no surrogate, but the medical record mentions a sister who the SW attempts to find. Meanwhile, there is significant concern about the patient’s medical conditions. His imaging identified multiple lytic lesions in the axial skeleton with compression deformities of the thoracolumbar spine concerning for multiple myeloma or lytic bone metastases. The team is seeking a bone biopsy, but the patient lacks capacity to consent. The conversations make him agitated and he consistently states that he does not want to be touched. The ethics committee is consulted to determine if a bone biopsy is appropriate despite his apparent refusal.

IMPACT: While all hospitals see patients who lack capacity, a large, urban, safety net hospital like Grady Memorial Hospital in Atlanta sees these cases with an amazing frequency, and the patients are some of the most vulnerable because of factors like race, poverty, nationality, and social network. Patients may vocally or physically refuse care. We on the Grady ethics committee field so many such cases that we’ve internalized an algorithmic approach to the questions. This case motivated us to put on paper our approach in the hopes that other clinicians could make the best decisions in such scenarios.

DISCUSSION: Patients who lack capacity pose ethical challenges, especially when they are declining care their surrogates and/or clinicians feel are indicated. These patients are a vulnerable population and should receive standard of care that is in line with their authentic self’s values, just as any other patient would. But forcing treatment on patients who refuse but lack capacity carries medical and psychological risks to the patient and the staff involved in their care. It is also often simply impractical to force some treatments, especially long-term. For example, independent of the ethical “should” question, how *would* one force hemodialysis three times per week for the rest of someone’s life? How would one force a surgery that requires weeks of post-operative physical therapy? Using our algorithm, we can help clinicians think through these questions and arrive at the most ethical and practical decision, achieving best outcomes for patients and reduced moral distress for their caretakers and clinicians.

DIABETES, DIARRHEA AND DEFICIENCY Mohammad F. Mathbout; Monika G. Spacil; Joseph R. Sweigart. University of Kentucky, Lexington, KY. (Control ID #2672626)

LEARNING OBJECTIVE #1: Understand when it is appropriate to consider diabetic diarrhea as a diagnosis

LEARNING OBJECTIVE #2: Recognize vitamin C deficiency as a potential sequalae of long standing diarrhea

CASE: A 43-year-old man with a history of uncontrolled type-1 diabetes presented with acute onset nausea and vomiting. He also reported several months of persistent, watery, non-bloody diarrhea and weight loss. He appeared frail and cachectic. The patient was edentulous with gum ulcers. Skin examination was remarkable for generalized roughness, bruises, and petechia. Initial work up showed diabetic ketoacidosis (DKA) and he was treated immediately with intravenous fluids and insulin. His DKA resolved, but his chronic diarrhea did not. Stool electrolytes were consistent with a secretory process. Infectious etiologies, including giardia, HIV, Whipple’s disease, cryptosporidium, and microsporidium were all negative. Ensophagogastroduodenoscopy and colonoscopy with biopsies were also unrevealing. Laboratory investigation for gastrinoma, VIPoma, somatostatinoma, and carcinoid also returned negative. He was initiated on octreotide for a presumed diagnosis of diabetic diarrhea, with significant improvement in his symptoms. Because of his generalized skin and oral findings in the setting of persistent diarrhea, Vitamin-C level was checked and found to be severely diminished. He was diagnosed with scurvy and started on Vitamin C replacement.

IMPACT: The general medicine physician must be mindful of malabsorption from severe secretory diarrhea secondary to uncontrolled diabetes. If no inflammatory, autoimmune, infectious, or malignant sources are found, diabetic diarrhea is a likely explanation for persistent secretory diarrhea and can precipitate nutritional deficiencies. Management is mostly supportive with hydration, glucose control, and replacing nutrient and electrolyte deficiencies. Octreotide use has only been recorded in case reports to treat diabetic diarrhea. It was highly effective for our patient.

DISCUSSION: Scurvy is classically regarded as a disease of pirates, replete with an image of a grizzled peg leg with missing teeth, wiry hair, bruises, and cuts covering his body. This image exists for good reason: Vitamin C deficiency causes such manifestations and has all but left the forefront of physicians’ minds while treating patients in developed nations. However, in the case of this patient, scurvy was a very real issue in the setting of his malnutrition and chronic diabetic diarrhea. Severely uncontrolled diabetes can cause multiple common symptoms, but one often overlooked is diabetic diarrhea. Generally painless, non-bloody, and watery, occasionally causing incontinence, diabetic diarrhea is a diagnosis of exclusion for secretory diarrhea. Functional impairment of small and large intestine motility, enteral bacterial overgrowth, and increased intestinal secretion from autonomic neuropathy have all been linked as possible mechanisms in its pathogenesis.

DIAGNOSING HYPOXIC RESPIRATORY FAILURE IN A PATIENT WITH IDIOPATHIC HYPERTROPHIC PACHYMENINGITIS. Sarah Koumtouzoua. Emory University, Atlanta, GA. (Control ID #2701982)

LEARNING OBJECTIVE #1: Discuss presentation of PCP in HIV non-infected patients, including those with autoimmune or rheumatologic dysfunction treated with immune suppressive therapies.

LEARNING OBJECTIVE #2: Review recommendations for PCP prophylaxis in HIV non-infected patients with immune compromise.

CASE: A 69 year-old female presents with shortness of breath for two weeks. She also reports lethargy, dry cough, chills, lower extremity edema, proximal muscle weakness and difficulty walking. Past medical history is notable for idiopathic hypertrophic pachymeningitis with chronic dysphagia and dysarthria, treated with three months of high dose prednisone and rituximab. On admission, she was hypotensive, tachycardic and hypoxic. Exam revealed diffuse crackles and edema to her knees bilaterally. ABG showed respiratory alkalosis with a pH of 7.50, PCO2 of 34 and PO2 of 57 on 5L O2. BNP was 57. CT of the chest revealed diffuse ground glass opacities and septal thickening. Broad spectrum antibiotics and stress-dose steroids were initiated for sepsis. Despite treatment, hypoxia continued. LDH was elevated at 520, raising suspicion for Pneumocystis pneumonia (PCP). Empiric PCP treatment with pentamidine was started and bronchoscopy on day 5 revealed cytology positive for PCP. She improved with clindamycin and primaquine with steroids and was weaned off oxygen. Following treatment, she continued atovoquone for PCP prophylaxis.

IMPACT: Our case illustrates that PCP and other opportunistic infections should be considered in HIV non-infected patients who present with respiratory failure on immunosuppressive medications, especially those on multiple therapies. Additionally, consideration should be given to PCP prophylaxis for patients with rheumatologic disease on combined steroids and immunosuppressive therapies for greater than one month.

DISCUSSION: Pneumocystis pneumonia is an opportunistic fungal infection caused by *Pneumocystis jirovecii*. Clinical presentation of PCP in non-HIV infected patients includes subacute shortness of breath (as opposed to indolent progression in HIV patients), dry cough, fever, and hypoxia with diffuse interstitial infiltrates on imaging. Elevated LDH above 250 is suggestive of PCP, with cytology allowing for a definitive diagnosis. PCP typically causes an atypical pneumonia in immune-comprised hosts. It is traditionally associated with HIV infected patients, but can also occur in HIV non-infected hosts, specifically those with hematologic malignancies, transplant patients, and primary immunodeficiencies. Less commonly, PCP can occur in patients immunocompromised from the use of combined steroids and immunosuppressive medications to treat rheumatologic disease. In a retrospective study of patients on rituximab from 1998 to 2011, 73% of the patients that developed PCP were also receiving concomitant prednisone. As our case illustrates, PCP can occur in patients on immunosuppressive therapies and especially those on multiple therapies that include steroids.

DIAGNOSING MYOCARDIAL INFARCTION IN A VENTRICULAR-PACED RHYTHM Anish Vani[1]; Lauren Yokomizo[1]; Matthew Vorsanger[2]. [1]New York University School of Medicine, New York, NY; [2]New York University Langone Medical Center, New York City, NY. (Control ID #2671971)

LEARNING OBJECTIVE #1: Diagnose myocardial infarction (MI) in patients with ventricular-paced rhythms by using the Sgarbossa criteria

LEARNING OBJECTIVE #2: Recognize the limitations of the Sgarbossa criteria

CASE: A 93 year-old Polish man with complete heart block, treated with a dual-chamber pacemaker, presented with acute onset chest pain to the emergency room of our institution. His electrocardiogram (ECG) showed sinus rhythm with atrial sensing and right ventricular pacing. There were >1mm ST segment depressions in leads V3-V5, leads in which the QRS complex was predominantly negative. His initial troponin I level was 1.9 ng/mL. Due to suspicion of an acute coronary plaque rupture, the patient was referred for urgent coronary angiography, which revealed severe stenosis of the distal right coronary artery, mid posterior descending artery, left main coronary artery, mid left anterior descending artery, and the ostial left circumflex artery. An intra-aortic balloon pump was placed to maintain coronary perfusion. The patient subsequently underwent successful coronary artery bypass grafting, with saphenous vein grafts placed on the left anterior descending artery, first obtuse marginal, and posterior descending artery, and was discharged home in stable condition.

IMPACT: This case validates the application of the Sgarbossa criteria to the ECG of ventricular-paced patients to diagnose acute MI. It also highlights significant limitations of the Sgarbossa criteria and suggests a need to develop a more comprehensive system to allow for greater sensitivity in diagnosing acute MI in ventricular-paced patients.

DISCUSSION: Interpreting the ECG in the setting of a left bundle branch block (LBBB) or ventricular-paced rhythm can be challenging. Depolarization and repolarization through the ventricular myocardial tissue, instead of the specialized conduction system, produces ST segment changes discordant to the major vector of the QRS complex, which may obscure underlying ischemic ST changes. Sgarbossa et al. found that ST elevations ≥5mm in leads with predominantly negative QRS complexes, ST elevations ≥1mm in leads with predominantly positive QRS complexes, or ST depressions ≥1mm in leads V1-V3 were all highly specific for an acute MI, based on a 17 patient cohort from the GUSTO-1 trial. There are significant limitations of the Sgarbossa criteria, however. It has not been validated for use in patients with biventricular pacing and the criteria are specific, but not sensitive. Other scoring systems exist, although they have been validated in patients with a LBBB, not in ventricular-paced patients. Subsequent research with a larger patient cohort is needed, due to the increasing number of ventricular-paced patients in our aging population and the importance of the emergency room ECG to triage patients with acute MI for immediate fibrinolytic therapy or percutaneous coronary intervention.

DIAGNOSIS OF ISOLATED UNILATERAL ABSENCE OF THE LEFT PULMONARY ARTERY (IUAPA) IN AN ADULT Dorothy Charles; Steven Mckee; Michael goodwin; Lindsey Merrihew; Deepa R. Nandiwada. University of Pennsylvania, Philadelphia, PA. (Control ID #2706735)

LEARNING OBJECTIVE #1: Recognize the differential and diagnose previously unrecognized isolated unilateral absence of pulmonary artery (IUAPA)

LEARNING OBJECTIVE #2: Manage complications for patients who have IUAPA

CASE: A 55-year-old non-smoking man with a history of recently recurrent pneumonia and worsening dyspnea on exertion presented with right-sided chest pain. For the past 6 months he presented to clinic with progressive lower extremity edema and dyspnea on exertion with an echo ordered by his primary care physician revealing a normal ejection fraction and mild diastolic dysfunction. On the day prior to admission he described sudden onset of 7/10 pain after bending over and feeling a "pop in his chest". Vital signs revealed a blood pressure of 196/116 mmg/hg and an oxygen saturation of 94% on room air. On pulmonary exam, breath sounds were decreased on the left. The lungs were otherwise clear. Troponin T and brain natriuretic peptide levels were normal. An EKG was remarkable for T wave inversions. Chest x-ray demonstrated opacities in the left upper, middle, and lower lobes and the right lower lobe associated with volume loss suggestive of chronic post-inflammatory fibrosis

but could not rule out pneumonia. Computed Tomography of the chest showed a hypoplastic left lung with multifocal pulmonary infiltrates, left-ward deviation of the mediastinum and trachea, with right lung hyperinflation and mild right lower lobe peribronchial cuffing. Hospital Course: Initial concern for pneumonia was discussed, however clinically the patient had no other signs of infection so antibiotics were not started. Continuous oxygenation saturation monitoring overnight revealing sustained desaturations at 70% to 80% on room air, which improved with oxygen alone.

IMPACT: This is a rare diagnosis in an asymptomatic adult with only case reports available to guide diagnosis and management. It also shows how premature closure can delay the diagnosis of a long standing progressive pathology. In the clinic this patient's work up for dyspnea on exertion was stopped after congestive heart failure had been ruled out via echocardiogram. Additional anchoring and premature closure biases may have come into play with his recurrent pneumonias over the past few years.

DISCUSSION: This case brings up a rare diagnosis of asymptomatic IUAPA in an adult with a sub-acute progression later in life. Unlike most cases, he did not have a significant childhood history of pulmonary disease or congenital heart disease. Patients with absence of the left artery can be asymptomatic as the right lung is more able to compensate with hypertrophy as compared to the left. Complications of IUAPA include severe pulmonary hypertension, pulmonary hemorrhage, and recurrent infections. Monitoring with serial echocardiograms to assess for the progression of pulmonary hypertension is the mainstay of therapy. Supportive care including emobolization for hemoptysis and lobectomy or pneumonectomy for recurrent infections have also been reported.

DIFFUSE LIVER METASTASES UNDETECTED BY MULTIPLE IMAGING MODALITIES IN EXTENSIVE-STAGE SMALL CELL LUNG CANCER Benjamin D. Gallagher. Columbia University Medical Center, New York, NY. (Control ID #2673513)

LEARNING OBJECTIVE #1: Recognize the limited sensitivity of diagnostic imaging in detecting small liver lesions.

CASE: A 66-year-old former heavy smoker with a history of non-alcoholic steatohepatitis presented to the emergency department with several days of exertional dyspnea and 30 lbs. of weight loss over several months. He was found to have a large left hilar mass, as well as hypokalemia, metabolic alkalosis, abnormal liver function tests, and thrombocytopenia. The plasma cortisol and ACTH levels were markedly elevated, and Cushing's syndrome secondary to ectopic ACTH production by small cell lung cancer was suspected. This diagnosis was confirmed by transbronchial biopsy of the mass. Staging imaging revealed a right cerebellar lesion, but multiple modalities (ultrasound, CT, and MR) failed to demonstrate any liver metastases. Because the patient's hepatic dysfunction continued to worsen without an apparent cause, he underwent percutaneous liver biopsy, which showed extensive infiltration by tumor. Unfortunately the procedure was complicated by intraperitoneal hemorrhage, and the patient suffered a cardiac arrest soon afterwards. On autopsy more than 50% of the hepatic parenchyma was infiltrated by more than 100 discrete metastatic lesions, most of them <1 cm in diameter.

IMPACT: When treating patients with cancer and abnormal liver function tests, clinicians must maintain a high index of suspicion for metastatic disease even when imaging studies are unrevealing.

DISCUSSION: Small cell lung cancer is an aggressive, smoking-associated malignancy with a poor prognosis. The objective of staging is to identify the minority of patients with limited-stage disease, in whom lesions are confined to a single hemithorax, because they benefit from combination radiation and chemotherapy. Most patients (60-70%) have extensive-stage disease on presentation and are offered chemotherapy alone. This patient had extensive-stage disease based on his brain lesion, so ascertaining the presence of liver metastases would not have affected management. However, the degree of hepatic dysfunction was so severe (total bilirubin reached 22 mg/dL) as to preclude systemic therapy, so finding a reversible cause of liver failure would have been necessary for him to receive treatment. Ultrasound is 40-70% sensitive for detecting liver metastases, and contrast-enhanced CT (the modality most often used) is 80-85% sensitive. MR provides the best lesion-to-liver contrast but is still insensitive to lesions smaller than 1 cm. Thus this patient's innumerable tiny metastases on a background of steatohepatitis went unnoticed by imaging.

DISCORDANCE IN BICARBONATE MEASUREMENT IN A PATIENT WITH HYPERTRIGLYCERIDEMIA Susan Tran[1]; Angela W. Fung[1]; Ivan M. Blasutig[1, 2]; Savannah Cardew[3]. [1]University of Toronto, Toronto, ON, Canada; [2]University Health Network, Toronto, ON, Canada; [3]Women's College Hospital, Toronto, ON, Canada. (Control ID #2684680)

LEARNING OBJECTIVE #1: Assess spurious laboratory values by ordering appropriate follow-up investigations

LEARNING OBJECTIVE #2: Recognize the effect of hypertriglyceridemia on biochemical assays

CASE: A 44-year old man presented to the emergency department with decreased level of consciousness after alcohol consumption. Medical history is significant for alcohol use of 30 bottles of beer per week, hypertension, and depression. On examination, he was hemodynamically stable, fatigued but rousable and oriented. His ethanol level was 53 mmol/L (normal <1). He received thiamine and intravenous fluids. He returned to baseline after further monitoring for several hours and was appropriate for discharge. However, bloodwork revealed a plasma bicarbonate level of 6 mmol/L (normal 23–29). This value was confirmed on repeated measurements. Anion gap was 27. As this result was unexpected and unexplained we tested bicarbonate level on arterial and venous blood gas samples and results were normal, as were pH and pCO_2. Electrolytes, creatinine, hemoglobin, and bilirubin were normal, serum ketones were negative, drug screen was negative, and lactate was only slightly elevated at 2.6 mmol/L (normal 0.5-2.0). After consultation with a clinical biochemist, a lipid profile was collected which detected a triglyceride level of 40 mmol/L (normal <1.7). In this case, plasma bicarbonate level was erroneous due to interference from high triglyceride levels. Bicarbonate from blood gas measurement was considered the true bicarbonate value. The patient was discharged home following this finding.

IMPACT: Understanding how laboratory results are measured, especially when discordance exists between two measurements of the same blood marker, is important to identify the true value. Biochemical interference leads to spurious results and occurs when the presence of a substance causes deviation from the true value of the analyte. Common endogenous substances causing interference include triglycerides, hemoglobin and bilirubin.

DISCUSSION: Bicarbonate is a routinely ordered laboratory test to detect acid–base disturbances. Bicarbonate can be measured directly in plasma/serum

or calculated from a blood gas whole blood sample using pH, pCO_2 and the Henderson-Hasselbalch equation. In general, bicarbonate values obtained from plasma/serum and blood gas are concordant. If discordant, ordering a lipid profile should be considered. High triglyceride levels may affect spectrophotometric analysis of plasma/serum bicarbonate, as used in our laboratory. This may be attributed to light scattering from the turbidity of the specimen causing interference with the assay. Hypertriglyceridemia also displaces the aqueous portion of the centrifuged plasma/serum sample with lipid, leading to erroneously lower values. In contrast, the blood gas measurement of bicarbonate is calculated from the Henderson-Hasselbalch equation and is not subject to spectral interferences. If high triglycerides are detected, blood gas measurement of bicarbonate should be considered more precise.

DISSEMINATED VARICELLA AFTER VACCINATION: VACCINE OR WILD-TYPE? Anthony Nicolas[2]; Deirdre Lewis[1]; Riffat Sabir[2]; Mini Hariharan[2]. [1]Baystate Medical Center, Northampton, MA; [2]Baystate Medical Center, Springfield, MA. (Control ID #2706625)

LEARNING OBJECTIVE #1: Recognize varicella as an uncommon cause of acute pancreatitis

LEARNING OBJECTIVE #2: Recognize the need for varicella vaccination after hematopoietic stem cell transplantation

CASE: A 57 year old man with a history of non-Hodgkin's lymphoma and autologous hematopoietic stem-cell transplant (HSCT) in remission was admitted to a community hospital with 3 days of epigastric pain. One week prior, patient had been vaccinated for varicella (VZV), MMR and pneumococcus. There was no history of trauma or alcohol abuse. Laboratory studies revealed elevated lipase, transaminitis, and indirect hyperbilirubinemia. A right upper quadrant ultrasound showed no gallstones or duct dilation. MRCP revealed mild pancreatic edema consistent with acute pancreatitis. On hospital day 2, patient's LFTs rose raising concern for an underlying hepatic process and was transferred to Baystate Medical Center for possible transjugular hepatic biopsy. On the day of transfer, the patient was noted to have a new vesicular rash. On admission, patient was afebrile and mildly tachycardic. Physical exam revealed a diffuse, pruritic, vesicular rash involving the limbs, torso and face. A PCR swab from an unroofed vesicle was positive for VZV, and IV acyclovir was initiated. The patient's hospital course was complicated by VZV hepatitis with prolonged hyperbilirubinemia and VZV pneumonitis requiring intubation and mechanical ventilation. The patient completed a 15 day course of acyclovir and was successfully extubated on Day 17. He was discharged on Day 30 to a rehabilitation facility.

IMPACT: This case adds to the literature by describing disseminated VZV infection and its complications in a patient post autologous HSCT, ultimately found to be wild-type strain but confounded by recent VZV vaccination.

DISCUSSION: Acute pancreatitis is a common cause of hospital admission with a broad differential. The patient's initial presentation was typical of acute pancreatitis; however diagnostic workup was unrevealing for a clear etiology. In such cases, consideration of less common causes such as viral infection is warranted. In this case, the patient's VZV pancreatitis heralded the onset of disseminated VZV infection. The temporal relationship between VZV vaccination and onset of illness initially suggested infection with vaccine strain, but serologic testing revealed a wild-type strain. Persons who have undergone HSCT are at increased risk for VZV reactivation, and so undergo vaccination. While data is limited, vaccination is thought to be safe and efficacious 2 years after HSCT in patients without ongoing immunosuppression or chronic graft versus host disease. Furthermore, disseminated VZV with vaccine strain following immunization is exceedingly rare in the immunocompetent, and generally occurs only when administered to a patient with an unrecognized immunodeficiency. This case describes an uncommon cause of VZV pancreatitis followed by disseminated VZV in a patient with a history of autologous HSCT who was recently vaccinated against VZV.

DON'T MAKE LIGHT OF PAINFUL INTERCOURSE -A 44-YEAR-OLD WOMAN WITH DYSPAREUNIA- KAZUKI SHIMIZU; Takuji Ueno; Hidenori Oguchi; Mitsunori Iwase. TOYOTA Memorial Hospital, Toyota, Japan. (Control ID #2702724)

LEARNING OBJECTIVE #1: When you encounter unexplained pleural effusion or ascites, consider tuberculosis as the potential cause.

LEARNING OBJECTIVE #2: Surgical approach is useful for definitive diagnosis of infectious diseases.

CASE: A 44-year-old G2P1 woman was referred for dyspareunia. She had history of cervical dysplasia and myoma uteri. She had no respiratory symptoms or abdominal distention, took no medications and had a benign family history. Her vital signs were normal. She had no rales in her lungs. Her abdomen was soft and flat, with normal bowel sounds and without tenderness. A pelvic exam showed normal uterine adnexa without tenderness. Blood tests identified elevated levels of CRP and CA125 but other serum chemistry and tumor markers were within normal limits. MRI detected fluid around the uterus; there were no peritoneal nodules or enlarged lymph nodes. She was clinically diagnosed as endometriosis and dysmenorrhea. Oral progestin replacement and oral contraceptive therapies were prescribed. However, her menstrual cramps worsened. Chest radiography detected no signs of malignancy or tuberculosis but enhanced abdominal CT detected signs of disseminated peritoneal lesions. We collected fluid from the pouch of Douglas. Microbiologic testing and cytologic examination of the fluid were negative but ADA was elevated. Ziehl-Neelsen stain was negative but interferon-gamma release assays were positive. We conducted diagnostic laparoscopy which revealed numerous tiny nodular lesions on the peritoneal surfaces. Pathological examination showed epithelioid granuloma and Langhans giant cells with caseous necrosis. Tuberculous peritonitis (TBP) was diagnosed and a combination-drug regimen of rifampin, isoniazid, pyrazinamide and ethambutol was initiated. At follow-up, her clinical symptoms were improving.

IMPACT: Microbiologic testing and cytologic examination were negative but ADA level was elevated. Ziehl-Neelsen stain was negative but interferon-gamma release assays were positive. Diagnostic laparoscopy was useful for definitive diagnosis.

DISCUSSION: TBP becomes a continuing problem in populations with a high prevalence of tuberculosis. Tuberculosis is known as the top 10 causes of death worldwide and one-third of the world population is still at risk. Tuberculosis is often misunderstood as the disease in developing countries but some cases are imported to developed countries. TBP is a form of abdominal and pelvic tuberculosis. It affects about 0.04% of all cases of tuberculosis. The risk increased in patients with cirrhosis, AIDS, diabetes, steroid use, underlying malignancy and undergoing continuous ambulatory peritoneal dialysis. TBP is diagnosed late due to lack of specific symptoms and laboratory findings and therefore associated with high mortality rate. We should consider TBP in the differential diagnosis of ascites and fluid around the uterus of unknown cause. Since preoperative diagnosis of TBP is difficult, pelvic laparoscopy is helpful to distinguish TBP from malignancy, including widespread ovarian cancer.

DON'T YOU KNOW THAT YOU ARE TOXIC Douglas Lim; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Control ID #2707502)

LEARNING OBJECTIVE #1: Recognize the risk of baclofen use in patients with kidney disease.

LEARNING OBJECTIVE #2: Develop a systematic approach to the patient with altered mental status.

CASE: A 34 year-old woman presented with several hours of confusion. She appeared obtunded with incomprehensible speech. She was unable to open her eyes. Her medical history included diabetes related end-stage renal disease and has been compliant with her maintenance hemodialysis; she has chronic muscle spasms as well. Her blood urea nitrogen was 69 mg/dL. A head CT was normal. Records revealed she was given dilaudid and baclofen for leg pain a few hours before her symptom onset. She showed no improvement after receiving naloxone. Baclofen toxicity was thought to be the culprit and she was treated with hemodialysis. She showed significant improvement after 3 days.

IMPACT: This case emphasized the importance of keeping a systematic approach to altered mental status given the limited history that is often able to be obtained. Medications that can cause toxicity may not be listed as a medication that requires decreased dosing. Thus, competing diagnoses must be excluded, requiring a systematic approach

DISCUSSION: Altered mental status is a problem often encountered by the general internist. The differential is very broad and identifying the cause can be challenging. History is by definition unreliable, and a systematic approach must used to effectively diagnose and treat the patient. This can look at all of the factors that transport oxygen to the brain, including the lungs, heart, blood vessels, the brain, and the contents of the blood carrying everything. Baclofen toxicity is a rare cause of encephalopathy and individuals with kidney disease are at greater risk. Baclofen is renally eliminated with an average reported half-life around 6.6 h. Dosing recommendations only recommend decreased dosing and caution advised. However, doses as low as 5mg dose can result in life threatening toxicity in those with impaired renal function. The patient from this case required urgent dialysis and intubation after she was given a total of 40mg of baclofen. Baclofen is used for muscle spasticity as well alcohol withdrawal syndrome. It acts as a gamma-aminobutyric acid (GABA) agonist but the complete mechanism is not fully understood. Due to its lipophilic nature, it can cross the blood brain barrier and have significant nervous system side effects; the more severe side effects are coma and respiratory distress as seen in the patient in the case. Individuals without renal impairment can develop baclofen toxicity as well if exposed to high doses. There are no standard treatment guidelines. But, others have also reported effective treatment of baclofen toxicity with dialysis and pulmonary support. Regardless of the dose, general internists should be aware of the serious risk of baclofen toxicity especially, in patients with kidney disease

DON'T ALWAYS FOLLOW YOUR HEART: A CAVEAT TO TROPONIN-T Kaylan Christianer; Heidi Lumish. New York Presbyterian- Columbia, New York, NY. (Control ID #2702933)

LEARNING OBJECTIVE #1: Recognize conditions that can lead to false-positive elevations in cardiac enzymes, particularly troponin-T and CK-MB

CASE: A 64yo Dominican man with HTN, depression, and pleural and peritoneal mesothelioma presented to the ED with 3 weeks of progressive dyspnea. Medications were escitalopram and gabapentin. He had received 1 year of pembrolizumab and carboplatin, followed by 7 cycles of gemcitabine and oxaliplatin, most recently 6 months ago. He had no family history of cardiovascular or autoimmune disease. Vitals were T 36.7 C, BP 120/82 mmHg, P 100/min, RR 20/min, and O2 sat 99% on room air. Cardiac and pulmonary exam were normal. He had several circular erythematous patches on the forehead and erythema of the nasolabial folds. Strength was 2/5 in the shoulders and hip flexors, and 3-4/5 in the distal upper and lower extremities. Sensation was decreased to pinprick in the fingers and toes bilaterally. Labs revealed elevated troponin-T (8.1 ng/mL, normal <0.01) and CK-MB (262 ng/mL, normal <7.7). ECG showed normal sinus rhythm. He was treated empirically for acute coronary syndrome with heparin and dual antiplatelet therapy. On day 2, echocardiogram was normal, and CPK was elevated (4715 u/L, normal <499), but troponin-I was normal (0.01 ng/mL). On day 4, heparin and antiplatelet therapy were discontinued, and methylprednisolone was started for empiric treatment of inflammatory myositis. Subsequent workup revealed + ANA (1:1280, speckled), +anti-PM/Scl Ab and + anti-ssA/Ro Ab. Electromyography was consistent with an inflammatory myopathy. Biopsy of the left quadriceps muscle confirmed an active, early chronic myopathy. The patient's proximal muscle weakness and respiratory status gradually improved with steroids, and troponin-T and CPK levels normalized. On day 12, the patient was discharged home on methotrexate.

IMPACT: While troponin-T and CK-MB are regarded as specific markers of myocardial injury, our case illustrates a caveat in patients with myopathies, and is unique in that the myopathy causing elevated enzymes was previously undiagnosed. Our case highlights the importance of keeping a broad differential and being wary of confirmation bias when treating patients with elevated cardiac enzymes in the absence of other signs of myocardial ischemia.

DISCUSSION: In patients with inflammatory myopathies, elevations in troponin-T and CK-MB have been reported in the absence of myocardial injury (Aggarwal, Dhir, Hamilton). This was initially thought to reflect cross-reactivity between skeletal muscle troponin and the troponin-T assay, or active inflammation of the cardiac muscle itself. Recent studies, however, suggest that in patients with continuous skeletal muscle breakdown and regeneration, skeletal muscle reverts to embryonic form which expresses cardiac troponin-T and CK-MB, unlike healthy adult skeletal muscle (Jaffe). The same phenomenon is not observed with troponin-I, suggesting it may be a more specific marker for cardiac ischemia in patients with underlying myopathies.

DONATING BLOOD GONE A-MRSA Kate Hust. Hennepin County Medical Center, Minneapolis, MN. (Control ID #2702695)

LEARNING OBJECTIVE #1: Recognize complications of thrombophlebitis.

LEARNING OBJECTIVE #2: Manage persistent methicillin-resistant *Staphylococcus aureus* bacteremia.

CASE: A 50-year-old man presented to the emergency room with dyspnea, cough, and pleuritic chest pain for 3 days. He also noted left arm pain and redness since donating blood 5 days prior. He was ill-appearing, febrile, tachypneic, tachycardic, and hypoxic with coarse breath sounds on pulmonary exam. His left forearm was erythematous and mildly tender in the antecubital fossa. Chest imaging showed multifocal consolidations. Upper extremity ultrasound showed superficial and deep venous thrombosis. Within 12 hours of collection, blood cultures were positive for methicillin-resistant *Staphylococcus aureus* (MRSA) in all 4 bottles. Despite treatment with vancomycin, the patient remained critically ill, requiring high-flow oxygen supplementation.

Daily blood cultures persistently grew MRSA. On hospital day 4, ceftaroline was added for synergy with vancomycin, and he had his first negative blood cultures 2 days later. He continued on dual therapy throughout his hospitalization and was ultimately discharged on hospital day 31 with supplemental oxygen and home services to complete a course of ceftaroline.

IMPACT: While blood donation, line placement and other venipuncture are commonplace in medical practice, it is important to both recognize their potential complications and also to educate patients about how to recognize them so timely management can be initiated and more severe complications avoided.

DISCUSSION: Blood donation and other venipuncture are common in medicine, and while they rarely lead to major complication, it is important to promptly recognize and intervene when they do arise. Bruising, bleeding, hematoma formation or extravasation may occur somewhat commonly while phlebitis is less frequent. Thrombophlebitis affects superficial veins and is diagnosed when there is thrombus associated with inflammation, usually after a vascular trauma. Management with elevation, warm compress, and analgesia is often sufficient for resolution. While considered a low risk location, superficial thrombophlebitis in the upper extremity may also lead to deep vein thrombosis or sepsis when bacteria seed the thrombi. MRSA bacteremia is often treated in hospitalized patients, beginning with source removal and intravenous antibiotics, usually vancomycin or daptomycin. With a good minimum inhibitory concentration (<1 mcg/mL), MRSA bacteremia should begin to resolve after 1–2 days of vancomycin therapy. When bacteremia is persistent despite appropriate antibiotics and occult infectious foci have been addressed, the regimen should broaden to dual-therapy with ceftaroline for synergism. Ceftaroline, a 5th-generation cephalosporin, has bactericidal activity against MRSA as well as gram-negative organisms. Once the bacteremia has resolved, ceftaroline may be continued as monotherapy with close monitoring of hematologic parameters due to possibility of bone marrow suppression.

DOUBLE TROUBLE: A CASE OF CONCOMITANT OPPORTUNISTIC INFECTIONS

Shradha A. Kulkarni. Baylor College of Medicine, Houston, TX. (Control ID #2707598)

LEARNING OBJECTIVE #1: To create a broad differential in immunocompromised patients with respiratory symptoms.

LEARNING OBJECTIVE #2: To emphasize the importance of prescribing PJP prophylaxis for patients on long-term high-dose steroids.

CASE: A 60-year-old male with hepatitis C infection status-post treatment with a negative viral load and chronic kidney disease (CKD) due to biopsy-confirmed focal segmental glomerulosclerosis (FSGS) presented with pleuritic chest pain, dyspnea, fever, and cough for a few days. He denied hemoptysis, sweats, weight loss, travel, or sick contacts. Of note, he had been prescribed high-dose steroids one month prior to presentation for FSGS and had not been prescribed any prophylactic antibiotics. Examination was notable for tachypnea to 24 breaths per minute, hypoxia to 92% on room air, and crackles auscultated in the left lung base. Laboratories were notable for leukocytosis to 27,000 cells/uL, acute kidney injury on his baseline CKD, and a negative human immunodeficiency virus (HIV) screen. Chest x-ray showed a left lower lobe infiltrate. He was treated empirically for community-acquired pneumonia with levofloxacin. PJP prophylaxis was also started given his steroid use; atovaquone was selected as trimethoprim-sulfamethoxazole could not be used given his CKD. He became febrile on this regimen, so coverage was broadened to vancomycin and cefepime until sputum cultures grew Gram-positive branching rods suggestive of *Nocardia*. Antibiotics were narrowed to linezolid and atovaquone prophylaxis. Brain magnetic resonance imaging was performed and did not show an abscess. Interestingly, PJP sputum stains also returned positive a few days later, so atovaquone dosing was increased to complete treatment. On a subsequent clinic visit, the patient had completed PJP treatment and was continuing pulmonary nocardiosis treatment for a total of six months. His cough, dyspnea, and hypoxia had resolved.

IMPACT: This case demonstrates the diagnostic challenges encountered when treating acutely-ill immunocompromised patients and the need to maintain a broad differential. It also demonstrates the utmost importance to consider PJP prophylaxis for any patient on high-dose steroids.

DISCUSSION: Nocardiosis is an uncommonly diagnosed infection, with less than 1,000 new cases in the United States every year per the Centers for Disease Control. Significant risk factors are corticosteroid use, HIV infection, and malignancy. Pulmonary involvement can be seen in approximately two-thirds of cases. Even more uncommonly seen is concomitant pulmonary nocardiosis and PJP. There are case reports detailing such instances, however all described patients were either receiving chemotherapy, post-transplant on multiple systemic immunosuppressive agents, or HIV positive. Our patient presented unusually, as he had only been taking high-dose steroids for one month.

DRAMATIC LEUKOCYTOSIS IN POLYCYTHEMIA VERA: NOT ALWAYS VERA RUBRA

Jonathan Wolfe[1]; William Levin[2]. [1]University of Pittsburgh Medical Center, Pittsburgh, PA; [2]University of Pittsburgh Medical Center, Gibsonia, PA. (Control ID #2705736)

LEARNING OBJECTIVE #1: Recognize dramatic leukocytosis as a complication of polycythemia vera (PV).

LEARNING OBJECTIVE #2: Diagnose and treat hyperviscosity symptoms related to PV.

CASE: A 74-year-old female with a history of PV on hydroxyurea and prior splenectomy presented with shortness of breath. Acute cardiac and pulmonary pathology were ruled out. She was found to have a WBC of 108,700, hemoglobin of 8.1, and platelets of 2.1 million. Her baseline WBC was 20,000. Labs were also notable for mild tumor lysis syndrome. She was treated with intravenous fluids and her hydroxyurea was increased. Her shortness of breath resolved with treatment. A peripheral smear demonstrated polychromasia, anisopoikilocytosis, changes consistent with a prior splenectomy, and no evidence of blasts. JAK2 testing was positive. She then underwent bone marrow biopsy, which revealed hypercellular marrow, mild fibrosis, and no evidence of dysplasia or leukemia. Cytogenetic studies showed a normal karyotype, and FISH was negative for multiple cytogenetic abnormalities. The findings were most consistent with PV. With the increased dose of hydroxyurea, her counts normalized. Her hospital course was complicated by a spontaneous hematoma in the rectus sheath. She was treated supportively and recovered.

IMPACT: Although PV is classically associated with an increase in hemoglobin, leukocytosis and thrombocytosis are common and can be dramatic. Hyperviscosity symptoms due to extreme erythrocytosis or leukocytosis are not unusual in the proliferative phase of the disease.

DISCUSSION: PV is a chronic myeloproliferative neoplasm associated with a mutation in the JAK2 signaling protein. In PV, all cell types often derive from a single neoplastic stem cell, and the erythroid progenitor cells are capable of growing and dividing in the absence of erythropoietin. The disease has three phases termed the latent, proliferative, and spent phases. Most patients are

diagnosed in the latent phase when they are relatively asymptomatic. Typically, patients present with hemoglobin of greater than 18.5 in men or 16.5 in women. In the case of our patient, her hemoglobin count was likely suppressed by her home hydroxyurea regimen. In the proliferative phase, hyperviscosity and thrombosis may develop. Concomitant leukocytosis and thrombocytosis are common in PV, with elevations of additional cell lines occurring in over 50% of patients. This case illustrates an extreme example of both leukocytosis and thrombocytosis associated with the proliferative phase of disease. Her presenting symptom of shortness of breath was likely a result of hyperviscosity given her dramatically increased WBC from baseline. Treatment may involve phlebotomy in the case of increased hemoglobin, hydroxyurea, or other immunosuppressive agents. Approximately 20% of patients enter the spent phase, where progressive fibrosis drives hematopoietic activity into the liver and spleen.

DRAMATIC RESPONSE TO HIGH-DOSE INTRAVENOUS METHYLPREDNISOLONE IN A PATIENT REFRACTORY TO ORAL PREDNISONE IN HASHIMOTO'S ENCEPHALOPATHY Mukund Das; Gregory Cunn; Nina Hein; Miran Salgado. New York-Presbyterian Brooklyn Methodist Hospital, Brooklyn, NY. (Control ID #2706157)

LEARNING OBJECTIVE #1: Treat Hashimoto's Encephalopathy with a trial of high dose intravenous Methylprednisolone in patients who fail oral Prednisone treatment in Hashimoto's Encephalopathy.

CASE: A 29 year-old female with newly diagnosed hyperthyroidism presented with worsening paranoia, palpitations, and chest pain. For the past four months she has had worsening agitation with frequent mood swings, constant pacing, insomnia, paranoia, and pressured speech. Exam findings included tachycardia and thyromegaly. Laboratory findings included TSH < 0.005 u/mL and free T4 level of 5.92 ng/dL. She was started on Propranolol and Methimazole. She then became paranoid and suicidal. Further workup revealed elevated TPO level of 789 IU/mL, elevated TSI level of 167 IU/mL, and low thyroglobulin antibodies. Despite treatment with Methimazole, there was no change in free T4 and treatment was changed to Propylthiouracil. Thyroid sonogram showed nodular right lobe thyroid, and fine needle aspiration showed a benign follicular nodule. She was started on Hydrocortisone and Phenobarbital, and underwent Radioactive iodine-131 ablation therapy. Her free T4 decreased by half; however, her psychosis persisted. Several autoimmune panels including NMDA receptor, anti-HU, CASPR2, GAD65, anti-MA, GABA-Br were negative, ruling out other causes of autoimmune encephalitis. She was started on pulse dose IV methylprednisolone for three days, and on day two her psychosis and suicidal ideation resolved. Considering the dramatic response to steroids in a patient with thyrotoxicosis with elevated TPO antibodies, and in the absence of other autoimmune disorders, a diagnosis of Hashimoto's encephalopathy was made. She was started on Mycophenolate mofetil, oral Prednisone taper for four weeks, and discharged home. At four weeks following discharge, she remained at baseline.

IMPACT: Hashimoto's encephalitis is a difficult diagnosis to make since no accepted diagnostic criteria exist. When dealing with diseases in which the clinical picture is complicated by other manifestations, in this case psychosis, it is crucial to have a wide range of differential diagnosis.

DISCUSSION: Hashimoto's encephalopathy, also known as steroid-responsive encephalopathy associated with autoimmune thyroiditis, is a rare syndrome associated with Hashimoto thyroiditis. The exact mechanism remains unknown; however, it is thought to be an immune-mediated disorder without direct effects of high thyroid level on the central nervous system. Most patients show good clinical response to steroids. Although optimal steroid dose has yet to be defined, current literature supports treatment with oral prednisone dose ranging from 50 mg to 150 mg daily. Benefits of high dose steroid compared to low dose steroids is unknown. Our patient did not respond to low dose oral corticosteroid treatment; however, responded dramatically to high-dose IV corticosteroid therapy. Therefore, if there is a poor response to oral steroids, high dose IV methylprednisolone should be tried.

DYSPNEA IN AIDS Akshar Chauhan[1]; Brandon J. Mauldin[2]; Deepa Bhatnagar[1]. [1]Tulane University, New Orleans, LA; [2]tulane university, New Orleans, LA. (Control ID #2705861)

LEARNING OBJECTIVE #1: Review the differential diagnosis of dyspnea in a patient with AIDS

LEARNING OBJECTIVE #2: Recognize the subtle clinical presentation of pericardial effusion

CASE: A 42-year-old African American man presented with complaint of progressive dyspnea on exertion for 2 weeks. He had a history of AIDS with unknown CD4 count. Prior history included atypical mycobacterial pulmonary infections and M. tuberculosis. He denied any chest pain, hemoptysis, edema, orthopnea, or weight loss. His physical examination showed no arrhythmia, murmur, friction rub, or peripheral edema apparent. Clear lung fields were noted. At rest, he had normal oxygen saturation. Upon physical exertion, he desaturated to 70-80 and became visibly short of breath. Complete blood count, basic metabolic profile, liver function tests, troponin I, BNP, TSH, and lactate were normal. Chest x-ray, EKG, and arterial blood gas taken at rest were normal. LDH was mildly elevated, and CD4 count was 11. Sputum DFA and acid fast staining was negative for P. jiroveci pneumonia and M. tuberculosis. Cultures from bronchoalveolar lavage were negative for bacterial or fungal organisms. CT chest angiogram showed no evidence of pulmonary embolism, AV malformations, or infiltrative disease. Echocardiogram revealed an ejection fraction 40-45% with a large pericardial effusion but no evidence of right ventricular dysfunction. A pericardial window was placed to drain the effusion, and the patient's dyspnea was noted to have markedly improved upon recovery. Analysis of the fluid was negative for malignancy or pathogens.

IMPACT: When caring for a patient with uncontrolled AIDS, a large number of infections can be the culprit for dyspnea. However, alternative causes may include cardiovascular diseases such as pericarditis.

DISCUSSION: In HIV-infected patients, cardiovascular disease may be due to HIV, opportunistic infections, malignancy, or non-HIV risk factors such as tobacco abuse and age. HIV or opportunistic infections may cause pericardial or myocardial disease. Pericardial disease is often due to pericarditis that leads to a pericardial effusion. Patients often present primarily with dyspnea (75%). Echocardiogram is the initial evaluation to determine the presence of a pericardial effusion. Pericardiocentesis allows for diagnosis of the cause of the effusion and therapeutic relief of symptoms. Where HIV and tuberculosis are endemic, HIV-associated pericardial effusions are often caused by M. tuberculosis. Other infectious organisms such as bacteria, viruses, and fungi can also result in pericardial effusions. With an incidence of up to 11% per year, pericarditis with cardiac effusion can be an easily overlooked cause of shortness of breath in these individuals. While usually asymptomatic, in rare cases these effusions can lead to respiratory distress and even cardiac tamponade. Unfortunately, pericardial fluid analysis is often negative, making the true etiology difficult to identify.

EAGLE IN A TAILSPIN (STYLOHYOID SYNDROME LEADS TO VERTIGO) Harshal G. Tejale; Bharat Khandheria; Roger D. Smalligan. Texas Tech Univ HSC-Amarillo, Amarillo, TX. (Control ID #2704259)

LEARNING OBJECTIVE #1: Identify the differential diagnosis of dizziness and distinguish between the rare causes by careful consideration of patient presentation

LEARNING OBJECTIVE #2: Diagnose Eagle's syndrome in the general population

CASE: A 68yo woman with hypertension, diabetes, migraines with aura and previous cervical spine surgery presented with 2 episodes of vertigo with diaphoresis, nausea, dyspnea, left leg weakness and neck pressure. Symptoms resolved each time she laid flat on her back. She denied loss of consciousness, visual changes, fever and chills with the episodes. PMH: cervical fusion 9 yrs ago. Meds: losartan, clonidine, acetaminophen, morphine and insulin. Social: denied smoking, alcohol and illicit drug use. Physical exam: HEENT normal, TMs nl, no carotid bruits, pulses 2+, lungs, heart, abdominal and detailed neuro exam were normal. Labs: Na: 137, K: 4.1, Glu: 103, Trop I: <0.02 ng/mL, TSH 2.0. Images: Head CT: normal, CTA Head and neck: normal flow and calcification of the stylohyoid ligaments was noted. Cardiac stress test: Negative. Similar episodes were elicited upon her turning the head to the right and on palpation of ipsilateral stylohyoid ligament. Due to suspicion of stylohyoid syndrome she was started on NSAIDS and referred to an otolaryngologist for further evaluation and treatment.

IMPACT: This case shows the importance of careful consideration of all available historical and physical findings to arrive at the diagnosis of a rare condition. Our patient presented with symptoms due to compression of the carotid artery when turning her head or with palpation of the stylohyoid ligament. Treatment options were discussed and she was given NSAIDs along with referral to an otolaryngologist for further treatment based on her preference.

DISCUSSION: The stylohyoid complex consists of the styloid process, stylohyoid ligament and the lesser cornu of hyoid bone. Irritation of cranial nerves V, VII, IX and/or X can cause facial pain on turning the head, tinnitus, otalgia, dysphagia or trismus. Carotid artery compression leads to visual symptoms, syncope, eye pain, or parietal pain. Typically, symptoms are exacerbated on palpation of the styloid process as in our case. Studies have shown that approximately 4% of the general population has an elongated styloid process but less than 5% of these people develop any symptoms. The normal range of length of a styloid process is 2 to 3 cm and the probability of Eagle's syndrome is greater with a styloid length more than 3 cm. Treatment options include a trial of antiinflammatories, analgesics, anticonvulsants or surgical shortening of the styloid through a transoral or lateral approach in refractory cases. Local infiltration with steroids or longacting local anesthetic has also been used with some success.

EMERGING HYPERVIRULENT KLEBSIELLA PNEUMONIAE LIVER ABSCESSES IN THE UNITED STATES: A NEED FOR A SCREENING PROTOCOL IN PREDISPOSED PATIENTS Steven Song; Joselle Cook. SUNY Downstate Medical Center, Brooklyn, NY. (Control ID #2694506)

LEARNING OBJECTIVE #1: Recognize potential for liver abscess and metastatic infection in a patient with Klebsiella pneumoniae bacteremia from an endemic region.

LEARNING OBJECTIVE #2: Implement a screening protocol with liver imaging and detailed ophthalmologic exam in such patients.

CASE: A 67-year-old Taiwanese man with no medical history presented with complaints of malaise, subjective fevers, and back pain for the past week. The patient was febrile to 102°F. Labs revealed leukocytosis (WBC 13x10^9 cell/L) and transaminitis (AST 134mg/dl, ALT 136mg/dl). MRI revealed discitis of the lumbar spine. Blood cultures grew ESBL Klebsiella pneumoniae (K. pneumoniae) and meropenem was started. Several days later, the patient complained of decreased vision in his left eye. Visual acuity decreased to "counting fingers" compared to 20/100 on admission. Orbit CT revealed periorbital soft tissue swelling, hyperenhancement of the uveal-scleral layer and vitreous body, choroidal detachment, and subchorionic abscess consistent with endophthalmitis. Intravitreal culture was also positive for ESBL K. pneumoniae. Intravitreal amikacin and vancomycin were administered. CT abdomen performed for abdominal pain showed multiple abscesses in both hepatic lobes and intrahepatic biliary ductal dilatation suspicious for cholangitis. The treatment course was interrupted as the patient left against medical advice.

IMPACT: The constellation of K. pneumoniae bacteremia, liver abscess, and further metastatic complications is a growing public health concern in the US due to increase in international travel. It is imperative to recognize potential devastating complications such as endophthalmitis and meningitis. Maintaining a high index of suspicion in patients with K. pneumoniae bacteremia traveling from endemic areas and instituting a screening protocol may improve clinical outcome with earlier treatment.

DISCUSSION: While K. pneumoniae is often associated with pneumonia and UTI, emergence of a K1 serotype has been implicated in K. Pneumoniae liver abscess (KLA). KLA was predominant in Southeast Asia, but increased prevalence in the US over the last decade has been recognized. Translocation of specific capsular subtypes of K. pneumoniae from the gastrointestinal tract predisposes to sepsis, with special tropism for the liver. Host susceptibilities such as diabetes and an immunocompromised state also influence the natural history of infection. Ultrasonography and CT will detect the presence of liver abscess. First line treatment combines systemic antibiotics with percutaneous drainage. Seeding of metastatic infection from KLA can result in endophthalmitis and discitis, as described in this index case; also osteomyelitis and meningitis. Endophthalmitis can cause permanent vision loss and is associated with significantly higher mortality rates. Early institution of systemic and intravitreal antibiotics may salvage vision. An established screening protocol may detect metastatic complications early in patients with KLA.

EMPHYSEMATOUS CYSTITIS: A SURPRISE! Supriya P. Singh[1]; Dipen B. Khanapara[2]; Marilou Corpuz[2]. [1]Montefiore, Bronx, NY; [2]Montefiore Medical Center, Bronx, NY. (Control ID #2707533)

LEARNING OBJECTIVE #1: 1: Recognize emphysematous cystitis (EC) as a complication of urolithiasis or recurrent urinary tract infection in elderly women with uncontrolled diabetes mellitus.

LEARNING OBJECTIVE #2: 2: Initiate early treatment of EC to avoid the potential morbidity and mortality associated with this infection.

CASE: A 54-year-old woman with poorly controlled diabetes and many clinic visits for Urinary Tract Infections presented with three days of suprapubic abdominal pain. She also complained of nausea, vomiting, dysuria, and foul-smelling urine. On examination, she was afebrile, and was tender in the lower abdomen. She was not adherent to insulin. Laboratory finding were significant for white blood cell count 12,500, hemoglobin 12.7 mg/dl and platelets 389,000/dl. Urinalysis revealed many leucocytes and was negative for nitrite. Imaging

was considered to rule out kidney stones or anatomical anomaly. CT scan of the abdomen showed a large amount of intraluminal air within the bladder, with large amount of air in the bladder wall, compatible with emphysematous cystitis without pyelonephritis. Urine culture grew Escherichia coli. She was treated with intravenous antibiotics with significant clinical improvement.

IMPACT: Any diabetic woman with recurrent UTIs should have imaging to rule out EC, as well as to evaluate the severity, extent of disease, and to assess for ascending infection.

DISCUSSION: EC is a rare disease characterized by primary infection of the urinary bladder with gas-producing pathogens. EC is typically defined and diagnosed radiographically. The incidence of reported cases is increasing with increased use of abdomino-pelvic imaging. However, as imaging is not routinely indicated in patients with urinary tract infections, EC might be under-reported and under-diagnosed. A review study of 102 relevant articles, including 135 reported cases, revealed the median age at presentation was 66 years; most were women and two thirds of were cases associated with diabetes. Most cases were diagnosed using plain films of the abdomen (84%); abdominal CT (40%), cystourethroscopy (39%), and bladder ultrasonography (7%). Causative pathogens are Escherichia coli (58%), Klebsiella pneumoniae (21%), Clostridium species (7%), and Enterobacter species (7%). EC has a mortality of 7% which can rise to 50% when perivascular gas migrates up the urinary tract leading to emphysematous pyelitis and pyelonephritis. Delayed diagnosis can lead to critical and even fatal complications. The treatment generally consists of antibiotics for longer duration (up to 2 weeks), bladder drainage, and glycemic control. Patients resistant to medical management or those with severe necrotizing infections might require partial cystectomy, cystectomy, or surgical debridement.

EOSINOPHILIC ESOPHAGITIS PRESENTING WITH EOSINOPHILIC GASTROENTERITIS Nirmal Guragain[1]; Dipen B. Khanapara[1]; Pranav D. Patel[2]. [1]Montefiore Medical Center, Bronx, NY; [2]Montefiore Medical Center Wakefield Campus, Bronx, NY. (Control ID #2706316)

LEARNING OBJECTIVE #1: To recognize eosinophilic gastroenteritis as etiology of diarrhea

LEARNING OBJECTIVE #2: To understand management of eosinophilic gastroenteritis.

CASE: A 43 year-old man with 5 year history of stable eosinophilic esophagitis on budesonide respules presented with one week of nausea, vomiting, diarrhea, and abdominal pain. He had no sick contacts or change in diet. This presentation was different from his typical flare, which consisted of dysphagia and chest pain. Physical exam was remarkable for diffuse abdominal tenderness. Laboratory investigation revealed absolute eosinophil count 2052/microL and elevated IgE level. Infective workup, including strongyloides, trichinella, toxocara screen, and stool for ova and parasite, was negative. Celiac panel was negative and IgA level was normal. CT abdomen and pelvis revealed thickening of the wall of the esophagus, stomach, small bowel and colon, likely enterocolitis. Endoscopy and colonoscopy with biopsies revealed eosinophils in lamina propria in esophagus, stomach, duodenum, and jejunum, consistent with diffuse eosinophilic gastroenteritis. He was treated initially with PO prednisone with slow taper over 2 weeks and then transitioned to inhaled steroid. He improved and was discharged with outpatient GI and allergy immunology follow up.

IMPACT: Clinician should be vigilant to recognize eosinophilic gastroenteritis as etiology of diarrhea, especially in patients with history of food allergy, eosinophilic esophagitis, or other atopic conditions, as treatment is steroid rather than antibiotics or conservative management

DISCUSSION: Eosinophilic gastroenteritis is rare and should be suspected in a patient with abdominal pain, nausea, vomiting, diarrhea, weight loss, or ascites associated with peripheral eosinophilia (absolute eosinophil count >500/microL in blood), and/or a history of food allergy or other atopic conditions. The diagnosis is based on the presence of eosinophilic infiltration of the gastrointestinal tract on biopsy and/or eosinophilic ascitic fluid, lack of involvement of other organs, and absence of other causes of intestinal eosinophilia. Hypereosinophilic syndrome, parasitic infestation, inflammatory bowel diseases, celiac disease, neoplasia, connective tissue, systemic mastocytosis, collagen vascular disorders, and medications are common differentials which can have similar clinical presentation and gastrointestinal eosinophilia. Thus, initial evaluation of diarrhea should always include stool studies to rule out infectious etiologies, followed by work-up for eosinophilia. An acute flare of eosinophilic gastrointestinal disorder may require systemic steroid for 1–2 weeks with subsequent taper over several weeks. Resistant cases may require high-dose intravenous steroids or even immunosuppressive therapy, such as azathioprine or 6- mercaptopurine. Dietary modification in cases of food allergy and discontinuation of offending medication are important to prevent further episodes.

EPISODIC WEAKNESS IN A YOUNG MALE Alexandra R. Lane; Nicolette A. Oleng'. Boston Medical Center, Boston, MA. (Control ID #2671541)

LEARNING OBJECTIVE #1: Learn about the careful repletion of potassium

LEARNING OBJECTIVE #2: Understand the difference between TTP and Familial Hypokalemic Periodic Paralysis

CASE: A 25-year-old Cambodian male with no medical or family history presented with two days of weakness. He was heathy until he woke up with inability to stand due to weakness in his lower extremities. He twice presented to an outside emergency room wtih transient weakness. He was given potassium for hypokalemia and after the second presentation he was refered to an a tertiary care center for workup. On arrival the patient was noted to be obese Asian male. Vital signs notable for tachycardia. Exam notable for 5/5 strength throughout with the exception of 4/5 in R hip flexors with a bilateral pronator drift. His bilateral patellar, brachioradialis and biceps reflexes diminished to 1+. Thyroid was non-tender and slightly enlarged. Lab values were significant for K of 3.1meq/L, TSH <0.01, Free T4 1.79 and T3 190.Thyroid stimulating immunoglobulin (TSI) was elevated at 416 and thyroid peroxidase antibody was normal. Patient was admitted for electrolyte management and diagnosed with Thyrotoxic Perioidc Paralysis.. The next morning, his potassium corrected. He was treated with propranolol 20mg three times a day and methimazole 5mg daily.

IMPACT: This case reflects the need to think carefully about the etiology of electrolyte disorders prior to aggressive correction

DISCUSSION: Thyrotoxic Periodic Paralysis (TTP) is characterized by recurrent episodes of transient paralysis and hypokalemia in the setting of hyperthyroidism. Thyroid hormones directly stimulate the sodium-potassium ATPase (Na+/K + −ATPase) leading to increased activity on skeletal muscles. This causes hypokalemia through intracellular shift of potassium leading to hyperpolarization of the myocytes, cellular dysfunction and clinical paralysis. A hyperinsulinemic state activates the Na/K ATPase pump, consistent with the observation that heavy

carbohydrates and alcohol precipitate TTP. Urine and fecal potassium are normal and a urinary transtubular potassium gradient is used to exclude urinary losses. In one study, recovery time was shorted when IV KCL was given compared to saline alone. However, 70% of patients given IV KCL at a rate of 10mmol/hr developed rebound hyperkalemia to greater than 5.0mmol/L. Supplementation is reasonable in severe hypokalemia to prevent cardiopulmonary complications but because total body potassium is normal, there is a risk for rebound hyperkalemia with aggressive repletion when the cells release K during the recovery period. TTP is similar to familial hypokalemic periodic paralysis (FHPP). Typically a male patient in the first or second decade of life presents with episodic weakness and hypokalemia. Presence of hyperthyroidism in TTP distinguishes the two. Additionally, FHPP is an autosomal dominant disease, although incomplete penetrance is common. Thus when a young male presents with transient paralysis is it imperative to measure TSH and thyroid hormone levels.

ESOPHAGEAL SQUAMOUS CELL CARCINOMA WITH METASTASES TO THE PHALANX AND GINGIVA Mariya Rozenblit; Kristen DeCarlo; Daniel Lin; MaryLynn Nierodzik. NYU, New York, NY. (Control ID #2688874)

LEARNING OBJECTIVE #1: Recognize oral cavity and hand lesions as possible sites for metastases

CASE: A 53 year old man with a history of stage III squamous cell carcinoma (SCC) of the esophagus (pT3N3) was admitted for dysphagia and found to have a mandibular mass and a painful finger nodule. The patient initially presented to an outside hospital four months prior with dysphagia and found to have an esophageal mass on endoscopy with SCC on biopsy. Chest CT showed precarinal, subcarinal, and gastroesophageal lymphadenopathy. The patient underwent esophagectomy without preoperative chemoradiation and pathology confirmed moderately differentiated invasive SCC with 6/12 lymph nodes positive for metastatic SCC. Adjuvant radiation had been delayed due to insurance issues and loss to follow up. A PET scan one month prior showed a right paratracheal mass and locoregional lymph nodes concerning for recurrent disease, but no distant metastatic disease. Seven days prior to admission, the patient noticed an erythematous nodule on his index finger. He completed seven days of antibiotics for presumed skin infection with no improvement in symptoms. At the same time, he also noted a small mass below his left premolar. On admission, physical exam was notable for a tender, necrotic-appearing 1cm nodule above the nail bed of the left 2nd digit distal phalanx, and a 2cm painful, immobile mass in the buccal mucosa below the left mandible. A bone scan demonstrated focal increased uptake only in the phalanx. Neck CT confirmed a superficial soft tissue mass along the buccal surface of the left mandibular body. Punch biopsy of both lesions revealed invasive high grade SCC. CT of the chest/abdomen/pelvis showed a paratracheal mass and regional lymphadenopathy, consistent with prior PET scan, with no evidence of distant metastases. The patient underwent palliative amputation of the distal phalanx, excision of the left mandibular gingiva, and was subsequently started on chemotherapy for recurrent metastatic esophageal cancer.

IMPACT: This is only the second reported case in the literature of esophageal SCC with metastases to the phalanx and gingiva. These lesions are often misdiagnosed as infections or unrelated processes but they may represent distant metastatic cancer and require further workup.

DISCUSSION: Esophageal carcinoma typically metastasizes to the liver, lungs, or bone. SCC metastases are usually intra-thoracic. Metastases to the buccal mucosa and gingiva are very rare, representing only 1% of oral cavity malignancies and often arise from lung, kidney, skin, or breast cancers. Chronic inflammation from gingivitis or periodontitis is hypothesized to play a role in attracting metastatic cells. Metastases to the hand are exceedingly rare since there is less red marrow, and comprise only 0.1% of bony metastases, often arising from lung, kidney, or breast cancers. Repetitive trauma is hypothesized to increase blood flow to the area and metastases to the phalanges are often observed in the dominant hand.

EUGLYCEMIC DIABETIC KETOACIDOSIS INDUCED BY NEW GENERATION ORAL HYPOGLYCEMICS Chandana Shekar; Niralee Patel; Alexander Miller; Kushani Gajjar. University of Connecticut School of Medicine, Farmington, CT. (Control ID #2706954)

LEARNING OBJECTIVE #1: Recognise a fatal complication of diabetes mellitus despite a normal blood glucose level

LEARNING OBJECTIVE #2: Recognise a rare yet fatal side effect of a newer generation medication

CASE: A 71 year old female with non insulin dependent diabetes mellitus and gastroparesis presented to our hospital with generalized abdominal pain, nausea and vomiting for 2 days. Pertinent positives included myalgia, loss of appetite and recent change in medications. She had been on SGLT2 (Sodium-glucose cotransporter 2) inhibitor Canaglifozin for a year now and the dose was increased two weeks ago. She did not have a history of alcohol use. On arrival to our hospital, she was hemodynamically stable. Physical examination was normal except for dry mucus membranes and diffuse abdominal tenderness. Lab investigations revealed a normal complete blood count. Blood glucose was normal at 91 mg/dL and hemoglobin A1c was 4.5%. Serial blood glucose levels also remained within normal limits. GAD-65 (Glutamic Acid Decarboxylase-65) antibody to rule out type I diabetes mellitus/latent autoimmune diabetes mellitus was also normal at <5. Chemistries showed anion gap metabolic acidosis with an anion gap of 32 and bicarbonate of 10 mmol/L. Blood urea nitrogen was 13 mg/dL and creatinine was 0.6 mg/dL. Serum acetone level was 80 mg/dL. Urine ketones were >160. Venous blood pH was 7.02. Lactic acid was 0.4 mmol/L and liver function panel was within normal limits. She was diagnosed with euglycemic diabetic ketoacidosis secondary to SGLT2 inhibitor therapy. Canaglifozin was stopped. She was treated per protocol with intravenous insulin infusion until ketoacidosis resolved. She was also maintained on dextrose infusion to avoid hypoglycemia. She was later transitioned to subcutaneous insulin. She did well and was discharged on metformin therapy for type II diabetes mellitus. She follows up as an outpatient and has not had such episodes ever since.

IMPACT: Our case emphasizes that patients on new generation medications should be monitored closely for side effects. It reiterates prompt recognition of rare presentations of fatal complications of diseases. We seek to describe the association of SGLT2 inhibitors with euglycemic diabetic ketoacidosis in hopes that it will enhance recognition of this potentially life-threatening complication.

DISCUSSION: Diabetic ketoacidosis is a fatal complication of diabetes mellitus, which can rarely occur despite normal glucose levels. This form is seen more commonly in type I diabetes mellitus than type II. SGLT2 inhibitors are a new class of oral hypoglycemics indicated for type 2 diabetes mellitus. They prevent the reabsorption of glucose from primary urine at the proximal renal tubules by targeting SGLT2, thus lowering plasma glucose levels. This in turn reduces insulin secretion, which lowers antipolytic activity of insulin and consequently stimulates free fatty acid production, which are converted to ketones, resulting in euglycemic diabetic ketoacidosis.

EUGLYCEMIC DKA: AN ATYPICAL AND MISLEADING PRESENTATION OF DKA Rohini Meka; Suresh K. Chirumamilla. Baystate Medical Center, Holyoke, MA. (Control ID #2708637)

LEARNING OBJECTIVE #1: Recognize DKA in patients presenting with normal blood sugars

CASE: A 41-year-old male with past medical history of insulin-dependent diabetes mellitus, hypertension, hyperlipidemia and fatty liver was brought to the emergency room by his wife for evaluation of agitation, "night terrors and restlessness". Because of the recurrent vivid bad thoughts, he has been binge drinking for the last 5 days. The patient usually takes insulin at home; however he was unable to recall the dose. Vitals on presentation were within normal limits. Initial blood work revealed Na 137mEq/L, K 4.1mEq/L, chloride 93 mEq/L, bicarbonate 13mEq/L, anion gap 30, BUN 8mg/dl, creatinine 0.9mg/dl, serum beta hydroxybutyrate 4.7 (normal 0.0-0.27), and serum glucose 163mg/dl. The diagnosis of diabetic ketoacidosis (DKA) was made based on elevated serum ketones and a low bicarbonate level, despite his normal blood sugar. He was then started on aggressive IV fluids and insulin drip; his electrolytes were monitored every 4 hours. D51/2 NS was started and continued to prevent hypoglycemia as blood sugars were never over 200mg/dl. The anion gap closed on hospital day 2 and on day 3 the patient was discharged home.

IMPACT: This case emphasizes that one cannot rely exclusively on elevated glucose levels to consider the diagnosis of DKA. It is important to recognize unexplained acidosis in diabetic patients as a sign of DKA and obtain ketone levels.

DISCUSSION: Diabetic ketoacidosis is one of the serious complications of diabetes mellitus. Diagnostic criteria of DKA by American Diabetes Association includes hyperglycemia (blood sugars >250mg/dl), metabolic acidosis (pH <7.3, serum bicarbonate < 18mEq/L) and ketosis. Even though hyperglycemia is an important criteria of DKA, sometimes it can present with normal blood glucose levels (<200mg/dl), which is defined as euglycemic DKA. Metabolic conditions that associate with euglycemic DKA include decreased calorie intake, heavy alcohol consumption, chronic liver disease, pregnancy, and use of sodium glucose contransporter 2 (SGLT2) inhibitors. Patients with euglycemic DKA pose a diagnostic challenge to physicians. Recognizing low bicarbonate levels and elevated anion gaps and obtaining serum/urine ketones is key to promptly making the correct diagnosis of DKA in these patients. Management of euglycemic DKA is similar to patients with DKA, in that volume resuscitation, insulin infusion and electrolyte replacement are key steps in treatment. However, given that blood glucose levels are <200mg/dl in these patients, insulin infusion can be given at lower rate 0.02-0.5 units/kg/hr and dextrose containing fluids should be used early to prevent hypoglycemia.

EVIDENCE OF INCREASING INCIDENCE: PRESENTATION OF A YOUNG HISPANIC MALE WITH ADVANCED GASTRIC CANCER BEENISH AHMED[1]; Dana M. Larsen[2]; Nedaa Husainat[2]; Jing H. Kees[1]. [1]BAYLOR COLLEGE OF MEDICINE, HOUSTON, TX; [2]Baylor College of Medicine, Houston, TX. (Control ID #2706936)

LEARNING OBJECTIVE #1: To recognize the increasing incidence of gastric adenocarcinoma in young Hispanic males

CASE: A 21-year-old Hispanic male with a history of Helicobacter pylori (H. pylori) gastritis and iron deficiency anemia presents with two years of decreased appetite, fatigue, ten pound weight loss, new onset coffee ground emesis, dizziness with standing, and syncope. One year prior to presentation, he was diagnosed with H. pylori and iron deficiency anemia. He completed a triple therapy regiment, but was not on iron therapy and did not follow up for eradication testing. On admission, he was orthostatic, hypotensive to 93/57, and tachycardia to 106. Exam showed a thin and pale young man, without palpable lymphadenopathy or rectal findings of hemorrhoids, masses, or blood. His labs were significant for microcytic iron deficiency anemia (hemoglobin 3.6, ferritin of 0.8). An EGD showed a 4-6cm tumor in the prepyloric, pyloric and duodenal bulb area with multiple bleeding ulcerations. Biopsy of the mass confirmed signet cell type invasive adenocarcinoma and H. pylori gastritis. His hemoglobin improved with blood transfusions, and he was started on quadruple therapy for chronic H. pylori gastritis before discharge. On follow up with oncology clinic, he underwent endoscopic ultrasound (EUS) with diagnostic peritoneal washings and biopsies, revealing invasion of the malignant cells to the muscularis propria and enlargement of perigastric lymph nodes. CDH1 testing was unable to be performed due to a scant number of malignant cells, and he was referred to genetics for germline evaluation. He has since received four cycles of FOLFOX chemotherapy and has undergone a subtotal gastrectomy. His most recent CT showed no evidence of disease.

IMPACT: This case led our team to recognize that the increased cases of gastric adenocarcinoma in young Hispanic males seen at our facility was indicative of an increase noted worldwide. This has heightened our diagnostic index of suspicion regarding possible malignancy in subsequent young patients who have presented with similar symptoms.

DISCUSSION: Gastric cancer is the fifth most common malignancy in the world and the third leading cause of cancer deaths, most commonly affecting males of Eastern Asia, Central and Eastern Europe and developing nations. The global incidence has rapidly decreased since 1975, a change presumed to be partially accounted for by the discovery of *H. pylori* and modification of risk factors (obesity rates, genetic susceptibility, and socioeconomic disparities). However, new concern has been raised over the growing number of young Hispanic males (age 20–49) diagnosed with gastric cancer. This subgroup had an annual percent change from 1992 to 2011 of 1.6 and is the only group that saw a rising incidence. Additionally, these patients are more likely to present with advanced disease. Continued studies are necessary to identify additional causal factors and identify appropriate screening methods for at risk individuals.

EXACERBATING THE PROBLEM: COMPLICATIONS OF MECHANICAL VENTILATION Michael A. Garcia; Maher Tabba. Tufts Medical Center, Boston, MA. (Control ID #2706221)

LEARNING OBJECTIVE #1: Recognize life-threatening complications of positive pressure ventilation

CASE: A 72 year old female with history of severe anxiety and end-stage COPD was brought to a tertiary care center by EMS for evaluation of respiratory distress and lethargy. In the field, her oxygen saturation was in the low 80's with subsequent clinical deterioration requiring intubation by EMS. On arrival to the emergency department, vital signs were notable for sinus tachycardia to the 120s, blood pressure of 160/70, respiratory rate of 12 with oxygen saturation of 87% on assist control ventilation with FiO2 of 100 and PEEP of 10. Exam revealed subcutaneous emphysema in the right chest and neck, absent right-sided breath sounds, and her abdomen was rigid and tympanic to percussion. Given her hemodynamic stability, a chest x-ray confirmed a right tension pneumothorax as well as pneumoperitoneum. A right-sided chest tube was placed with resolution of the pneumothorax and subsequent improvement in oxygenation to

95% on FiO2 of 60 and PEEP of 5. CT abdomen and pelvis was negative for perforated bowel as an etiology of pneumoperitoneum. Bladder pressures were monitored for development of abdominal compartment syndrome. The subcutaneous emphysema, tension pneumothorax and pneumoperitoneum were secondary to barotrauma from positive pressure ventilation. Labs were notable for a white blood cell count of 22.7. She was started on methylprednisolone and broad-spectrum antibiotics for presumed COPD exacerbation as a trigger of her respiratory decompensation. Her lung mechanics and abdominal distension improved with several days of supportive care and she was subsequently extubated to her home oxygen. The right chest tube was removed without complication and she was discharged on a prednisone taper.

IMPACT: Every intervention has its risks and complications should be quickly recognized in concordance with the ethical principle of do no harm.

DISCUSSION: The case highlights the recognition and management of several complications from positive pressure ventilation related to barotrauma. Barotrauma occurs when elevated transalveolar pressure causes alveolar rupture. Patients with acute COPD exacerbation are at highest risk of barotrauma due to dynamic hyperinflation. This patient exhibited the major complications of barotrauma including tension pneumothorax, subcutaneous emphysema, pneumomediastinum, and pneumoperitoneum. Tension pneumothorax should be identified on physical exam with tracheal deviation, absent breath sounds and hypoxia with immediate needle decompression. Subcutaneous emphysema, pneumomediastinum and pneumoperitoneum are self-limited and resolve with reduction in ventilator pressures. Barotrauma is a rare cause of pneumoperitoneum which prompted further evaluation for perforated bowel with a CT abdomen and pelvis. Early recognition and management of complications related to mechanical ventilation is imperative to prevent further harm to patients.

EXPANDING THE DIFFERENTIAL TO C MORE Justin S. Louie. Kaiser Permanente San Francisco, Berkeley, CA. (Control ID #2692535)

LEARNING OBJECTIVE #1: Recognizing that Vitamin C deficiency is an important reversible cause of unexplained bleeding and anemia

CASE: A 59 year old female with bipolar disorder and hypothyroidism presented to the emergency department with syncope in the setting of 3 months non-traumatic bruising, found to have a new anemia, Hgb 8.1. Vital signs were stable, and initial labs were negative for hemolysis, bleed, or reversible coagulopathy. Physical exam showed numerous ecchymosis and purpura on her lower extremities. After admission, rheumatology and dermatology were consulted given concern for a vasculitic process. A full hematologic and rheumatologic workup was negative, and a skin biopsy noted nonspecific results. Additional history revealed the patient normally ate a very bland diet and had been having worsening mood swings. Furthermore, while in the hospital she noted blood after brushing her teeth. A vitamin C level was sent and returned undetectable. She was started on vitamin C replacement for scurvy, with interval resolution of her symptoms.

IMPACT: This case is a classic presentation of scurvy, illustrating the insidious onset culminating in numerous cutaneous, systemic and hematologic manifestations. It highlights the need to keep nutritional deficiencies within our differential diagnoses to avoid missing these otherwise treatable conditions. Moreover, earlier consideration may limit the otherwise extensive and invasive workups that these patients receive.

DISCUSSION: Scurvy is a disease arising from vitamin C deficiency. The human body is unable to synthesize vitamin C, and therefore depends on exogenous dietary consumption. Thought to be a disease of the undeveloped world, and thus often not considered in initial differential diagnoses, there is still a notable prevalence of vitamin C deficiency in modernized countries. This can lead to a delay in diagnosis, allowing potentially life-threatening complications to develop in patients who have an otherwise treatable disease. Vitamin C is required in many biological processes, including the formation of collagen. Early manifestations are nonspecific, but as deficiency is prolonged, patients can develop potentially fatal cerebral hemorrhage, seizures, and hemopericardium. Population studies suggest that vitamin C deficiency is more prevalent than typically thought. The National Health and Nutrition Examination Survey (NHANES 2003–2004) found 7.1% overall prevalence, though subsequent data has noted some improvement. There are many at risk populations including the elderly, economically disadvantaged, and patients with gastrointestinal or psychiatric disease. Typically, scurvy carries an excellent prognosis if diagnosed and treated appropriately. Vitamin C deficiency should be suspected in high risk patients who present with signs of cutaneous bleeding and anemia with an otherwise negative workup. Treatment should include dietary counseling, vitamin C replacement therapy, as well as determination and correction of reversible risk factors.

EXPECT THE UNEXPECTED - A CASE OF NECROTIZING PANCREATITIS John Ning[3]; Bao Chau Nguyen[3]; Thamer A. Kassim[2]; Renuga Vivekanandan[1]. [1]Creighton Medical center, Omaha, NE; [2]Creighton University, Omaha, NE; [3]Creighton University School of Medicine, Omaha, NE. (Control ID #2705864)

LEARNING OBJECTIVE #1: Recognize the clinical features of necrotizing pancreatitis

LEARNING OBJECTIVE #2: Treat necrotizing pancreatitis conservatively in patient with multiple co-morbidities

CASE: A 61 year-old female presented with acute abdominal pain, shortness of breath and fever. The patient was in respiratory failure with an elevated White Blood Cell (WBC) count at 20.7 k/ul, elevated inflammatory markers and a serum Lipase of 3198 u/l. Patient was resuscitated aggressively with Intravenous (IV) fluids, started on IV Meropenem, and placed on oxygen. The patient's past medical history included hemothorax status post Video-Assisted Thoracoscopic Surgery, Heart Failure with preserved ejection fraction, Chronic Kidney Disease stage III, and Chronic Obstructive Lung Disease. The patient smoked 0.25 packs/day and had no history of alcohol use. Abdominal ultrasound (US) showed findings suggestive of acute cholecystitis with cholelithiasis. Abdominal computerized tomography (CT) scan showed findings consistent with cholelithiasis, acute pancreatitis with necrosis of the uncinate process and pancreatic body with no pancreatic duct or common bile duct dilatation. Due to concern from findings of necrotizing pancreatitis multiple teams were consulted. After stabilization, the patient underwent a cholecystectomy by our general surgery team without complications. On post-op day 2, patient developed a fever and went into respiratory distress, requiring 8 Liters on oxymizer. After a 10-day antibiotic treatment, her symptoms resolved. The patient was discharged home in stable condition.

IMPACT: This case has significant impact on our management of pancreatitis. Due to its unlikely occurrence, necrotizing pancreatitis may be overlooked by clinicians as a potential diagnosis. With the possibility of severe sequelae in

mind, it is imperative to formulate a systematic and thorough differential diagnosis that includes all possible causes in order to provide prompt evaluation with proper imaging and treatment.

DISCUSSION: Acute pancreatitis can be divided into two subtypes—interstitial edematous pancreatitis and necrotizing pancreatitis. Majority of patients with acute pancreatitis have diffuse inflammatory edema, while only 5-10% develop necrosis of the pancreatic parenchyma, peripancreatic tissue, or both. Bacterial infections developed in 40-70% of those with necrotizing pancreatitis with mortality rates up to 40%. Recent articles have discussed the use of prophylactic antibiotic treatment. One meta-analysis has suggested that the use of prophylactic antibiotics did not reduce the incidence of infected necrosis, while another meta-analysis on randomized control trials showed a statistically significant decrease in mortality rates in those who took antibiotics (7.4% vs. 14.4%). Due to its high morbidity and mortality rates, it is imperative to recognize the prospect of necrotizing pancreatitis when suspecting acute pancreatitis and initiate prompt evaluation and effective treatment.

EXTREMELY HIGH SERUM FERRITIN: A DEFINITIVE MARKER OF MASQUERADING ADULT ONSET STILL'S DISEASE WITH HEMOPHAGOCYTIC SYNDROME. Shun Yamashita; Yuka Naito; Akihiko Ogushi; Naoko E. Furukawa; Masaki Tago; Shu-ichi Yamashita. Saga University Hospital, Saga, Japan. (Control ID #2690766)

LEARNING OBJECTIVE #1: Recognize that extremely high serum ferritin can be a definitive indicator of adult onset Still's disease with hemophagocytic syndrome, even of a patient without typical rash or arthritis.

CASE: An 88-year-old woman had fever non-responsive to extended-spectrum antibiotics for 6 days. She only showed a non-specific erythema with infiltration on her trunk without any other abnormality including arthritis. Even in the absent of typical rash which is salmon pink ones appearing with fever and disappearing with defervescence, her fever over 39 degrees Celsius for more than a week, leukocytosis with neutrophilia of 80%, splenomegaly, hepatic dysfunction, normal level of rheumatoid factor and antinuclear antibody were compatible with adult-onset Still's disease (AOSD) according to Yamaguchi's criteria.Complicated disseminated intravascular coagulation (DIC) and hemophagocytic syndrome (HPS) were diagnosed by thrombopenia, elevated d-dimer, soluble IL-2 receptor antibody and extremely high serum ferritin (78,662 ng/mL). On the diagnosis of AOSD complicated with HPS and DIC, we started the treatment with recommended dose of prednisolone (30 mg/day). However, her condition deteriorated and pleuritis in the left side developed. In addition to 3 days of methylprednisolone 500mg/day followed by prednisolone 30mg/day, immunosuppressive agent (Cyclosporine 50mg/day) was started, which improved her general condition, elevated CRP and severe hyperferritinemia.

IMPACT: What does this case add to the literature? Extremely high serum ferritin can help make diagnosis of AOSD and HPS with atypical and rare presentations, including the absence of typical rash or arthritis and oldest age of ever reported.

DISCUSSION: AOSD with rare and atypical presentations is a diagnostic challenge, though 30% of AOSD were reported not to have arthritis and 23 cases only with atypical rash in the last 5 years. The median serum ferritin level of AOSD is 4,752 ng/mL. Extremely high serum ferritin over 10,000 ng/mL is reportedly caused by only three conditions, severe hepatic dysfunction, multiple blood transfusions or HPS. The presence of DIC, Leukopenia and thrombopenia can help make diagnosis of AOSD with HPS, the median serum ferritin level of which is 18,179 ng/mL. Corticosteroids are the mainstay treatment of AOSD with overall efficacy of more than 60%, and 78% in AOSD without arthritis.. We started recommended dose of prednisolone, 0.85mg/kg/day (30mg/day), which was not effective to our patient. About 55% of HPS was reported to be resistant to recommended dose prednisolone, which might require methylprednisolone pulse therapy and/or immunosuppressive agents.. We here report severe AOSD with HPS and DIC, whose extremely high serum ferritin was useful in the diagnosis, treated successfully with methylprednisolone pulse therapy and Cyclosporine.

EYING OTHER CAUSES John P. Haydek; Margaret Q. To; Meredith H. Lora. Emory University School of Medicine, Atlanta, GA. (Control ID #2700627)

LEARNING OBJECTIVE #1: Understand the differential diagnosis of optic neuropathy.

LEARNING OBJECTIVE #2: Recognize the epidemiology and clinical presentation of neuromyelitis optica.

CASE: A 26-year-old African-American woman presented with a four month history of bilateral blurry vision that developed over several days. An optometrist initially found anisocoria and referred her to neurology, but she did not follow-up until seen in primary care clinic. Her past medical history included bipolar affective disorder treated with lithium. Her exam was notable for dilated pupils measuring 7 mm bilaterally and poorly responsive to light without a relative afferent pupillary defect (RAPD). Visual exam revealed an inability to differentiate colors. Fundoscopic exam showed bilateral optic pallor without papilledema[LMH1][JH2]. The rest of her neurologic exam was intact. Magnetic resonance imaging (MRI) revealed bilateral atrophy and enhancement of the optic nerves without abnormalities in the brain or spinal cord. Labs showed normal folate, vitamin B12 of 131 pg/mL, serum ACE of 13 units/L, normal TSH and negative RPR[LMH3][JH4]. Lumbar puncture revealed a normal cell count, glucose of 94 mg/dL and protein of 32 mg/dL. Serum neuromyelitis optica IgG levels were >40 units/mL. The patient was started on high-dose intravenous steroids for neuromyelitis optica and discharged on a steroid taper and vitamin B12 supplementation. Her vision did not improve. She declined further interventions.

IMPACT: This case highlights the importance of considering neuromyelitis optica in patients whom present with bilateral optic neuropathy.

DISCUSSION: The classic clinical signs of optic neuropathy are central visual field defects, washed out color vision, and a RAPD, unless both eyes are affected symmetrically. Rapid onset of symptoms usually indicates an inflammatory or ischemic cause such as multiple sclerosis (MS), neuromyelitis optica (NMO) or ischemic optic neuropathy. A gradual course over months is typical of toxic/nutritional or compressive causes such as vitamin B12 deficiency or sarcoidosis. This patient presented with acute bilateral visual loss and clinical signs consistent with optic neuritis. The most common cause of optic neuritis is MS, but often is unilateral and affects white females. Given her demographics and bilateral symptoms, NMO was appropriately investigated and diagnosed. Clinical presentations of NMO include acute bilateral or sequential optic neuritis or extensive transverse myelitis. It is recognized as a distinct clinical entity than MS by its pathologic and highly specific biomarker, NMO-IgG, as well as its lack of brain involvement and more longitudinally extensive spinal cord involvement. Workup for NMO includes MRI of the brain and spinal cord, lumbar puncture, and NMO antibody. CSF abnormalities may include

pleocytosis and elevated protein; Oligoclonal bands are notably absent. NMO exacerbations are managed with high-dose steroids. Systemic immunosuppression is the mainstay of long-term prevention of future attacks.

FACIAL CELLULITIS AND SINUSITIS LEADING TO CAVERNOUS SINUS THROMBOSIS, MENINGITIS, AND SUBARACHNOID HEMORRHAGE Fahad Juboori[1]; Sandi Khin[1]; Jannatun Sikder[2]. [1]NY Presbyterian Brooklyn Methodist Hospital, Jersey City, NJ; [2]NY Medical College, Valhalla, NY. (Control ID #2707299)

LEARNING OBJECTIVE #1: Recognize the symptoms and physical exam findings of cavernous sinus thrombosis.
LEARNING OBJECTIVE #2: Treat facial cellulitis and sinusitis aggressively to prevent progression to cavernous sinus thrombosis.
CASE: A 69-year-old female with medical history of hypertension, type II diabetes mellitus, and non-ischemic cardiomyopathy presented to the emergency department with altered mental status, worsening sinus pain, and bilateral eye redness and swelling for two days. The history was provided by the husband. Physical exam was pertinent for orbital and nasal cellulitis with left proptosis, chemosis, and purulent discharge. Labs were notable for a neutrophilic leukocytosis of 15 with bandemia of 30%, lactate of 3, and procalcitonin of 5. Vancomycin IV, ceftriaxone, and acyclovir IV were started for suspected meningitis. She progressively became obtunded. She was emergently intubated for airway protection and transferred to the ICU. CT of the brain demonstrated a subarachnoid hemorrhage in the left supraclinoid carotid terminus region. CT of the maxillofacial region revealed sinusitis in the bilateral frontal and sphenoid and right maxillary sinuses. Lumbar puncture revealed four tubes of grossly bloody cerebrospinal fluid (CSF). CSF and blood cultures grew MSSA. The antibiotics were changed to clindamycin, nafcillin, and rifampin. CTA of the head and neck were negative for an aneurysm. CT venogram of the brain demonstrated thromboses of bilateral cavernous sinuses, left superior jugular vein, sigmoid sinus, lateral left transverse sinus, and partial thrombosis of the right internal jugular vein with marked interval worsening of the subarachnoid hemorrhage. Video EEG suggested severe encephalopathy. Due to the extent of the hemorrhage, meaningful recovery was unlikely.
IMPACT: The morbidity and mortality risk associated with cavernous sinus thrombosis cannot be understated. Its ability to rapidly progress to meningitis and subarachnoid hemorrhage is rare, but documented. Early recognition of infections in the face and sinuses with appropriate antibiotic coverage can most certainly minimize progression of disease.
DISCUSSION: The sequence of events leading to cavernous sinus thrombosis, meningitis, and subarachnoid hemorrhage is rapid and carries a high mortality risk. A patient presenting with facial cellulitis or sinusitis, fever, visual disturbances, headache, and altered mental status should raise suspicion for involvement of the cavernous sinuses. Lateral gaze palsy may be the primary extraocular muscle deficit. Empiric antibiotics include IV vancomycin to cover MRSA and cefepime or piperacillin-tazobactam to cover gram negatives and anaerobes. Diagnosis of cavernous sinus thrombosis is confirmed with CT/MRI with contrast. Anticoagulation with unfractionated heparin is a controversial method of treatment and is an option if no hemorrhage or bleeding diathesis is present. The goal is to prevent further thrombosis and to reduce the incidence of septic emboli.

FAHR FROM NORMAL AN INTERESTING CASE OF TRANSIENT DYSARTHRIA Ana I. Velazquez; Mariana Mercader; Nina Nguyen; Anjanet Perez-Colon; Geeta Varghese. Mount Sinai Beth Israel, New York, NY. (Control ID #2707153)

LEARNING OBJECTIVE #1: Recognize Fahr's syndrome.
LEARNING OBJECTIVE #2: Distinguish the most common differentials of cerebral calcifications.
CASE: 70y/o female with hypertension and osteoarthritis presented with slurred speech for 24 hours. Patient and family described development of slurred speech acutely upon patient waking on the morning prior to presentation. Symptoms affected both English and patient's primary language. Dysarthria gradually improved, however it persisted for 24 hours and the patient subsequently pursued medical evaluation. She denied fevers, headaches, vertigo, weakness, numbness, vision changes, and frequent falls. No prior episodes. Patient denied toxic habits or known family history. Home medications included daily aspirin 81mg. Physical exam was significant for mild dysarthria with fluent speech and intact naming, registration, repetition, and reading; otherwise unremarkable neurological exam with preserved strength, sensation, and otherwise normal cranial nerves. Initial labs were unremarkable including normal CBC and chemistry, including normal renal function with creatinine 0.96mg/dL and calcium 9.5mg/dL. Noncontrast head CT showed dystrophic calcifications in the basal ganglia, right frontal white matter, bilateral corona radiata, dentate nuclei, and cerebellar white matter bilaterally. MRI brain confirmed aforementioned findings. Further workup to exclude metabolic etiologies included negative thyroid panel, PTH, ferritin, iron, and RPR. CT-angiogram was negative for significant vascular head and neck disease. Findings were consistent with idiopathic basal ganglia calcification also known as Fahr's disease.
IMPACT: Fahr's disease is a rare disease with a wide variety of presenting symptoms that represents a diagnostic challenge to physicians. Given the myriad of symptoms associated with this disease, knowledge of the classical radiological findings is imperative for the evaluation and diagnosis of Fahr's disease.
DISCUSSION: Fahr's disease or idiopathic basal ganglia calcification is a rare, neurological disorder characterized by abnormal calcified deposits in basal ganglia and cerebral cortex. Calcified deposits are made up of calcium carbonate and calcium phosphate. Fahr's disease commonly affects young to middle aged adults and follows an autosomal inheritance pattern. Clinical manifestations include a wide variety of symptoms, ranging from extrapyramidal symptoms to neuropsychiatric, as schizophrenia or dementia, to movement disorders including Parkinsonism, chorea and tremors amongst others. Diagnosis is confirmed by brain imaging after excluding other metabolic, toxic, infectious, or traumatic etiologies. As there is no cure for Fahr's disease and treatment is symptom based, familiarity with this entity and early recognition are imperative to offer patients and family members screening neuroimaging and genetic counseling.

FAILURE TO COMMUNICATE: DELAYED NOTIFICATION OF A PATIENT DEATH Braden K. Mogler[2]; Margot Kushel[1]; Katie Raffel[2]. [1]UCSF, San Francisco, CA; [2]University of California San Francisco, San Francisco, CA. (Control ID #2706846)

LEARNING OBJECTIVE #1: Identify guidelines for communication between inpatient and outpatient providers, focusing on discussions around goals-of-care and end-of-life

LEARNING OBJECTIVE #2: Recognize the strengths and weaknesses of EMR-based communication

CASE: A 74 year-old woman with history of advanced dementia and end-stage renal disease on hemodialysis was found down, asystolic, at home. She was intubated and received ACLS with return of spontaneous circulation. Upon emergency department arrival, she was registered under a temporary medical record number (MRN). Her exam was notable for hypothermia, hypotension requiring dopamine infusion, fixed and dilated pupils, and an absence of voluntary extremity movement or brainstem reflexes. Laboratory studies were notable for an anion gap metabolic acidosis with pH 6.97 and lactic acid 9. The patient's permanent medical record was later identified, noting a recently completed POLST with DNR/DNI code status. After communication with the family, the patient's care was transitioned to a comfort focus, and the patient died unbeknownst to the primary care provider (PCP), who practiced within the same institution. Two months later, the outpatient clinic contacted the patient's family with an upcoming appointment reminder and discovered the patient's death.

IMPACT: While guidelines for inpatient-outpatient communication exist, this case highlights the fact that communication remains infrequent and unreliable and can negatively impact patients, family members and providers. Use of the electronic medical record (EMR) holds promise for standardizing this communication but is insufficient in isolation both due to duplicate MRNs and the absence of a platform for two-way communication.

DISCUSSION: The primary team in this case failed to adequately communicate with the primary clinic regarding the patient's management and death leading to exclusion of PCP from end-of-life discussion and family support. While consensus guidelines for inpatient-outpatient communication do not explicitly address end-of-life scenarios, they clearly state the expectation for timely, two-way communication. There were multiple contributing factors but, notably, the patient's temporary MRN at admission prevented automatic notifications of patient admission and discharge from reaching the PCP. This is significant, as at this institution an estimated 800 duplicate MRNs are created monthly. When such EMR based notifications are functioning appropriately, only 39% of PCPs describe them as adequate for patient care. These notifications do not allow for two-way communication (i.e. telephone or email) forms of communication that only 31% of PCPs receive. In summary, timely communication of patient presentation and death from inpatient to outpatient providers did not occur in this case, negatively affecting the patient, family and outpatient caregivers. EMR-based alerts may increase PCP notification when patients are appropriately registered under existing MRNs, but cannot replace guideline recommended two-way communication.

FALSE ASSURANCE: A CASE OF SEVERE RESPIRATORY FAILURE BY ATYPICAL PATHOGEN Upasana Bagaria; Heather Root; Jennifer O. Spicer. Emory University School of Medicine, Atlanta, GA. (Control ID #2706114)

LEARNING OBJECTIVE #1: Review the diagnosis of *Chlamydia pneumoniae*

LEARNING OBJECTIVE #2: Recognize the need for antibiotic coverage for atypical pathogens

CASE: A 78-year-old healthy male with hypertension presented with difficulty breathing. He reported cough, congestion, progressive dyspnea, and subjective fevers for two weeks prior to admission. His travel history was significant for trips to Alaska, North Carolina and Orlando with recent exposure to two parakeets. At presentation, he was febrile, tachycardic and hypoxic to 78% on room air. Exam revealed labored breathing with crackles in bilateral lung bases. Laboratory studies were notable for WBC 28,000/mcL, platelets 527,000/mcL, and D-dimer 2907 ng/mL. CT chest was negative for pulmonary embolism but showed patchy consolidation in bilateral lower lobes. He was intubated within 48 hours after failing non-invasive ventilation. His antibiotics were broadened from ceftriaxone to vancomycin, piperacillin-tazobactam and azithromycin. Additional tests included bronchoalveolar lavage which showed multiple neutrophils but no organisms on gram stain with negative bacterial and fungal cultures, negative influenza PCR, negative urine Legionella and Histoplasma antigens, and negative Legionella respiratory culture. Given his exposure to parakeets, *Chlamydia* serologies were sent. The diagnosis was established when *C. pneumoniae* IgG titer resulted at 1:1024. Antibiotics were switched to doxycycline and he defervesced within 24 hours with improvement in respiratory function.

IMPACT: This case highlights the importance of including atypical coverage in a patient with severe respiratory failure. Clinicians must have a high index of suspicion for atypical pathogens as diagnostics are limited and common empiric antibiotic coverage may be insufficient.

DISCUSSION: *C. pneumoniae* is an obligate, intracellular bacterium that commonly causes mild respiratory infections, but can result in severe multifocal pneumonia with ARDS. It accounts for up to 20% of pneumonia in older adults. Despite high incidence, diagnosis is challenging as antibody testing, polymerase chain reaction and direct antigen detection modalities are not routinely available and *C. pneumoniae* does not have any distinguishing clinical characteristics. Moreover, the historical distinction between atypical and typical bacterial pneumonia can lead to a false sense of security that atypical pathogens do not cause severe disease. Patients admitted with acute respiratory failure are commonly covered with broad-spectrum antibiotics such as vancomycin and beta-lactams, which do not treat atypical infections. However, when patients continue to decline despite empiric antibiotics, it is crucial to think about atypical organisms such as *C. pneumoniae* since they do not grow in routine cultures. Our patient's gram stain had many neutrophils but no organisms, suggesting an atypical pathogen. These gram stain characteristics should prompt a search for atypical pathogens, including viruses, atypical bacteria, and fungi.

FECAL INCONTINENCE SECONDARY TO PERFORATED COLON CANCER Ekta Kakkar; Rosa Schmidt. Baylor College of Medicine, Houston, TX. (Control ID #2706343)

LEARNING OBJECTIVE #1: Fecal incontinence is a underreported condition that can have many different causes including perforated malignancy.

CASE: A 49-year-old man with a history of well controlled non-insulin dependent type 2 diabetes and recently diagnosed internal hemorrhoids presents to clinic complaining of fecal incontinence for one week. The patient says he has daily bowel movements, but he is unable to feel them. He denies changes in the quality of his stools or abdominal pain. He has noticed streaks of bright red blood in his stools and on his soiled clothes. He denies back pain, numbness, weakness, or bladder incontinence. He says he has lost 50 pounds over the past several months. He denies family history of GI cancers, NSAID use, fevers, joint pain, and rash. On exam he appears pale with conjunctival pallor and tachycardia. The patient is sent to the emergency room for further

workup. He is found to be severely anemic and iron deficient with a hemoglobin of 6.6 g/dL, and he is transfused. CT scan of his abdomen reveals a rectosigmoid mass with perforation and a pelvic abscess. Flexible sigmoidoscopy confirms presence of this mass, and due to concern for perforation, the patient is taken to the Operating Room for exploratory laparotomy and hemicolectomy. Staging CT of his chest reveals no lesions and his CEA is within normal limits. Post-operatively, the patient is doing well with a recovering blood count and no further hematochezia.

IMPACT: This is a case of ruptured rectosigmoid cancer that led to formation of a pelvic abscess and caused fecal incontinence due to pudendal nerve involvement. Prognosis for patients with fecal incontinence secondary to malignancy is usually poor due to the advanced stage of cancer at diagnosis resulting from the delay in presentation. Paying attention to the history and physical in a clinic setting can raise suspicion for urgent conditions that should be addressed in a higher acuity inpatient ward such as in this case. Clinicians should have a high index of suspicion for perforated malignancy in patients who do not respond to medical management of fecal incontinence.

DISCUSSION: Intra-abdominal abscess formation from perforated colon cancer is rare (incidence <1%). This patient presented to clinic for his hemorrhoids, but further questioning revealed his fecal incontinence and weight loss. The differential diagnosis for causes of fecal incontinence is broad with pelvic floor dysfunction being a major cause in women. The prevalence of fecal incontinence is higher than reported data suggests largely due to the embarrassment the patient experiences. Perforated colon cancer is a rare initial presentation of this condition.

FECAL TRANSPLANT IN RECURRENT CLOSTRIDIUM DIFFICILE ENTERITIS

Ekta Kakkar; Mohamed Othman. Baylor College of Medicine, Houston, TX. (Control ID #2706327)

LEARNING OBJECTIVE #1: Fecal transplant is a relatively new therapy shown to be very effective in treating multiple recurrent Clostridium difficile infections (CDI).

CASE: A 30-year-old female with a history of ulcerative colitis (UC) diagnosed in 2012 status post a proctocolectomy with end ileostomy presents with severe generalized abdominal pain associated with nausea, decreased oral intake, and decreased ostomy output for 1 week. The patient says the pain is constant, nonradiating, and severe. She feels bloated if she tries to eat. She has been on a clear liquid diet for 5 days prior to presentation because she called her primary doctor when the pain worsened and was advised to do so. She has decreased stool output but no diarrhea or bloody stools. She denies fevers, sick contacts, rashes, joint pain, or recent travel. Her end ileostomy was recently revised from a diverting loop ileostomy 2 months ago due to a history of recurrent clostridium difficile infection (CDI) requiring a fecal transplant 2 years ago. Prior to that, she had an ileal pouch-anal anastomosis or J-pouch that was complicated by recurrent pouchitis. Her last hospitalization was at the time of her ostomy revision 6 weeks ago where she was treated with oral vancomycin for CDI. She has also previously received fidaxomicin for CDI. She is hemodynamically stable and exam is significant only for diffuse abdominal tenderness with voluntary guarding but no rebound tenderness and normoactive bowel sounds. Her ostomy site appears uninfected. Initial CT scan of her abdomen shows no bowel obstruction and her basic labs are within normal limits. She is found to have CDI and CT enterography shows enteritis. She is started on oral vancomycin and scheduled for a fecal transplant due to her multiple recurrent CDI of the small bowel.

IMPACT: This is a unique case of recurrent CDI of the small bowel likely due to her multiple hospitalizations and colonic surgeries. Risk factors for clostridium difficile enteritis are recent antibiotic use or hospitalization, history of inflammatory bowel disease, and history of colonic surgery. The morphology of the small bowel changes after colectomy which predisposes these patients to infection. Studies have shown more patients with ulcerative colitis develop C. difficile enteritis than patients with Crohn's disease.

DISCUSSION: To date, there are no official guidelines for when to treat CDI with fecal transplant, but it has been shown to be >90% curative in treating multiple recurrent CDI. Additionally, there are ongoing trials investigating the efficacy of fecal transplant in treating inflammatory bowel syndrome and inflammatory bowel disease. CDI of the small bowel is rare but has a high mortality rate (60-83%). For this reason, it is important to have a high suspicion for this disease in high risk patients and to perform fecal transplant in an attempt to prevent further recurrence.

FEVER COUGH AND HEMOPTYSIS - AORTIC GRAFT ABSCESS AS A RARE CAUSE OF BRONCHO-AORTIC FISTULA

Timothy J. Brown; Stan D. Atkin; Jason Clark. The University of Texas Southwestern Medical Center, Dallas, TX. (Control ID #2707081)

LEARNING OBJECTIVE #1: Form broad differential for hemoptysis and hematemesis

LEARNING OBJECTIVE #2: Manage long-term complications of aortic grafts

CASE: A 57 year-old Mexican male with a history of type 2 diabetes, hypertension, Barrett's esophagus, peptic ulcer disease, and aortic coarctation repair 30 years ago presented to the emergency department with hemoptysis and hematemesis. Initially, he was having occasional blood-speckled productive cough, but two days prior to presentation progressed to frank hemoptysis. On presentation he had two large volume episodes of coagulated hematemesis. Two weeks earlier, he was treated for pneumonia; blood cultures from then grew *Peptostreptococcus*. Vital signs were significant only for tachycardia. Exam revealed a 2/6 systolic murmur heard over the precordium and posterior left lung. Labs were significant for hemoglobin of 9.8 g/dL. T-spot was negative. A chest x-ray was negative. A CT angiogram of the chest demonstrated soft tissue swelling around prior aortic coarctation repair with foci of air. He was admitted to the ICU for stabilization. He continued to have hemoptysis in the ICU; bronchoscopy showed pooling of blood in the left lower lobe. Thoracic surgery was consulted and he was taken to the operating room. In the operating room, he was found to have an infected aortic graft with fistulization into the left lung. His graft was replaced. Cultures grew *Prevotella*, *Streptococcus viridans*, and *Candida glabrata*. He was discharged following his surgery and is doing well six months later.

IMPACT: Careful history and physical exam revealed several aspects of the patient's presentation that were not consistent with common causes of hemoptysis or an upper gastrointestinal bleed. Based on his past history of aortic coarctation repair, a differential diagnosis was formed that more broadly included aortic pathology. The patient underwent a CT angiogram of his chest that revealed the abscess with fistulization, allowing for rapid surgical intervention.

DISCUSSION: This patient had numerous reasons for both hemoptysis and hematemesis, including peptic ulcer disease, Barrett's esophagus, and immigrant status from a tuberculosis-endemic area. However, the recent pneumonia with blood cultures positive for *Peptostreptococcus* (an abscess-forming organism) and history of prosthetic aortic graft prompted the team to search for

more serious aortic pathologies as a cause for his symptoms. As a result, a prosthetic aortic graft infection with fistulization was discovered. Long-term complications of prosthetic aortic grafts include infections, which can occur 20 years or more following placement. Diagnosis can be made by presence of perigraft fluid with or without associated gas on CT, loss of normal mediastinal tissue planes, or pseudoaneurysm formation. Management of aortic graft infections consists of debridement with replacement and 4 to 6 weeks of antibiotics. Infections requiring graft reconstruction via thoracotomy have a 27% hospital mortality rate and 36% 1-year mortality rate.

FIBROMUSCULAR DYSPLASIA PRESENTING AS A RENAL INFARCT Sidra Khalid; Suryanarayan Mohapatra; Ashoka Nautiyal; Hamed Daw. Fariview Hospital - Cleveland Clinic, Cleveland, OH. (Control ID #2706691)

LEARNING OBJECTIVE #1: − to recognize renal infarct as an initial presentation of fibromuscular dysplasia (FMD) involving the renal artery

CASE: A 49 year old male presented with a sudden onset of severe, left sided abdominal pain radiating to the groin for one day. He is a nonsmoker, with a non-significant past medical and surgical history. His family history is contributory for factor V Leiden mutation in his brother and factor XII deficiency in his half-sister. On examination, vitals were afebrile, BP 154/90 mmHg, pulse 55/min, RR 22/min with an unremakeable physical excpet for generalized abdominal pain on palpation. A CT abdomen and pelvis showed poor opacification of the upper and interpolar segments of the left kidney, that were concerning for a renal infarct. Hypercoagulability work-up was sent and enoxaparin was started. The PT, aPTT, factor V Leiden mutation, antithrombin III, prothrombin gene mutation, lupus anticoagulant, factor XII, protein C & S were negative. To rule out an embolic source, TEE was performed which showed no evidence of a thrombus in the heart. To further delineate the underlying pathology and for revascularization, a renal artery angiography was planned. The angiography revealed FMD with a clot in the anterior division branch of the left renal artery. He was started on apixaban for the clot and amlodipine for hypertension. In the outpatient setting, renal artery duplex showed 0–59% stenosis of the left renal artery. Carotid and abdominal visceral arterial ultrasounds were unremarkable. The apixaban was discontinued after one month of therapy, as the patient was asymptomatic with a BP of 120/82 mmHg. In three months, he would undergo repeat imaging studies of the renal vasculature.

IMPACT: When our patient presented with renal infarction, our differential diagnoses included cardio-embolic phenomenon, localized renal pathology, and hypercoagulability. When we performed a renal angiography, it revealed FMD with thrombus in the left renal artery. FMD rarely presents with renal infarction. This impacted our clinical approach to include FMD in the differential diagnosis and our management included anticoagulation, blood pressure control, and imaging other vasculatures.

DISCUSSION: 29% of renal infarctions are iatrogenic, which includes FMD. The incidence of FMD involving the renal arteries is 5.7%. Patients can present with flank pain or hypertension. The diagnosis is made with digital subtraction angiography, CTA, MRA or duplex ultrasonography. Angiography of the vessels can either present with a beaded or focal stenosis appearance. Management depends on blood pressure control, or revascularization with PTA or surgery. FMD involves the carotid or vertebral arteries in about 65% of cases; hence additional vessel imaging is necessary in these patients.

FLANK PAIN IN A YOUNG FEMALE - IT WASN'T PYELONEPHRITIS Nandini Mehta; Daniel Mazori; Bushra Mina. Lenox Hill Hospital - Northwell Health, New York, NY. (Control ID #2704103)

LEARNING OBJECTIVE #1: Recognize flank pain as a clinical presentation of pulmonary embolism

CASE: A 21-year-old female with a past medical history significant for low-grade glioma suspicious for diffuse astrocytoma (WHO grade II) status-post partial resection and hemicraniectomy presented with left flank pain for two days. The day prior, she had been diagnosed with a urinary tract infection and prescribed cefuroxime at an outside hospital. Despite taking antibiotics, the patient had persistent left flank pain and subjective fever, prompting her to seek evaluation at our ED. Physical exam on presentation was notable for a temperature of 100.7 F, regular heart rate of 130, and left flank tenderness. Urinalysis was negative. CT abdomen/pelvis with IV contrast did not show pyelonephritis, but rather a filling defect in a subsegmental left lower lobe pulmonary artery. Follow-up CT angiogram showed bilateral pulmonary emboli. Additionally, there was a left posterior lower lobe consolidation and atelectasis, suspicious for infarction. On further questioning, the patient reported that she had been bed bound since undergoing neurosurgery 3 weeks prior. Ultrasound revealed no thrombus in her lower extremities. The patient had an inferior vena cava filter placed given the risk of intracranial hemorrhage after brain surgery with anticoagulation, with eventual resolution of her tachycardia and flank pain.

IMPACT: Pulmonary embolism is a potentially life-threatening event that should be considered in a physician's differential diagnosis for patients with otherwise unknown cause of flank pain. Clinical prediction scores exist for suspected PE. However, high clinical suspicion for PE relies heavily on an accurate and thorough history and physical exam to uncover the potentially fatal disease.

DISCUSSION: Pulmonary embolism has been called "the great masquerader," because it may present with nonspecific physical exam findings, such as abdominal pain, or as in this case, flank pain. Pulmonary infarction may cause irritation of the parietal pleura and subsequent pleuritic pain. Irritation of parietal branches of intercostal nerves may also cause hyperesthesia of the cutaneous branches innervating the flank region. Fortunately for this case, PE was incidentally discovered after imaging ruled out pyelonephritis. In retrospect, the patient's Well's score for PE was 3.0 - 4.0, indicating moderate risk for the following criteria: heart rate > 100, immobilization at least three days or surgery within the past four weeks, +/− malignancy with treatment (diffuse astrocytoma is not considered benign).

FOLLICULAR LYMPHOMA: A RARE CAUSE OF HYPERCALCEMIA Nina Nguyen[1]; Rifat Mamun[1]; Doyun Park[1]; Anish Parikh[1]; Ilan Shapira[2]. [1]Mount Sinai Beth Israel, New York, NY; [2]The Beth Israel Medical Center, New York, NY. (Control ID #2706167)

LEARNING OBJECTIVE #1: Identify hypercalcemia as a rare presenting sign of follicular lymphoma

LEARNING OBJECTIVE #2: Consider Richter's syndrome as an etiology of hypercalcemia in low grade lymphomas

CASE: A 59 year-old man with history of hypertension and gout presented with six weeks of fatigue, persistent left sided abdominal discomfort leading to poor oral intake, and unintentional 40-pound weight loss. Physical examination showed bilateral inguinal adenopathy, left lower quadrant abdominal tenderness and a palpable spleen. Initial labs were significant for

hypercalcemia 15.3 mg/dL and creatinine elevation 3.32 mg/dL. Complete blood count showed white blood cell count 11.0 K/UL with left shift and hemoglobin 10.4 G/dL. Further workup showed normal intact parathyroid hormone (PTH) 13 pg/mL and elevated 1,25-dihydroxy vitamin D 126 pg/mL. Serum and urine protein electrophoresis (SPEP and UPEP) were negative for a monoclonal protein. CT chest/abdomen/pelvis was significant for diffuse abdominal lymphadenopathy, as well as splenomegaly measuring 20 cm with multiple hypodense splenic masses. His calcium levels normalized and creatinine improved after treatment with intravenous fluids, calcitonin, and zoledronic acid. Right inguinal lymph node biopsy showed effacement of lymph node architecture by neoplastic follicles, with immunohistochemistry positive for CD10, CD20, BCL-2 and Ki67 of 10%, favoring a diagnosis of follicular lymphoma. The patient was discharged home for further outpatient workup and initiation of chemotherapy.

IMPACT: We describe a rare case of follicular lymphoma that presented with hypercalcemia. While hypercalcemia is often associated with malignancies such as multiple myeloma and solid tumors found in lung or breast cancer, it is seldom a presenting finding in lymphoma. There are few reports of follicular lymphoma presenting with hypercalcemia, and this case adds to the literature and raises awareness of a rare malignant cause of hypercalcemia that should be considered in a differential diagnosis.

DISCUSSION: Follicular lymphoma is the most common form of indolent non-Hodgkin lymphoma (NHL) comprising approximately 20-30% of cases. It generally presents with lymphadenopathy, commonly in the neck, axilla, or groin, and sometimes with symptoms such as fatigue, night sweats, and weight loss. Diagnosis is obtained via lymph node biopsy. Hypercalcemia is a rare finding in B cell lymphomas in general and complicates only 0.3-4% of cases, mostly seen in the aggressive subtypes of NHL. There have been reports of hypercalcemia occurring with Richter's syndrome which is the transformation of low grade lymphomas into high grade and can occur in 5-10% of patients with previously diagnosed entities such as follicular lymphoma, Waldenstrom's macroglobulinemia, and chronic lymphocytic leukemia. While no systematic study of hypercalcemia in B-NHL has been published, Richter's syndrome should be kept in mind in low grade lymphoma patients with hypercalcemia.

FOR ALTERED MENTAL STATUS, CHECK A STOOL SAMPLE?

Nicholas Hendren; Shahzad Chindhy; Kaylee J. Shepherd. University of Texas-Southwestern, Irving, TX. (Control ID #2702104)

LEARNING OBJECTIVE #1: Recognize the relationship between *Strongyloides stercoralis* and gram negative rod (GNR) bacteremia or meningitis.

LEARNING OBJECTIVE #2: Diagnose a *Strongyloides stercoralis* infection with evidence based testing.

CASE: A 57 year-old Hispanic male with a history of embryonal sarcoma of the liver presented with one day of altered mental status. The day prior to admission he had a witnessed mechanical fall without a loss of consciousness. He developed progressive confusion, chills, mild headache and fevers. He was diagnosed with stage IV embryonal sarcoma of the liver one year prior to admission. Despite local surgical resection and adjuvant chemotherapy, his cancer progressed with recurrent liver lesions and metastatic spinal disease requiring palliative radiation and dexamethasone therapy. He was a citizen of Mexico and last traveled to Mexico in 2008. Admission vital signs were unremarkable. He appeared comfortable, but was only oriented to his person. Other than baseline right upper quadrant and back pain, his exam was unremarkable. Blood cultures were positive for *Escherichia coli* and a lumbar puncture revealed glucose <2 mg/dL, protein of 495 mg/dL, 82,350 nucleated cells and a positive culture for *Escherichia coli*. Given his immunosuppression, travel history and GNR meningitis, a stool ova and parasite was obtained to screen for *Strongyloides stercoralis*. His stool was markedly positive for *Strongyloides stercoralis* larvae and he was diagnosed with *Strongyloides* hyperinfection syndrome. Given his poor prognosis, the patient declined medical therapy and elected home hospice.

IMPACT: Clinicians should have a high level of suspicion for *Strongyloides stercoralis* in patients with unexplained GNR infections and a history of travel to endemic areas of transmission. Suspicion should be heightened for patients on steroids or with an immunocompromised state.

DISCUSSION: *Strongyloides stercoralis* is a neglected tropical disease that infects people mainly in developing countries, but remains endemic in rural pockets of the United States. *Strongyloides* is capable of chronically re-infecting human hosts without an external host via autoinfection which allows for chronic infections to persist. In patients with chronic infection, hyperinfection can be triggered with immunosuppressed state and/or advanced malignancies. Hyperinfection syndrome is characterized by a heavy larval stool burden, disruption of the intestinal wall by a disseminated parasitic infection with concomitant bacterial translocation that can cause life threatening infections. Disseminated *Strongyloides* should be considered as the source for unexplained GNR bacteremia or meningitis especially in immunosuppressed patients. Our patient likely had a chronic asymptomatic *Strongyloides* infection acquired in Mexico that became a hyperinfection after starting high doses of dexamethasone for spinal metastatic disease. This led to bacterial translocation resulting in a classic case of GNR infection secondary to *Strongyloides* hyperinfection.

FRIENDS WITH LOW PLATELETS

Mary Moellering[1]; Chetan Prasad[1]; Roger D. Smalligan[2]. [1]Texas Tech Univ HSC-Amarillo, Amarillo, TX; [2]Texas Tech Univ Health Sc Center - Amarillo, Amarillo, TX. (Control ID #2699649)

LEARNING OBJECTIVE #1: Understand how to arrive at a diagnosis of idiopathic thrombocytopenic purpura

LEARNING OBJECTIVE #2: Understand new treatment options for ITP

CASE: A 74yo man with CAD s/p CABG, stroke, HTN, and HLD presented with prolonged bleeding from a laceration and petechiae and bruising all over his body. Meds: aspirin, clopidogrel, cephalexin, ferrous sulfate; NKDA; FHx negative for bleeding disorders; SHx: no alcohol, smoking or drugs. Physical exam: BP 150/69, HR 83, RR 17, T 37C, SpO2 99% on RA. Alert, oriented, oral mucosa bruised, lungs clear, heart RRR no murmurs, abdomen was soft, no HSM, bruises and petechiae seen on entire body. Labs: glucose 142, BUN 38, Cr 1.3; LFTs normal, albumin 1.9; WBC 5,400, Hgb 10.1, platelets 3,000; INR 1.1, PTT 25.4s (nl). Peripheral smear showed markedly decreased platelets and no schistocytes. Hospital course: Hematology consult felt the patient had ITP. Aspirin, clopidogrel and cephalexin were discontinued. Bone marrow biopsy was negative for malignancy. ADAMTS13 mutation, anti-nuclear antibodies, HCV, and leukemia markers were all negative. Patient received platelets and was started on prednisone and IVIG. Initial treatment failed, so romiprostim was given with platelets, and after several days, the platelet count was 35,000. The patient received meningococcal, pneumococcal, and HIB vaccines to prepare for possible splenectomy. After platelets fell to 6,000 he was given prednisone and eltrombopag and did well.

IMPACT: Severe thrombocytopenia is a serious condition that needs prompt treatment. Internists must know the potential causes of, and treatment for, the many etiologies of thrombocytopenia. This case demonstrates a logical and careful approach to diagnosis and treatment.

DISCUSSION: Prolonged bleeding is always a concern. Severe thrombocytopenia with petechiae and purpura immediately suggests DIC, ITP, TTP, HUS, leukemia, SLE, and other possible etiologies.The patient was on aspirin, clopidogrel and cephalexin, all of which can cause drug-induced thrombocytopenia, hence they were stopped. The patient had not received heparin to consider HIT. Mutations in the ADAMTS13 gene would have supported TTP (though the typical pentad was not present). SLE, HCV and leukemia can cause severe thrombocytopenia but testing was negative for these leading to the diagnosis of ITP. First-line treatment for ITP is corticosteroids and IVIG therapy, as was done with our patient, in addition to repletion of platelets if counts <10,000 or active bleeding is present. Next line is a thrombopoietin receptor agonist (TRA) like romiprostim. The TRAs act on thrombopoeitin receptors on megakaryocytes, activating JAK-STAT and MAP kinase pathways leading to increased platelet production. Some patients, like ours, respond better to another TRA, eltrombopag. If these measures fail, patients undergo splenectomy, which is often helpful. Internists need to keep the diagnosis of ITP in mind as they approach patients with severe thrombocytopenia.

FROM VASCULITIS TO SUBACUTE BACTERIAL ENDOCARDITIS

Natasha A. Kassim; Dayakar Kancherla. UPMC, Pittsburgh, PA. (Control ID #2701210)

LEARNING OBJECTIVE #1: Diagnose subacute bacterial endocarditis (SBE) in patients presenting with features of small vessel vasculitis.

LEARNING OBJECTIVE #2: Recognize that SBE may cause false positive ANCA and associated small vessel inflammation will respond to treatment with antibiotics, not immunosuppressants.

CASE: A 54-year-old man with recent diagnosis of ANCA vasculitis presented with pancytopenia, rash, and acute kidney injury. His course began six months prior to presentation when he presented with rash and hematuria, prompting a full rheumatologic evaluation and renal biopsy. Laboratory results were notable for positive ANA, ASO, PR-3 antibodies, and low C3 and C4. Renal biopsy showed focal membranocapillary and membranoproliferative glomerulonephritis (GN) with C3 and IgM deposits by immunofluroescence. Blood cultures were not obtained at time of initial diagnosis. He was treated with steroids and mycophenolate mofetil. During steroid taper, his rash returned, and he was found to have worsening renal function and pancytopenia, prompting current admission. On physical exam he had a diffuse purpuric and petechial rash, anasarca, and a new diastolic murmur on cardiac exam. Due to his atypical presentation and course, repeat rheumatologic evaluation was completed and was negative except for continued low complements. On hospital day 3, blood cultures returned positive for streptococcus sanguinis. Immunosuppressants were stopped, and he was started on antibiotics. A TEE demonstrated a bicuspid aortic valve with multiple vegetations and severe aortic insufficiency (AI), all consistent with the diagnosis of SBE. His course was complicated by progressive renal failure leading to initiation of hemodialysis. He was discharged on a prolonged course of IV antibiotics and ultimately underwent aortic valve replacement. His kidney function did not recover, but his rash resolved with antibiotics.

IMPACT: This case demonstrates an atypical presentation of SBE that led to initial misdiagnosis and incorrect management. Similar cases of patients presenting with presumed ANCA-associated vasculitis who were ultimately diagnosed with SBE are found only in case reports and case series. However, despite the rarity of this presentation, blood cultures should be obtained in patients presenting with features of vasculitis to rule out infection.

DISCUSSION: SBE and ANCA-associated vasculitis have overlapping clinical manifestations including fever, constitutional symptoms, GN, and cutaneous purpura. For patients with suspected vasculitis, ruling out active infection with blood cultures is necessary before establishing the diagnosis. Notably, SBE can cause false positive ANCA. However, the vasculitis in SBE is not pauci-immune and thus not mediated by ANCA. SBE associated vasculitis typically responds to appropriate antibiotic therapy and immunosuppressants are not indicated, and in fact could worsen disease.

FULMINANT HEPATITIS SECONDARY TO HERPES SIMPLEX VIRUS INFECTION

John D. Herlihy; Anthony Roohollahi. Carolinas Medical Center, Charlotte, NC. (Control ID #2687406)

LEARNING OBJECTIVE #1: Recognizing an atypical cause of acute fulminant hepatitis

LEARNING OBJECTIVE #2: Management of disseminated HSV

CASE: 39 year old male with no medical history presented with 2 weeks of fever, weakness, diffuse arthralgia, and anorexia. He had gone to urgent care 10 days prior this hospitalization and completed short course of Levaquin and Prednisone for presumed CAP. Over the past 2–3 days he had been taking Motrin 400mg every 4 hours and Acetaminophen 3 tablets every 6 hours for persistent fevers. The patient denied any rash, recent travel, abdominal pain, nausea, or vomiting. On arrival he had a low grade fever (Tmax 100.1), HR in the 70s, and BP of 90s-100s/60s. On exam he was in no significant distress with normal exam other than a small bleeding sore over lower lip and multiple smaller sores on his tongue. Initial labs showed platelet count < 10, Hgb 12.5, WBC 5900, creatinine 7.52, INR >8, ALT of 6200, AST 11780, Alkaline phosphatase 457, total bilirubin 4.0, LDH 12.2, ammonia level 62, fibrinogen <50, lactic acid 4.5, and hepatitis panel negative. Abdominal US showed small amounts of fluid around the gallbladder, Morison's pouch, and the pancreatic head. The patient was admitted to the ICU and started on IV NS, HCO3, and NAC. Shortly after admission patient went into cardiac arrest and despite prolonged resuscitative efforts unable to achieve ROSC. Autopsy showed severe disseminated herpes infection with severe herpes hepatitis and extensive hepatic necrosis, herpetic esophagitis, herpetic involvement of the lungs with early diffuse alveolar damage, small volume ascites, and hemorrhage involving the gallbladder and peripancreatic area.

IMPACT: This case changed my practice because I will now be much more inclined to include HSV on my differential for acute fulminant hepatitis. I will have a much lower threshold for starting Acyclovir empirically when there is unclear etiology for a patient with acute hepatitis, especially in patients with the classic triad of leukopenia, fever, and significantly elevated transaminases.

DISCUSSION: Severe disseminated HSV infection is rare and often rapidly fatal. Patients with a defect in cell mediated immunity are at greater risk. The prognosis is poor despite effective antiviral therapy likely due to delayed diagnosis as symptoms are nonspecific and mucosal lesions are frequently absent. Correct diagnosis prior to death is made in only 23% of cases and mortality rate is >80%. Classic symptoms are a triad of high fever, markedly elevated aminotransferase levels, and leukopenia. Patients typically feel moderately ill for 3 to 10 days then suddenly deteriorate with hepatic necrosis, DIC,

hypotension, and death within 1 week. Limited cases to guide management however Acyclovir has been shown to improve outcomes. Patients presenting with fulminant hepatitis with no other clear etiology should be started on Acyclovir empirically until definitive diagnosis can be made with liver biopsy.

FUN ON THE FARM. A CASE OF Q-FEVER ENDOCARDITIS

Christopher C. Richardson. University of South Florida, Saint Petersburg, FL. (Control ID #2707605)

LEARNING OBJECTIVE #1: Recognize the initial laboratory workup for a patient with suspected blood culture negative endocarditis

LEARNING OBJECTIVE #2: Learn how to interpret the laboratory testing for acute versus chronic Coxiella burnetii infections as prompt diagnosis and treatment is essential for chronic infections such as Q-fever endocarditis which carries such a high mortality rate

CASE: A 60-year-old female with a past medical history of cirrhosis secondary to Hepatitis C and alcoholism who presented with confusion, abdominal distention and discomfort. Spontaneous bacterial peritonitis was ruled out on admission and patient was placed on lactulose and rifaximin with improvement of her encephalopathy. Two days into admission the patient developed new onset dyspnea with hypoxia. A transthoracic echocardiogram was ordered that showed no evidence of shunting that would suggest hepatopulmonary syndrome and dyspnea resolved with fluid restriction and diuresis. However, an incidental finding on the echocardiogram revealed a 7.8 mm mobile echodensity on the aortic valve, which prompted further evaluation. A transesophageal echocardiogram confirmed the presence of three mobile echodensities with the largest measuring 12 mm × 5 mm, consistent with aortic valve vegatations. Infectious disease specialists were consulted and a gambit of tests were ordered to evaluate for patient's culture negative endocarditis. At the time she did not meet "Duke criteria" for infective endocarditis. Regardless, the patient was started on empiric ceftriaxone and doxycycline, and was felt to be suitable for discharge, planning six weeks of outpatient IV antibiotic therapy. Two weeks after discharge patient's send out labs for Coxiella burnetii had resulted revealing a positive phase II IgM titer of 1:32, with negative phase I IgM antibody and negative Phase I and II IgG antibodies. Given the specific marked election of phase II IgM titer, the diagnosis of Coxiella or Q-fever endocarditis was confirmed. Patient was then contacted who confirmed exposure to farm animals in the months prior to the admission.

IMPACT: This clinical vignette highlights the importance of considering uncommon etiologies for infective endocarditis in a patient with negative blood cultures and confirmed vegetations on echocardiogram. Broad screening for Legionella, HACEK organisms, Bartonella, Brucella, Mycobacterium and Coxiella should all be considered

DISCUSSION:.Q-fever is a zoonotic disease caused by the bacterium Coxiella burnetii that can cause acute and chronic illness with transmission occurring most often through inhalation of contaminated soil with animal waste. Only 20–40 percent of patients who develop chronic Q-fever have symptoms of acute infection. In contrast to acute Q-fever, chronic Q-fever can manifest as endocarditis months to years after exposure and carries a high mortality rate with most cases being fatal without treatment, stressing the importance of prompt recognition and treatment with doxycycline per "Center for Disease Control" recommendations

GANGRENOUS GASTRITIS: UNUSUAL CAUSE OF UPPER GI BLEEDING

Umair Iqbal[2]; Mohammad Arsalan Siddiqui[1]; Ahmad Chaudhary[2]; Hafsa Anwar[3]. [1]Henry Ford Hospital, Detroit, MI; [2]bassett medical center, Cooperstown, NY; [3]dow university of Health sciences, Karachi, Pakistan. (Control ID #2700892)

LEARNING OBJECTIVE #1: Mesenteric ischemia can present without abdominal pain especially if chronic due to formation of collateral vessels

LEARNING OBJECTIVE #2: Weight loss in elderly can be the only sign of chronic mesenteric ischemia

CASE: *A 6*7 year old male with history of COPD and coronary artery disease presented with hematemesis and black stools for a day. He denied any abdominal pain, loss of appetite, or weight loss. No prior history of GI bleeding or postparandial abdominal pain. He was a current smoker with 50-year smoking history. On presentation he had BP of 146/94, pulse 83 and afebrile. Abdominal exam was unremarkable for tenderness. Bowel sounds were present. Rectal exam revealed black stools. Labs showed hemoglobin of 16. g/dl1, hematocrit 45%, WBC of 34,000 with 83% neutrophils, bicarbonate 20 mmol/L and INR of 1.7. EGD revealed inflamed gangrenous-appearing gastritis throughout with multiple clean ulcers, raising suspicion for ischemia. Cardia revealed extensive gastric ulcer; 5–6 cm in greatest dimension, with a large visible vessel. CT angiographyof abdomen showed proximal occlusion of Superior mesenteric artery (SMA), near complete occlusion of celiac artery and hypertrophic Inferior mesenteric artery which is likely the supply of much of his GI tract. Patient underwent successful SMA bypass from left iliac to mid. He was discharged home on aspirin daily.

IMPACT: Clinicians should have a high index of suspicion in diagnosing intestinal ischemia in elderly patients with risk factors for atherosclerosis as clinical presentation can be misleading. Early diagnosis can prevent morbidity and mortality associated with this serious disease by decreasing the dreadful complication of bowel gangrene as developed in our patient.

DISCUSSION: Patients with chronic mesenteric ischemia (CMI) typically present with recurrent abdominal pain after meals, resulting in fear of eating and weight loss. In a survey of 270 patients, weight loss, postprandial pain, adapted eating pattern, and diarrhea are associated with CMI. Probability of diagnosis increases to 60% with all four symptoms, and reduces to 13% if none are present. Few patients present with non-specific symptoms of nausea, vomiting and/or GI bleeding. This patient was unique in that he had no abdominal pain even with a total occlusion SMA, possibly due to well-formed collaterals which were seen in his CT abdomen. His upper GI bleeding as a result of gangrenous gastritis resulted from ischemic bowel from total occlusion. Review of literature shows delay in diagnosis ranges from 10.7 months to 15 months in diagnosing CMI, resulting in more complications. CT angiography abdomen is more than 90 sensitive and specific in diagnosing it. Endovascular therapy with stenting is the preferred method of revascularization in these patients and has widely replaced open surgical management. The non-specific symptoms and unremarkable physical exam in our patient demonstrate how silently intestinal ischemia can present.

GASTROINTESTINAL MANIFESTATIONS OF ACUTE THYROTOXICOSIS

Sana Tariq; Tehseen Haider; Colette Knight. montefiore medical center, Bronx, NY. (Control ID #2703137)

LEARNING OBJECTIVE #1: Recognize the gastrointestinal manifestations of hyperthyroidism.

LEARNING OBJECTIVE #2: Identify thyrotoxicosis in the absence of overt physical examination findings.

CASE: A 67 year-old woman with past medical history of dermatomyositis was referred to endocrine clinic for abnormal thyroid function tests. She was initially seen in the GI clinic one month prior for evaluation of intermittent diarrhea and unintentional 23 lb weight loss. Her exam was notable for cachexia and tachycardia; there was no resting tremor, proptosis, or stare. Thyroid gland was normal in size. Abdominal exam was unremarkable. Given the patient's history of dermatomyositis, a work up for malabsorptive syndromes was done and was negative. However, thyroid profile revealed suppressed thyroid stimulating hormone (TSH): 1000 and thyroid stimulating immunoglobulin (TSI): 351%. Thyroid nuclear imaging showed homogeneous radioactive iodine uptake of 46.4%, consistent with Graves' disease. The patient was treated with methimazole and diarrhea resolved after several weeks of treatment. She regained her baseline weight. Thyroid function tests normalized with continued anti-thyroid treatment: TSH 1.26 uU/ml and FT4 1.64 ng/dl.

IMPACT: Early detection of hyperthyroidism in patients who present with chronic diarrhea and weight loss can result in appropriate treatment and prevention of unnecessary tests.

DISCUSSION: Graves' disease accounts for 60-80% of thyrotoxicosis and is often associated with adrenergic symptoms, weight loss, orbitopathy, and goiter. However, in select patients, especially the elderly, symptoms can be subtle and exam can be unremarkable. Weight loss is the most common presenting symptom of hyperthyroidism (present in 60.7%), and many patients gain considerable weight after treatment. Recent studies have shown that in hyperthyroid patients treated with radioiodine, thionamide or surgery the average weight gain was 5.4 ± 0.5 kg and increase in body mass index (BMI) was 8 ± 1 percent. Diarrhea is present in 22.3% of patients and is due to enhanced intestinal mobility with reduced transit time from the small to large bowel. There are multiple causes of chronic diarrhea and weight loss including infectious, non-infectious, autoimmune and parasitic, however it is important to keep endocrinopathies such as hyperthyroidism in your differential diagnosis. A careful history and judicious clinical acumen can help to associate presenting symptoms and signs such as weight loss and diarrhea with hyperfunctioning thyroid disease. Appropriate management of hyperthyroidism can lead to resolution of gastrointestinal symptoms such as weight loss and diarrhea.

GENITOURINARY PERIOPERATIVE INFECTION ASSOCIATED WITH SODIUM GLUCOSE CO-TRANSPORTER 2 INHIBITOR USE

Stephen Melnick[1]; Anthony A. Donato[2]. [1]Reading Health System, Lebanon, PA; [2]Reading Hospital and Medical Center, W Reading, PA. (Control ID #2706459)

LEARNING OBJECTIVE #1: Describe the association between genitourinary tract infections and SGLT-2 inhibitors

CASE: A 47 year old male with history of diabetes mellitus type 2 presented with acute onset progressive scrotal swelling and pain and fever 3 weeks after penile implant surgery. His current medications included canagliflozin-metformin, added just before surgery to improve his perioperative glucose control. On physical examination, the patient was febrile with scrotal swelling and tenderness to palpation. The patient laboratory evaluation was unremarkable including WBC count of 7.5/μl and serum lactate of 1.0 meq/L. Urinalysis was positive for glucose and trace ketones but negative for bacteria and white cells. A CT pelvis showed scrotal fluid consistent with abscess, and he was brought to the OR for penile prosthesis explant. Cultures grew MRSA and gram-negative rods. Blood cultures found MRSA bacteremia on second day of hospitalization. The patient was eventually discharged on IV vancomycin and amoxicillin-clavulanic acid for 14 days. In addition, the patients sodium glucose co-transporter 2 (SGLT-2) inhibitor, canagliflozin, was discontinued. The incident was reported to the FDA's post-marketing surveillance system.

IMPACT: This case emphasizes the importance of shared decision making prior to surgery. As the SGLT-2 inhibitors are gaining in popularity the provider must be aware of the potential adverse outcomes and may even considering holding or discontinuing this medication in the setting of impending GU surgery as the risks of this medication class include increased risks of genitourinary infections

DISCUSSION: SGLT-2 inhibitors are a novel treatment option for type 2 diabetes mellitus which have been shown to lower hyperglycemia, systolic blood pressure, and promote weight loss with reported adverse events including infections involving the genitourinary(GU) tract due to the medication mechanism of action. Canagliflozin is a selective SGLT-2 inhibitor which increases urinary excretion of glucose but is associated with an increased the rate of GU infections. The incidence of GU infections on an SGLT-2 inhibitor in the setting of GU surgery has not been described, but caution should be taken in perioperative use of this class in light of this risk.

GIANT CELL ARTERITIS COULD CAUSE DYSGEUSIA: A CASE REPORT AND FEATURES OF SEVEN CASES DIAGNOSED IN THE DEPARTMENT OF GENERAL MEDICINE

Yuichi Takahashi[1]; Taiju Miyagami[4]; Hiromizu Takahashi[5]; Yuki Uehara[3]; Toshio Naito[2]. [1]Juntendo Hospital, Tokyo, Japan; [2]Juntendo University, Tokyo, Japan; [3]Juntendo University School of Medicine, Tokyo, Japan; [4]Juntendo University of school, Bunkyo-ku, Japan; [5]Juntendo university, Tokyo, Japan. (Control ID #2706253)

LEARNING OBJECTIVE #1: Exploring dysgeusia as a diagnostic clue of giant cell arteritis

CASE: A 65-year-old man visited our clinic of general medicine because of headache and dysgeusia. Two months before admission, his symptoms started and got worse gradually, so he was referred to our clinic by his primary care phycisian, and hospitalized for diagnosis and treatment. His had a history of traumatic subdural hematoma, otherwise no particlar medical history. On admission, his body temperature was 36.9 ° C, blood pressure 108/60 mmHg, heart rate 90/min, respiration rate 13/min, and oxygen saturation was 98 percent while he was breathing ambient air. By reviewing of the systems, he stated he had headache, dysgeusia (feeling too salty for everything he ate), hyperacusis, hyperosmia, and physical examination revealed jaw claudication. Laboratory findings were as follows: WBC 12,000/μL, CRP 7.6 mg/dL, and erythrocytes sedimentation rate 110 mm/hour. After admission, induration of the left temporal artery appeared which was not seen in outpatient clinic. Whole trunk contrast CT showed thickened wall of the left subclavian artery and the brachiocephalic artery, and the 3D-CT showed stenosis of the left subclavian artery. Giant cell arteritis was highly suspected and biopsy of the left temporal artery was performed. Biopsy showed moderate to high inflammatory cell infiltration, and the appearance of multinucleated giant cells. In addition, the endothelium was thickened and a stenosis was found in a part of the blood vessel cavity. He started 60 mg of oral prednisolone daily, and headache, dysgeusia, hyperacusis and hyperosmia disappeared.

IMPACT: In this case, headache and dysgeusia appeared as the initial symptoms of giant cell arteritis and disappeared with steroid administration. It is

important to consider giant cell arteritis as urgent differential diagnosis when we see patients with dysgeusia.

DISCUSSION: We experienced a case of giant cell arteritis that caused dysgeusia. In addition, retrospective review of the 7 cases (including this case) of giant cell artritis diagnossed in our department, from 2008 to 2016, found another one case with dysgeusia as initial symptom. Giant cell arteritis is an urgent disease which can cause loss of vision, so for patients over 50 years old with dysgeusia, it is important to consider giant cell arteritis as an urgent disease. It is necessary to have additional investigation about other abnormal sensation such as hyperacusis and hyperosmia are related to giant cell arteritis as well as dysgeusia.

GOUTY PANNICULITS: A RARE MANIFESTAION OF GOUT

Hrudya Abraham[1]; Jacquelin R. Chua[2]; Ailda Nika[2]. [1]MacNeal Hospital, Berwyn, IL; [2]Rush Univeristy Medical Center, Chicago, IL. (Control ID #2679791)

LEARNING OBJECTIVE #1: Since gouty panniculitis is a rare entity, it can often be overlooked. Thus in the right clinical setting it is important to include it in the differential to guide further management.

LEARNING OBJECTIVE #2: Low dose corticosteroids with long term therapy with high dose allopurinol can be used as the first line of therapy for gouty panniculitis.

CASE: 42 year old male with history of alcoholism and chronic tophaceous gout on allopurinol 300 mg, presented with acute left elbow pain and swelling. Exam showed synovitis of left wrist and elbow, distal interphalangeal joint (DIJ) and right knee and tophi on left DIJ. Arthrocentesis of left elbow revealed purulent fluid with leukocytosis (5000,000/mm^3) and mono sodium urate (MSU) crystals with negative culture. Uric acid level was 10.1mg/dl with peripheral leukocytosis(16,000/mm3). His joint pain improved with antibiotics and steroids. On second day of admission tender nodular eruptions were noticed over extensor surfaces of distal lower extremities. Chalky while amorphous material was expressed from these lesions and biopsy showed evidence of acute suppurative panniculitis with presence of eosinophils. Allopurinol dose was increased to 600 mg while continuing prednisone 40 mg. There was improvement in skin lesions and joint pain in 2 months.

IMPACT: There is no specific treatment recommendations for gouty panniculitis due to lack of experience and rarity of this entity. Several case reports suggested long term therapy with high doses of allopurinol (600-1200mg/day) and short duration of low dose corticosteroids (prednisone 30-60mg). Our patient was treated with prednisone 40 mg for 2 weeks and allopurinol dose was increased from 300 to 600 mg daily There was improvement in skin lesions and joint pain thus supports the data from literature.

DISCUSSION: Gouty panniculitis is a non-vasculitic inflammation of the hypodermis, predominantly in the lobular hypodermis due to MSU deposition. It is a very rare manifestation of gout and can often be overlooked. Histologically, amorphous eosinophlic material and foreign body granulomas can also be seen. Skin lesions can occur before, concomitantly or even years after the onset of gout. Clinically it presents with erythema, induration and tender nodules with tendency to ulcerate and drain opaque or serous MSU rich fluid. Underlying mechanism is still unknown. One proposed mechanism is localized inflammation and tissue injury from disruption of arterial blood supply or micro trauma to terminal capillary walls in dermis and adipose tissue by MSU crystal deposition. Uric acid levels can be variable in these patients. Definitive diagnosis can be made only by biopsy of the lesions. There is no specific therapy for gouty panniculitis due to lack of experience and rarity of this entity. Several case reports suggested long term therapy with high doses of allopurinol (600-1200mg/day) and short duration of low dose corticosteroids (prednisone 30-60mg).

GRANULOMATOSIS WITH POLYANGIITIS (GPA); AN UNUSUAL PRESENTATION

Sina Houshmand; Aiman Zafar; Barry Fomberstein; Olena Slinchenkova. Albert Einstein College of Medicine/Montefiore Medical Center Wakefield Campus, Bronx, NY. (Control ID #2701554)

LEARNING OBJECTIVE #1: To recognize vasculitis as one of the differentials of headache in high risk patients.

LEARNING OBJECTIVE #2: To recognize the role and indication of serologic studies and imaging techniques in the diagnosis of granulomatosis with polyangiitis.

CASE: A 55 years old woman with 5 days of severe left-sided throbbing headache in occipital and neck region, associated with blurred vision, photophobia, occasional dizziness, and nausea, which did not respond to pain medication, presented to the hospital. Her past medical history was significant for nasal congestion, bronchitis, 5cm intracranial aneurysm, subarachnoid hemorrhage (SAH), diabetes, hypertension and chronic kidney disease. Physical exam was unremarkable. MRI/MRA of the head was suggestive of vasculitis. No intracranial aneurysm was seen. The vasculitis workup was negative except cANCA (proteinase PR3), which was positive twice. Lumbar puncture revealed only mildly elevated glucose (86mg/dl). Headache improved with therapeutic trial of prednisone within 1 week. In view of her elevated PR3 antibodies, MRI/MRA findings and response to steroids, granulomatosis with polyangiitis was considered as a diagnosis. Biopsy for definite diagnosis has been deferred at this time since her symptoms have resolved after 3 months of follow up.

IMPACT: There have been only a few cases of GPA presenting with headache and although extremely rare, GPA should be considered in differential diagnosis. Thorough workup can lead to proper diagnosis when clinical judgement and imaging studies points towards the possibility of vasculitis. This case adds to the pre-existing literature on a few number of cases of GPA that have presented with headache.

DISCUSSION: Granulomatosis with polyangiitis is a necrotizing granulomatous vasculitis involving medium and small vessels. Its prevalence in US is approximately 3 per 100,000 individuals. GPA has a strong association with c-ANCA with PR3 specificity. It can involve any organ but primarily affects respiratory tract (pulmonary capillaritis with hemorrhage) and kidneys (necrotizing glomerulonephritis); fewer than 10% of patients have neurological manifestations. A big challenge in the practice of modern medicine is the management of a disease in a cost effective and efficient manner and avoidance of misdiagnosis. In this case, the patient had a common presenting symptom (headache) which constitutes a large percentage of the primary admissions to ED. Therefore, it is not possible to perform a complete workup for every patient. Since the patient had history of SAH, her headache was considered high risk and was investigated by MRI which revealed the abnormal findings suggestive of vasculitis. Further serologic workup revealed the abnormal cANCA and led to the diagnosis of GPA. From this case, we can conclude that a fair combination of clinical judgement, application of the available guidelines and paraclinics should be present in our daily practice in order to have an optimal diagnostic performance.

HARK THE HERALD GI BLEED: A RARE CAUSE OF GASTROINTESTINAL BLEED REQUIRING EMERGENT SURGICAL INTERVENTION

Candace A. Worsham; Bryan Doherty; Charles Frost; Andrew Pearson; Baby Kodali; Vinod E. Nambudiri. Grand Strand Medical Center, Myrtle Beach, SC. (Control ID #2706331)

LEARNING OBJECTIVE #1: Describe the clinical features of an aortoenteric fistula (AEF)

LEARNING OBJECTIVE #2: Diagnose an AEF with imaging

CASE: A 66 year old female with past medical history of a cerebrovascular accident with residual right-sided weakness, hyperlipidemia, hypertension, and peripheral vascular disease treated with an aortobifemoral bypass presented to her primary care physician with complaints of fever, chills, and melena. Her home medications included aspirin and clopidogrel. She was found to have a white blood cell count of 16,000 and hemoglobin of 7.6 (from a baseline of 10.5) and was referred to the emergency room. Upon arrival, her blood pressure was 93/51, pulse was 86, respiratory rate was 20, temperature was 101.7, and O_2 saturation was 94% on room air. On physical exam, she had no abdominal tenderness but was found to have maroon-colored stool. The patient was started on pantoprazole and an upper endoscopy was performed, which showed evidence of bleeding and an eroded mesh in the D2 portion of the duodenum; surgery was consulted. A CTA of the abdomen was done, which revealed a fistula between the duodenum and the aorta as well as a partially occlusive mural thrombus at the origin of the right common iliac branch of the graft. Given these findings, the patient underwent emergent surgical intervention. GI surgery mobilized the duodenal fistula and repaired the duodenal enterotomy by two layers; they also placed open J and G tubes. The graft was removed, and the aorta was then transected and its proximal stump was oversewn by vascular surgery. The patient was stable after the procedure.

IMPACT: Aortoenteric fistula is a rare life-threatening diagnosis that may initially present as a minor gastrointestinal bleed but will inevitably become a surgical emergency. This case highlights the need for a high clinical index of suspicion of aortoenteric fistulas in patients with a history of prior aortic surgery to avoid diagnostic delay, which is often fatal.

DISCUSSION: Aortoenteric fistulas (AEFs) are uncommonly encountered but are important to consider in the differential diagnosis of gastrointestinal bleeding in patients who have had prior aortic surgery. Primary AEFs arise de novo between the aorta and bowel, while secondary AEFs (SAEFs) are usually caused by prosthetic vascular grafts eroding into the intestine as in our patient. Pulsation of vascular grafts against the intestine may cause erosion of the duodenal wall, leading to hemorrhage. The third part of the duodenum (D3) is the most frequent gastrointestinal tract location of AEFs. SAEFs may present as gastrointestinal bleeding and occasionally as sepsis. Patients initially have "herald bleeding" - intermittent episodes of bleeding due to thrombus formation - followed by massive hemorrhaging. A CT abdomen with contrast is the best diagnostic test if an AEF is suspected; AEFs may also be detected on endoscopy as in our patient. Emergency exploratory laparotomy is warranted immediately upon diagnosis, as mortality is 100% if not surgically treated.

HE WHO KNOWS SYPHILIS, KNOWS MEDICINE

Vytas P. Karalius; Jaime De La Fuente; Adam P. Sawatsky. Mayo Clinic, Rochester, MN. (Control ID #2699393)

LEARNING OBJECTIVE #1: Recognize and diagnose atypical presentations of neurosyphilis.

LEARNING OBJECTIVE #2: Recognize common findings of neurosyphilis on neuroimaging.

CASE: A 78-year-old Filipino male was admitted to the hospital for acute polyarticular arthritis. Six months prior to admission, he had an acute gout flare with acute worsening of his mental status that persisted after resolution. During the current hospitalization, he showed signs of disorientation, behavioral changes, mood liability and memory loss. He was restless and combative, with persecutory delusions and confusion. MRI of the head demonstrated chronic ischemic changes, moderate generalized cerebral and cerebellar atrophy, and ex-vacuo dilatation of the ventricles. There was no evidence for acute ischemia. During the hospitalization, VDRL and confirmatory testing was positive. Lumbar puncture was VDRL-negative, but he was treated for neurosyphilis with 14 days of IV penicillin. The patient's mentation improved during the hospitalization, corroborating the diagnosis of neurosyphilis. He reported decreased visual acuity and he had signs of possible ocular syphilis on eye exam.

IMPACT: Sir William Osler called syphilis "the great imitator" based on its diverse presentation and offered that, "he who knows syphilis, knows medicine." Our patient embodies this unique presentation of syphilis and highlights the importance of considering atypical presentations of typical problems when a patient presents with a complex array of symptoms.

DISCUSSION: Syphilis rates have been increasing in the US since 2000. The presentations of neurosyphilis are incredibly diverse and difficult to suspect, because neurosyphilis can arise at any time after initial infection, even in previously asymptomatic patients. Neurosyphilis can present with behavioral changes, dementia, disorientation, cognitive deficits, memory deficits, mood lability, delusions, psychosis, mania, seizures and changes in sleep. Some of these symptoms can mimic other common causes of dementia, however neurosyphilis is often more abrupt in onset. There are no pathognomonic findings on imaging to suggest neurosyphilis. However, studies have reported generalized cerebral atrophy, frontal lobe atrophy, temporal-parietal atrophy, non-specific changes consistent with infarction, and increased signal intensity on T2-weighted images. Ocular syphilis can occur in conjunction with neurosyphilis. There are no pathognomonic findings for ocular syphilis on eye exam. Several presentations exist, including keratitis, anterior uveitis, chorioretinitis, retinal vasculitis, exudative retinal detachment and optic neuropathy. CSF-VRDL tests may be falsely negative in late stages of neurosyphilis, and positive serum treponemal tests in the presence of a high clinical suspicion are considered sufficient for diagnosis. Improvement in our patient's condition after receiving appropriate treatment suggests that neurosyphilis was a large factor in his cognitive decline.

HEERFORDT'S SYNDROME

Mina A. Ferig[1]; Amani F. Sargios[2]; Preeyanka R. Sundar[1]; Pena Sisto Cecilia[1]. [1]Berkshire Medical Center, Pittsfield, MA; [2]Berkshire medical center, Wappingers falls, NY. (Control ID #2682921)

LEARNING OBJECTIVE #1: Heerfordt's syndrome is an extremely unusual manifestation of systemic sarcoidiosis. It is characterized by three major findings: enlargement of parotid gland, uveitis, facial nerve palsy and is usually associated with fever. If only two of three characteristic findings of Heerfordt's syndrome are present, it is known as incomplete Heerfordt's syndrome

CASE: A 33-year old man with significant family history for Rheumatologic diseases presented with persistent fever, nonproductive dry cough, fatigue for 2 weeks, unintentional weight loss of 10 pounds in one month, dry mouth, blurry vision, and bilateral knee and ankle joint pain. On exam, patient appeared fatigued

with mild dyspnea. Examination showed temperature was 99.5°F, blood pressure 122/87 mm Hg, pulse 96 beats/min, respiration 21 breaths/min, and oxygen saturation 95% on room, bilateral parotid enlargement, tachycardia without murmurs, bilateral rales, with decreased range of motion of both knees with tenderness, and later developed erythema nodsum on extensor surface of both tibias.Labs revealed leukocyte count of 8.500 cells/mm3 with 89.9% polymorphonuclear leukocytes, hemoglobin of 13.6 g/dL, platelet count of 341,000/mm3, elevated CRP 10.6, angiotensin converting enzyme 71, and low MCV 80.6 and Hematocrit 39.4. Urine analysis showed microscopic hematuria and hypercalciuria. PPD and Quantiferon Gold tests were negative. RF, Anti-CCP-IgG, ANA, SS-A/Ro, SS-B/La were negative. Chest radiograph showed bilateral hilar lymphadenopathy, further CT imaging showed multiple bilateral pulmonary nodules and enlarged hilar lymphadenopathy, and renal ultrasound revealed right kidney stones. Patient referred to pulmonologist for bronchoscopy and biopsy.

IMPACT: The patient later developed Bell's palsy, was started on 70mg prednisone, and his symptoms improved except the fatigue. Pathology confirmed non-caseating granuloma and diagnosis of Sarcoidosis made

DISCUSSION: The diagnosis of sarcoidosis, a systemic granulomatous disease, is based on a compatible clinical-radiological picture and the histological evidence of noncaseating granulomas. There is no single test for sarcoidosis, and the presence of granulomas alone does not establish the diagnosis. Symptoms of sarcoidosis are nonspecific and can be markedly different according to organ involvement and disease course. Respiratory symptoms and fatigue may be identified at any stage of disease. Histological confirmation is not needed for Heerfordt's syndrome. Sarcoidosis has a significant genetic susceptibility, which has been shown from family and case–control studies. Sarcoidosis is associated with a genetic risk profile made up of many variant genes, so there is no single Bsarcoidosis gene^. MHC-2 alleles can determine the course of disease, e.g., in Scandinavians HLADRB1*03 predisposes to disease with spontaneous resolution. A German study found a strong association for polymorphism in butyrophilin-like 2 gene with development of sarcoidosis

HEMORRHAGIC HEPATOCELLULAR CANCER: A SINISTER CAUSE FOR SYNCOPE

Sowjanya Naha[2]; Kushal Naha[2]; Pratyusha Bollimunta[1]. [1]Presence Saint Francis Hospital, Evanston, IL; [2]Presence St Francis Hospital, Evanston, IL. (Control ID #2707027)

LEARNING OBJECTIVE #1: Evaluate for occult hemorrhage in patients presenting with syncope and anemia

LEARNING OBJECTIVE #2: Evaluate for hepatocellular cancer in patients with spontaneous hemoperitoneum

CASE: We report an 80 year old Asian female who presented with recurrent episodes of syncope. Physical exam was significant for orthostatic hypotension and tender hepatomegaly. Cardiac examination was entirely normal. Preliminary blood work showed moderate anemia but was otherwise unremarkable. Telemetry monitoring showed paroxysmal atrial fibrillation but these episodes were temporally unrelated to her symptoms. Abdominal computed tomography showed hemorrhagic hepatic masses and intraperitoneal bleeding. Serial monitoring revealed rapidly dropping hemoglobin. The patient was managed conservatively with blood transfusions after which her hemoglobin stabilized and she had no further episodes of syncope. Percutaneous liver biopsy subsequently demonstrated well differentiated hepatocellular carcinoma. Screening for hepatitis B and C viruses was negative. The patient was evaluated by oncology and then discharged home with further management planned as outpatient.

IMPACT: How did this case change my thinking? Syncope is widely encountered in everyday practice, yet diagnosing the underlying disorder can be a daunting task. Although vasovagal syncope that is most frequently seen is relatively benign, syncope can be the presenting symptom for serious underlying disease. Occult hemorrhage is a well-recognized cause of syncope and can easily be overlooked. Careful abdominal examination and a high index of suspicion in the presence of unexplained coincident anemia are essential to making the right diagnosis in such cases. Any patient presenting with syncope, abdominal pain and anemia should be meticulously evaluated for occult hemorrhage.

DISCUSSION: Presentation with syncope is well described in ectopic pregnancy; an analogous mechanism operates in other causes of intraperitoneal hemorrhage such as was seen in our patient. A key finding in such patients is unexplained anemia or anemia that is disproportionate to any visible bleeding. Another important finding is that of orthostatic hypotension in a patient who has no reason to be volume depleted. While resuscitation with fluids and blood products is key, it is equally important to diagnose the underlying source of blood loss in a timely manner. Emergent abdominal imaging is invaluable in such cases as a clinical abdominal examination can be deceptively subtle. Hemoperitoneum as first manifestation of hepatocellular cancer is frequently encountered in countries with a high incidence of this cancer such as countries of the far East but is uncommon in the West. Interestingly, as an immigrant from the Philippines, our patient conformed to this pattern of presentation. Transcatheter arterial embolization can be effective in patients with uncontrolled bleeding; however this was not required in our patient as she stabilized after resuscitation with blood products.

HEMOSUCCUS PANCREATICUS: A RARE CAUSE OF UPPER GASTROINTESTINAL BLEEDING

Brian V. Dinh; Asghar Ali; Srivats Madhavan; Pallavi Rao. Wright State University, Dayton, OH. (Control ID #2706072)

LEARNING OBJECTIVE #1: Recognize clinical, radiologic, and endoscopic findings of hemosuccus pancreaticus.

CASE: A 36-year-old male presented with acute epigastric abdominal pain radiating to the back, nausea, vomiting, hematemesis, and melena. Chart review revealed two admissions in regional hospitals for upper gastrointestinal hemorrhage without an identifiable source.Past medical history included recurrent alcoholic pancreatitis and a hemorrhagic pancreatic cyst evaluated by prior EUS. Exam revealed a pale-appearing, orthostatic hypotensive male with epigastric tenderness with diminished bowel sounds. No stigmata of chronic liver failure, Grey Turner's sign, or Cullen's sign noted on exam. Labs were significant for Hb of 3.4 g/dl, and lipase of 262 U/L. The patient was resuscitated with intravenous fluids, transfused 4 units of blood, and started on a pantoprazole drip. Esophagogastroduodenoscopy (EGD) revealed a normal esophagus and stomach. The ampullary region appeared mildly prominent with a hemorrhagic spot at the papilla. CT abdomen with contrast showed evidence of a 4.2 × 4.1 cm pancreatic pseudocyst with a partially thrombosed left gastric artery pseudoaneurysm (PSA) traversing the cyst. Abdominal angiography revealed a PSA with hemorrhage into the pseudocyst. He underwent successful interventional radiology (IR)-guided embolization and gel foam injection to the right and left gastric arteries to control the hemorrhage. Repeat mesenteric angiography four days later showed no further source of bleeding.

IMPACT: Our practice has changed greatly to include a larger differential of upper GI bleeding following this case. The case emphasizes the need to consider all causes of bleeding, which will aid any clinician in making appropriate diagnostic and management decisions to avoid anchoring.

DISCUSSION: Intermittent bleeding from PSA into the pancreatic duct is called hemosuccus pancreaticus. PSA develops in 3.5-10% of cases of pancreatitis, leading to gastrointestinal bleeding with a reported rate of 4-10% of all cases of pancreatitis. PSA formation in pancreatitis is well established phenomenon resulting from erosion of nearby vessels by pancreatic enzymes, an established pseudocyst eroding into a visceral artery, or pseudocyst eroding the bowl wall with bleeding from mucosal surface frequently involving the splenic artery. PSA rupture can present as occult or massive bleeding and accounts for about 1% of all cases of GI bleed. Hemorrhage into the intestines, pancreatic duct, or peritoneal cavity, as well as intrasplenic and subcapsular hematoma formation, splenic rupture, and infarction have been reported. Even with early diagnosis, the mortality can be as high as 15-50%. EGD may be unremarkable or reveal hemorrhage from the ampulla of Vater. Dynamic contrast-enhanced CT scans can delineate the location of the bleeding PSA. Arterial embolization is often successfull. However, recurrent bleeding occurs in 10-50% of cases, and patients should undergo surgery to achieve hemostasis.

HEPARIN INDUCED THROMBOCYTOPENIA VERSUS THROMBOTIC THROMBOCYTOPENIC PURPURA: A CHALLENGING CLINICAL SCENARIO Hassan Zeb; Zainab Jalal; Zeeshan Khakwani. Conemaugh Memorial Medical Centre, Johnstown, PA. (Control ID #2706648)

LEARNING OBJECTIVE #1: Recognize hematological causes of thrombocytopenia and understand the significance of prompt and appropriate management.

CASE: A 68 years old female with one week history of left knee arthroplasty complicated with periprosthetic femur fracture requiring surgical correction presented with lethargy, abdominal pain and watery diarrhea. Post-surgically, she was on Low Molecular Weight Heparin (LMWH) for Deep Venous Thrombosis (DVT) prophylaxis. Initial workup showed platelet count of 20000/μL, leukocytosis and acute kidney injury. Further evaluation revealed findings for hemolytic anemia. Patient received broad spectrum antibiotics for a possible infection. CT scan abdomen and pelvis showed right adrenal hemorrhage with left adrenalitis and steroids were given. Peripheral smear, ADAMTS13 levels and a HIT panel were ordered due to intermediate 4T score. On repeat analysis, platelets of 8000/μL and 2% schistocytes led to ICU transfer for possible TTP. Plasmaphresis was initiated but despite five sessions, platelet count improved only partially (53000/μL). HIT panel returned positive and ADAMTS13 was intermediate ruling out TTP. The partial platelet response was considered secondary to antibody removal during plasmapharesis and adrenal hemorrhage was believed to be a result of adrenal vein thrombosis causing passive congestion. Argatroban infusion was started, platelets improved by day 8 of hospital stay and she was bridged with coumadin once platelets returned to 150000/μL.

IMPACT: Thrombocytopenia can be a result of numerous etiologies among which hematological ones are of prime significance. In clinical settings, HIT can be difficult to differentiate from TTP but a wider thought process, early risk factors identification and prompt management leads to better survival rates.

DISCUSSION: Severe thrombocytopenia is a life threatening condition with multiple etiologies and treatment options, making prompt management a challenging scenario. Risk factors identification, intermediate 4T score and a positive HIT panel helped us diagnose HIT. A platelet count below 20000/μL is rare in HIT and common in TTP but it should not be the only factor to dismiss HIT as a cause of thrombocytopenia.

HEPATOCELLULAR CARCINOMA FOUND AFTER STREPTOCOCCUS BOVIS INFECTION Dianne Thompson; Jillian S. Catalanotti. The George Washington University, Washington, DC. (Control ID #2703543)

LEARNING OBJECTIVE #1: Recognize the association between Streptococcus bovis infection and liver disease.

CASE: A 59 year old woman with chronic hepatitis C and a recent history of S. bovis endocarditis requiring aortic valve replacement was brought to the emergency department by her family for confusion, fatigue and constipation for one week. On arrival, the patient was not alert and was dehydrated. She was found to have hypercalcemia (calcium level of 18.9 mg/dL) and was treated with intravenous hydration, bisphosphonate and calcitonin. An abdominal CT scan with contrast was ordered to evaluate for possible colon cancer. The CT scan showed no colon masses, but did show multiple liver masses, concerning for hepatocellular carcinoma affecting both lobes of the liver. Her serum AFP level was 17,320 ng/ml (normal is less than 200 ng/ml) which further supported a hepatocellular carcinoma diagnosis. The patient's calcium level returned to normal with medical treatment. Her functional status remained poor. Consistent with the wishes of the patient and her family, she was discharged to home with hospice care.

IMPACT: The association between S. bovis infections and colon cancer is well known. In fact, guidelines recommend screening patients diagnosed with S. bovis for colon cancer. There is also a strong association between chronic liver disease such as chronic viral hepatitis or cirrhosis, and S. bovis infections, but this association is rarely described in the literature and is less well-known to clinicians. Current recommendations do not suggest a workup for liver disease if no colon cancer is found in patients with S. bovis infection, however this patient illustrates that doing so may be prudent.

DISCUSSION: This patient's S. bovis endocarditis was associated with chronic hepatitis C and hepatocellular carcinoma, and colon cancer workup was negative. Although the mechanism of the association between S. bovis and liver disease is unknown, it is theorized to be due to an impaired immune system that allows the infection to spread through the portal system. S. bovis bacteremia is known to be associated with colon cancer and with liver disease, however the latter is rarer, less often discussed in the literature, and less well-known to clinicians. A triad of concurrent colon cancer, liver disease and S. bovis infection has also been described in the literature. This case reminds us that patients with S. bovis infections should be evaluated for colon cancer, and if such workup is negative, they should also be evaluated for underlying liver disease.

HEPATOCELLULAR CARCINOMA RUPTURE: A RARE COMPLICATION OF HCC Fabiola Rios de Choudens. University of South Florida, Tampa, FL. (Control ID #2690379)

LEARNING OBJECTIVE #1: Recognize this rare and life threatening complication of hepatocellular carcinoma in a patient with acute symptomatic anemia.

LEARNING OBJECTIVE #2: Treat ruptured hepatocellular carcinoma tumors with emergent transarterial embolization.

CASE: A 62-year-old male with history of cirrhosis and hepatocellular carcinoma (HCC) secondary to hepatitis C and chronic alcohol abuse was admitted after experiencing syncopal episode. The day prior to admission, the patient had undergone large volume therapeutic paracentesis with aspiration of 4.4 liters of serosanguinous fluid. On admission, labs were notable for a

hemoglobin of 5.7, platelet count of 53, and INR of 2.04. He denied any other complaints. CT abdomen/pelvis revealed a perihepatic hemorrhage secondary to rupture of a large hepatic mass in the dome of the liver. While in the ED, the patient underwent emergent transfusion of 2 units of blood and 2 units of FFP. Emergent hepatic artery embolization was done. Hemostastasis was achieved with successful embolization of an anterior division of the right hepatic arterial branch. Post embolization, the patient required another 8 units of blood, 10 units of FFP, and 20 units of platelets. He was started on Zosyn due to high risk of infection/abscess after embolization. Serial ammonia levels were monitored following procedure to monitor for liver failure and possible hepatic encephalopathy.

IMPACT: Complications of cirrhosis are commonly encountered in the inpatient and ER setting and as an internal medicine resident, I feel that I am becoming more comfortable in managing them. This patient had received a paracentesis prior to admission and his symptoms could have been attributed to a complication from that procedure. However, the etiology of his complaint was completely different and associated directly with his hepatocellular carcinoma. Prior to this case, I was unaware of tumor rupture as a consequence of HCC. Now I know that at least 15% of HCC patients can present acutely with this complication and need urgent treatment.

DISCUSSION: Hepatocellular carcinoma (HCC) is the most common primary cancer of the liver and its incidence in developed Western countries is increasing. Annual incidence of HCC is 3-5% in patients diagnosed with cirrhosis. HCC can further compromise a patient's health by tumor progression, liver failure, and, rarely, spontaneous rupture of the tumor itself. Rupture occurs in 3-15% of HCC patients and has very high mortality acutely. Proposed risk factors for rupture include rapid tumor growth with necrosis, erosion of hepatic vessels, vein thrombosis, direct tumor invasion of vessels, or superficial location of tumor. Although spontaneous rupture of HCC has a high mortality, transarterial embolization (TAE) is effective in controlling bleeding in the acute setting. Definitive treatment involves staged liver resection which can result in long-term survival in compensated patients.

HEY DOC, I AM LOSING WEIGHT: A 30 POUND WEIGHT LOSS IN AN AFRICAN AMERICAN MALE Stephanie C. Holt; Natalia Morone. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2700474)

LEARNING OBJECTIVE #1: Diagnose Graves' disease with a normal thyroid exam

LEARNING OBJECTIVE #2: Recognize the treatment of this condition

CASE: 60-year-old African American male who has not seen a doctor in "over 10 years" presenting for 30 pound weight loss in an unknown time period. He has decreased appetite, palpitations, increasing SOB, and fatigue. He denies bloody stools, chest pain, headache, diarrhea, blurred vision, orthopnea, and prior cancer screening. Social history was remarkable for 22 pack year history and unprotected sex. Family history was remarkable for father with unknown cancer. No medications. Physical exam revealed a pleasant, thin male in NAD. BP 206/112 with repeat 194/102. HR 98. BMI 18.9. HEENT: normal thyroid size without nodularity or goiter, no lid lag, and no exophthalmos. Cardiac, lung, and abdominal exams unremarkable. Neurological exam: patellar reflexes 3+ and fine tremor bilaterally in hands. He was started on amlodipine for BP. Lab work revealed negative HIV, TSH <0.01, and free T4 4.6(0.8–1.8 ng/dL). CT scan and colonoscopy unremarkable. Then he was started on atenolol. Subsequent workup revealed free T3 > 20(2.3–4.2 pg/mL), thyrotropin-binding inhibitory immunoglobulin 76.3(<16%), thyroglobulin antibodies <1(<1 IU/mL), and thyroid peroxidase antibodies >900(<9 IU/mL), thyroid stimulating immunoglobulin 443(<140% of baseline), and radioiodine uptake scan showed homogeneous uptake in a slightly enlarged thyroid gland. He continued to lose weight and remained hypertensive (158/89) with a tremor. He was then started on 10 mg methimazole. Currently, he is followed by Endocrinology who is increasing his methimazole. His palpitations have stopped. He is gaining weight. However, his TSH and free T4 are not fully responding after 2 months, and if they remain abnormal, the next step is radioiodine ablation.

IMPACT: I now appreciate that a profound weight loss can be the presenting complaint of a patient with Graves' even without a goiter. In addition, starting methimazole early has an immediate impact on a patient's signs and symptoms and should be considered by the primary care physician.

DISCUSSION: Graves' disease is a syndrome of hyperthyroidism, goiter, and eye pathology caused by the stimulation of the thyroid gland due to thyrotropin receptor antibodies. There are several predisposing factors including genetics, female gender, smoking, infections, stress, and iodine/iodine containing drugs. The clinical presentation of Graves' is classically characterized by diffuse goiter, ophthalmopathy, and pretibial myxedema. Treatment consists of symptomatic control with a beta-blocker that decreases the beta-adrenergic tone. Then for definitive treatment of Graves', there are three options: antithyroid medications, radioiodine, or surgery. The goal is to achieve a euthyroid state quickly (3–8 weeks). The risk of recurrence after discontinuing the medications is higher than the rates after radioiodine or surgical treatment. The choice of treatment depends on the patient's risks and benefits.

HIP PAIN IN A YOUNG ADULT Mahreen Arshad[1]; Richard Jones[2]. [1]Brookwood Baptist Health, Birmingham, AL; [2]Clinic For Rheumatic Diseases, Tuscaloosa, AL. (Control ID #2707459)

LEARNING OBJECTIVE #1: To recognize inflammatory etiology of hip pain.

LEARNING OBJECTIVE #2: To review the radiographical findings and analysis of axial spondyloarthritis.

CASE: This case is about a 26 year old Caucasian female with a past medical history of ADHD who was seen in the rheumatology clinic for a 2 to 3 month history of hip pain. The patient's symptoms were progressively worsening and at the time of presentation she required help with some activities of daily life due to stiffness and pain. On exam the patient had slightly decreased strength in her right thigh when compared to her left and was noted to have a rash at the insertion of her Achilles tendon bilaterally. She also had a slight limp when she walked; her physical exam was otherwise insignificant. The patient had a MRI of the right hip 2 months before presentation that showed unilateral sacroiliitis. A repeat MRI of the hips 5 weeks later showed worsening right hip sacroiliitis and developing left hip inflammatory changes.

IMPACT: Hip pain is one of the most common complaints seen in primary care clinics. There are many different etiologies, but one of the most debilitating can be spondyloarthritis. It is also one of the more difficult diagnosis, however, this case helps clarify the new guidelines to help identify patients with the disease.

DISCUSSION: Non-radiographic axial spondyloarthritis (Nr-axSpA) is a fairly new classification that incorporates axial spondyloarthritis with no x-ray evidence of sacroiliitis. Studies have shown that most of the patients with Nr-axSpA are young females (with an average age of less than 45 years) and the duration of their symptoms is usually less than 10 years. Certain lab work can be elevated

including ESR and hsCRP along with a positive HLA-B27 although not necessary. In many cases with Nr-axSpA, ESR and CRP are both within normal limits while HLA-B27 is positive in over 80% of the cases. Patients with Nr-axSpA have been shown to have a good response to treatment with TNF α inhibitors. Recent studies have shown that early diagnosis and treatment can help prevent progression of disease. In the case of this patient she was started on adalimumab and had good response with notable decrease of hip pain within two days. New guidelines have been developed to help diagnose Nr-axSpA in a timely manner. It thus becomes imperative to have a high suspicion for inflammatory causes of hip pain and necessitates earlier referral for treatment. In the case of this patient it saved her from additional invasive procedures, provided improvement in symptomology, and halted disease progression.

HISTORY KEY TO CLARIFYING SIGNIFICANCE OF INCIDENTAL FINDINGS Farah Ladak[3]; Faraz Fiazuddin[2]; Temple Ratcliffe[1]. [1]UTHSCSA, San Antonio, TX; [2]University of Texas Health Science Center - San Antonio, San Antonio, TX; [3]University of Texas Health Science Center San Antonio, San Antonio, TX. (Control ID #2687802)

LEARNING OBJECTIVE #1: To recognize the multiple manifestations of hereditary hemorrhagic telangiectasia and the importance of obtaining a thorough patient history to make a prompt diagnosis and prevent negative outcomes.
CASE: A 37-year-old woman with history of ulcerative colitis and focal nodular hyperplasia (FNH) of the liver presented with right upper quadrant (RUQ) abdominal pain. An extensive workup including endoscopic retrograde cholangiopancreatography (ERCP) eventually diagnosed primary sclerosing cholangitis (PSC). Interestingly, the anti neutrophil cytoplasmic antibody was negative. However, review of systems was also significant for epistaxis. Family history was significant for father with hereditary hemorrhagic telangiectasia (HHT). Physical exam did not reveal any lesions. MRI liver showed dilated bile ducts, prominent vascular channels at hilum, hepatic congestion, right lobe cystic lesions and left lobe FNH. These findings prompted a liver biopsy which revealed arteriovenous malformation. A diagnosis of HHT was made based on the consensus criteria. Of note, CT chest revealed cardiomegaly and findings suggestive of pulmonary arterial hypertension. She was discharged with transplant hepatology follow up for her PSC.
IMPACT: HHT has several manifestations associated with high morbidity and mortality. The diagnosis is easy to miss without high clinical suspicion. A thorough patient history along with a high clinical suspicion is key to diagnosing HHT. Lack of appreciation of HHT manifestations can delay diagnosis resulting in progression of the disease and ultimately, poor outcomes for patients and families.
DISCUSSION: HHT is a rare autosomal dominant disorder involving the vasculature in multiple organ systems. Clinical features include epistaxis, gastrointestinal bleeding, anemia, mucocutaneous telangiectasia and visceral arteriovenous malformations (AVM). Consensus criteria conclude a definite diagnosis if three or more of the following are present: epistaxis, mucocutaneous telangiectasia, visceral AVMs and 1st degree relative with HHT. HHT is likely under recognized and diagnosis requires a high index of clinical suspicion. Interestingly, our patient's FNH may be related to her HHT as well. FNH has a much higher prevalence in HHT patients with liver AVMs. The increased blood supply due to the AVMs is considered responsible for hepatic hyperplasia. In addition, patients with HHT can have multiple areas of intrahepatic biliary dilation similar in pattern to sclerosing cholangitis as this patient had. This is thought to occur due to ischemic changes secondary to AVMs. Diagnosis of HHT is important because screening for visceral AVMs may be important to avoid negative outcomes such as pulmonary hypertension, heart failure, cerebral bleeding, and stroke. Our patient's possible pulmonary hypertension was found incidentally on CT and should be followed up with a transthoracic echocardiogram or right heart catheterization.

HOLY MOLDY! A CASE OF A PHAEOHYPHOMYCOSIS IN AN IMMUNOCOMPETENT PATIENT Michele A. Sundar[1]; Mitchell A. Blass[2]. [1]Emory University, Atlanta, GA; [2]Georgia Infectious Diseases, PC, Atlanta, GA. (Control ID #2700699)

LEARNING OBJECTIVE #1: Recognize phaeohyphomycosis as a cause of clinical disease in humans
LEARNING OBJECTIVE #2: Examine the most common disease presentations of *Exophiala dermatitidis*
CASE: A 39 year old immunocompetent female with medical history significant only for well controlled intermittent asthma, came to the Emergency Department for acute onset of shortness of breath. Her lungs on presentation were clear to auscultation with decreased breath sounds on the right, but no wheezing or rhonchi. Initial chest radiograph showed a moderate to large right sided pneumothorax. In addition to the pneumothorax, multiple nodules were found, with both cavitary and solid features. She underwent chest tube placement and bronchoscopy with tissue biopsy of one nodule, and pathology confirmed *Exophiala dermatitidis*. The patient improved initially with chest tube placement and had appropriate lung re-expansion, but unfortunately, relapsed three weeks later, presenting again to the Emergency Department with a right sided pneumothorax. At this time, Video-Assisted Thoracoscopic Surgery was performed for definitive treatment. Posaconazole was started for treatment of *Exophiala dermatitidis*, and she responded well to therapy.
IMPACT: This case highlights a rare presentation of phaeohyphomycosis in an immunocompetent patient. Thus far, the literature fails to show any case reports describing *Exophiala dermatitidis* in an immunocompetent patient that presented as solitary pulmonary nodules with a spontaneous pneumothorax. This case will help alert physicians to a newly described clinical syndrome associated with phaeohyphomycosis, thus improving their ability to recognize this uncommon disease.
DISCUSSION: Phaeohyphomycosis is the term used to describe infections caused by black molds with melanin containing cell walls. The molds are ubiquitous in soil and had previously been considered contaminants when isolated in culture.[1] Today, over 100 species have been identified, 60 of which have been linked to diseases in humans. Documented clinical syndromes from *Exophiala dermatitidis* include pneumonia, disseminated infection (most common), and subcutaneous lesions. Not only does our patient have a new clinical syndrome associated with *Exophiala dermatitidis*, but she represents the immunocompetent minority in which these infections occur. In a review of phaeohyphomycosis cases from 1993–2011, 30 cases were identified to have been caused by *Exophiala. dermatitidis*; however 71% of these cases had an underlying immunodeficiency or risk factor, such as malignancy, peritoneal dialysis, diabetes mellitus, HIV, steroid use, or bronchiectasis1. In cases where asthma was the only risk factor in an immunocompetent patient, the clinical disease was similar to that of Allergic bronchopulmonary aspergillosis, and almost exclusively due to B*ipolaris* or C*urvularia* species3(and not *Exophiala dermatitidis*).

HOW A BLADDER HELD A GALLON OF URINE Vassiliki Pravodelov. Boston University Medical Center, Boston, MA. (Control ID #2707084)

LEARNING OBJECTIVE #1: Describe a case of severe bladder outlet obstruction due to acquired bladder diverticula (BD)

LEARNING OBJECTIVE #2: Outline the diagnosis and management of BD

CASE: A 59 year old man presented to the clinic with constipation, bilateral lower extremity edema, and urinary hesitancy for 2 weeks. The patient noted abdominal distension without pain, nausea, or vomiting. He had no hematuria, dyspnea, or leg pain. His exam was remarkable for abdominal distension without rigidity, tenderness, or a fluid wave. He had bilateral 1+ lower extremity edema. A urine culture ruled out infection. Furosemide was started. Three days later, the patient's abdominal distension was more pronounced with new tenderness. The edema was now 3+. He had new hyponatremia and acute kidney injury and he was sent to the ED. A CT scan showed a severely distended bladder and a bladder wall defect with a diverticulum extending into the lower pelvis, exerting a mass effect on the rectum and prostate. A urinary catheter was placed with rapid removal of 4 liters of urine. The abdominal distension and extremity edema resolved soon after the catheterization. Outpatient urologic workup included a CT urogram and cystoscopy. The prostate was not enlarged. He had high post-void residuals (PVR) and discomfort with daily catheterizations. After shared decision making regarding treatment options, the patient had an uncomplicated robot-assisted laparoscopic bladder diverticulectomy. His PVR improved and he was able to stop the catheterizations. However, given the size of the excised diverticula, he was still at risk for recurrence. Therefore, he underwent a transurethral incision of the prostate (TUIP). Since then, the patient has been asymptomatic.

IMPACT: This case illustrates an unusual case of bladder outlet obstruction due to BD leading to abdominal distension, constipation, and lower extremity edema. It reminds us that BD should be on the radar when patients present with signs of urinary retention.

DISCUSSION: BD are pouches in the bladder wall. Acquired BD develop due to bladder outlet obstruction (i.e. prostate enlargement), neurogenic bladder, or prior bladder surgery. It is still unclear what caused the BD in this patient as BD are more common in children (congenital) and the elderly (acquired due to prostate hyperplasia). Urinary retention, recurrent urinary tract infections, and renal failure have been described as complications of BD. Malignant neoplasms may also develop within BD. The diagnosis of BD is through imaging, with a CT urogram done first. If concerning findings are noted, a cystoscopy can follow. Treatment of BD may be conservative with intermittent urinary catheterization and PVR monitoring. Surgical intervention is curative. This patient had high PVR and significant discomfort with intermittent urinary catheterization. A robotic-assisted bladder diverticulectomy resolved his symptoms. The risk of recurrence is high in patients with acquired BD. This is why the patient underwent a TUIP despite a normal prostate.

HUNGRY AND ANGRY CELLS Hadi Zein; Yehuda Fuzailov; Binh Huynh. New York Presbyterian Queens, Flushing, NY. (Control ID #2706734)

LEARNING OBJECTIVE #1: Recognize and treat hemophagocytic lymphohistiocytosis in adult patients

CASE: A 39-year-old female with chronic anemia presented to her primary care physician with fever and fatigue of 10 days duration. Her symptoms started with fatigue and mild shortness of breath. After 3 days, she developed fevers and myalgias. She sought medical attention at an urgent care center. The patient was positive for influenza and was not initiated on antivirals because of her late presentation. Over the next few days, she developed diarrhea associated with nausea and vomiting and presented to the ED. Physical examination was notable for tachycardia and fever with multiple bruises over her lower extremities. Laboratory testing showed pancytopenia, hemoglobin of 4.5 g/dL, white cell count of 600 cells/μL and platelet count of 8,000/μL. She was started on broad spectrum antibiotics and oseltamivir. Viral serologies (CMV, EBV, HIV, parvovirus B19, influenza) and blood cultures were negative. She was given multiple red blood cell and platelet transfusions over her hospitalization course, with no appropriate response to her cell counts. A bone marrow biopsy showed a hypercellular marrow with numerous large hemophagocytic histiocytes and macrophages. She was diagnosed with hemophagocytic lymphohistiocytosis (HLH). She was started on dexamethasone and etoposide with improvement in her symptoms and cell counts

IMPACT: HLH is a syndrome mainly encountered in infants and children. Because of its diverse presentation and being the target to the pediatric population mainly, it can be a diagnostic challenge for internists. The greatest hurdle to the survival of the patients is a delay in diagnosis.

DISCUSSION: HLH is a syndrome of excessive immune activation. It is most commonly encountered in children. In adults, there is usually an underlying trigger; most likely influenza in our patient. Macrophages secrete an excessive amount of cytokines ("cytokine storm"), and the negative feedback exerted on the immune system is inhibited. The most common clinical features of HLH are hepatosplenomegaly, lymphadenopathy, fever, and rash. The diagnosis is based on meeting 5 out of 8 criteria. Our patient had the following five criteria: fever, splenomegaly, peripheral cytopenia, hemophagocytosis in the bone marrow and a high ferritin level. Treatment of HLH depends on the hemodynamic stability of the patient. If the patient is acutely ill, HLH specific treatment should be initiated immediately. Otherwise, the underlying trigger should be identified. The specific treatment consists of dexamethasone and etoposide. A minority of patients would require an allogeneic hematopoietic stem cell transplant if they do not respond to the treatment or have an underlying genetic predisposition. Supportive care consists of prevention and treatment of opportunistic infections, transfusions, and treatment of bleeding.

HYPERKALEMIA DUE TO PSEUDOHYPOALDOSTERONISM TYPE II Patrick J. Sayre; Anita Lee. University of Pennsylvania, Philadelphia, PA. (Control ID #2703440)

LEARNING OBJECTIVE #1: List common causes of outpatient hyperkalemia

LEARNING OBJECTIVE #2: Employ a stepwise algorithm to evaluate outpatient hyperkalemia

CASE: TH is a 70 year old man who presented with 2 months of fatigue. He also reported a history of hyperkalemia (potassium 6.1 mEq/L) for which he was started on hydrochlorothiazide (HCTZ) 50 mg daily. His medical history was notable for hypertension well controlled on HCTZ, BPH on finasteride, and arthritis with intermittent use of naproxen. His family history was notable for hypertension. Social history was non-contributory. His exam was normal. He had a normal CBC and BMP with a potassium of 3.8 mEq/L while on HCTZ 50 mg. Given concern for adrenal insufficiency in the setting of fatigue and hyperkalemia, serum cortisol was obtained and was low at 3.7 ug/ml. Subsequent cosyntropin stimulation test was normal. Plasma renin activity

(PRA) and aldosterone were both normal at 3.4 ng/ml/hr and 10.2 ng/dl, respectively. Prior records were obtained and showed similar low-normal aldosterone in the presence of hyperkalemia. These results were concerning for hypoaldosteronism. Renal consultation was obtained, with the most likely diagnosis felt to be pseudohypoaldosteronism type II.

IMPACT: Hyperkalemia is a common outpatient laboratory abnormality with potentially serious consequences.[1,2] We found that many available diagnostic algorithms for hyperkalemia were more relevant for inpatients than outpatients. In addition, many such algorithms continued to use the trans-tubular potassium gradient, which has fallen out of favor due to invalid underlying assumptions.[1] This unusual case prompted us to develop a rational, stepwise algorithm for the evaluation of outpatient hyperkalemia.

DISCUSSION: Hyperkalemia is defined as a serum potassium greater than 5.5 mEq/L and is estimated to occur in 2-15% of outpatients.[1–3] Mechanisms for hyperkalemia can be categorized as either excess potassium intake, cellular shifts, or decreased potassium excretion.[1] Evaluation of hyperkalemia requires a stepwise approach that includes focused history and exam, potassium level re-check, identification and cessation of medications that cause hyperkalemia, then initial laboratory evaluation with CBC, BMP, serum osmolality, and urine electrolytes. These results are then used to successively rule in or out pseudohyperkalemia, cellular shifts, and inadequate distal sodium delivery.[1,4] If the above workup is unrevealing, this suggests insufficient mineralocorticoid activity, and PRA and aldosterone level are used to characterize the problem as either aldosterone blockade, adrenal insufficiency, or hyporeninemic hypoaldosteronism. TH presented with hypertension, hyperkalemia, normal PRA and aldosterone level, and low urine sodium. This is consistent with pseudohypoaldosteronism type II, which is caused by a mutation in the Na-Cl cotransporter, and corrects completely with thiazide diuretic therapy.[5] [1–5] References available upon request

HYPERLEUKOCYTOSIS IN ACUTE PROMYELOCYTIC LEUKEMIA: AN UNCOMMON PRESENTATION

Martin C. Fried[1]; Benjamin Kwok[2]. [1]NYU, Astoria, NY; [2]New York University, New York, NY. (Control ID #2705042)

LEARNING OBJECTIVE #1: Initiate treatment for leukostasis in APL

LEARNING OBJECTIVE #2: Recognize lethal complications of induction therapy for APL

CASE: A previously-healthy 72-year-old woman presented with two weeks of progressive fatigue. Laboratory tests revealed a white blood cell (WBC) count of 140x10^9/L and peripheral blood smear showed greater than 90% blasts and promyelocytes. Chest radiograph and transthoracic echocardiogram (TTE) were unremarkable. She was started on all-*trans* retinoic acid (ATRA), idarubicin, and dexamethasone. Molecular cytogenetics confirmed the diagnosis of acute promyelocytic leukemia (APL). WBC count decreased to 70x10^9/L by day three of treatment, but she developed hypoxemic respiratory failure with extensive pulmonary consolidations on chest CT. She required invasive mechanical ventilation with increasing oxygenation needs and later developed acute ischemic stroke of the left middle cerebral artery territory and NSTEMI with new McConnell's sign on repeat TTE.

IMPACT: Hyperleukocytosis is an uncommon and understudied presentation of APL that puts the patient at high risk for severe complications. A critical look at literature behind expert opinions and practices highlights several issues that need further investigation.

DISCUSSION: Patients with APL typically present with pancytopenia; hyperleukocytosis on presentation portends greater risk of differentiation syndrome (DS) and leukostasis. DS, a clinical diagnosis characterized by respiratory distress, fever, edema, hypotension, and renal failure, is a cytokine-mediated vasodilatory complication of ATRA that occurs in up to 25% of patients with APL. DS may occur as early as two days after initiation of therapy and has a mortality of 30%, primarily from respiratory failure or cerebral edema. Prompt treatment with corticosteroids and possible temporary discontinuation of ATRA improves mortality to 5%. Steroid prophylaxis is typically started for patients with WBC count greater than 10x10^9/L, though this recommendation has not been rigorously studied. Leukostasis is end-organ damage by WBC plugging of microvasculature. Management involves cytoreduction to prevent further end-organ damage. Leukapheresis is a treatment often used in hematologic malignancies but is not recommended in APL because cell lysis may release leukemic granules, worsen coagulopathy, and create a cytokine storm. Evidence for leukapheresis in APL is conflicting and incomplete. One small study showed fatal or near-fatal hemorrhage in a majority of APL patients who underwent leukapheresis. Another study showed that median overall survival and 3-year overall survival were not significantly affected in APL patients with WBC count greater than 50x10^9/L who underwent leukapheresis when compared to those who did not undergo leukapheresis. The preferred treatment for leukostasis in APL is induction therapy with ATRA or arsenic trioxide, but a case-by-case consideration of leukapheresis is warranted for those with severe leukostasis and multiple organ damage.

HYPERSENSITIVITY PNEUMONITIS IN A BIRD OWNER: THE IMPORTANCE OF ASKING ABOUT PETS IN THE SOCIAL HISTORY

Melissa Chamblain[1]; Johanna Martinez[2]; Zara Muzaffar[2]. [1]Northwell Health, Manhasset, NY; [2]Northwell Health, Lake Success, NY. (Control ID #2707383)

LEARNING OBJECTIVE #1: Review the pathophysiology and management of hypersensitivity pneumonitis (HP)

LEARNING OBJECTIVE #2: Raise awareness of the importance of conducting a thorough history, as early diagnosis and intervention can reverse a disease process

CASE: A 57 year-old, previously healthy woman presented to the Emergency Department with chief complaints of a dry, progressive cough and subjective fevers for one month. All other organ systems were reviewed and were negative. She is an every day smoker. On physical exam, she was an overweight woman in mild distress, with a low grade fever and scattered expiatory wheeze. Routine blood tests (CBC, CMP, blood cultures, viral respiratory panel) were performed. Results showed a WBC of 12 and the rest of the work-up was negative. Additionally, a chest x-ray revealed multi-lobar opacities. Treatment for community-acquired pneumonia was initiated. A CT chest revealed bilateral ground-glass opacities. She progressively became hypoxic and tachypneic, requiring transfer to the Intensive Care Unit. In the team's attempt to seek alternative diagnoses, her social history was revisited. It was found that she had purchased a parakeet about a month ago. In light of this new information steroids were started for presumed hypersensitivity pneumonitis. Within two days, she recovered clinically and was extubated.

IMPACT: This case highlights the importance of history taking. Studies dating back from the mid-twentieth century to most recently in 2012 attempted to measure the relative contribution of history taking, compared to physical exam

and laboratory tests in obtaining a correct diagnosis. As suspected, the most important factor in both diagnosis and treatment lied in the history which decided more than half of diagnoses and therefore management (Markert, 2004). Diagnosing HP can be challenging; it requires known antigen exposure, clinical, radiologic, laboratory and pathologic findings validating a clinical suspicion. In mild HP, simple avoidance of the antigen in question may be sufficient. In severely symptomatic patients, a tapered steroid regimen is started and mechanical ventilation may be required. In the case mentioned above, perhaps such clinical course could have been avoided with thorough history taking.

DISCUSSION: Histologically, HP presents as granulomatous lymphocytic alveolitis which can evolve into fibrosis in chronic advanced disease. On CT scan, ground glass opacities or nodules can be seen in acute/subacute cases whereas reticular opacities and traction bronchiectasis point towards a chronic disease. What remains intriguing is that only a few of the exposed develop the disease. A two-hit model (i.e. genetic and environmental factors) has been hypothesized to provoke an immune-complex mediated response in both the acute and subacute/chronic cases. Reference: Markert, R. J., Haist, S. A., Hillson, S. D., Rich, E. C., Sakowski, H. A., & Maio, A. C. (2004). Comparative Value of Clinical Information in Making a Diagnosis. Medscape General Medicine, 6(2), 64.

HYPERTENSION AND HYPOKALEMIA: MAKING THE (CONN)ECTION Melissa Magrath; Brooks Brodrick. University of Texas Southwestern, Dallas, TX. (Control ID #2706260)

LEARNING OBJECTIVE #1: Recognize when to screen for primary aldosteronism

LEARNING OBJECTIVE #2: Assess the necessity of adrenal vein sampling to characterize PA

CASE: A 62 year old male with a history of coronary artery disease and hypertension presented to a primary care clinic to establish care. On review of his medical history, he reported an inguinal hernia, for which surgical repair was aborted two years ago due to hypokalemia. Vital signs were significant for blood pressure of 180/109. The remainder of the physical exam was normal with the exception of a large inguinal hernia. Labs were significant for a potassium of 2.0 mmol/L and a bicarbonate of 38 mmol/L. Plasma renin and aldosterone levels were obtained: renin <6 mg/ml/hr, aldosterone 38.7 ng/dl, with an aldosterone/renin ratio of 64. CT abdomen revealed a 1.4 cm mass on the left adrenal gland. Spironolactone was initiated with improved blood pressure control. He was scheduled for adrenal vein sampling (AVS) and referred for surgery.

IMPACT: This case highlights the diagnostic algorithm for suspected primary aldosteronism (PA). In addition, although this patient presented with profound hypokalemia, the majority of patients with PA are normokalemic. We should have a lower index of suspicion for PA in patients with resistant hypertension.

DISCUSSION: Primary aldosteronism, first described by Dr. Conn in 1955, is the leading cause of secondary hypertension and affects an estimated 5-18% of patients with hypertension. Patients should be screened for PA if they have hypertension on three conventional antihypertensive drugs (including a diuretic), normotension on four or more antihypertensives, or hypertension and spontaneous or diuretic induced hypokalemia. Guidelines recommend screening with plasma aldosterone/renin ratio because it is constant over many physiologic conditions. Confirmatory tests should be performed except in the setting of spontaneous hypokalemia, plasma renin below detection levels plus plasma aldosterone concentration >20 ng/dL (as illustrated in the case above). All patients with PA should undergo adrenal computed tomography (CT) as the initial study in subtype testing. PA is treated with adrenalectomy in patients with unilateral disease (most often adenoma) and mineralocorticoid antagonists (MRA) in the remaining patients. PA patients are at increased risk of cardiovascular complications due to excess aldosterone so it is not merely sufficient to control hypertension in patients with adenoma. Prior to adrenalectomy, AVS is performed to confirm unilateral versus bilateral disease. However, a recent RCT of 200 patients with PA challenged the necessity for AVS to characterize PA. Treatment of PA based on CT or AVS revealed no difference between groups in intensity of hypertensive medications, quality-of-life, or adverse events at one year of follow-up. These results suggest that AVS, an invasive test requiring technical expertise, may not be necessary in all patients with PA.

HYPERVISCOSITY SYNDROME AS A POTENTIAL CONTRIBUTOR TO MYOCARDIAL ISCHEMIA Guramrinder S. Thind; Yashwant Agrawal; Richard Roach. Western Michigan University School of Medicine, Kalamazoo, MI. (Control ID #2701327)

LEARNING OBJECTIVE #1: Recognize the importance of checking serum viscosity in multiple myeloma with high paraprotein load.

LEARNING OBJECTIVE #2: Identify hyperviscosity syndrome as a potential contributor of myocardial ischemia.

CASE: A 79-year old female with past medical history of coronary artery disease presented with a subacute onset of chest pain. Patient had been experiencing progressively worsening chest pain for two days. On presentation, the pain was present at rest and was associated with nausea and diaphoresis. Nitroglycerin patch was prescribed and the pain was relieved. EKG showed minimal ST depressions in the anterior leads. Troponin level was 1.01 ng/mL and trended up to 1.77 ng/mL. Patient was diagnosed with non ST-segment elevation myocardial infarction (NSTEMI) and started on heparin infusion. Initial workup showed: hemoglobin = 7.7 gm/dL, platelet count = 101,000/mm3, globulin = 8.5 g/dL, and albumin = 2.3 g/dL. Reticulocyte index was 0.5 suggesting marrow suppression as the cause of patient's anemia. Multiple myeloma was suspected, and serum protein electrophoresis with immunofixation revealed an IgG monoclonal spike of 6.3 g/dL. The diagnosis was confirmed by bone marrow biopsy that showed 90–95% plasma cells. Because of high load of the monoclonal protein, serum viscosity was checked, and it was 3.4 centipoise. Patient did not meet the hyperviscosity criteria for plasmapheresis (4.0 centipoise) and had no other obvious signs of hyperviscosity syndrome. However, high serum viscosity in the setting of pre-existing coronary artery disease was suspected to be responsible for patient's NSTEMI. Plasmapheresis was contemplated for this reason, but patient's symptoms improved and troponins trended down. Patient was discharged with outpatient Hematology follow up planned.

IMPACT: This case identifies hyperviscosity as a potential contributor to myocardial ischemia, especially in the presence of underlying coronary artery disease. Serum viscosity levels should be checked in all cases of multiple myeloma when the paraprotein load is significantly high. The subacute onset of symptoms in our patient was more consistent with hyperviscosity-induced myocardial ischemia, as opposed to an acute thrombotic event.

DISCUSSION: Hyperviscosity syndrome describes the various clinical manifestations of high serum viscosity. It is typically seen with leukemia, polycythemia, or paraproteinemias. In Waldenstrom macroglobinemia, IgM being a

much larger molecule than the other immunoglobulins is more likely to cause hyperviscosity. However, paraproteinemia in multiple myeloma can also cause hyperviscosity, especially if the load of IgA or IgG monoclonal spike is > 6 g/dL. Although normal serum viscosity is 1.4 to 1.8 centipoise, clinical features of hyperviscosity are usually seen with levels of >4 centipoise. Vision changes and neurological manifestations are the common symptoms. However, myocardial ischemia can occur, especially in pre-existing coronary artery disease. Plasmapheresis is the definitive treatment.

HYPOPHYSITIS AND ADRENAL INSUFFICIENCY SECONDARY TO IPILIMUMAB AND NIVOLUMAB: A NEARLY LIFE THREATENING SIDE EFFECT OF NOVEL IMMUNOTHERAPY AGENTS

Samir Bhalla[2]; Kevin Hauck[1]. [1]NYU Langone Medical Center, Brooklyn, NY; [2]NYU School of Medicine, New York, NY. (Control ID #2670508)

LEARNING OBJECTIVE #1: Discuss the clinical utility and mechanism of action of a widely used novel immunotherapeutic agents.

LEARNING OBJECTIVE #2: Highlight the incidence of endocrinopathies associated with Ipilimumab and Nivolumab.

CASE: A 70 year old female with metastatic melanoma presented to the emergency department with fatigue and lethargy for one month. She had recently completed 6 cycles of Nivolumab and Ipilimumab and was currently receiving Nivolumab monotherapy. Over the past month she had worsening fatigue associated with nausea and decreased appetite. Lab work one week prior to admission was significant for newly elevated TSH and low T4, and thyroid replacement therapy was initiated. On the day of admission, she had a syncopal episode at home prompting presentation. On arrival, she was hypotensive to 89/57. Lab work was significant for hyponatremia, hypokalemia, and hypochloremia. Due to concern for adrenal insufficiency, she was started on stress dose hydrocortisone. An AM serum cortisol was 1.5 and ACTH level was undetectable. FSH and LH levels were also low. An MRI of the brain was notable for enhancement of the pituitary gland suggestive of hypophysitis, which was likely a side effect of her immunotherapy.

IMPACT: Ipilimumab and Nivolumab are novel immunotherapeutic agents used in the treatment of melanoma, with research investigating their use into other malignancies as well. Endocrinopathies are relatively common side effects of these agents, especially when given as combination therapy. Nonspecific complaints, such as fatigue and nausea in our patient, should warrant a thorough investigation for endocrinopathies in patients with treatment exposure to ipilimumab and/or nivolumab.

DISCUSSION: Nivolumab and Ipilimumab are novel immunotherapeutic agents that are currently used for metastatic melanoma and squamous lung carcinoma. Nivolumab antagonizes the binding of Programmed Cell Death Ligand 1 to the programmed cell death 1 receptor (PD-1), activation of which would normally promote T-cell apoptosis. Ipilimumab antagonizes the cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), preventing down regulation cytotoxic T lymphocytes. Endocrinopathies are relatively common side effects of checkpoint inhibitors and are thought to be result of auto-immune inflammation. They can manifest as primary hyper/hypothyroidism, primary adrenal insufficiency and/or hypophysitis thereby affecting the multiple hormonal systems. A retrospective review from Memorial Sloan Kettering showed an incidence of hypophysitis of 8 and thyroiditis of 6% following treatment with ipilimumab. The incidence of hypophysitis and thyroiditis increased to 9 and 22% respectively in patients who received combination therapy with ipilimumab and nivolumab. Our patient seemingly developed primary hypothyroidism and hypophysitis causing a secondary adrenal insufficiency secondary to her combination therapy. The initiation of levothyroxine therapy likely precipitated her adrenal insufficiency leading to her syncopal event.

HYPOTENSION AFTER CARDIAC CATHETERIZATION.

Idrees Azher[2]; Murtaza A. Sundhu[2]; Mubbasher Syed[2]; Ashoka Nautiyal[1]. [1]Fairview Hospital, Fairview Park, OH; [2]Fairview Hospital/Cleveland Clinic Hospital, Fairview park, OH. (Control ID #2705930)

LEARNING OBJECTIVE #1: Complication of temporary pacemaker lead causing tamponade.

LEARNING OBJECTIVE #2: Early recognition and emergent treatment of tamponade.

CASE: 68 year old women with past medical history of hypertension peripheral arterial disease and hypothyroidism presented to hospital with acute onset severe sub-sternal typical chest pain. Her initial physical examination was unremarkable except for ejection systolic murmur best heard over the right sternal border. Her initial troponin T was 0.267. There were no electrocardiogram (ECG) changes. Chest CT revealed bilateral lower lobe consolidation suggestive of bilateral lower lobe infiltrates. Patient was subsequently diagnosed with pneumonia and Non ST elevation MI and was started on broad spectrum antibiotics and intravenous heparin infusion. Transthoracic echocardiogram revealed dilated left ventricle with an ejection fraction of 42%. Cardiac catheterization revealed a significant rim of calcification and severe stenosis at the ostium of right coronary artery (RCA) that prevented its intubation with catheter. There was significant occlusive disease in left anterior descending and circumflex artery as well. Cardiothoracic surgery was consulted. Her severe vascular disease precluded coronary bypass surgery for near future and percutaneous coronary intervention of RCA lesion was planned. A successful rotational atherectomy using a rotabladder and angioplasty with drug eluting stenting was done. During the procedure, temporary pacemaker was inserted that was removed at the end of the procedure without any complications. Patient was transferred to the floor where she became bradycardic and hypotensive. Intravenous fluids were started as her blood pressure was 70/30. ECG showed a concave downwards ST elevation in V2 and V3. Emergent bedside echocardiogram showed diastolic collapse of the right atrium with a moderate pericardial effusion. Emergent pericardiocentesis was performed and after removal of 50 mL of blood, her condition improved. A catheter was left in the pericardial space and a total of 150 mL of blood was removed. Repeat echocardiogram showed minimal residual pericardial effusion. She made good recovery after this.

IMPACT: This case brought my attention to the early recognition and emergent treatment of cardiac tamponade.

DISCUSSION: Acute pericardial effusion resulting in tamponade is a life threatening condition and any cardiac intervention including pacemaker wire may cause this. In our patient, although the position of the wire appeared to be excellent during the procedure with normal pacing and sensing parameters, we believe that pericardial effusion resulted as a complication of pacing wire. In addition, patient being on dual antiplatelet agents and bivalirudin during the procedure, increased her risk of bleeding. Prompt recognition and management of tamponade are essential.

I'M JUST PSAYING SOMETHING ISN'T RIGHT Valentine O. Millien; Ryle Przybylowicz; Janis L. Sethness; Lee Lu. Baylor College of Medicine, Houston, TX. (Control ID #2707288)

LEARNING OBJECTIVE #1: Recognize diagnostic errors in clinical reasoning based on the interpretation of the standard screening test.

LEARNING OBJECTIVE #2: Recognize that neuroendocrine small cell carcinoma (SCC) of the prostate has a high mortality.

CASE: A 69-year-old Caucasian male with myelodysplastic syndrome and urinary retention from urethral stricture, with suprapubic tube, presented with 3 weeks of progressive left leg swelling. Physical exam was notable for pitting edema of the left lower extremity and scrotum. A Doppler ultrasound of left leg was negative for deep venous thrombosis. A CT abdomen/pelvis revealed retroperitoneal and bilateral pelvic lymphadenopathy with compression of the left external iliac vein and an enlarged nodular prostate with mass effect on the bladder outlet and serum PSA of 0.17 ng/mL. He has had regular follow up by urology for his urinary retention presumed due to urethral stricture, and his PSA had been very low since 2010. A PET/CT was significant for markedly avid uptake in an enlarged heterogeneous prostate gland, lymphadenopathy, hepatic hypodensities, and pelvic bony erosion, all of which were concerning for diffusely metastatic disease. He underwent prostate biopsy with pathology showing neuroendocrine SCC of the prostate. After an extensive discussion, he decided to pursue hospice care.

IMPACT: Premature diagnostic closure may have occurred in this case due to clinician cognitive errors with reasoning process assuming a low probability of prostate cancer given low PSA levels. It may be possible that the patient's urinary retention might have been due to his prostate cancer which was never investigated due to bias secondary to his low PSA value. Therefore, a negative PSA, in the proper clinical setting, should not decrease suspicion for a malignancy of the prostate.

DISCUSSION: Prostate cancer is a common type of cancer, occurring in older men. Approximately 1 out of 7 men will be diagnosed with prostate cancer in their life. The estimated 10-year survival rate is 98%. However, neuroendocrine SCC of the prostate is an aggressive rare variant of androgen resistant prostate cancer found in 0.35 cases per million per year. This type of cancer is a devastating disease due to the typical late stage at diagnosis and association with paraneoplastic conditions that are typical of small cell carcinomas of other organ systems. It is also an extremely aggressive malignancy, as compared to adenocarcinoma, with a median survival of <1 year despite chemotherapy. Screening with PSA lacks utility as levels are unlikely to be elevated in this malignancy. Hence, this case highlights the importance of recognizing physician cognitive errors with reasoning process in diagnostic delay and awareness of the aggressiveness of neuroendocrine small cell prostate cancer.

ICU DELIRIUM MISDIAGNOSED AS DELIRIUM TREMENS

James Rotenberg; Malcolm D. Kearns; Seneca Harberger; Christopher Magoon. University of Pennsylvania, Philadelphia, PA. (Control ID #2699691)

LEARNING OBJECTIVE #1: Re-evaluate a diagnosis of alcohol withdrawal delirium in light of conflicting evidence.

LEARNING OBJECTIVE #2: Treat hyperactive delirium in the setting of a prolonged QTc.

CASE: A 77 year-old man with no known medical history was transferred to our ICU for NSTEMI management; a cardiac catheterization on day 2 showed multivessel stenoses which were medically managed. Post-procedure, the patient was confused, agitated and pulling his lines. He told staff he drinks "6 scotches daily" though admission AUDIT-C score was zero. Regular CIWA assessments were started (initial scores 18 and 28) and 2 mg iv lorazepam given with mild improvement. Telemetry 1 hour later showed new rapid atrial fibrillation treated with IV metoprolol and amiodarone. He received 25 mg chlordiazepoxide then 50 mg diphenhydramine for ongoing agitation overnight. Repeated rapid atrial fibrillation and worsening agitation required further boluses of metoprolol, lorazepam and mechanical restraints. Empiric therapy for alcohol withdrawal was continued (700 mg diazepam-equivalents over 7 days) without improvement in delirium and leading to respiratory depression requiring BiPAP. The patient's relative denied any excessive alcohol use and found no alcohol after searching his home. Benzodiazepines were weaned and aripiprazole started for agitated delirium in the setting of a prolonged QTc (>500 msec). As delirium cleared, the patient repeatedly reported he had "never been drunk in my life".

IMPACT: This case reinforces the risks of diagnostic bias delaying recognition of iatrogenic harm. We describe the patient-level risks of inappropriate prescription of psychotropic medications to elderly patients. In future cases of delirium in patients with unclear medical histories, we will be more likely to check objective measures of alcohol consumption and gather collateral from family before medical decision making if at all possible.

DISCUSSION: Delirium is exceedingly common in the ICU (1). Alcohol withdrawal is a relatively uncommon cause, even in patients with known alcohol abuse (2), and requires alcohol reduction in addition to the characteristic withdrawal syndrome (3). While the CIWA scale is useful for rating alcohol withdrawal severity (4) it is not sufficient to diagnose alcohol withdrawal delirium. Diagnostic biases (e.g., overconfidence and anchoring (5), confirmation, diagnostic momentum, and base-rate neglect) are important barriers to accurate diagnosis (6). In managing acute agitation and psychosis in the setting of a persistently prolonged QTc, aripiprazole has a relatively low risk of torsades de pointes (7). 1. Lancet 2014; 383: 911–22 2. Am J Addict. 2008 Sep-Oct;17(5):452 3. *Diagnostic and statistical manual of mental disorders* (5th ed.) 2013. 4. N Engl J Med. 2014 Nov 27;371(22):2109–13 5. IFOSFAMIDE INDUCED ENCEPHALOPATHY AND ITS REVERSAL WITH METHYLENE BLUE Tejas Karawadia[1]; Arthur Topilow[1]; Michael P. Carson[2]. [1]Jersey Shore University Medical Center, Woodbridge, NJ; [2]Jersey Shore University Medical Center, Neptune, NJ. (Control ID #2672519)

LEARNING OBJECTIVE #1: Diagnose and treat encephalopathy, a rare complication of ifosfamide chemotherapy.

CASE: A male in his 40's was diagnosed with testicular germ cell cancer two months ago, and treated with unilateral orchiectomy. Chemotherapy with EP (etoposide and cisplatin) was completed 2 months before admission, followed by VIP (etoposide, ifosfamide and cisplatin) 1 month ago. He was admitted to receive his third session of chemotherapy with VIP daily for 5 days. The blood counts before chemotherapy were: Hb 10.5 gm/dl, WBC 11 K/ul, PLT 370 k/ul and he was treated with filgrastim 600mcg daily. Tumors markers LDH (2790 - > 241 iu/l), HCG (256323 - > 2118 miu/ml) and AFP (29825 - > 42 ng/ml) had dramatically improved with previous chemotherapy. BUN was 15 mg/dl and creatinine 0.95 mg/dl after completion of chemotherapy. Twenty-four hours after

completion of chemotherapy (day 6) he became confused, agitated and delirious. Given the timing, ifosfamide induced encephalopathy was the most likely diagnosis, so 50mg IV methylene blue was administered. Within 4 hours he became awake and coherent, with almost complete reversal of the neurologic symptoms. He later described the experience felt "like an LSD trip".

IMPACT: Although there are no established guidelines in management of ifosfamide induced encephalopathy, this case highlights the significance of methylene blue in treating this acute adverse event.

DISCUSSION: In addition to testicular cancer, ifosfamide is used to treat soft tissue sarcoma, cervical cancer, and lymphomas. Adverse effects include myelosuppression, nephrotoxicity, hemorrhagic cystitis and neurotoxicity. Frequently, IV fluids and mesna are given with ifosfamide to prevent nephrotoxicity and hemorrhagic cystitis, respectively. Ifosfamide induced encephalopathy is thought to result from accumulation of chloroacetaldehyde, a breakdown product of ifosfamide. Currently, there is no standard recommended treatment for this adverse effect. However, many reports suggest that methylene blue may be an effective treatment of this toxic and reversible complication. A PubMed search (ifosfamide; encephalopathy; methylene blue), did not identify any clinical trials, but there are 14 case reports in which methylene blue appeared to aid in resolution of ifosfamide induced encephalopathy. One author reported three patients with the history of ifosfamide induced encephalopathy who received prophylactic methylene blue prior subsequent treatments. In each case the treatment reduced severity as compared to previous chemotherapy sessions. In conclusion, when ifosfamide induced encephalopathy is suspected, treatment should include stopping the infusion, exclusion other causes of delirium, and administration of IV methylene blue 50mg every 4 hours till symptoms subside. For patients with a past history of ifosfamide induced encephalopathy, it seems reasonable to administer IV methylene blue as a prophylactic measure before any subsequent chemotherapy with ifosfamide.

IMATINIB INDUCED ACUTE HEPATIC INJURY Mohammad A. Selim[3]; Thamer A. Kassim[1]; Osman Bhatty[2]; Jaya S. Gupta[1]; Lakshmi M. Chintalacheruvu[3]. [1]Creighton University, Omaha, NE; [2]Creighton University GME, Omaha, NE; [3]Creighton university, Omaha, NE. (Control ID #2707030)

LEARNING OBJECTIVE #1: Recognize the clinical features and different presentations of Imatinib induced liver injury.

LEARNING OBJECTIVE #2: Assess the role of oral glucocorticoids as an early management strategy in severe cases of Imatinib induced liver injury.

CASE: 71-year-old woman presented with jaundice, pruritus, lethargy, pale stool, and dark urine without fever and abdominal pain. Past medical history was significant for Sjogren's disease, CML, breast cancer, choledocholithiasis, and history of self-limited liver enzymes elevation in 2007. No significant family history and she denies alcohol use. She was taking Imatinib, Tamoxifen, Plaquenil, and Duloxetine. No recent history of Acetaminophen ingestion. Physical exam revealed overt jaundice and pedal edema. MELD score was 28. Initial labs revealed markedly elevated transaminases, total bilirubin, INR, borderline Alkaline phosphate, and Acetaminophen level was not elevated. Imaging did not show biliary duct obstruction without any evidence of thrombosis, cirrhosis, or mass. Workup including autoimmune hepatitis; AMA, ANA, Anti-smooth muscle, and infectious hepatitis panel were negative. Liver biopsy performed and showed acute hepatitis and acute cholangitis consistent with drug induced liver injury. Liver enzymes trended down after cessation of Imatinib and dramatically improved after commencing the patient on Prednisone. Follow up labs showed continued decrease LFTs and marginal improvement of total Bilirubin. Patient presented back with RUQ abdominal pain approximately 2 weeks after steroid therapy started. Given the prior history of choledocholithiasis and persistent hyperbilirubinemia the patient had EUS, which did not reveal any obstruction or stricture but revealed a gastric ulcer. Prednisone discontinued and LFTs continued to trend down.

IMPACT: There are few case reports of Imatinib induced liver injury. Acute hepatitis is the most common reported form. Our case presented with acute hepatitis and acute cholangitis, adding to the diagnosis and recognition of such cases. Prednisone had been tried in a study and recent case reports. However, side effects led to its discontinuation in our case. LFTs and bilirubin continued to trend down despite steroid cessation. This case highlights that steroids maximum benefit is in the early few weeks.

DISCUSSION: Literature review revealed that high elevation of liver enzymes, occur in less than 4% of cases. Furthermore, it demonstrates that most of the severe cases were female patients who presented in the first 3 to 6 months after starting Imatinib. Prednisone had been tried before in some cases and it showed better outcomes. Based on that, we started the patient on prednisone. Our patient developed some side effects and Prednisone ceased. LFTs and bilirubin continued to trend down despite steroid cessation. The role of steroids still unclear and controversial. Given the lack of large studies and the side effect profile, risk and benefit of glucocorticoid therapy will need to be assessed on a case by case basis.

IMPENDING PARADOXICAL EMBOLUS IN A PATIENT WITH ENDOCARDITIS AND PFO Mubashir H. Bahrami[1]; Joshua Meskin[2]. [1]Medical College of Wisconsin, Wauwatosa, WI; [2]Medical College of Wisconsin, Milwaukee, WI. (Control ID #2701267)

LEARNING OBJECTIVE #1: Recognize the clinical features of Infective Endocarditis with Patent Foramen Ovale (PFO)

LEARNING OBJECTIVE #2: Manage Endocarditis and PFO both medically and surgically in the setting of impending paradoxical emboli

CASE: A 28-year-old Caucasian woman with history of intravenous drug abuse (IVDA) was found down by her family and brought to a nearby hospital. The patient did not have any pertinent past medical, surgical or family history. Upon examination the patient was altered, febrile, hypotensive, tachycardic and had a grade IV holosystolic murmur. Neurologic assessment revealed absence of movement in bilateral lower extremities, presence of clonus, and lack of sensation. A MRI of the cervical spine revealed cervical stenosis with a C2-T1 ventral epidural phlegmon. A MRI of the brain showed an acute right MCA and cerebellar infarct. Laboratory studies were significant for leukocytosis, and the patient was started on empiric broad-spectrum antibiotics for presumed infective endocarditis. A transthoracic echocardiogram (TTE) revealed a large tricuspid valve vegetation and a PFO with right-to-left shunting. Blood cultures revealed Staphylococcus Aureus and the antibiotics were narrowed appropriately. Orthopedic spinal surgery was consulted and urgently performed a C3-C7 posterior decompression and fusion with instrumentation. Neurology and Cardiothoracic surgery were consulted regarding the large tricuspid valve vegetation and associated PFO seen on TTE. There was consensus amongst the teams that pursuing surgery for secondary stroke prevention would be the appropriate course. An intraoperative transesophageal echocardiogram (TEE) showed no evidence of previously seen vegetation on

the tricuspid valve, however it showed impending paradoxical emboli. An approximately 25 mm vegetation was noted in the PFO, extending from the right to left atrium. The patient underwent successful removal of the vegetation and closure of the PFO. Postoperatively, the patient continued on antibiotics and was subsequently managed by therapy and pain services for her incomplete quadriplegia.

IMPACT: This particular case will supplement the limited data and radiographic evidence available on impending paradoxical embolism. Currently there are no standard guidelines available on management of a biatrial thromboembolus. This case demonstrates successful surgical removal of such vegetation with closure of a PFO.

DISCUSSION: Patients with infective endocarditis and PFO can present with various forms of paradoxical embolism. This case is unique in that there were multiple septic embolic phenomena including the multiple acute strokes and ventral epidural phlegmon that were visualized on MRI. There have been case reports that have described impending paradoxical emboli that are trapped across a PFO like the vegetation seen on the intraoperative TEE in this case. Medical management comprises 6 weeks of intravenous antibiotics, and these patients are evaluated for surgical thromboembolectomy, anticoagulation or thrombolysis.

INDEX OF SUSPICION: NEGATIVE LUMBAR PUNCTURE DOES NOT ALWAYS RULE OUT SERIOUS NEUROLOGIC ILLNESS Saundra Nguyen; Oanh K. Nguyen; Blake R. Barker. UT Southwestern Medical Center, Dallas, TX. (Control ID #2704982)

LEARNING OBJECTIVE #1: Recognize the role of lumbar puncture in diagnosing Guillain-Barre syndrome (GBS)

LEARNING OBJECTIVE #2: Recognize the characteristic clinical features of GBS

CASE: A 32 year-old man with history of cerebellar medulloblastoma resection was transferred from an outside hospital for management of severe hyponatremia. He reported a 2-week history of progressive weakness, gait instability with falls, nausea, vomiting, decreased PO intake, and a 17-lb weight loss. Physical exam was notable for pulse of 123, slowed verbal responses, and 4/5 lower extremity strength. Laboratory studies showed serum sodium 118 mg/dL, creatinine 1.51 mg/dL, and WBC count 13.8x109 cells/L. CT of the brain showed no acute abnormalities. He was admitted to the ICU and started on IV normal saline. Despite appropriate correction of hyponatremia, he developed worsening confusion, somnolence, profound weakness, urinary retention, and leukocytosis (WBC 23.1). Empiric antibiotics were started for presumed sepsis. Lumbar puncture (LP) revealed unremarkable CSF with protein 47 mg/dL, glucose 71 mg/dL, and no nucleated/red blood cells. MRI of the brain was unremarkable; EEG showed a mild nonspecific encephalopathy. On hospital day 12, the patient developed episodes of oxygen desaturation to 80 and was noted to be quadriplegic and areflexic. Given his symptoms, plasmapheresis and IV immunoglobulin were initiated for suspected GBS. The patient subsequently recalled a preceding diarrheal illness. Repeat LP showed CSF with protein 72 mg/dL; EMG showed severe axonal polyneuropathy without signs of demyelination, supporting the diagnosis. He was discharged to a skilled nursing facility after a 1.5-month hospitalization complicated by respiratory failure requiring mechanical ventilation.

IMPACT: Although lumbar puncture is an integral part in diagnosing GBS and excluding other causes of weakness, negative LP results are not sufficient to rule out GBS in patients with high pre-test probability and characteristic clinical symptoms.

DISCUSSION: Guillain-Barre syndrome is an acute immune-mediated peripheral neuropathy characterized by ascending symmetric motor weakness and areflexia, often triggered by a preceding infection (usually diarrheal). GBS can result in life-threatening respiratory failure and autonomic dysfunction, with mortality rates of 3-7%. Early diagnosis and treatment is critical to optimizing a patient's recovery. Initial diagnosis of GBS is based on clinical presentation, though this can be highly variable, and CSF demonstrating cytoalbuminologic dissociation (elevated CSF protein with normal cell count) is supportive. However, normal CSF does not make GBS less likely or exclude it, as elevation of CSF proteins depends on the timing of LP. In one study, the classic cytoalbuminlogic dissociation was noted in only 64% of patients; CSF protein was elevated in 49% of patients on the first day, 53% in the first 3 days, and 88% at 3 weeks. This is an important consideration when using CSF findings to aid in the diagnosis of GBS.

INHERITED NEUROMUSCULAR DISORDERS: NOT FOR THE FAINT OF HEART Kenneth M. Fifer; Jennifer P. Weintraub. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2706051)

LEARNING OBJECTIVE #1: Identify neuromuscular disorders as a rare cause of conduction abnormalities

LEARNING OBJECTIVE #2: Describe common physical exam findings and cardiac complications of inherited neuromuscular disorders

CASE: A 20 year-old Ecuadorian man with a history of end-stage renal disease secondary to focal segmental glomerulosclerosis (FSGS) presented to the emergency room after a five minute syncopal episode. Ten-point review of systems was otherwise negative. He denied tobacco, alcohol, or drug use. Family history was significant for consanguinity (patient's parents were first cousins) and ptosis in a maternal aunt and cousin. There was no known family history of cardiac disease. Physical exam demonstrated a short, thin male with small facial features. Cardiac exam was significant for a heart rate of 24. Extremity exam showed decreased muscle bulk, tone, and strength diffusely. Electrolytes, inflammatory markers, blood cultures, and Lyme testing were unremarkable. Electrocardiogram demonstrated marked bradycardia with complete heart block. Echocardiogram was significant for mild left ventricular dilatation and an ejection fraction of 60%. The patient was externally paced and admitted to the cardiac intensive care unit. A permanent cardiac pacemaker was placed. A presumptive diagnosis of inherited neuromuscular disorder was made following genetics consultation and the patient underwent further genetic testing.

IMPACT: As a practitioner of adult internal medicine, this case emphasizes the importance of identifying the physical exam findings of inherited neuromuscular conditions in adults who may have previously gone undiagnosed. Recognition of these genetic syndromes and their associated complications may help reduce patient morbidity.

DISCUSSION: The etiologies of complete heart block are many including infectious, infiltrative, ischemic, neuromuscular, and metabolic causes, as well as adverse medication effects. In this case a presumed diagnosis of inherited neuromuscular disease was made. Inherited neuromuscular disorders such as Duchenne and Becker muscular dystrophy affect multiple organ systems. Progressive weakness is often one of the first symptoms, affecting first proximal then distal muscle groups, usually first in the lower extremities. Associated physical exam findings include wide gait, lumbar lordosis, and calf enlargement. Multiple types of inherited neuromuscular disorders have been associated with conduction abnormalities. Duchenne muscular dystrophy has

been shown to cause progressive ventricular dilatation and dysfunction, predisposing those affected to cardiac arrhythmias. Myotonic dystrophy and muscular dystrophy associated with the LMNA gene have been associated with significant conduction abnormalities. Recognition of the complications of these inherited conditions should prompt providers to monitor closely for conduction abnormalities and consider prophylactic device implantation to prevent serious adverse cardiac events.

INSULIN INFUSION FOR SEVERE HYPERTRIGLYCERIDEMIA-INDUCED PANCREATITIS Takaaki Kobayashi[1]; Michael J. Lau[1]; Akihiro Kobayashi[1]; Heather Siedenburg[2]; Alfredo J. Astua[2]. [1]Mount Sinai Beth Israel, New York, NY; [2]Mount Sinai Beth Israel, New york, NY. (Control ID #2694030)

LEARNING OBJECTIVE #1: Recognize insulin infusion as a treatment option to effectively lower triglyceride (TG) levels in hypertriglyceridemia (HTG)-induced pancreatitis.

CASE: A 45-year-old woman with type 2 diabetes mellitus (DM) and dyslipidemia presented with a 2-day history of nausea, vomiting, and epigastric pain. Two years earlier, she had an episode of acute pancreatitis (AP) secondary to HTG (1,120 mg/dL), which was treated with gemfibrozil and atorvastatin. Her family history was significant for hyperlipidemia and type 2 DM. She denied alcohol use but admitted noncompliance with medication. Vital signs were as follows: blood pressure, 132/78 mmHg; heart rate, 90 beats/min; respiratory rate, 18 breaths/min; and body temperature, 97.9°F. Physical examination revealed moderate epigastric tenderness. Laboratory tests revealed TG, lipase, and glucose levels to be 3,793 mg/dL, 11,911 units/L, and 361 mg/dL, respectively. Ultrasound of the right-upper abdominal quadrant showed no cholelithiasis or obstruction. Subsequently, a diagnosis of AP secondary to HTG was confirmed. Treatment included pain management with opioids and HTG reduction with continuous insulin infusion at 0.05 units/kg/h, with intravenous (IV) 5% dextrose in normal saline titrated to a blood glucose level of 120–180 mg/dL. On day 2 of hospitalization, her TG level had dropped to 1,226 mg/dL. On day 5, she was switched to subcutaneous insulin (TG, 668 mg/dL); on day 6, she was discharged symptom free (TG, 586 mg/dL).

IMPACT: Previous studies have demonstrated the efficacy of apheresis for acutely lowering TG levels; however, its cost and feasibility are prohibitive. We can treat HTG-induced AP effectively with continuous insulin infusion, which is safe, simple, and cost-effective. With frequent blood glucose monitoring, this treatment can be safely achieved even beyond the intensive care unit.

DISCUSSION: HTG is the third most common cause of AP after alcohol and gallstone. The risk of developing AP is approximately 5% with TG > 1,000 mg/dL and 10-20% with TG > 2,000 mg/dL. The breakdown of TG into toxic free fatty acids is thought to be the cause of lipotoxicity during AP. HTG treatment includes conventional treatment of AP and management of serum TG levels (<500 mg/dL). Fibrates, nicotinic acid, and statins are commonly used to decrease serum TG concentration; however, insulin infusion acutely lowers TG levels. It decreases TG by enhancing lipoprotein lipase activity, thereby accelerating chylomicron and very low density lipoprotein metabolism to glycerol and fatty free acids. Moreover, it inhibits lipase in adipocytes, leading to an overall reduction in lipolysis. An initial rate of 0.1 to 0.3 units/kg/hour of insulin is recommended; IV administration may be more effective than subcutaneous. The main adverse effect of insulin infusion is hypoglycemia, which can be avoided with IV 5% dextrose.

INTERPROFESSIONAL MANAGEMENT OF A PSYCHIATRIC EMERGENCY IN THE PRIMARY CARE SETTING David Alajajian; Daniel J. Coletti; Leslie Rosenberg; Frank Cacace. Hofstra North Shore LIJ, Great Neck, NY. (Control ID #2701865)

LEARNING OBJECTIVE #1: Recognize and address social barriers to the treatment of acute psychiatric emergencies by collaborating with behavioral health professionals.

LEARNING OBJECTIVE #2: Engage patients and behavioral health professionals in constructing a safe and sustainable plan to manage depression with suicidal ideation.

CASE: “Carmen” is a 48-year-old Latina woman; history includes left breast LCIS (with lumpectomy) and a depressive disorder. She presents with severe anhedonia, insomnia, and worry about her medical and social situation, most notably her son’s welfare if she becomes ill again. She is undocumented, uninsured, and dependent on her income as a house cleaner (now part-time due to cancer treatments). Of primary concern is her report that she has frequent thoughts of jumping in front of a train near her home. However, she cites her 5 year-old son as a reason not to commit suicide, as worry about her son both exacerbates her anxiety and protects from self- harm. Carmen had been prescribed citalopram, which she took briefly but discontinued. She declines a referral for inpatient treatment because she can identify no one to care for her son. The team considers the risks and benefits of facilitating a psychiatric admission, which is likely to result in child protective service involvement. Furthermore, her insurance status complicates expediting referral to outpatient treatment. To address these barriers, an embedded Behavioral Health Consultant conducts a risk assessment during the office visit. She arranges a teleconference with a psychiatrist, who interviews Carmen and recommends resuming Citalopram at a higher dose in addition to a brief course of clonazepam. Carmen returns home with a safety plan. Meanwhile, the team monitors her clinical status with telephone calls, investigates child care support services that might facilitate hospitalization and aids with solution-focused counseling sessions. Her mood improves over the next several weeks and by the time a grandparent is identified to care for the child, hospitalization is deemed unnecessary.

IMPACT: Engaging a remote psychiatrist for a consultation is an efficient way to manage mental health crises in primary care. Psychosocial barriers can alter the costs/benefits of off-site evaluation and emergent hospitalization. On-site behavioral health consultants can provide crisis assessment and facilitate psychiatric evaluation to stabilize a patient and avoid hospitalizations that are ultimately unnecessary.

DISCUSSION: The case of Carmen illustrates how outpatients with urgent psychiatric needs can be managed within an interdisciplinary team. This patient met criteria for hospitalization but practical barriers made this option untenable and might have even exacerbated her symptoms. Patients such as Carmen are less likely to pursue specialists, follow or adhere to medication regimens. An integrated behavioral health program provides an important clinical service for patient stabilization outside of the emergency room.

INTRAABDOMINAL MAC INFECTION IN AN IMMUNOCOMPETENT CROHN’S DISEASE PATIENT Harry R. Powers; Lennox Archibald. University of Florida, Gainesville, FL. (Control ID #2707083)

LEARNING OBJECTIVE #1: Recognize MAC as a cause of intraabdominal abscess in immunocompetent patients

CASE: The patient was a 29 year old man who was evaluated for abdominal pain and anemia in an outpatient setting. He reported that the abdominal pain was localized to the umbilicus and was cramping in nature. He also reported having watery diarrhea. He endorsed drenching night sweats and 12 pound weight loss. His initially work up was significant for iron deficiency anemia. Computed tomography (CT) of abdomen and pelvis was performed to evaluate the abdominal pain. The scan revealed inflammation of terminal ileum and multiple abscesses. The patient was admitted to the hospital for further evaluation. On admission, the patient had normal vital signs. His physical exam was only significant for extremely thin appearance. His labs were significant for low hemoglobin and elevated white blood cell count. Colonoscopy was performed and showed severe ileitis with stricture in the terminal ileum. Pathology from terminal ileum showed ulceration and granulation tissue. He was tenatively diagnosed with Crohns' disease. The patient underwent CT-guided drainage of abscess by interventional radiology. He was put on oral antibiotics and discharged from the hospital. The patient was readmitted 20 days later for similar complaints. The abscess was noted to be growing *Candida albicans* and mycobacterium avium complex (MAC). The patient was started on fluconazole for candida, and clarithromycin, rifampin, and ethambutol for MAC. The patient was discharged from the hospital with drain in place. He completed 6 weeks of antifungal therapy. He was to continue on the anti-MAC therapy for 12 months.

IMPACT: This case has a practical effect on the approach to infected patients. In immunocompetent individuals, atypical organisms are often overlooked on initial diagnosis. Overlooking these organisms can lead to prolonged hospital course and complications such as from unnecessary antibiotics. This case also demonstrates the difficultly in diagnosing MAC infection, because it is a very slow growing organism. In cases where MAC infection is a possibility, culture results need to be followed up on passed the usual five days.

DISCUSSION: This is the first reported case of MAC leading to intraabdominal abscess in an immunocompetent patient. The vast majority of extrapulmonary MAC infections are found in patients with compromised immune systems. Rarely, extrapulmonary MAC can be found in individuals without any apparent immunodeficiency. Interestingly, there has been an association between the MAC subtype paratuberculosis and Crohn's disease noted. Some believe that MAC may contribute to the development of Crohn's disease. However, it has never been noted to cause an intraabdominal abscess in a Crohn's patient. This case gives insight into the ability of MAC to cause intraabdominal infections in patients that were previously not thought susceptible to them.

INTRACRANIAL HYPOTENSION SYNDROME IN A PATIENT WITH DOWN AND OUT PUPIL. Maria D. Garcia-Jimenez; Maranatha Gabaud; Douglass Bails. New York University School of Medicine, New York, NY. (Control ID #2670735)

LEARNING OBJECTIVE #1: Recognize the risk of intracranial hypotension after dura mater invading procedures.

LEARNING OBJECTIVE #2: Review symptoms and treatment of intracranial hypotension, emphasizing high clinical suspicion needed to identify it.

CASE: A 26 year-old man with left hemicraniectomy a month prior presented with one week of headache and neck pain. Vital signs were normal and non-contrast head computed tomography (NCHCT) was unremarkable. Lumbar puncture was performed; CSF studies were negative for infection. He was discharged with improved symptoms after Vicodin. He presented two days later reporting double vision, headache worse with standing, relieved by lying flat, and neck stiffness. Vital signs were normal, and he was alert, oriented, with normal neurological exam and intact extraocular muscles. His complex medical history, however, led to his admission and initiation of empiric antibiotics for treatment of meningoencephalitis. On hospital day one he exhibited new right ptosis, right pupil dilation, and right "down and out" gaze concerning for partial right CN III palsy. NCHCT showed mild midline shift. He was placed in Trendelenburg and given 1 Liter intravenous fluids with stabilization of symptoms. The next day he became somnolent with progressing right eye symptoms now including impaired right eye adduction indicating complete CN III palsy. Repeat NCHCT showed sinking of the cranioplasty skin flap, increased midline shift, and medial displacement of the left uncus. MRI confirmed this and noted enlargement of dural venous sinuses, consistent with intracranial hypotension. Antibiotics were stopped and an epidural blood patch was placed with gradual resolution of symptoms.

IMPACT: In this case re-evaluating the diagnosis as the physical exam evolved was crucial to appropriate therapy. This taught us the diagnostic impact of frequent serial physical exams, and the importance of seeking alternative diagnoses if aspects of the case do not fit or are changing.

DISCUSSION: Symptoms of intracranial hypotension syndrome (IHS) include orthostatic headache, nausea, diplopia, mental status changes, and cranial nerve palsies. CN VI palsy is seen in 83% of cases but CN III is rare. IHS can occur spontaneously or after spinal trauma or dura mater disrupting procedures. It can occur days to weeks post procedure and is associated with decreased CSF opening pressure or imaging suggesting CSF leak, such as dilated epidural venous plexus. High clinical suspicion for IHS is crucial in individuals post lumbar puncture with orthostatic headache and cranial nerve abnormalities. Delay in diagnosis, as in this patient, can lead to worsening brain parenchyma shifts. Conservative management includes bed rest, intravenous fluids (IV), or IV caffeine. Trendelenburg positioning, an established treatment for "sagging brain," is also used. If these fail, epidural blood patch can result in dramatic symptom improvement, though the amount of blood and number of blood patches is not standardized.

INTRAMURAL DUODENAL HEMATOMA: A CASE OF PANCREATITIS AND A BLEEDING ANEURYSM Lorick E. Andersen[3]; Joel H. Witter[1, 2]. [1]Presbyterian/St. Lukes Hospital, Denver, CO; [2]University of Denver, Aurora, CO; [3]Colorado Health Foundation, Denver, CO. (Control ID #2706185)

LEARNING OBJECTIVE #1: Recognize intramural duodenal hematoma (IDH) as unique complication of acute pancreatitis

LEARNING OBJECTIVE #2: Diagnose etiology of IDH using visceral angiography

CASE: 52-year-old African-American male with a PMH of HTN, alcoholism and pancreatitis presented to ER with complaint of right > left lower back and abdominal pain. The pain started a month prior and had been gradually getting more severe in the past week, becoming a constant, sharp pain with associated nausea and vomiting. He had a previous episode of pancreatitis four months ago thought to be attributed to his heavy alcohol use. Exam was remarkable for tenderness to palpation in the right upper and lower quadrants. Labs were notable for a lipase of 5171, WBC of 13.56, and Hgb of 12.6. In addition to evidence of acute moderate pancreatitis, CT imaging of the abdomen showed a large,

retroperitoneal 13x7 cm ovoid IDH and a small amount of ascites in the right retroperitoneum extending along the psoas muscle. CTA was subsequently performed which showed a small foci of active bleeding in duodenum. The patient was hemodynamically stable at the time and the decision was made to admit for management of pancreatitis and further evaluation of IDH with visceral angiography. A coil embolization of a pancreaticoduodenal artery pseudoaneursym was performed by IR; this was likely the cause of the intramural duodenal hematoma. His hemoglobin dropped to 8.6 after admission but then remained stable without intervention through the remainder of his hospital course. The patient was discharged home after six days with close follow up for resolution of hematoma.

IMPACT: IDH is a relatively rare condition and is even less common in the absence of trauma. Previous case reports suggest spontaneous IDH as an etiology for pancreatitis via obstruction; however, this case supports pancreatitis as the ultimate cause of IDH through local inflammation of the visceral vasculature and subsequent pancreaticoduodenal artery aneurysm (PDAA) and rupture.

DISCUSSION: IDH is an uncommon condition in adults with few case reports described in the literature. Causes include abdominal trauma, underlying vascular malformations, pancreatitis and idiopathic. In this case, the finding of a PDAA in this patient with pancreatitis in the absence of trauma suggests the pseudoaneurysm and subsequent hemorrhage were related to inflammation from pancreatitis. Signs and symptoms are nonspecific and typically include abdominal pain, nausea and vomiting. A high index of suspicion is needed in those patients at risk to identify IDH given the morbidity and mortality associated with its complications, specifically the possibility of ongoing hemorrhage. Utilization of visceral angiography after initial diagnosis of IDH is made with abdominal imagaing is suggested by some in the literature. In this case, angiography was both diagnostic of PDAA and therapeutic to control the source of hemorrhage. This case supports the use of angiography in the evaluation of IDH in those with pancreatitis.

IRONING-OUT ABNORMAL URINE: A CASE OF VIN ROSé

Peter M. Finin; Clark A. Veet; Eliana Bonifacino. UPMC, Pittsburgh, PA. (Control ID #2675638)

LEARNING OBJECTIVE #1: Differentiate causes of red urine discoloration

LEARNING OBJECTIVE #2: Identify indications and side effects of iron chelation

CASE: A 59 year old man with a history of sickle cell disease requiring frequent blood transfusions causing hemosiderosis-induced cirrhosis managed with regular large volume paracentesis and oral iron chelation with deferiprone presented with abdominal distention and new atrial fibrillation. As both his cirrhosis and arrhythmia were attributed to iron overload, iron chelation was intensified with the addition of intravenous deferoxamine. To facilitate ongoing large volume paracentesis, a peritoneal pigtail catheter was placed. Later that day, he reported red urine without abdominal pain, dysuria, or other new symptoms. Urine centrifugation with microscopic analysis showed only 1–2 RBCs per high powered field. The red color remained in the supernatant with a bland urine pellet. His urine discoloration was judged not to be hematuria but rather medication induced discoloration.

IMPACT: Urine discoloration commonly signals illness and causes consternation among patients and physicians. This case illustrates the well-known side effect of urinary discoloration associated with iron chelation and outlines a general approach to red urine.

DISCUSSION: Bright red urine is an alarming finding that warrants careful workup. The patient was asymptomatic without flank pain to suggest nephrolithiasis. Urine microscopy showed few red cells and urinalysis showed no significant blood. This patient developed hemosiderosis from red blood cell transfusion in the context of chronic hemolytic anemia due to sickle cell disease. In these cases, iron chelation is generally recommended to maintain ferritin between 1000–1500 ng/mL. The patient's ferritin was 3058 ng/mL. In order to manage this, the patient received daily infusions of deferoxamine at 30 mg/kg prior to development of red urine. Deferoxamine is a specific iron chelator that binds ferric iron and forms a water-soluble compound that is excreted by the kidney, causing a "vin rosé" discoloration of urine. The presence of color change serves as an indicator of effective iron chelation. Careful history and exam of urine can help identify patients who may be at risk for non-adherence and sequelae of iron overload. Urine discoloration should always prompt careful medication history, urinalysis and a focused examination including assessment for costovertebral tenderness and genitourinary abnormalities. Many processes and agents can change urine color red. Most commonly, red urine is due to blood in the genitourinary tract. However, medications including deferoxamine, rifampin, warfarin, phenazopyridine, chloroquine, and ibuprofen can cause red urine discoloration. In addition, processes such as intravascular hemolysis including G6PD deficiency or hemolytic anemias, nephrolithiasis, porphyria, or Nutcracker syndrome can cause urine color changes from hemoglobinuria. Finally, foods including beets, blackberries, and carrots can dye the urine red.

IS IT WORTH THE POUND? THINK TWICE! Majlinda Xhikola; Daniel Goldsmith; Abisoye V. Fakayode. Capital Health Regional Medical Center, Trenton, NJ. (Control ID #2701685)

LEARNING OBJECTIVE #1: Recognize the significance of depression, suicidality and seizure in patients treated with naltrexone/bupropion for obesity

LEARNING OBJECTIVE #2: Recognize the limited post marketing data available for naltrexone/bupropion use

CASE: We present the case of a 67 year old caucasian female with medical history of dyslipedemia, hypertention and obesity who was admitted to critical care unit for new onset witnessed seizure activity resulting in airway compromise. Witnesses of the seizure reported that the patient confessed to having swallowed several weight loss pills prior to the event and that she was holding a note saying: "Can't go on like this anymore" From her family and co-workers we learned that the patient was recently started on naltrexone/bupropion. They described the patient as a very energetic and pleasant person with future oriented goals. She enjoyed her job as a high school clerk. Patient had been trying to lose weight and was started on naltrexone/bupropion therapy 25 days prior to this event with up-titrating doses. Once the patient was out of the critical care, she explained that after starting naltrexone/bupropion, she started feeling "queasy" and "listless" at around week 3 of therapy. "I had never felt like this before" she noted. As the days progressed the nausea and the state of depressed mood got worse and nothing seemed to help. She reported ingesting "a dozen" of the naltrexone/bupropion pills in a suicide attempt on the day of the hospitalization.Soon after the ingestion, she developed generalized seizures which led to airway compromise and critical care was required.

IMPACT: New recognized case of acute progressive mood changes that led to a serious suicide attempt after starting naltrexone/bupropion for obesity. Need for close follow up on not only efficacy and common side effects but dedicated focus on mood assesment, expecially in the dose escalation phase. Allow for more post marketing data before widely reccomending naltrexone/bupropion for obesity.

DISCUSSION: Efficacy and safety of naltrexone/bupropion was studied in 4 phase 3 trials.Results of these studies looking at the weight loss endpoint were reported as statistically significant and clinically meaningful weight loss compared to placebo.Average weight loss from baseline observed with treatment across the 4 studies corresponded to between approximately 11–22 pounds in 56 weeks. Nausea was a common side effect(31% vs 6.7% in placebo)and was noted to happen during the dose-escalation phase as happened to our patient. Seizures incidence <0.1% vs 0 in placebo. Depression incidence 2.8% vs 3.4% in placebo. Suicidality incidence <0.1% vs 0.2% in placebo. Although these trials showed a lower incidence of depression and suicidality compared to the placebo group, our patient developed acute progressive mood changes that led to a serious suicide attempt. New pharmaceutical products must be evaluated regarding benefit versus risk in light of the fact that little time for post marketing monitoring has occurred

IS RIGIDITY REQUIRED FOR DIAGNOSIS OF NEUROLEPTIC MALIGNANT SYNDROME NMS? Nabil Mesiha[2]; Nagham Jafar[2]; Hossein Sadrzadeh[1]; Sree Yelamanchili[1]; Manish Gugnani[1]; Daniel Goldsmith[1]. [1]Capital Health Regional Medical Center, Trenton, NJ; [2]Capital health Regional Medical Center, Trenton, NJ. (Control ID #2698371)

LEARNING OBJECTIVE #1: To demonstrate that rigidity and elevated CK is not mandatory for diagnosis of NMS.
LEARNING OBJECTIVE #2: Significant elevated temperature should draw the attention for other unusual etiology.
CASE: Neuroleptic malignant syndrome is a life-threatening, neurological disorder most often caused by an adverse reaction to neuroleptic or antipsychotic drugs.In most cases, the disorder develops within the first 2 weeks of treatment, however, it may develop any time during therapy. Morbidity and mortality results from systemic complications and from dysautonomic manifestations, including high fever, sweating, unstable blood pressure, stupor, and muscular rigidity. We report one case with a temperature of 108 F who was eventually diagnosed with NMS with neither significantly elevated creatinine kinase nor rigidity. A 52 year old male with history of schizoaffective disorder presented from his group home in summer with altered mental status and suspected seizure. He had been sweating for several days despite working air conditioning and confused. He was evaluated in the ED one day prior for bizarre behavior, and discharged home on the same day. Medications were trazodone, ziprasedone (recently prescribed), lithium, and clonazepam. Physical examination showed T 108.3 F, BP 170/99, Heart rate 132, RR 25, O2sat 99%. Patient was not seizing and showed no rigidity, but he was obtunded, perspiring, and no signs of acute trauma. Neck was supple. Laboratory showed WBC 14.4 without bandemia. Lactate and CK were normal. UDS was negative. Patient was intubated in ED to secure airway. Continuous EEG showed no seizure activity. Lumbar puncture showed no meningitis. Cold IV fluids, cool saline through NG-tube and Foley' catheter and cooling blankets brought the temperature to 104 after a few hours. Because of high suspension of NMS, all antipsychotic medications were held and started on dantrolene and bromocriptine. On the second day, temperature and BP normalized. HR fluctuated between 50–120 bpm. Results of all cultures came back negative, and he was successfully extubated. Valproic acid was started, and he was transferred to inpatient psychiatry for further management
IMPACT: We should suspect NMS as a diagnosis in patient with 2 or more of 4 features in the setting of neuroleptic use. Diagnosis is always challenging and other serious condition should be ruled out.
DISCUSSION: Diagnosis of NMS can be challenging, and should be suspected with 2 or more of the 4 cardinal features: mental status changes, rigidity, fever, and dysautonomia, appearing in the setting of neuroleptic use or dopamine withdrawal. Diagnostic evaluation is aimed at ruling out other possible diagnoses, and treatment includes withholding of all neuroleptics, supportive care, dantrolene, and bromocriptine should be considered. Clinicians must recognize that rigidity and elevated CK may not be present in severe NMS cases, and a high index of suspicion is required to correctly identify NMS and differentiate from other critical conditions.

ISCHEMIC STROKE: THE GREAT MASQUERADER OF AN AORTIC DISSECTION Lakshmi Kallur; Nanette Bentley. East Tennessee State University, Johnson City, TN. (Control ID #2706426)

LEARNING OBJECTIVE #1: Diagnosing an aortic dissection with an initial presentation of neurological deficit
CASE: A 48- year old obese, non smoker, female with a past medical history of untreated hypertension presented to the emergency department with confusion, lethargy and altered mental status that began the day of presentation. She was unable to provide a detailed history but could sluggishly respond to verbal commands. Upon questioning, she specified that she had chest pain earlier in the day for ten min accompanied by nausea, dizziness, dyspnea, lightheadedness and fatigue. Patient has not followed with a physician since 2009 and was not on any medications. Vitals included blood pressure 162/105, pulse 75 and oxygen saturation on room air of 97. Her speech and responses were slurred and slow. All other systemic exams were unremarkable. Initial ABG showed pO2 51, CMP 3.1 and cardiac troponins and CBC within normal limits. EKG revealed T wave inversions in lead I and aVL with ST elevation in lead III only. Shortly after admission, her respiratory status declined and she was intubated. CT Head showed hypodensities in the white matter reflecting chronic small vessel ischemic changes. MRI of Head confirmed acute ischemic process/multifocal lacunar infarct, representing showering emboli. Given the patient's symptoms of chest pain earlier, a CT chest was ordered, indicating a thrombosed type B aortic dissection (AD). A continuous infusion of esmolol and nicardipine were initiated with a goal systolic blood pressure of 100–120.
IMPACT: Ischemic stroke presentation combined with vague cardiac symptoms should lead to investigation of the aortic arch to exclude a dissection. The case highlights the many ways that a diagnosis of AD can be delayed while a stroke presentation is being pursued.
DISCUSSION: Cerebral ischemic complications occur in 18-30% of aortic dissections. While the complications of stroke are expected in these patients, it may be difficult to evaluate further in a patient with presenting symptoms of altered mental status. Atypical chest pain should be carefully evaluated in stroke patients with a differential diagnosis including AD. Past medical history can assist in diagnosis as chronic systemic hypertension is the most common risk factor for an AD. In a retrospective study performed by Seung-J et al., analyzing 278 patients with AD, the dominance of neurological symptoms in the initial stages of presenting may make its diagnosis challenging. Ischemic strokes are the most frequent neurologic manifestation. Another complication can be if the stroke is originally found and IV thrombolysis is administered leading to disastorous outcomes. Per Seung et al., a literature review of 8 cases of patients with AD treated with full dose IV thrombolysis resulted in 3 out of 4 patients dying of hemorrhagic complications. It is fortunate that for our patient, the underlying pathology of aortic dissection was identified not too far along her clinical course and treated accordingly.

ISOLATED MONOPARESIS IN AN ADULT WITH SICKLE CELL DISEASE. Nurilign A. Bulcha. Montefiore Medical Center, Bronx, NY. (Control ID #2707616)

LEARNING OBJECTIVE #1: Diagnose strokes in adults with sickle cell disease
LEARNING OBJECTIVE #2: Recognize the mechanism of stroke in sickle cell disease
CASE: A 27 year old man presented with difficulty gra with his left hand. He had a history of Hemoglobin SC disease and a left cerebellar stroke one year prior. He was not on aspirin. Physical examination revealed a power of 1/5 on the flexor, extensor and intrinsic muscles of the left hand. Deep tendon reflexes were 3+ on the left upper extremity. The rest of the neurological exam was unremarkable. His laboratory tests revealed a white blood cell count of 11,200 and hemoglobin of 13.1 g/dl. Liver function tests, haptoglobin and serum lactate dehydrogenase were normal. An MRI of the brain revealed an acute segmental right pre-central gyrus infarct. The patient was started on aspirin and underwent red blood cell exchange transfusion.
IMPACT: Recognition of stroke and initiation of preventive therapy in adults with Sickle cell disease is essential to avoid recurrence
DISCUSSION: Strokes are frequently seen in patients with sickle cell disease and may be ischemic or hemorrhagic. Ischemic are more common with an occurrence rate of 54%. Patients with Hemoglobin S disease have a much higher risk of stroke. Baseline low hemoglobin and a high white cell count may also be associated with higher incidence of stroke in sickle cell disease. In contrast to most ischemic strokes that involve emboli affecting mostly smaller vessels, ischemic strokes in sickle cell disease involve large vessels such as the middle cerebral artery. The mechanism is not yet well understood but likely involves vascular occlusion due to intimal proliferation and thrombus formation. Sickle red cells adhere to endothelial cells through Von Willebrand's factor. Abnormalities within their membranes, then act as a pro-coagulant initiating the coagulation cascade and thrombus formation. Sickle cell disease patients with ischemic strokes are also at risk for intracranial hemorrhage due to formation of aneurysms and Moya Moya vessels which are a network of small, delicate vessels with a high risk of rupture. Due to high risk of recurrence, prevention is the main component of therapy in adults with SCD. Current guidelines recommend antiplatelet therapy. Unlike in children, however, there is a lack of evidence to support chronic transfusions for stroke prevention in adults with sickle cell disease. Our patient's presentation with isolated monoparesis is rare accounting for about 1% of all strokes. Isolated monoparesis is due to small branch vessel involvement which is very rare in sickle cell disease. It is important to recognize unusual presentations of stroke especially in sickle cell disease as treatment can prevent severe morbidities associated with recurrence. Our case also illustrates the need for further research to establish the efficacy, goals and duration of other preventive therapy including chronic transfusions in patients with sickle cell disease.

ISOLATED THROMBOCYTOSIS AND A MASS IN THE HEART
Milna Rufin; Fiyinfolu Balogun; Diana Randlett. New York University, New York, NY. (Control ID #2704760)

LEARNING OBJECTIVE #1: Recognize historical and clinical findings to diagnose Essential Thrombocythemia
CASE: An 84-year-old woman with diabetes, hypertension and hyperlipidemia presented after a 30-min episode of slurred speech, lip numbness, and confusion. She also reported 1 week of intermittent tongue and lip tingling. A complete physical exam was notably absent of neurological or cardiovascular abnormalities. She was admitted for a transient ischemic attack (TIA) with laboratory values significant for chronically elevated platelet counts of 778K. Studies of the brain and head/neck vessels were unremarkable except for a chronic cerebellar infarct. A transthoracic echocardiogram (TTE) revealed a large mobile mass in the right atrial cavity. At this time, the mass was thought to be a primary cardiac tumor with concern for a hypercoagulable state of malignancy causing the TIA or a benign mass with embolic phenomena. A repeat TTE with a bubble study showed an atrial right-to-left shunt and a subsequent transesophageal echocardiogram confirmed a 2cm shaggy mass, concerning for thrombus. With imaging studies that better characterized the mass and revealed an atrial shunt, the etiology of her TIA became more likely secondary to emboli from a thrombotic mass versus a diseased aortic arch. Her severe thrombocytosis raised the concern for a hematologic process. She was discharged on Aspirin, Statin, and Coumadin to prevent further clot formation. At hematology clinic follow up, her counts remained elevated in spite of iron supplementation. Bone marrow biopsy was deferred given the patient's age and fragility. She was empirically treated with hydroxyurea, improving platelet counts to 200K. The JAK2-V617F mutation was detected, confirming the diagnosis of Essential Thrombocythemia (ET).
IMPACT: Our case highlights the need for a thorough evaluation of platelet aberrations, which can aid in the diagnosis and treatment of disorders like ET. In our patient's case, several clinical encounters showed sustained thrombocytosis of more than 600K, without any ensuing significant etiological inquiry. Given the heightened risk for thrombotic or hemorrhagic events in patients with ET, who often have multiple comorbidities, the diagnosis is paramount to risk reduction with therapy.
DISCUSSION: ET is a myeloproliferative disorder, usually diagnosed after 60 years of age, with a female predominance. Only 1/3 of patients are symptomatic, typically with hemorrhage or thrombotic/embolic episodes like TIA. As was the case for our patient, a handful of reports have shown the formation of intracardiac thrombi in the setting of ET. The diagnosis of ET requires all four major criteria: a sustained platelet count of more than 450K; a bone marrow sample showing primarily megakaryocytic proliferation; presence of a JAK2 or MPL mutation; and no evidence of reactive thrombocytosis. Treatment is usually aimed at decreasing platelet counts to prevent thrombotic events, especially in patients with heightened risk (prior thrombosis).

IT'S GETTING HOT IN HERE: A CASE OF HEAT STROKE CAUSING HYPONATREMIA AND SUBSEQUENT RHABDOMYOLYSIS
Claire Popplewell[2]; Jennifer Verbsky[1]. [1]North Shore LIJ Health System, Great Neck, NY; [2]Northwell Health, Manhasset, NY. (Control ID #2702567)

LEARNING OBJECTIVE #1: Recognize symptoms and complications of hyponatremia and its treatment
LEARNING OBJECTIVE #2: Manage hyponatremia complicated by rhabdomyolysis
CASE: A 49-year-old man was brought to the Emergency Room in July by his family due to altered mental status. The patient had been in his usual state of health until 8 days prior to presentation when he developed headaches, dizziness, and malaise. He was initially diagnosed with a viral syndrome by his physician, but his symptoms worsened over the next few days with development of abdominal pain and nausea. On the 8th day, his family found him in

bed confused and agitated and brought him immediately to the hospital. His medical history was significant for chronic hepatitis B, for which he had been taking Viread for years. He had no significant surgical or family history. He denied tobacco, alcohol, or drug use. He worked in a local warehouse and had been working more lately due to layoffs. He did a great deal of manual labor, and the warehouse was not air-conditioned during the hot summer. He frequently skipped meals and did not stay well-hydrated at work. Upon presentation to the ER, the man was afebrile and normotensive. His physical exam was significant for agitation and inability to answer simple questions. Labwork showed a sodium level of 112, a serum osmolality of 255, and a creatine kinase (CK) level of 4338. The patient was admitted to the Medical Intensive Care Unit with a diagnosis of severe hypovolemic hyponatremia caused by heat stroke. Sodium correction was initiated, but as the patient's sodium level corrected, his CK levels rose to above 200,000. The patient's IV fluids were then changed to include both 0.045% Normal Saline and Lactated Ringers, in an effort to slowly correct his hyponatremia and manage his severe rhabdomyolysis. The patient's mental status improved with sodium correction, and CK levels improved with aggressive hydration. The patient was discharged with a sodium level of 139 and CK level of 11,405.

IMPACT: This case adds a great deal to the literature. This patient presented with hyponatremia caused by volume depletion and sweltering work environment. His medical condition was further complicated by rhabdomyolysis, which in this case was due both to the initial hyponatremia and its subsequent correction. Rhabdomyolysis is a serious complication of hyponatremia that occurs infrequently, and it is an important consideration for anyone diagnosing or treating this condition.

DISCUSSION: Hyponatremia should always be considered in a patient presenting with altered mental status. A comprehensive history can provide clues as to the etiology of the hyponatremia. Rhabdomyolysis is a complication of both hyponatremia and the correction of hyponatremia; the literature shows few case reports of this phenomenon. Fluid management is extremely important in patients with both hyponatremia and rhabdomyolysis.

IT'S TB. NO REALLY, IT'S TB! Heather Root. Emory University, Atlanta, GA. (Control ID #2706103)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of pulmonary TB.

LEARNING OBJECTIVE #2: Review the diagnostic testing for latent and active TB.

CASE: A 43 year-old woman presents following an assault is incidentally found to have bilateral upper lung field cavitary lesions. She reported 10-months of productive cough without hemoptysis and 30-pound weight loss over the 8 months prior. TB risk factor exposure included homeless shelters and prison. She reported a negative PPD, 30 pack-years tobacco, everyday beer drinker and past cocaine use. Non-contrast chest CT showed multiple bilateral upper lung nodular opacities (some cavitary) and a large mediastinal node. AFB sputum stain x3, PPD, quantiferon gold, MTB-PCR sputum and HIV tests were negative. ID was consulted. She underwent bronchoscopy and biopsy of the LN. Cytology was negative for malignancy and showed non-necrotizing granulomatous inflammation; AFB and GMS stains were negative. Despite negative testing, given the high suspicion for TB, the patient was discharged to a TB hotel on RIPE therapy. All AFB cultures remained no growth except for one positive for mycobacterium avium complex.

IMPACT: This case highlights the challenges and complexity of diagnosing TB. Even after sending off many diagnostic tests, we were unable to confirm the clinical suspicion for TB. In the end, clinical judgment in the setting of years of experience dictated the presumed diagnosis and thus treatment.

DISCUSSION: TB is a communicable infectious disease transmitted by cough aerosol, caused by the *Mycobacterium tuberculosis* complex, and characterized pathologically by necrotizing granulomas. Presenting symptoms include fever, weight loss, drenching night sweats, productive cough, and sometimes hemoptysis. Classic imaging shows unilateral upper zone infiltrates, often with cavitation. Diagnosing latent TB cannot be made with certainty. The likelihood of latent TB is inferred via skin tests (e.g. TST) or blood assays (e.g. Quantiferon Gold). Neither test can distinguish latent from active TB. A positive result might signify active TB, previous TB, recent or remote exposure, latent TB, or exposure to specific environmental mycobacteria. One should target screening of high-risk groups - people with HIV, in shelters or in/from high prevalence settings, prisoners, close contacts. Despite suboptimum sensitivity (50%), smear microscopy is the standard of care in most settings. Same-day microscopy of 2 specimens is recommended. Automated liquid culture is regarded as the gold standard diagnostic confirmatory test. Nucleic acid amplification tests are other confirmatory tests that are fairly expensive, miss roughly one-third of smear-negative cases, perform poorly in some forms of extrapulmonary TB, and are not ideal point-of-care tests. This case highlights testing for TB and how the clinical presentation can be diagnostic as well. Despite all negative tests, ID specialists felt that her overall clinical picture was strongly suggestive of active TB and should therefore be treated as such.

JUST A BAD CASE OF PSORIASIS? Erick Oran; Danit Arad. Montefiore Medical Center, Bronx, NY. (Control ID #2705836)

LEARNING OBJECTIVE #1: Identify the differential diagnosis of rupioid rash associated with arthritis

LEARNING OBJECTIVE #2: Recognize challenges associated with treatment of psoriatic arthritis

CASE: A 41-year-old man with psoriasis, untreated latent tuberculosis and renal cell carcinoma status post resection two months ago presented with two weeks of diffuse large joint pains and worsening rash. The patient had applied topical corticosteroids without significant improvement for the last six weeks. He had no fevers, chills or sick contacts. He had lost two or three pant sizes in the last six months. He was afebrile and normotensive. He appeared cachectic. His scalp, back and abdomen exhibited patchy erythema diffuse scaly plaques. Both arms and legs were covered with hyperkeratotic, rupioid brown plaques. His nails showed onychomadesis. Labs revealed leukocytosis, microcytic anemia and elevated alkaline phosphatase. CT imaging revealed collection at nephrectomy surgical site and multiple hepatic lesions. Follow up imaging showed no evidence of metastatic disease. Final skin biopsy showed confluent mounds of parakeratosis and psoriasiform epidermal hyperplasia consistent with psoriasis. Patient was started isoniazid and discharged on methotrexate with rheumatology follow up.

IMPACT: Joint pain and skin rashes are common conditions encountered in the realm of general medicine. This case illustrates the importance of considering a broad differential given this particular patient's comorbidities and severity of rash. Furthermore, it highlights some of the limitations of current available treatments and controversies around the use of systemic corticosteroids.

DISCUSSION: Psoriatic arthritis affects as many as 2 per 1000 in the general population. The hallmark of disease consists of psoriasiform lesions plus a combination of arthritis, enthesitis, dactylitis and nail disease. Psoriasis precedes the onset of psoriatic arthritis in 60-80% of patients. Based on physical exam alone, psoriatic flares can be indistinguishable from other severe inflammatory dermatoses, such as acrokeratosis neoplastica, disseminated histoplasmosis and secondary syphilis. Hence, the gold standard for diagnosis remains a 4mm punch biopsy looking for parakeratosis, neutrophils in the stratum corneum and thinning of the supra-papillary dermal plates. Once appropriately diagnosed, treatment will differ based on the severity of dermato-articular disease and comorbidities. Mild disease can be managed with nonsteroidal anti-flammatory drugs and topical steroids. Moderate to severe disease requires the use of conventional disease modifying antirheumatic drugs (DMARD) and tumor necrosis factor (TNF) inhibitors if disease persists. The use of anti-TNF agents, however, requires screening for latent tuberculosis and are relatively contraindicated with active malignancy. Systemic steroids are reserved for severe flares unresponsive to conventional or biologic DMARDs as prompt discontinuation of steroids may trigger a severe erythrodermic psoriasis flare.

KAPOSI SARCOMA WITH PULMONARY MANIFESTATION: A DISSEMINATED PRESENTATION SUMAIRA ZAREEF MD, DIPEN KHANAPARA MD, PRANAV PATEL MD. Sumaira Zareef. Montefiore Medical Centre, Bronx, NY. (Control ID #2704331)

LEARNING OBJECTIVE #1: Recognize pulmonary presentation of Kaposi sarcoma (KS) in Acquired Immune Deficiency Syndrome (AIDS)-related complex.

LEARNING OBJECTIVE #2: Recognize steroid use can cause worsening of the KS in AIDS.

CASE: A 53 year-old woman with AIDS was admitted for altered mental status, fever, hemoptysis, and cough. She was not adherent to anti-retroviral medication and had CD4 count of 9 cells/µl. Physical examination was significant for multiple scattered small brown/violaceous nodules extending all over the body. Her initial blood gases were significant for PaO2 on room air of 52 mmhg. In view of bilateral nodular opacities in chest X-ray, empiric treatment with antibiotics and steroids were initiated. CT chest revealed bilateral nodules and mass-like opacities. Microbiology including sputum for acid fast bacilli and blood and urine cultures were unremarkable. Skin lesion biopsy was positive for KS. Steroids were discontinued; however she did not improve clinically despite appropriate anti-microbial coverage. CT-guided biopsy of pulmonary nodules revealed disseminated KS. She developed acute respiratory distress syndrome (ARDS) followed by alveolar hemorrhage.

IMPACT: Clinicians should have a high suspicion for pulmonary KS in patients with AIDS with skin lesions along with radiological findings of reticulonodular opacities. It is also important to consider the fact that treatment with steroids causes rapid progression of KS.

DISCUSSION: Pulmonary malignancies contribute significantly to morbidity and mortality in HIV-infected individuals. KS and pulmonary lymphoma are the two most common AIDS-defining lung malignancies. Overall, KS is the most prevalent AIDS-defining malignancy. KS is a micro-vascular tumor derived from lymphatic endothelium, which progresses from an early patch stage to tumor nodules. It originates due to uncontrolled expression of latency genes of Human Herpesvirus-8. Ninety percent of KS lesions are cutaneous, but it can involve any site in the body in advanced stage. KS has been seen to involve heart, pericardium, lung, bone marrow, GI tract, and other viscera. Pulmonary KS is rare, but can be indistinguishable from other AIDS-related infections. Pulmonary KS generally appear as reticulonodular opacities (often described as flame shaped lesions), hilar adenopathy, peripheral infiltrates, and pleural effusions on chest imaging. Steroid use in PCP has showed mortality benefit, but KS is one of the conditions that have been identified to rapidly progress with steroid use. Thus it is very crucial to avoid steroid use when clinical suspicion for KS is high. Advanced broncho-pulmonary involvement in KS often leads to fatal alveolar hemorrhage, as seen in our patient. Overall, KS has high malignant potential with short median survival times. Liposomal anthracyclines and paclitaxel are used as therapeutic options for advanced disease.

KEEP AN EYE OUT FOR THIS GRAVE DIAGNOSIS! Katherine Baker[1]; Ryan Nall[2]. [1]University of Florida, Gainesville, FL; [2]University of Florida, Gainseville, FL. (Control ID #2705328)

LEARNING OBJECTIVE #1: Recognize the diverse presentation of thyroid orbitopathy

CASE: A 49yo male with no significant PMHx presented with a 3-week history of painful left proptosis, periorbital edema, and conjunctival chemosis. Pt noted paint splashing into eyes prior to onset of symptoms. Prior to admission, patient was prescribed oral antibiotics and switched to steroid eye drops due to lack of improvement. At the time of admission, ROS was positive for blurred vision and watery discharge and negative for fever, weight gain or loss, constipation, or diarrhea. FHx was non-contributory. Physical exam showed bilateral periorbital edema, conjunctival erythema, and severe chemosis of left eye extending 270° with bulging towards the cornea. EOM were intact. Visual acuity was 20/20 OD, 20/40 + 2 OS and there was no loss of color vision. CT orbit performed at OSH showed preseptal and postseptal tissue swelling with inflammatory changes along the superior rectus muscle of both orbits with greater involvement of the left. TSH was elevated at 77.40mIU/L, free T4 was low at 0.66ng/dL and free T3 was elevated at 9.7pg/mL.

IMPACT: This patient with significant asymmetric eye involvement and lack of clear hyperthyroidism demonstrates a unique presentation of thyroid orbitopathy. This led us to consider a differential diagnosis of unilateral proptosis including orbital cellulitis, orbital pseudotumor, and other neoplastic processes as opposed to thyroid orbitopathy. Accordingly, this case contributes to the understanding of the diverse presentation of thyroid orbitopathy.

DISCUSSION: Thyroid orbitopathy has an annual incidence rate of 16 women and 3 men per 100,000 population. The condition generally occurs in hyperthyroid patients but can sometimes occur in patients with euthyroid or chronic autoimmune thyroiditis. The 5% of patients who are euthyroid or hypothyroid generally have low titers of anti-thyrotropin-receptor antibodies which can be difficult to detect in some assays. Euthyroid Grave's disease is the presence of thyroid orbitopathy in patients with thyroid hormone levels within normal limits and no prior treatment for hyperthyroidism. However, with further examination, most of these patients can be shown to have some degree of thyroid dysfunction and are also more likely to manifest eye disease before hyperthyroidism. While thyroid orbitopathy typically is bilateral, unilateral eye disease occurs in 5-14% of patients. However, in 50- 90% of these patients CT demonstrates contralateral eye muscle involvement. Unilateral eye involvement is important because it requires rapid exclusion of other causes of unilateral proptosis, many of which

are neoplastic in nature. In contrast to true unilateral disease, asymmetric eye involvement is common occurring in 22% of patients. However, a proptosis distance greater than 6mm should raise concern for a space-occupying lesion. In summary, thyroid orbitopathy is a condition with a diverse presentation both in terms of thyroid function testing and laterality.

KEEPING ABREAST OF ATYPICAL BREAST CANCER

Muddasir Ayaz[1]; Amy Weil[2]. [1]UNC Chapel Hill, Raleigh, NC; [2]UNC Chapel Hill School of Medicine, Chapel Hill NC, NC. (Control ID #2688176)

LEARNING OBJECTIVE #1: Review the epidemiology and presentation of breast cancer in men

LEARNING OBJECTIVE #2: Recognize the value of the physical exam in the work-up of breast cancer

CASE: Clinicians emphasize early detection of breast cancer in women, but the disease occurs in both men and women, and early recognition in men can also be vital to identifying appropriate therapy. A 55 year-old man with a history of hypertension, factor V Leiden, deep vein thrombosis, anxiety, and drug dependence presented with left chest and neck pain for six months following a motor vehicle collision. His chest wall was tender to palpation. He denied any exertional pain, dyspnea, fevers, weight loss, or GI symptoms. His exam revealed a hyperpigmented plaque with raised borders extending from the left sternoclavicular joint down to the fourth intercostal space, extending laterally to the midaxillary line. Two irregular masses were palpated on the left breast. No nipple discharge or lymphadenopathy was noted. Labs were unrevealing. His ultrasound revealed two irregular high density masses in the left breast and axilla measuring $6x1x1cm^3$ with internal vascularity. Biopsy and immunohistochemical staining revealed CD-20(+) and Bcl-2(+) with a high Ki-67 proliferative index suggestive of a mature B-cell lymphoma consistent with nHL (non-Hodgkin lymphoma). Cervical MRI revealed lymphadenopathy at C5. PET/CT revealed a left anterior chest wall mass with diffuse lymphadenopathy. The patient started chemotherapy for Stage III nHL of the breast with six cycles of R-bendamustine and restaging for further evaluation.

IMPACT: The case emphasizes the need for clinicians to be keenly aware of the possibility of breast cancer in men and diagnose the condition early to facilitate treatment. It also underscores the role of the physical exam in initiating diagnosis of life-threatening diseases.

DISCUSSION: Less than 1% all breast cancer diagnosed in the U.S. occurs in men. Risk factors include a strong family history of breast cancer, conditions with abnormal estrogen-to-androgen ratios (such as Kleinfelter syndrome or obesity), radiation exposure, age, sedentary lifestyle or exposure to volatile organic compounds. Due to lack of systematic screening, clinicians often diagnose male breast cancer at an advanced stage. It often presents with painless, firm, sub-areolar masses or lumps with bloody discharge in about half of all cases. Breast masses in men have a wide differential, including cysts, abscesses, gynecomastia or lipomas. In many cases, treatment comprises mastectomy with or without radiation or systemic antihormonal therapy. This patient's primary nHL of the breast is exceedingly rare, given the lifetime probability of nHL in men is near 2 and breast invasion represents only up to 0.5% of all breast cancers. No available data exists to measure the incidence of nHL of the breast especially in men and most literature on nHL of the breast is through various case series and case reports, making its prognosis and natural history poorly defined.

KIKUCHI DISEASE PRESENTING AS NEUTROPENIC FEVER OF UNKNOWN ORIGIN

David Olshan[2]; Emily Fessler[1]; Nancy Aitcheson[1]. [1]Hospital of the University of Pennsylvania, Philadelphia, PA; [2]University of Pennsylvania, Philadelphia, PA. (Control ID #2706529)

LEARNING OBJECTIVE #1: Appreciate the role of tissue diagnosis in fever of unknown origin

LEARNING OBJECTIVE #2: Recognize the clinical presentation of Kikuchi disease

CASE: A 33-year-old previously healthy woman presented with 3 months of intermittent fevers, night sweats, and hand stiffness. She had no sick contacts, family history of autoimmune disease, or relevant travel or exposures. During two recent admissions an extensive infectious, rheumatologic, and hematologic workup was only notable for neutropenia and mildly elevated erythrocyte sedimentation rate (ESR). Autoimmune serologies were negative, HIV was nonreactive, and EBV panel was consistent with prior infection. A bone marrow biopsy was unremarkable. A bronchoscopy with biopsy, obtained given small ground glass nodules on chest CT, showed normal lung parenchyma. The patient was re-admitted after spiking high fevers now associated with tender cervical lymphadenopathy. Her absolute neutrophil count fell to 380/mm3 and she was placed on empiric cefepime. Culture data was negative. Differential included rheumatologic disorders (e.g. seronegative-systemic lupus erythematosus (SLE)), primary hematologic disorders (e.g. Castleman's Disease, cyclic neutropenia), or malignancy. An excisional cervical lymph node (LN) biopsy was performed. In addition, review of her bone marrow slides showed a minute non-necrotizing granuloma. The patient was therefore started on prednisone with a provisional diagnosis of sarcoid. After discharge, LN biopsy revealed necrotizing histiocytic lymphadenitis consistent with Kikuchi disease.

IMPACT: In this case, multiple tissue samples were obtained before reaching a final diagnosis. A LN biopsy was ultimately key to finding a unifying explanation for the patient's symptoms. Her clinical course underscores the value of tissue diagnosis, particularly when a) symptoms are protracted and debilitating, b) extensive non-invasive workup is unrevealing, and c) life-threatening conditions (e.g. malignancy) remain high on the differential.

DISCUSSION: Kikuchi-Fujimoto disease is a rare, generally benign disease of unknown etiology. Clinical presentation is characterized by tender lymphadenopathy but can otherwise vary; common findings include fever, leukopenia, high ESR, and anemia[1]. It usually self-resolves within 1–4 months[2]. Epidemiologically, Kikuchi is diagnosed most often in Asian women under age 40[2,3]. It may be precipitated by prior EBV infection, though this remains controversial. In addition, a subset of patients with Kikuchi disease may develop SLE suggesting possible autoimmune etiology[2]. Diagnosis requires histopathologic confirmation via excisional LN biopsy: involved nodes show characteristic necrotic foci with karyorrhectic debris and surrounding histiocytes[2,3]. Tissue pathology allows for alternative diagnoses, namely SLE, viral infection, and lymphoma, to be excluded[3].

KILL TWO BIRDS WITH ONE STONE

Nabil Mesiha[2]; Stephen Tieku[3]; Naresh Nagella[4]; Pirouz Parang[1]; Daniel Goldsmith[1]. [1]Capital Health Regional Medical Center, Trenton, NJ; [2]Capital health Regional Medical Center, Trenton, NJ; [3]Capital Health Medical Regional Center, Trenton, NJ; [4]Robert Wood Johnson University, New Brunswick, NJ. (Control ID #2697439)

LEARNING OBJECTIVE #1: To demonstrate that aquired vWD (Heyde syndrome) due to any cause of shear stress blood flow, can be a cause of recurrent GI bleeding.

LEARNING OBJECTIVE #2: To be aware that routine screen for aquired vWD is not diagnostic,and more detailed laboratory testing should be considered for diagnosis.

CASE: Acute lower GI bleeding is a medical and potentially surgical emergency, requiring urgent attention of the treating team. Management includes resuscitation with intravenous crystalloids and blood products. After stabilization, it is mandatory to find the bleeding source. We report one case of recurrent GI bleeding found to be from angiodysplasia, secondary to a cardiac cause. A 71 year old woman with history of paroxysmal atrial flutter, hypertrophic cardiomyopathy, and transient ischemic attack, was admitted three times in one year with massive GI bleeding and severe symptomatic anemia, requiring multiple blood transfusions. During the first admission the patient was on rivaroxaban for atrial flutter. A GI work up, including upper GI endoscopy, colonoscopy, and capsule endoscopy showed duodenal angiodysplasia. Rivaroxaban was discontinued, and after a period of time with no bleeding, she was placed on warfarin. A few months later, she had another lower GI bleed. At that time, upper and lower endoscopy found no significant abnormality. Warfarin was discontinued, but she had a third massive lower GI bleed, despite cessation of anticoagulants. Echocardiogram showed moderate concentric left ventricular hypertrophy with normal EF, and hematological evaluation showed high partial thromboplastin time (PTT). Routine testing for von Willebrand disease(vWD) was normal. The patient was sent to a tertiary center for a left ventricular myomectomy, maze procedure, and left atrial appendage excision. After surgery PTT was normal. She resumed anticoagulants and is currently in good health in outpatient care. For the last 8 months, she has not had any further episodes of bleeding.

IMPACT: Recurrent GI bleeding in patients with a clinical reason for turbulent blood flow should undergo more detailed laboratory testing for acquired vW factor deficiency than the routine screen

DISCUSSION: Heyde syndrome is a triad of acquired vWD, aortic stenosis, and bleeding from intestinal angiodysplasia. The mechanism of bleeding is from degradation of vW factor multimers by shear stress through the diseased aortic valve leading to significant blood loss through areas of angiodysplasia. We postulate that hypertrophic cardiomyopathy, or any cause of shear stress of blood flow similar to aortic stenosis, is another condition which may be associated with acquired vWD. Definitive management of GI bleeding in the setting of Heyde syndrome should be directed to the cause of turbulence of the blood flow inside or outside the heart. Routine screening tests for acquired vWD are usually normal, therefore to confirm acquired vWD a gel electrophoresis is required..

LARYNGEAL ACTINOMYCOSIS CAUSING AIRWAY OBSTRUCTION REQUIRING INTUBATION, MECHANICAL VENTILATION, AND TRACHEOSTOMY Fahad Juboori[1]; Jannatun Sikder[2]; Kayur Shah[1]. [1]NY Presbyterian Brooklyn Methodist Hospital, Jersey City, NJ; [2]New York Medical College, Valhalla, NY. (Control ID #2707258)

LEARNING OBJECTIVE #1: Recognize the risk factors for actinomycosis infection.

LEARNING OBJECTIVE #2: Recognize actinomycosis as a common infection in the head and neck region with atypical presentations.

CASE: A 55-year-old female with a medical history of uncontrolled type II diabetes mellitus, polymyositis, and coronary artery disease presented with low grade fevers, odynophagia, dysphagia, and dysphonia that was worsening over the past three weeks. She is a non-smoker and does not drink alcohol. On presentation, she was noted to have a hoarse voice. She was afebrile, saturating 100% on room air, and vitals were within normal limits. Physical exam was negative for oropharyngeal erythema, lymphadenopathy, and thyromegaly. Her labs were notable for a leukocytosis of 13.2 and ESR of 110. Initial laryngoscopy revealed a 1.5 mm, adherent, white supraglottic mass over the left true vocal cord grossly suggestive of malignancy. CT of the neck revealed a heterogeneous collection of air, soft tissue, and fluid extending from the epiglottis to the vocal cord with an air-filled tract from the larynx to the esophagus. She was empirically started on IV clindamycin. The next morning, she developed stridor with dyspnea requiring supplemental oxygen. Repeat laryngoscopy revealed partial airway obstruction requiring emergent intubation and subsequent tracheostomy. Pathology results from the biopsy demonstrated extensive acute necrotizing soft tissue with ulceration, polymicrobial overgrowth, and filamentous organisms with sulfur granules suggestive of actinomyces. No malignant cells were identified. Antibiotics were switched to ampicillin-sulbactam with significant improvement in mass size on repeat laryngoscopy.

IMPACT: This case provides an atypical presentation of a classic head and neck infection. Actinomycosis usually manifests in three ways: cervicofacial, abdomino-pelvic, or pulmonary. Laryngeal actinomycosis is rare. Actinomycosis has a long-standing reputation of being the great masquerader of head and neck disease. This comes from its ability to mimic malignancy, its chronic course, and due to its lack of familiarity to many clinicians.

DISCUSSION: Actinomycosis is a disease mainly caused by Actinomyces israelii, which is a gram positive, non-spore forming, anaerobe. It is a normal constituent of the oral cavity and is found within gingival crevices and tonsillar crypts. Risk factors for infection include poor oral hygiene, diabetes mellitus, immunosuppression, malnutrition, and local tissue damage. Due to its nonspecific presentation, it is often missed or commonly mistaken for malignancy. Actinomyces has the ability to invade fascial planes and create draining sinus fistulas. In this patient, it presented as a mass on the larynx and progressed to airway obstruction requiring intubation. Laryngoscopy with biopsy would be ideal for definitive diagnosis, as it is a potentially curative disease process. The drug of choice is penicillin, with tetracyclines and clindamycin as an alternative.

LEFT MANDIBULAR PAIN: A RARE INITIAL SYMPTOM OF ACUTE AORTIC DISSECTION WITHOUT CORONARY OBSTRUCTION Masaki Tago; Naoko E. Furukawa; Hidetoshi Aihara; Shu-ichi Yamashita. Saga University Hospital, Saga, Japan. (Control ID #2673549)

LEARNING OBJECTIVE #1: Recognize mandibular pain as a possible initial symptom of acute aortic dissection without myocardial ischemia.

CASE: An 88-year-old woman with chronic kidney disease and mild cognitive dysfunction experienced sharp pain in the left mandible for a few min 3 days prior to hospital presentation. At 4:00 am on the day of hospital presentation, the patient experienced sudden pain for more than an hour with a feeling of stiffness in the left mandible, cold sweating, nausea, vomiting and blurred vision, which left her unable to stand. On arrival at 5:30 am, there was only mild discomfort ranging from the left mandible to the neck, without definite pain. Physical examination revealed normal findings without tenderness from the left mandible to the neck. The laboratory findings revealed renal dysfunction (BUN 40.3 mg/dL, Cr 4.1 mg/dL), anemia (Hb 8.5 g/dL), and elevated aspartate aminotransferase (58 U/L), alkaline phosphatase (878 U/L) and C-

reactive protein (6.00 mg/dL). Chest radiography showed heart enlargement and a widened mediastinum. Electrocardiography did not show ST segment elevation or depression. Chest and neck computed tomography revealed cardiac effusion and slightly attenuated lesions in the vascular walls of the ascending and proximal aortic arch, brachiocephalic artery and left common carotid artery. Thus, an acute aortic dissection of Stanford type A was diagnosed. Surgical reparation of proximal cervical vascular and hemi-arch replacement was performed. The coronary arteries were found to be intact without myocardial infarction.

IMPACT: What does this case add to the literature? This case adds that mandibular pain is one of the first complaints of aortic dissection without obstruction of coronary arteries. Mandibular pain can be the only symptom of aortic dissection.

DISCUSSION: From 4-6% of acute aortic dissection occurs without any pain. The present case is the first presentation in which the patient had mandibular pain as the first complaint of aortic dissection without any chest or back pain, syncope, heart failure, cerebral infarction, or neurologic symptom. The mandibular pain was considered to be radiating pain elicited by the aortic dissection. Recurrent branches running around aortic arch, which contains visceral afferent fibers carrying sensory information from chest and abdominal organs, could be the route of radiating pain caused by an aortic dissection and cardiac diseases. Complaints, symptoms, and physical findings of elderly people can be atypical and elusive because of their impaired cognitive function, though the morbidity and mortality of them are higher. When seeing elderly patients, physicians should take possible keywords, such as "sudden", into serious account.

LEMIERRE'S SYNDROME: A POTENTIALLY DEADLY SORE THROAT Samir Bhalla[2]; Sara Stream[2]; Kevin Hauck[1]. [1]NYU Langone Medical Center, Brooklyn, NY; [2]NYU School of Medicine, New York, NY. (Control ID #2706346)

LEARNING OBJECTIVE #1: Recognize the clinical features and complications of Lemierre's syndrome.

CASE: A healthy 25-year-old male presented with 8 days of progressively worsening sore throat, fever and neck swelling which were unresponsive to 2 outpatient courses of clarithromycin. On presentation, he was febrile, tachycardic, hypotensive, tachypneic and hypoxic. Physical examination was significant for a palpable left-sided neck mass, trismus, and muffled voice. Initial labs revealed a white blood cell count of 26k, creatinine of 1.9mg/dL, and serum lactate of 4.5mg/dL. The patient was intubated for airway protection, and started on antibiotics and vasopressors. Ultrasound and CT imaging revealed left tonsillar, peritonsillar, and sublingual abscesses, pulmonary septic emboli, bilateral parapneumonic effusions and left internal jugular (IJ) thrombus. Wound cultures of left tonsillar abscess grew *Fusobacterium necrophorum* and antibiotics were narrowed to piperacillin-tazobactam. He underwent left IJ ligation and left lower lobe lobectomy, and gradually improved and was discharged home on a prolonged course of antibiotics.

IMPACT: Lemierre's syndrome is a potentially fatal disease that can cause rapid decompensation if untreated. When a young adult presents with worsening symptoms of acute pharyngitis, one must have a high suspicion for this disease in order to diagnose and treat it early.

DISCUSSION: Lemierre's syndrome is a rare and serious disease entity that primarily affects healthy young adults with an incidence of 1 in 1 million and a mortality rate of 4-12%. It involves oropharyngeal fusobacterium infection that can form abscesses and internal jugular thrombophlebitis. IJ thrombophlebitis results in bacteremia with septic emboli, commonly to the lungs and joints. The prevalence of Lemierre's syndrome has been rising in recent years due to more judicious use of antibiotics for acute pharyngitis.[2] This is also attributed to rising resistance of *fusobacterium* to macrolides that are often prescribed for pharyngitis, as illustrated by our patient who was initially treated with clarithromycin.

LESSON LEARNED FROM A CASE OF MULTIPLE SYSTEM ATROPHY Julie Worthington[1]; Charis Whitney[1]; Himabindu Lanka[1]; Chris Yeisley[2]. [1]Pinnacle Health System, Hummelstown, PA; [2]Pennsylvania State University College of Medicine, Hershey, PA. (Control ID #2706387)

LEARNING OBJECTIVE #1: Recognize multiple system atrophy in a patient already diagnosed with Parkinson's disease.

CASE: A 60 year old female with past medical history of Parkinson's disease was admitted to the hospital. Earlier the same day, she felt so fatigued that she was unable to stand. She admitted to not taking her prescribed fludrocortisone and midodrine. On exam, she had significant orthostatic hypotension (systolic blood pressure 160 millimeter of mercury while sitting versus systolic blood pressure 94 millimeter of mercury upon standing). Complete blood count and basic metabolic panel were within normal limits. Magnetic resonance imaging of the brain was stable and did not show any signs of atrophy.

IMPACT: Multiple system atrophy is a progressive neurodegenerative disorder with dysautonomia and abnormal movement. Presenting symptoms of multiple system atrophy, especially in the early stages, are similar to Parkinson's disease, making multiple system atrophy difficult to diagnose. During her hospital stay, she was found to have increased urinary frequency, urinary incontinence, impaired balance, tremor, and unconscious movements. Therefore, her initial diagnosis of Parkinson's disease was changed to multiple system atrophy. Her lightheadedness improved, so she was discharged to a skilled nursing facility for rehabilitation with a new diagnosis of multiple system atrophy.

DISCUSSION: This case demonstrates the difficulty in distinguishing Parkinson's disease from multiple system atrophy. Initially, the patient was diagnosed with Parkinson's disease and failed treatment with carbidopa-levodopa. On this presentation, she had increased urinary frequency and worsening hypotension. This presentation of parkinsonism, urinary incontinence, and hypotension is consistent with a diagnosis of multiple system atrophy, the parkinsonian type.

LET IT BLEED A CASE OF ACQUIRED HEMOPHILIA Margaret Zupa; Amar Kohli; Anita B. Lyons. UPMC, Pittsburgh, PA. (Control ID #2691942)

LEARNING OBJECTIVE #1: Identify at least 3 differential diagnoses for prolonged PTT

LEARNING OBJECTIVE #2: Determine the most appropriate initial laboratory workup for patients with spontaneous soft tissue hemorrhage

CASE: A 63 year old man with history of retroperitoneal fibrosis presented with acute left groin pain without trauma. Exam was notable for swollen left thigh, 2/5 strength in left hip flexion, and reduced sensation over medial and anterior thigh. CT scan showed left psoas mass, consistent with hemorrhage versus abscess. He had no fevers or leukocytosis. Labs revealed prolonged PTT to 69.5s with normal PT/INR. He denied easy bleeding or bruising and his only medication was aspirin. Records showed his PTT had been normal six months prior. A

mixing study failed to correct the PTT, suggesting the presence of a factor inhibitor. Recombinant factor VIIa was immediately started for acute bleeding and his aspirin was held. Further labs showed presence of Factor VIII inhibitor and he was treated with prednisone and cyclophosphamide long-term. His weakness improved and follow-up imaging showed resolving psoas hematoma.
IMPACT: This case changed my thinking about causes of spontaneous hemorrhage and the significance of an isolated prolonged PTT. My workup will now be focused on two branch points in diagnosis: type of coagulation abnormality (PT/INR, PTT or both) and the mixing study. This will facilitate prompt diagnosis of the defect in the coagulation cascade while avoiding unnecessary testing.
DISCUSSION: The differential diagnosis for isolated prolonged PTT includes hemophilia A and B, Von Willebrand disease, presence of a clotting factor inhibitor (acquired hemophilia), antiphospholipid antibodies (APLA) and heparin use. A mixing study measures coagulation time after a patient's blood is mixed with normal plasma. If clotting factors in the normal plasma do not correct the prolonged coagulation time, it suggests the presence of a factor inhibitor, APLA, or heparin. These diagnoses can be differentiated by measuring factor and inhibitor levels, the dilute Russell viper venom time for APLA, reptilase time to detect heparin, and the clinical presentation. Acquired hemophilia is a rare disorder with incidence estimated at 1 per million, most frequently due to an inhibitor of factor VIII. Usual onset is in women postpartum and in patients aged 68–80. Half of patients have an underlying cause including autoimmune disease, malignancy, infection and medications. Acquired hemophilia differs from congenital hemophilia in that patients with acquired inhibitors often present with spontaneous bleeding into soft tissue, muscle, or GI tract. In contrast, patients with congenital hemophilia due to factor deficiency present with hemarthroses of large joints. Treatment for acquired hemophilia involves acute therapy with recombinant factor VIIa and long-term therapy to eradicate the inhibitor with immunosuppression, most commonly prednisone and cyclophosphamide.

LET'S TAKE A PAUSE: A CASE OF SEVERE VASOVAGAL SYNCOPE

Amy D. Lu[2]; Jamie L. Stern[1]. [1]University of Pittsburgh, Pittsburgh, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2706703)

LEARNING OBJECTIVE #1: Utilize tilt table testing (TTT) appropriately in the diagnosis of syncope.
LEARNING OBJECTIVE #2: Recognize clinical indications for pacemaker placement for cardioinhibitory syncope.
CASE: A 25 year-old previously healthy female presents to the office with a dramatic episode of syncope. The episode occurred after exercise and her boyfriend, who witnessed the event, described it as her "eyes suddenly rolled back and she fell to the floor." She was noted to have posturing of her upper extremities and cyanosis of her lips. She regained consciousness within min and denied loss of bowel or bladder function. She did not exhibit any significant confusion. She denies prolonged fasting, dehydration, or any recent illness. She is otherwise healthy and takes no medications. She does admit to prior episodes of syncope preceded by prodromal lightheadedness. Family history is negative for sudden cardiac death, arrhythmia, early CAD, or cardiomyopathy. Orthostatic vital signs and physical exam were unremarkable. Laboratory studies including complete blood count and complete metabolic panel were within normal limits. Urine pregnancy test was negative. Electrocardiogram showed normal sinus rhythm without ischemia or arrhythmia. Transthoracic echocardiogram was normal. Tilt table testing resulted in rapid slowing of heart rate with a 20 second asystolic pause with reproducible syncope and tonic-clonic movements. Once returned to a supine position, she returned to a slow junctional rhythm at 40bpm which increased back to normal sinus rhythm of 80bpm. She eventually underwent placement of permanent pacemaker at the advice of her cardiologist.
IMPACT: This case highlights clinical considerations for pursuing TTT in the workup for suspected vasovagal syncope as well as indications for pacemaker insertion for cardioinhibitory vasovagal syncope.
DISCUSSION: Vasovagal syncope is the most common cause of syncope in the general population and can divided into three types of responses: cardioinhibitory, vasodepressor, or mixed. While cardioinhibitory response with asystole is rare, it is associated with more severe symptoms, physical injury, and recurrence. Tilt table testing is indicated in cases of unexplained syncope with questionable neurogenic features but without presence of organic heart disease. TTT has a sensitivity of 78–92 and specificity of 87–92%. An asystolic response provoked during testing is indicative of asystole occurring during spontaneous syncope with a positive predictive value of 75–80%. Patients with severe, recurrent cardioinhibitory syncope who are >40 years of age may benefit from pacemaker placement, though the effectiveness of pacing in preventing episodes of syncope remains unclear, especially in younger individuals <40 years of age. The optimal diagnostic tool to guide pacemaker insertion is also debated as implantable loop recorders enable identification of asystole during spontaneous syncope but may not be as cost effective as TTT.

LEUKOCYTOCLASTIC VASCULITIS AND COLONIC INVOLVEMENT

Manisha shastry[1]; Jill Elwing[2]; Marc Levin[2]; Detlef Ritter[3]. [1]Mercy hospital, St.louis, MO; [2]VA.St.louis health care system, St.Louis, MO; [3]St.Louis Va health care system, St.Louis, MO. (Control ID #2708692)

LEARNING OBJECTIVE #1: Leukocytoclastic vasculitis(LV) is a type of vasculitis that is characterized by transmural inflammation of blood vessels associated with fibrinoid necrosis of the vessel wall. It usually presents with cutaneous manifestations. There is paucity of literature of LV involving gastrointestinal tract(GI). This is a case describes vasculitis of GI tract with a brief review of manifestations.
CASE: A 63-year-old man was admitted with syncope and hematochezia of 3 days duration. His past medical problems include hypertension, congestive heart failure, diabetes mellitus, chronic eosinophilia, chronic osteomyelitis, venous insufficiency and cutaneous LV. Diagnostic workup showed an elevated ESR, CRP, CCP, ASO. Serologic studies including ANCA, ANA, ANTI-GBM, RF, cryoglobulins and stool studies were negative. Colonoscopy showed a large clean-based ulcer with ischemic features in the descending colon. Biopsy of the lesion was significant for mucosa with focal ulceration with predominant neutrophilic and eosinophilic infiltration. Differentials included systemic LV, infection, and drugs. CTA was negative for any large vessel involvement. He was started on prednisone for possible systemic vasculitis, given the negative workup and noticed resolution of symptoms in few days.
IMPACT: There have been very few cases of vasculitis involving GI tract, vasculitis should be in the differential diagnosis especially in a patient with rash and GI manifestations. There is no clear data about what dose of steroids is

used and for how long, often a multi-disciplinary approach is required, treatment is decided on case by case basis.Further studies are required on this uncommon condition.

DISCUSSION: LV is mainly a cutaneous disorder with rare Gastrointestinal (GI) manifestations. GImanifestations can vary from abdominal pain, nausea, vomiting, hematochezia, more serious presentations include ischemic colitis, acute diverticulitis and toxic megacolon. Vasculitis should be considered in the differential in a patient with GI symptoms and cutaneous rash. Common causes such as infections, drugs, other autoimmune disorders should be ruled out. In our patient, there was a high suspicion for LV involving the GI tract considering all the negative work up. Treatment usually involves steroids, refractory cases biologics and in severe or acute cases surgery may be required. Prompt diagnosis and treatment with steroids or biological agents could decrease the mortality and morbidity.

LEUKOCYTOCLASTIC VASCULITIS IN AN INJECTION DRUG USER

Eliezer Zachary Nussbaum; Gabriel Wishik. Boston University School of Medicine, Boston, MA. (Control ID #2700877)

LEARNING OBJECTIVE #1: Recognize the clinical appearance and histopathological features of leukocytoclastic vasculitis (LCV)

LEARNING OBJECTIVE #2: Formulate and prioritize a robust differential diagnosis for adults with LCV

CASE: A 53 y/o male with a history of active intravenous heroin use and hepatitis C presented with general malaise, diffuse arthralgias, and a bilateral lower extremity rash of two weeks duration. He was afebrile, with a pulse of 118, BP 110/60 and RR 18. Exam revealed a prominent non-blanching palpable purpuric rash on his feet and ankles as well as a tender left shoulder with limited ROM. Basic labwork was remarkable for WBC 28.4 and Creatinine 2.11 (baseline 0.9). 3/3 blood cultures and shoulder arthrocentesis were all positive for MRSA. Subsequent skin biopsy revealed superficial perivascular and interstitial neutrophilic infiltrate, leukocytoclasia, extravasated erythrocytes, focal thrombosis of small blood vessels and fibrinoid necrosis of vessel walls. Additional labwork for cryoglobulins, rheumatoid factor, ANA, and ANCA's was entirely negative. The patient was started on IV vancomycin and taken to the OR for washout of the shoulder joint. The rash disappeared within a week and upon completion of 6 weeks of antibiotic therapy he made a full recovery.

IMPACT: This case changed my thinking about the diagnostic approach to the patient with LCV by highlighting the need to search for underlying infection as the first step. Particularly in patients who use IV drugs, the finding of cutaneous LCV should heighten suspicion for a bacteremia.

DISCUSSION: This patient had LCV as a prominent presenting symptom of his MRSA bacteremia. LCV is a histopathologic term describing infiltration of small vessel walls by neutrophils leading to extravasation of blood into the cutaneous tissue. Clinically, this process results in the appearance of non-blanching, palpable purpura; the hallmark lesion of LCV. The etiologies of LCV can be divided into primary and secondary causes. Primary causes include various systemic vasculidites which, taken together, account for only 4% of cases. More commonly, LCV is secondary to an underlying disease process such as infection, medication-induced, connective tissue disease or malignancy. Infection accounts for a quarter of all cases of LCV. This case highlights the need to correctly prioritize a lengthy differential. In patients with hep C and a rash, cryoglobulinemia is a rare but well known consideration. However, the drug injecting population is also at high risk for bacteremia. Initial treatment for LCV prior to the resulting of confirmatory tests should focus on infection as it is the most common cause of LCV. Empiric steroid treatment for cryoglobulinemia is not advisable until bacteremia is ruled out. Testing for primary vasculitis as well as connective tissue disease was appropriate in this case, however only after the infectious workup had been completed.

LEVAMISOLE- COCAINE INDUCED NEUTROPENIA

Thamer A. Kassim[1]; Mohammad A. Selim[4]; Osman Bhatty[2]; Osama Diab[1]; Lakshmi Manogna Chintalacheruvu[3]; Maryam Gbadamosi-Akindele[1]. [1]Creighton University, Omaha, NE; [2]Creighton University GME, Omaha, NE; [3]Creighton University medical center, Omaha, NE; [4]Creighton university, Omaha, NE. (Control ID #2706972)

LEARNING OBJECTIVE #1: Raise the awareness that Levamisole have been contained in cocaine batches.

LEARNING OBJECTIVE #2: Diagnose Levamisole induced agranulocytosis and neutropenic fever in cocaine drug users.

CASE: By 2009, almost 70% of confiscated cocaine shipments were adulterated with Levamisole. We present a rare case of Levamisole - Cocaine induced neutropenia. 68 years old male patient presented with recurrent diarrhea and was found to have a very low White Blood Cell (WBC) count of 1.1 with an Absolute Neutrophil Count (ANC) of Zero. During first day of hospitalization the patient's diarrhea resolved but he started to spike a fever with his temperature maximum of 104.9. The patient was started on cefepime empirically. Blood cultures, urine analysis and culture and stool analysis and culture were negative. Chest/Abdomen CT scan showed no lung pathology but a small fluid collection in the abdomen was found. Paracentesis was performed for the concern of spontaneous bacterial peritonitis but fluid analysis yielded no abnormalities. Infectious disease and Hematology/Oncology teams were consulted for a source of infection and for the patient's isolated neutropenia, but the patient refused bone marrow biopsy and no source was found. Given that the patient's extensive history of cocaine dependence and use before admission, his recent WBC count of 4.1 a month before hospitalization, and the fact that his WBC/ANC started to elevate after three days of not using cocaine, his neutropenia was attributed to cocaine containing Levamisole.

IMPACT: Per the national institute of drug abuse, In 2014, there were an estimated 1.5 million current cocaine users and is trending up. This case has a significant impact on our approach to Agranulocytosis and neutropenic fever. Since cocaine drug abuse is getting more common, our role as physicians is to be prepared to manage the outcome. This type of neutropenia is rare which makes it easy to be overlooked. Being aware of such complications will raise the physician's attention and will reduce the costs of unnecessary investigations.

DISCUSSION: Neutrophils are the major white blood cells in our innate immune system defending against infections. Neutropenia is defined as ANC of less than 1500 cells/mm^3 with less than 500 cells/mm^3 being severe. Drug Induced Neutropenia is of rapid onset occurring within hours to 1–2 days. The drug acts as a Hapten inducing autoantibodies against neutrophils causing destruction. Levamisole is an immunomodulator that was used in the treatment of rheumatoid arthritis and colon cancer before it was withdrawn from the

market in 2005. It was found to cause agranulocytosis in 0.08-0.5%. Levamisole have been used an adulterant in cocaine since 2009. Since cocaine use is trending up, more cases of agranulocytosis and neutropenic fever are expected to be encountered. Recognizing this as a cause of neutropenia, providing appropriate medical management and treating cocaine dependence should be our primary goal as medical care providers for this target population.

LIMITATIONS OF NOVEL ANTICOAGULANT USE IN CANCER ASSOCIATED VENOUS THROMBOEMBOLISM Adil Yunis. Boston Medical Center, Boston, MA. (Control ID #2707551)

LEARNING OBJECTIVE #1: Recognize limitations of novel anticoagulants (NOAC) in cancer

LEARNING OBJECTIVE #2: Assessing bleeding risk when starting anticoagulation

CASE: A 65 year-old male with a history of pulmonary neuroendocrine carcinoma with liver and bone metastasis undergoing carboplatin/paclitaxel chemotherapy and complicated by port-a-cath associated thrombosis, now on *rivaroxaban*, presented to the hospital after a self-limited episode of hemoptysis with lightheadedness. He was otherwise asymptomatic with stable vital signs and a benign physical exam. Labs were significant for Hg 10.9 (his baseline), PLT 197, INR 1.07, PTT 29 and normal electrolytes and liver function tests. CT-PA showed no pulmonary embolism but interval increase of his pulmonary malignancy with new invasion of both the left bronchi and pulmonary artery branches as well as new thrombosis of the SVC surrounding the port-a-cath. Of note, 6 months prior to presentation a previous incidental SVC thrombus was treated with 3 months of low molecular weight heparin (LMWH) then transitioned to rivaroxaban when repeat imaging demonstrated thrombus resolution. Overnight, rivaroxaban was held and the patient had no episodes of hemoptysis. The next day he developed persistent sinus tachycardia and tachypnea with normal oxygen saturation while afebrile and normotensive. Facial plethora and edema were appreciated on repeat physical exam. SVC syndrome was diagnosed and anticoagulation with unfractionated heparin initiated. Interventional radiology subsequently performed thrombectomy with angioplasty and SVC patency returned. The port-a-cath was replaced for ongoing chemotherapy. At discharge rivaroxaban was discontinued and LMWH restarted. No hemoptysis was observed after restarting anticoagulation and repeat imaging at 3 months showed no thrombus.

IMPACT: As a result of this case I have continued to use LMWH in treating venous thromboembolism (VTE) in cancer pending further studies using NOAC's

DISCUSSION: Pathogenesis of VTE in cancer is multifactorial, resulting from direct and indirect activation of procoagulant pathways. Both VTE incidence and recurrence are higher compared to non-cancer patients. Though first line therapy in other forms of VTE, NOAC's are not recommended in cancer patients, including catheter associated thrombosis, due to a lack of prospective clinical trials on efficacy and safety in this patient population. In this case, the resolution of VTE with LMWH, and interval recurrence when on a NOAC supports LMWH as the conventional treatment for VTE in cancer. This case also depicts the clinical decision making process of anticoagulation in hypercoagualable patients with concurrent bleeding risks. This patient had a single self-limited and non-hemodynamically significant episode of hemoptysis, but his risk for clinical deterioration with symptomatic SVC syndrome was high. Had bleeding recurred with anticoagulation, heparin would be stopped, IV fluids and blood products provided for hemodynamic support, and urgent catheter embolization performed.

LISTERIA LURKING IN THE LIVER Jillian F. Sinkoff[1]; Pinky Jha[2]. [1]Medical College of Wisconsin, Milwaukee, WI; [2]medical college of wisconsin, Milwaukee, WI. (Control ID #2687520)

LEARNING OBJECTIVE #1: Recognition of liver abscesses secondary to *Listeria monocytogenes*

LEARNING OBJECTIVE #2: Management of *Listeria monocytogenes* infection in an immunocompromised patient

CASE: A 68 YO Hmong female with past medical history significant for ESRD on dialysis and rheumatoid arthritis was referred to an ED from outpatient clinic with a one day history of fever and RUQ pain. Prior to this presentation, the patient had been on prednisone 10 mg and azathioprine 25 mg daily for 4 weeks. Upon presentation, the patient was febrile, tachycardic, and tachypneic. Physical examination was benign except for RUQ tenderness. Significant laboratory results included a WBC of 19K, ANC of 14.44, CRP of 18.20, ESR of 116, AST of 40, and ALT of 16. CT scan of the abdomen showed >8 small bilobar hepatic lesions up to 1.3 cm in size concerning for micro-abscesses. The patient was empirically started on piperacillin-tazobactam and vancomycin. Initial blood cultures grew *L. monocytogenes* after 48 hours and piperacillin-tazobactam was then discontinued. IV Ampicillin and gentamicin were started and vancomycin was continued until 72 hours when the *L. monocytogenes* returned sensitive to ampicillin and gentamicin. IR felt abscesses were too small to be drained percutaneously. The patient remained afebrile from hospital day 3 until discharge on hospital day 8. Follow-up CT scan 1 week after discharge showed liver abscesses had resolved or decreased in size. The patient received 3 days of gentamicin and 4 weeks of IV ampicillin. At the 4 week follow-up WBC count was 24K and patient received an additional 6 weeks of IV ampicillin without complications.

IMPACT: No definitive guidelines are available for management of patients with these scenarios. Outcomes appear favorable with extended treatment with IV ampicillin and gentamycin as described in this case. Increased morbidity and mortality are seen in cases with multiple abscess and abscesses that are not suitable for drainage; increased vigilance is warranted in these patients.

DISCUSSION: *L. monocytogenes* involvement of the liver is exceptionally rare and often presents with nonspecific symptoms including fever and RUQ pain in immunocompromised people. 36 cases have documented a liver abscess secondary to *L. monocytogenes*. Here we report a rare case of multiple liver abscesses secondary to *L. monocytogenes* successfully treated with 10 weeks of IV ampicillin. Types of liver involvement include solitary abscess, multiple abscesses, and hepatitis. Multiple liver abscesses is a poor prognostic factor with only a 27% survival rate seen in the literature. This would be the first documented case of a patient surviving multiple abscesses without percutaneous drainage as part of their treatment. A current review of case reports shows outcomes are most favorable using a penicillin in combination with an aminoglycoside for at least 3 weeks and oftentimes longer. No controlled trials have been done to date to assess the best antibiotic protocol.

LITHIUM TOXICITY IN A PATIENT WITH A CONGENITAL SOLITARY KIDNEY - AVOIDING PITFALLS Aparna S. Daley; Daniel Goldsmith; Stephen Tieku; Iram Mahmood Arif. Capital Health Regional Medical Center, Trenton, NJ. (Control ID #2706385)

LEARNING OBJECTIVE #1: Recognize the importance of careful monitoring of lithium levels and avoidance of precipitants of lithium toxicity including dehydration and nephrogenic drug interactions.

LEARNING OBJECTIVE #2: Recognise patients with potential for substantial renal decline secondary to lithium toxicity, such as those with a solitary kidney.

CASE: A 41 year-old male with a history of schizophrenia was referred from a psychiatric facility for evaluation of leukocytosis and flu-like symptoms. He had been evaluated ten days prior for an asthma exacerbation and was discharged on prednisone and ibuprofen. He was fully alert and oriented but was a poor historian. He had been started on Lithium one month ago. Physical examination was unremarkable. Diagnostic tests were notable for mild hyperkalemia, marked leukocytosis, thrombocytosis and significantly elevated blood urea nitrogen of 62mg/dL and creatinine of 8.88 mg/dL. Urinalysis showed few eosinophils but no proteinuria. The Lithium level was 2.09 mmol/L, signifying Lithium toxicity. At the time of admission, there were no previous records at our hospital. The patient was admitted for acute kidney injury secondary to Lithium toxicity. Lithium was discontinued and the patient was given intravenous hydration. Records from a previous hospital were obtained the following day, which revealed a congenital left solitary kidney, and a previous admission for acute kidney injury secondary to rhabdomyolysis. The patient's creatinine and Lithium levels were normal six days prior to his current admission. Repeat ultrasound confirmed the presence of a sizable 19 cm solitary left kidney with compensatory hypertrophy. A screen for autoimmune causes was negative. Intravenous fluids were continued for several days and the patient's Lithium level normalized and his creatinine level gradually trended down to 2.31mg/dL.

IMPACT: This case served as an important reminder to me of the importance of careful monitoring in patients taking lithium, especially in patients who are unable to provide a comprehensive history and who are seen by multiple healthcare providers in different settings. This is particularly important in patients with a solitary kidney who may have potential for rapid renal decline. It is a reminder of the importance of attaining a comprehensive medication history.

DISCUSSION: This case illustrates the importance of close monitoring of medications administered in all contexts to a patient with a solitary kidney who is taking Lithium, which could easily result in renal toxicity. NSAIDs are known precipitants of Lithium toxicity and should be avoided in such patients. When a patient is unable to provide a good history, providers must be meticulous in tracking down all medical records to determine a patient's history and risk factors and to avoid precipitating lithium toxicity and renal injury in a patient with a solitary kidney.

LOOKING PAST PSYCHIATRIC LABELS: A NOT-SO-HIDDEN CAUSE OF CATATONIC DEPRESSION Michael D. Richter[1]; Adrian Vella[2]. [1]Mayo Clinic, Rochester, Rochester, MN; [2]Mayo Clinic, Rochester, MN. (Control ID #2701874)

LEARNING OBJECTIVE #1: Recognize the potential psychiatric manifestations of Cushing's Disease.

CASE: A 33-year-old man presented acutely for a second opinion regarding his severe depression. He had an eight-month history of progressive fatigue, weakness, depressed mood, and periods of confusion with memory impairment. A recent 17 day hospitalization for encephalopathy, which included evaluation by neurology, neurosurgery, and psychiatry, resulted in a diagnosis of catatonic depression with possible conversion disorder. An MRI from this visit was noted to have no significant findings. His medical history was also notable for hypertension, type 2 diabetes mellitus, and obesity. These comorbidities were all diagnosed within the past two years. Upon admission, physical exam revealed facial flushing, prominent preauricular and supraclavicular fat pads, central obesity, and proximal muscle weakness. Laboratory workup revealed an elevated 24-hour urine free cortisol at 1933μg/24h, and a morning cortisol of 13μg/dL after dexamethasone suppression test. MRI of the pituitary gland noted a 9mm heterogenously hypoenhancing mass in the anterolateral right sella. CT scan of the chest, abdomen, and pelvis was unremarkable. He was diagnosed with ACTH-dependent pituitary Cushing disease and underwent transsphenoidal resection of the mass. Pathology confirmed the diagnosis with staining positive for ACTH and chromogranin. He was treated with a postoperative course of prednisone for symptoms and signs of adrenal insufficiency, and one month later he resumed working and reported significant improvement in all of his presenting symptoms.

IMPACT: This case illustrates the psychiatric symptoms associated with Cushing's Disease and emphasizes the high degree of suspicion necessary for diagnosis. This can be challenging as many of the disease features, namely obesity, hypertension, diabetes, and depression, are remarkably common. Screening with overnight dexamethasone suppression test, 24-hour urine cortisol, and late-night salivary cortisol should be considered in patient with these comorbidities and characteristic physical findings.

DISCUSSION: The most common psychiatric disorders observed in patients with Cushing Disease are major depression (50-80%), anxiety or panic disorders (66%), and memory impairment (83%). Severe disease may present as psychosis or a catatonic state, characterized by immobility, mutism, and automatic obedience. Neuropsychiatric disorders usually improve after disease remission, though they can persist even after resolution of hypercortisolism.

LUMBAR ARTERY RUPTURE RESULTING IN RETROPERITONEAL BLEED LATE IN THE POST-OPERATIVE PERIOD Nilima Shet; Prashanth Venkatesh; James M. Horowitz. NYPH – Weill Cornell, New York, NY. (Control ID #2703284)

LEARNING OBJECTIVE #1: Observe clinical manifestations of spontaneous arterial RP bleed in the late post-operative period.

LEARNING OBJECTIVE #2: Note the increased risk of RP bleeds in a patient with CKD receiving anticoagulation.

CASE: A 67 year-old man with medical history significant for coronary artery disease, chronic renal insufficiency, insulin-dependent diabetes, and systolic heart failure (EF 45%) developed acute hypoxic respiratory failure 48 hours after L1-L2 laminectomy. He was emergently intubated and transferred to the cardiac care unit (CCU). Workup revealed non-ST elevation myocardial infarction, acute on chronic renal failure and a chest x-ray consistent with acute pulmonary edema. Cardiac catheterization was deferred due to instability and concern for irreversible renal insult. The patient was maintained on aspirin and clopidogrel. Renal replacement was started for persistent oliguria and need for ultrafiltration. He developed persistent atrial flutter refractory to anti-arrhythmics and was started on unfractionated heparin infusion in consult with orthopedics. The patient was transferred to the floor with plans for elective catheterization. Yet, he developed acute onset back and abdominal pain with rebound tenderness, altered mental status, hypotension and tachycardia. Labs revealed an acute hemoglobin drop from 8.0 to 4.5 g/dL with a lactate level of 8. Anticoagulation was held and reversed with protamine sulfate. CT scan revealed a new psoas hematoma near the site of laminectomy done 21 days

prior. He was taken to interventional radiology where an actively bleeding L3 lumbar artery was embolized.

IMPACT: Though spontaneous retroperitoneal (RP) hematomas are rare and usually venous, this case underscores the importance of lumbar arterial RP bleed in the differential diagnosis of shock in a patient on triple antithrombotic therapy. This case adds to the few existing reports describing this complication in a patient on anticoagulation. This, to our knowledge, is the only one describing spontaneous lumbar arterial bleed late after lumbar laminectomy.

DISCUSSION: RP bleeding can vary in presentation from minimal pain to hemodynamic collapse[1]. Spontaneous RP hematomas are most commonly diagnosed among patients on anticoagulation as well as those on hemodialysis though the specific mechanisms are not understood[2,3]. Spontaneous lumbar artery rupture is rarer still and the incidence is unknown with few reports in literature[4]. When Mr. G first began to decompensate, it was thought he may have been septic. Hypotensive and altered - he had plausible sources for infection: a central line, a large wound post-operatively, and a sacral decubitus ulcer. A new bleed was thought less likely given the patient had been three weeks post-procedure and vascular complications were known to occur earlier in the post-operative period[5]. Given Mr. G was both on dialysis and anticoagulated on numerous agents, considering an RP bleed may have allowed for sooner imaging or a shorter delay before undergoing embolization.

LUMP IN THE BREAST: CLEARED THE LITMUS TEST?

Niyati M. Gupta[1, 2]; Malav P. Parikh[1]; Sreelakshmi Panginikkod[3]; Harsh Rawal[4]; Sahil Gehlot[2]. [1]Cleveland Clinic Foundation, Cleveland, OH; [2]Grant Medical College and Sir J.J. Group of Hospitals, Mumbai, India; [3]Presence Saint Francis Hospital, Evanston, IL; [4]University of Illinois at Urbana Champaign, Champaign, IL. (Control ID #2694642)

LEARNING OBJECTIVE #1: Distinguish between granulomatous mastitis and breast cancer.

LEARNING OBJECTIVE #2: Diagnose and treat a patient with granulomatous mastitis.

CASE: A 30-year-old female presented to an outpatient clinic for evaluation of an accidentally noted right breast lump. The patient denied any weight loss, appetite change or use of oral contraceptives. There was no significant personal or family history of cancer. Spot urine pregnancy test was negative and the patient was not lactating. On examination, a 60 × 60 × 30 mm, firm lump was noted in the upper inner quadrant of the right breast. Nipple, areola, the skin overlying the breast were unremarkable and lymphadenopathy was absent. Left breast was normal on exam. Empiric treatment with trimethoprim-sulphamethoxazole for acute mastitis did not show any improvement. Subsequently, a diagnostic mammography and right breast ultrasound was performed, which showed a hypervascular, hypoechoic, 57 × 57 × 27 mm mass along with enlarged right axillary lymph-nodes, raising suspicion for malignancy. An ultrasound guided core biopsy of the nodule was performed. Surprisingly, on histopathologic analysis, patient was diagnosed with granulomatous mastitis (GM), with negative acid-fast bacilli stain and gram stain. The patient was treated with 40 mg of prednisone, which was tapered over a period of 8 weeks. This resulted in a significant improvement in the size of the breast lesion, but it did not resolve completely. Eventually the lesion was surgically excised and a diagnosis of GM was re-confirmed on histological exam.

IMPACT: How did this case change your thinking? GM is an uncommon benign breast disease that often masquerades as two other common conditions, breast abscess or carcinoma. Hence, GM should be included in the differential diagnosis when a woman of childbearing age presents with a lump in the breast.

DISCUSSION: GM is a rare chronic inflammatory disease that has clinical and radiologic findings similar to those of breast cancer. It usually affects women of childbearing age or those with a history of oral contraceptive use. It is not associated with trauma, specific infection, or foreign material. On examination, it generally manifests as a distinct, firm to hard mass that may involve any part of the breast. Reactive lymphadenopathy may be present in up to 15% of cases. Mammographic features can be variable, ranging from normal findings in patients with dense breasts to masses with benign or malignant features. A definitive etiology is unknown but an autoimmune factor is favored. It should be differentiated from other chronic inflammatory breast diseases such as plasma cell mastitis, Wegener's granulomatosis, sarcoidosis, tuberculosis, abscess, carcinoma, and fungal infection. Diagnosis is made by pathologic review where, chronic granulomatous inflammation of the breast lobules without necrosis is seen. Treatment depends on the severity of disease and may include observation, systemic steroids, methotrexate or surgery.

LUNG CANCER AND JOINTS: COMMON LINK?

Yekaterina Kim; Andrei Assa; Myung Woo; Geetali Mohan. Montefiore Medical Center, Bronx, NY. (Control ID #2699417)

LEARNING OBJECTIVE #1: Recognize physical exam findings of hypertrophic pulmonary osteoarthropathy

LEARNING OBJECTIVE #2: Recognize that hypertrophic pulmonary osteoarthropathy is associated with lung malignancy

CASE: A 47 year-old man with 20 pack-year smoking history, presented with three weeks of right-sided chest pain with bilateral knee and wrist swelling. Patient was febrile and tachycardic, with decreased breath sounds in upper lobes. He had increased girth of bilateral wrists, digital clubbing, bilateral knee synovitis, and symmetrical lower extremity edema. He denied cough, shortness of breath or weight loss. CT chest showed large right apical bulla with air-fluid level with questionable area of denser nodularity. Xray of bilateral wrists and feet showed periosteal reaction, suggestive of hypertrophic pulmonary osteoarthropathy. He was started on antibiotic therapy for suprainfected bulla for three weeks. Given high suspicion for lung malignancy based on HPO findings, follow up CT was obtained. It showed enlargement of right upper lung lesion. Patient underwent lung biopsy followed by right upper lobectomy revealing non-small cell carcinoma.

IMPACT: This case illustrates the importance of recognizing the physical exam findings of hypertrophic pulmonary osteoarthropathy and initiating timely workup for underlying chest pathology and possibly malignancy in patients without constitutional or pulmonary symptoms.

DISCUSSION: Hypertrophic osteoarthropathy (HOA) is a syndrome characterized by digital clubbing, inflammation of trabecular bones, and synovial effusions. Primary HOA is a rare, hereditary condition. Secondary HOA is more common than primary, comprising more than 95% of all cases, and is associated with lung malignancies, cystic fibrosis, pulmonary infections, and intra-cardiac shunts. When secondary HOA is of pulmonary origin, term hypertrophic pulmonary osteoarthropathy (HPO) is used. Majority of clinicians are familiar with clubbing, but other physical exam findings of HPO are not quickly recognized given rarity of the presentation, therefore prompting inappropriate referral to rheumatology. HPO has been associated with all

histological types of lung cancer, most commonly with non-small cell carcinoma. It is hypothesized that release of growth factors from abnormal malignant tissue, causes increased connective tissue and osteoid matrix deposition resulting in clubbing and periostosis. Clinical presentation of HPO can range from asymptomatic changes to extensive pain in bones. Important physical exam findings of HPO are digital clubbing, edema of extremities with increased girth of tubular bones near metaphysis, large symmetric joint swelling and effusions. Periosteal changes are most commonly seen in tibia, fibula, radius and ulna. They can precede other clinical presentations of underlying lung disease, therefore timely identification of these physical exam findings may lead to early diagnosis of lung malignancy.

MAKE ME LOSE MY BREATH: SUBMASSIVE PULMONARY EMBOLISM AND ANCILLARY DIAGNOSTICS Andy Y. Cheng[2]; Amar Kohli[1]. [1]UPMC, Mars, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2671988)

LEARNING OBJECTIVE #1: Recognize ancillary diagnostics pertinent to the management of pulmonary embolism (PE)

LEARNING OBJECTIVE #2: Interpret the significance of ancillary diagnostics in prognosticating PE outcomes

CASE: A 58-year-old woman afflicted by progressive supranuclear palsy rendering her bedbound for the past five years presented with chest pain and dyspnea. The patient experienced stabbing left-sided chest pain, worsened by inspiration, over the past 24 hours. Given persistent chest pain and worsening dyspnea, she saw her primary care physician, who then referred her to the Emergency Department for further evaluation. Initial laboratory studies revealed brain natriuretic peptide (BNP) of 583 pg/mL, troponin of 0.0 ng/mL, and D-Dimer of 432 ng/mL. Computed Tomography Pulmonary Angiogram (CTPA) demonstrated a saddle embolus, as well as extensive embolic burden extending throughout bilateral pulmonary vasculature. A Transthoracic Echocardiogram (TTE) demonstrated severely decreased right ventricular function, a flattened interventricular septum, and the presence of McConnell's Sign. An electrocardiogram (EKG) showed a "S1Q3" pattern, with reports that an initial outpatient EKG showed a full "S1Q3T3" pattern. Given a stable blood pressure of 104/74, but signs of right ventricular dysfunction, the patient was diagnosed with submassive PE and admitted to the Medical Intensive Care Unit for further management.

IMPACT: Ancillary diagnostics such as TTE and EKG help prognosticate PE severity and guide further treatment decisions, but do not replace Pulmonary Angiography, CTPA, or Ventilation-Perfusion Lung Scanning in the diagnosis of PE.

DISCUSSION: While Pulmonary Angiography remains the gold standard in diagnosing PE, its invasive nature has led to the development of noninvasive methods, including CTPA and Ventilation-Perfusion Lung Scanning, as alternative diagnostic modalities. There are also several ancillary diagnostics that play important roles in the prognostication of PE. -"McConnell's Sign" on TTE: Defined as hypokinesis or akinesis of the right ventricular free wall with preserved right ventricular apical motion, McConnell's Sign carries a low sensitivity of 77% but high specificity of 94% for PE detection. It is also seen more frequently in patients with high-risk PE, specifically those who have a systolic blood pressure of less than 90 or require vasopressor support. -"S1Q3T3" EKG Pattern: This classic finding continues to be taught in medical school as strongly suggestive of pulmonary embolism. However, one study found it to have a sensitivity of only 35%, while another found it to have no statistical significance when matched for age and sex to controls who did not have PE. Nevertheless, the S1Q3T3 finding does seem to be associated with higher frequency of right ventricular dysfunction, as well as increased risk of hemodynamic collapse and death within thirty days after initial diagnosis of PE. It also has a 90% specificity.

MAKE NO BONES ABOUT CANCER Reza Parungao; Danit Arad. Montefiore Medical Center, Bronx, NY. (Control ID #2703582)

LEARNING OBJECTIVE #1: Identify alarming signs for underlying malignancy in patients presenting with back pain

LEARNING OBJECTIVE #2: Recognize the clinical presentation of spinal cord compression

CASE: A 63 year-old woman presented with one month of worsening thoracic back pain radiating down her legs and two weeks of right leg numbness. She had no history of back pain or unexplained weight loss. She went to the ER and was treated conservatively. No imaging studies were done. She received opioids and outpatient follow up. One week later, she had acute right leg weakness along with difficulty walking. She presented again ten days later with inability to bear weight and urinary retention. Her medical history includes invasive ductal carcinoma thirteen years ago treated with mastectomy, chemotherapy, and radiation therapy. She had decreased proximal hip flexor strength, knee flexion and extension, ankle dorsiflexion and plantar flexion bilaterally and decreased sensation to pinprick. Knee and ankle reflexes were not elicited. An expansile mass at the left T5-T6 pedicle causing spinal cord compression was seen on MRI. She was evaluated by neurosurgery but due to tumor location and risk of cord instability, surgery was not offered. She was started on dexamethasone and emergent radiation treatment to T3-T7. However, she remained permanently paraplegic. Biopsy showed metastatic adenocarcinoma.

IMPACT: This case illustrates the importance of immediate evaluation for metastatic disease in patients with history of cancer presenting with back pain.

DISCUSSION: Back pain is a commonly encountered problem by the internist. Identifying "red flag" symptoms is important to risk stratify patients that could have underlying malignancy. The American College of Physician guidelines list the following as risk factors for malignancy: history of cancer, clinical suspicion, age greater than 50, unexplained weight loss, failure to improve after one month. There is no consensus among clinical practice guidelines on which symptoms have sufficient diagnostic accuracy. Thus, their value in clinical decision making is unclear. Based on literature review, the only "red flag" for which diagnostic accuracy data is available is "history of cancer." It has a positive likelihood ratio (+LR) of 14.7 whereas unexplained weight loss has a + LR of 2.7. Early diagnosis of back pain due to malignancy is crucial. It is the most common presentation of metastatic disease, namely prostate (19%), lung (18%) and breast (14%) cancer. Back pain often precedes development of neurologic deficits by weeks or months. Neoplastic epidural spinal cord compression is a complication that can cause irreversible loss of neurologic function. Clinical features to recognize include radicular pain, lower extremity weakness, saddle anesthesia, and bowel or bladder dysfunction. New onset back pain in a patient with history of malignancy should be considered spinal metastatic disease unless proven otherwise. It should prompt an immediate MRI as it can proceed into a neurologic emergency.

MALADY OR NOT? EXPLORING THE EVIDENCE BEHIND METFORMIN ASSOCIATED LACTIC ACIDOSIS. Galina S. Tan[2]; David Bor[1]; Richard Pels[1]. [1]Cambridge Health Alliance, Cambridge, MA; [2]Cambridge Health Alliance, SOMERVILLE, MA. (Control ID #2671068)

LEARNING OBJECTIVE #1: Assess the clinical significance of metformin associated lactic acidosis (MALA) and apply it to a patient case scenario.

CASE: 72yo female with history of DM2, CHF, Afib, HTN, CVA, dementia presenting to the ICU with acute progressive dyspnea, lactic acidosis, and multiorgan dysfunction without hemodynamic instability. Studies of note: Cr 3.3 (baseline 1), K 6.9 with tall T waves on EKG AST >3000, ALT >3500, elevated PT/INR NT-proBNP 12,425, trop 0.1, echo new EF 25%, EKG new LBBB WBC 13.3, RLL opacity/effusion on CXR, procalcitonin 0.29 ABG pH 7.36, pCO2 28, pO2 72, bicarb 20, AG 19 Lactic acid 10.7 Initial leading differential diagnoses included septic shock, cardiogenic shock, and metformin associated lactic acidosis. The patient's presentation was ultimately attributed to severe organ hypoperfusion due to a subacute anterolateral myocardial infarction. Her cardiac and renal function recovered partially by the end of this hospitalization. She was discharged on half her home dose of metformin and insulin. Of note, her hemoglobin A1C was 6% 4 months prior to this admission. Could metformin associated lactic acidosis (MALA) still partially explain this patient's initial presentation? Should the patient be restarted on her home metformin upon discharge from the hospital?

IMPACT: A thorough review of the literature on metformin associated lactic acidosis (MALA), as well as an understanding of its background and pathophysiology, suggests that the perceived risk of MALA is much higher than its clinical significance. MALA should not necessarily be considered in the differential diagnosis for all patients presenting with lactic acidosis who are taking metformin. Furthermore, we should reconsider whether the contraindications to metformin are overly conservative.

DISCUSSION: MALA is extremely rare with an incidence rate around 2–9 cases per 100,000 patient-years. The pathophysiology behind MALA is different from that of its biguanide cousin phenformin, which previously led to much higher rates of lactic acidosis. Case reports in MALA are often confounded by other acute conditions that predispose those patients to lactic acidosis, making the diagnosis of MALA difficult to establish. Furthermore, it is reassuring that patients with the traditional contraindications to metformin are often prescribed metformin in practice, and these cohorts have not been shown to have a significantly higher risk of MALA. However, there are limitations to the available studies on MALA, so its level of clinical significance would have to be appreciated on a case-by-case basis. For example, what we cannot rule out at this time is whether metformin itself confers additional risk of lactic acidosis in patients with severe underlying cardiac or renal disease, because these patient populations have been largely excluded in trials. For an incredibly rare event such as MALA, much larger-sized studies would need to be done to fully appreciate the clinical significance of this entity.

MALE BREAST CANCER IN A PATIENT WITH CIRRHOSIS AND MULTIPLE MALIGNANCIES Omotayo A. Arowojolu[1]; Michael Lattanzi[1]; Saleem Ali[1, 2]. [1]NYU School of Medicine, New York, NY; [2]New York Harbor VA Healthcare System, New York, NY. (Control ID #2700185)

LEARNING OBJECTIVE #1: Recognize the importance of the male breast exam

LEARNING OBJECTIVE #2: Workup a solitary brain metastasis

CASE: A 71-year-old man with HCV cirrhosis and a 50-pack-year smoking history presented to the VA Hospital with subacute left arm weakness. The physical exam at presentation was notable for cachexia, slurred speech, left arm hemiplegia, and ataxia. A non-contrast head CT was obtained, revealing a right frontal mass. The subsequent brain MRI identified a 1.2 cm mass in the right frontal lobe, concerning for a brain metastasis of unknown primary. A CT chest/abdomen/pelvis revealed multiple pulmonary nodules, thoracic lymphadenopathy, a small duodenal mass, and a 1.5 cm soft tissue density in the retroareolar region of the left breast. Upon further physical examination, a small breast mass was palpated, and a slight nipple retraction was noted. Breast biopsy subsequently confirmed adenocarcinoma, ER+/PR+/Her2-. In addition to steroids, the patient underwent prompt neurosurgical resection of the solitary brain metastasis. Unexpectedly, this brain mass was found to be most consistent with giant cell carcinoma of the lung. Additional workup and treatment is ongoing.

IMPACT: Male breast cancer is rare; therefore, men are identified at a later stage than women. Given the potential for elevated serum estrogen to drive the growth certain cancers, physicians should consider routine male breast exams among men with hyperestrogenic states such as cirrhosis. Increased surveillance for male breast cancer is particularly important for VA hospitals which serve a predominantly male patient population.

DISCUSSION: Male breast cancer accounts for 1% of all cases in the US. Incidence peaks in the 7th decade and presents at a more advanced stage than female breast cancer. Increased circulating estrogen, which is common in cirrhosis, is a major risk factor for male breast cancer; this phenomenon has also been well-documented in Klinefelter syndrome. Given the low incidence of male breast cancer, screening by mammography and breast exams are not routine in male patients. In fact, males are often reassured that asymmetric gynecomastia is usually benign or even anticipated. In the setting of a symptomatic solitary intracranial brain metastasis with cerebral edema, the standard of care definitive therapy is neurosurgical resection; this is particularly true of larger lesions. With regard to systemic treatments for ER+/PR+ breast cancer, palbociclib and ribociclib, two recently-approved CDK 4/6 inhibitors, have both been shown to increase the progression free survival in ER+/PR+/Her2- breast cancer among female patients receiving concurrent aromatase inhibitor. In conclusion, male breast cancer should be considered in men with hyperestrogenic states such as cirrhosis, especially in patients undergoing a workup for metastatic disease of unknown primary.

MALIGNANT BOWEL OBSTRUCTION IN ADVANCED ABDOMINAL MALIGNANCY Paul J. Pokrandt[3]; Christopher R. Smith[3]; Joseph A. Simonetti[1, 2]. [1]School of Medicine, University of Colorado, Denver, CO; [2]Denver VA Medical Center, Denver, CO; [3]University of Colorado, Denver, CO. (Control ID #2699886)

LEARNING OBJECTIVE #1: Distinguish functional ileus from mechanical obstruction by history, exam, and imaging.

LEARNING OBJECTIVE #2: Manage malignant bowel obstruction using pharmacologic and procedural options.

CASE: A 47-year-old man with family history of early colon cancer was admitted due to worsening abdominal pain, 30lb weight loss, and food intolerance due to pain and vomiting for 5 days. Symptoms began 4 weeks prior to admission. He was afebrile with stable vitals. His abdomen was diffusely tender with hypoactive bowel sounds but no rebound/guarding. Abdominal X-ray showed scattered, gas-filled 4cm small bowel loops and gas in the large

bowel. CT with IV contrast showed ascites and omental nodularity without focal obstruction. He was admitted for management of ileus due to presumed abdominal malignancy. His ileus was managed with nasogastric suction, anti-emetics, and pain control. Ascitic fluid analysis yielded no malignant cells and tumor markers were negative. Laparoscopy on day 16 revealed no mechanical obstruction and biopsy showed poorly differentiated mucinous adenocarcinoma with signet-ring features. After 3 weeks of persistent ileus, a PEG tube was placed for comfort and he pursued palliative chemotherapy given his poor prognosis.

IMPACT: Key history, clinical and radiographic features can help distinguish between mechanical obstruction and functional ileus in the setting of advanced abdominal malignancy. Differentiating between them is critical to guide treatment options; though the prognosis among such patients is extremely poor and early palliative care referral is recommended.

DISCUSSION: Malignant bowel obstruction (MBO) includes either functional (ileus) or mechanical obstruction. Mechanical obstruction presents with colicky pain and hyperactive bowel sounds because bowel repeatedly contracts against the blockage. Ileus presents with constant pain and hypoactive bowel sounds as inflammation paralyzes the bowel. Radiograph or CT (ideally with PO/IV contrast) often reveals dilated loops of bowel with air fluid levels proximal to mechanical obstruction and diminished air distally. Imaging of functional ileus shows gas throughout the small and large bowel and rectum without a transition point. Patients with MBO have a median life expectancy of 4–5 weeks; though this can be extended by nearly 6 months if obstruction can be relieved by endoscopic stenting or surgery. Treatment is often palliative. Bowel decompression with PEG tube may be more comfortable and effective at relieving nausea and vomiting than nasogastric suction. Haloperidol and ondansetron can be used to control nausea and vomiting. Though not well-studied among patients with MBO, steroids have antiemetic properties and may also reduce bowel inflammation and edema. Strong evidence supports using octreotide in reducing gastric secretions, intestinal motility, and edema. Opiate medications can be used to alleviate pain, but may also worsen functional ileus.

MALIGNANT MELANOMA- A RARE CAUSE OF METASTATIC PANCREATIC CANCER

Aneesh Kuruvilla; Anamaria Milas; Elizabeth Brindise; Amer Al Homssi; Tarek Almouradi. University of illinois/christ, Chicago, IL. (Control ID #2706348)

LEARNING OBJECTIVE #1: Diagnosing metastatic malignant melanoma after resection of superficial melanoma.

CASE: A 56-year-old Caucasian female who is a practicing minister started behaving unusually during one of her services. She began walking up to the alter at inappropriate times and her family was concerned about her behavior. This change in mentation continued into the next day and the decision was made to bring her to the hospital. The patient had a history of superficial malignant melanoma to the left axilla, which was treated with axillary dissection 13 years ago. Sentinel lymph node biopsy at the time was negative and the patient did not receive any further chemotherapy or radiation. She was monitored for 5 years with serial PET scans every 6 months along with chest X-rays, routine blood work and annual skin exams without evidence of disease recurrence. On this presentation, the patient had multiple episodes of tonic-clonic seizures while in the ED for which she was given Ativan, Versed and IV Keppra. The patient denied previous CNS symptoms including headache, seizures, or vision changes. Imaging of the head revealed a large hemorrhagic frontal temporal brain lesion with smaller scattered lesions concerning for metastatic disease. CT scan of the chest, abdomen and pelvis showed a 2.2 × 1.6 cm peripancreatic tail mass. An endoscopic ultrasound was performed which showed a mass in the region of the tail of the pancreas. FNA was done with pathology positive for metastatic melanoma. Patient was referred to Oncology service for further management.

IMPACT: Most pancreatic metastases occur in the first 1–3 years after treatment of the primary tumor and current guidelines recommend follow up 3–5 years thereafter. This case report raises a question about how long patient should be monitored after the successful treatment of superficial malignant melanoma.

DISCUSSION: A variety of primary neoplasms metastasize to the pancreas. About 2% of pancreatic tumors are metastatic tumors. Common metastatic sites include the kidney, lung and colon. Metastasis of malignant melanoma to pancreas occurs as manifestation of widespread disease burden. Several factors influence survival in patients with primary melanoma, including specific clinical and pathological factors, histological subtype, anatomical location and lymph node involvement. Prognostic factors influencing survival in patients with malignant melanoma are largely unknown, but a longer disease free interval between the successful resection of primary malignancy and eventual development of metastasis to the pancreas has been reported to be associated with improved survival. Our patient presented 13 years following the treatment of primary melanoma. The prognosis of metastatic malignant melanoma is poor. Studies suggest a mean survival of only 6–8 months in patients with systemic disease from melanoma. In several case series five-year survival rates are reported at less than 10%.

MALIGNANT OTITIS EXTERNA: IATROGENIC AND SOCIAL ORIGINS

Ann Wang; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (Control ID #2701785)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of malignant otitis externa (MOE)

LEARNING OBJECTIVE #2: Appreciate that socioeconomic barriers significantly add to clinical morbidity

CASE: A 55 year old Spanish speaking, uninsured, and legally undocumented male with uncontrolled type 2 diabetes mellitus presented with 5 months of progressive right ear otalgia and otorrhea. Bloody and then purulent ear discharge initially started while hospitalized for a stroke, secondary to the iatrogenic trauma of repeated aural thermometer measurements. Despite multiple subsequent visits to the ED, and repeated short courses of oral and topical antibiotics, his symptoms progressed with tinnitus, hearing loss, and TMJ involvement. He was unable to afford insulin and other medications during this period, but did obtain the antibiotics. He was referred to ENT, but he could not get an appointment until one week prior to admission. In addition to granulations in the external auditory canal (EAC) and otorrhea, a CT revealed findings of MOE with extension into the middle cranial fossa. IV antibiotics and tight glucose control, without initial surgical intervention, were started. Charity antibiotic infusion for 6 weeks and follow up were arranged.

IMPACT: This case illustrates an uncommon entity - MOE with skull base involvement - where morbidity was caused by an unfortunately common situation - lack of access. It is critical for clinicians to assess and address social determinants of health.

DISCUSSION: MOE is a rare but serious complication of otitis externa. Infection spreads from the EAC to the stylomastoid foramen, mastoid tip,

and jugular foramen. Severe disease can involve the cranial nerves (most often facial) and skull base, and can be fatal. Patients at highest risk for MOE are elderly, male, and immunocompromised (including diabetics). The diagnostic criteria for MOE include otalgia usually lasting >1 month, otorrhea, edema, granulations in the EAC, microabscesses, and failure to respond to topical antibiotics. Pseudomonas aeruginosa remains the most common causative organism, although blood and EAC cultures are most often negative. Due to emerging resistance, biopsy and culture for targeted antimicrobial therapy has become important in contemporary care. Treatment typically involves long term antibiotics, tight glucose control in diabetics, and surgical debridement for refractory or complicated disease. Social determinants of health (SDH) contribute significantly to morbidity and mortality. Approximately 10% of diabetic patients in the USA are uninsured. Uninsured diabetic patients are significantly less likely to have had a medical checkup in the last 2 years, or A1C, foot, or retinopathy screening in the last year. Diabetics with any financial barriers to care (including uninsurance) had higher rates of stroke, retinopathy, and non-healing foot sores compared to those without barriers. Screening for healthcare barriers and subsequent intervention in vulnerable diabetic patients can significantly reduce clinical morbidity.

MALIGNANT SYPHILIS: A CASE OF ULCERONODULAR SECONDARY SYPHILIS Swalpa Udit. UCSF, San Francisco, CA. (Control ID #2707064)

LEARNING OBJECTIVE #1: Diagnose lues maligna (ulceronodular secondary syphilis)

LEARNING OBJECTIVE #2: Utilize molecular techniques in diagnosis of syphilis

CASE: A 52 year old male with well-controlled HIV presented with 3 weeks of painful genital ulceration associated with chills, weight loss, and malaise. Exam revealed normal vitals except for mild tachycardia, diffuse edema of glans penis with large ulcerated plaque extending circumferentially around penile shaft and scrotum, and small ulcerative lesions on scalp, torso, chin, and heel with purulent discharge. Laboratory evaluation was notable for elevated WBC count of 16.8 ($\times 10^9$/L). Data was otherwise unremarkable with suppressed HIV VL and preserved CD4 count. Peripheral blood cultures were negative, and wound swab of ulcer grew Staph aureus. He was started on Vancomycin and Ertapenem but experienced no improvement. RPR then returned positive at a titer of 1:128 with positive Treponema Pallidum antibody. Patient declined skin biopsy, so a T. pallidum PCR was conducted on a skin lesion swab and returned positive, confirming a diagnosis of lues maligna or ulceronodular secondary syphilis. He was treated with a single dose of IM Penicillin with dramatic resolution of symptoms and lesions.

IMPACT: This case highlights an uncommon presentation of a clinical entity seen by general internists which requires a high index of suspicion for diagnosis. The presentation, as in this case, is initially concerning for a typical purulent bacterial infection, with the correct diagnosis only suspected when the patient fails to respond to therapy. This case also highlights diagnostic approaches to syphilis. Diagnosis of lues maligna is generally made with a skin biopsy based on pathologic appearance or immunofluorescence. As our patient declined invasive testing, we utilized PCR of T. Pallidum from swab of skin lesions, with confirmation from swift therapeutic response.

DISCUSSION: Lues maligna, also known as ulceronodular syphilis, is a rare, aggressive form of secondary syphilis, seen most frequently with HIV co-infection. It is characterized by multiple, polymorphic skin lesions, generally well-demarcated with central ulceration, thick crusts, and with minimal erythema of surrounding skin. Unlike chancres, these lesions are painful, and palmoplantar involvement is rare. Patients generally have constitutional symptoms and high RPR titers. Diagnostic criteria for lues maligna include: compatible gross and microscopic morphology of lesions; high RPR titer; development of a severe Jarisch-Herxheimer reaction upon therapy; and marked response to therapy. Historically, it was believed that the lesions of secondary syphilis are depleted of Treponemes, but molecular testing of skin lesions can identify organisms and increase diagnostic sensitivity. The CDC syphilis treatment guidelines have no specific recommendation for treatment, but lues maligna is treated most commonly as late latent syphilis with 3 doses of IM Penicillin.

MANIFESTATION OF STROKE AS ONE-AND-A-HALF SYNDROME IN PATIENT WITH ACUTE CORONARY SYNDROME
Prakrity Urja; Lakshmi M. Chintalacheruvu; Jason E. Lambrecht. Creighton University, Omaha, NE. (Control ID #2704066)

LEARNING OBJECTIVE #1: Identify the rare diagnosis if it is present simultaneously with the more prevelant disease condition.

LEARNING OBJECTIVE #2: Importance of the thorough history taking and careful physical examination.

CASE: A 54-year-old male with medical history of insulin-dependent diabetes mellitus, coronary artery disease, peripheral vascular disease, and heart failure with reduced ejection fraction was transferred from outside hospital for NSTEMI followed by a fall. On admission patient was confused, had short term amnesia, and was disoriented to time and place with negative infectious and toxicology screening. Computed Tomography(CT) head was unremarkable. His peak troponin was 0.79 and electrocardiogram showed sinus rhythm with no acute ST-T wave changes. Echocardiogram on admission showed severely reduced ejection fraction with no regional wall motion abnormalities. He was started on optimal medical management with no intervention planned per cardiology recommendations. On focused neurological examination, his motor and sensory examination was normal. But the cranial nerve examination showed loss of abduction and adduction on the right side and loss of abduction on the left side which is known as one-and-a-half syndrome. MRI brain was done to further evaluate the cause which showed subacute-appearing infarcts in the pons, right tegmentum, and right parietal periventricular white matter. Neurology recommended transesophageal echocardiography(TEE) to rule out embolic stroke. His TEE did not show a thrombus in the ventricles or atria but showed smoke in the left atrium. Cardiology thought that he could have had cryptic emboli and the smoke on TEE was secondary to sluggish blood flow. Anticoagulation was started. One-and-a-half syndrome was believed to be a manifestation from the brain stem stroke secondary to cryptic emboli. During his hospital course his memory gradually improved and he was discharged to a nursing facility for rehabilitation.

IMPACT: Rare conditions are easily missed when more prevalent disease and associated comorbidities are present and require management. This is an excellent case highlighting the importance of a thorough physical examine and recognition of a rare and unusual syndrome that help guide further investigation and management to improve the patient’s outcome.

DISCUSSION: One-and-a-half syndrome is a rare pathology of the conjugated horizontal eye movement of one eye and the intranuclear ophthalmoplegia of the opposite eye. This is caused by a lesion in the paramedian reticular formation (PPRF) and/or abducens nucleus and the median longitudinal fasciculus on the same side. Common causes are pontine or thalamus lesions including hemorrhage, embolic or ischemic stroke, tumor and multiple sclerosis. It can also be seen in tuberculoma, neurocycticercosis, acute myeloid leukemia and systemic lupus erythematosus.

MASTITIS - A RARE CAUSE OF TOXIC SHOCK SYNDROME

Santhi Gokaraju; Nancy Mutoro; Mark Feldman. Texas Health Presbyterian Hospital, Dallas, TX. (Control ID #2703801)

LEARNING OBJECTIVE #1: Recognize mastitis as a rare non-menstrual cause of Toxic Shock Syndrome (TSS)

CASE: A 28-year-old previously healthy female, presented 12 days after an uncomplicated vaginal delivery with a 2-day history of fever, nausea, vomiting and diarrhea. Her BP was 70/40 mmHg, HR 130/min, Temp 99.6 °F. She had dry mucous membranes and congenitally inverted nipples. Her left breast was engorged with a tender palpable mass in the left upper outer quadrant. Abdominal exam revealed mild right lower quadrant and suprapubic tenderness. Extremities were cool with 1+ pitting edema. Her skin was warm with diffuse erythema on the neck, abdomen and back. Pelvic exam was unremarkable. Her WBC count was 44,000/uL with 87% neutrophils, INR 1.6, bicarbonate 7 mmol/L, anion gap 26 mmol/L, BUN 31 mg/dL, Creatinine 3.5 mg/dL, AST 74 U/L, lactic acid 6.5 mmol/L, CRP 16 mg/dL and CK 388 U/L. She remained hypotensive despite aggressive fluid resuscitation, requiring norepinephrine and vasopressin infusion. Vancomycin, piperacillin/tazobactam and clindamycin were initiated. Stool and urine cultures were negative, as were ASO titers and rickettsial serologies. Blood cultures grew methicillin sensitive *Staphylococcus aureus*. Antibiotics were switched to naficillin and clindamycin. TTE/TEE were negative for endocarditis. Pelvic ultrasound and CT abdomen/pelvis were non-revealing. Gallium scan showed bilateral breast accumulations of radiotracer, consistent with mastitis. Patient had desquamation of her face, perioral and back region followed by her hands and feet 5–6 days after admission.

IMPACT: Emphasizes the need for a thorough physical exam in the clinical diagnosis of TSS and early initiation of antibiotic regimen to improve mortality

DISCUSSION: TSS is a life-threatening illness from colonization or local infection by *Staphylococcus aureus*. It is caused by the super antigen TSST-1, enterotoxin type B or C. TSS is characterized by fever, shock, multiple organ involvement, and an erythematous rash with subsequent desquamation. There have been many cases of menstrual-associated TSS with the use of absorbent tampons but lately, non-menstrual cases of TSS related to surgical and post-partum wound infections, as well as mastitis have been reported. In a literature review, only 5 cases of TSS secondary to mastitis have been reported. Three of these cases had isolates of *Staphylococcus aureus* from breast milk. TSS is diagnosed based upon clinical presentation and does not require isolation of *Staphylococcus aureus*. Our patient is non-lactating due to congenital inverted nipples but the cause of mastitis could still be pregnancy related. Although TSS secondary to mastitis is rarely described, the internist should be aware of non-menstrual TSS and have a high degree of clinical suspicion requiring thorough physical exam, especially when patient is too sick to provide any clinical history. The addition of clindamycin to antibiotic regimen inhibits both enterotoxins and TSST-1.

MAY THURNER SYNDROME: A RARE CAUSE OF DEEP VENOUS THROMBOSIS (DVT) Sidra Khalid; Tessy Meridores; Hamed Daw. Fariview Hospital - Cleveland Clinic, Cleveland, OH. (Control ID #2706611)

LEARNING OBJECTIVE #1: − to recognize and manage May Thurner Syndrome when it is the underlying etiology of lower extremity DVT

CASE: A 67-year-old female presented to the ED with worsening left leg pain and swelling for 2 days. On presentation, her vital signs and physical examination were unremarkable except for an extensive swelling and edema of the left lower leg. DVT ultrasound of the lower extremities revealed acute DVT of the left distal external iliac, common and superficial femoral veins. Heparin infusion was initiated. Since, the clot was large and recent, thrombolytic therapy was planned. From an ultrasound guided cannulation of the left popliteal vein, catheterization of the inferior vena cava (IVC) from the popliteal vein was performed. A left leg and abdominal venogram showed a patent dilated superficial femoral vein, with a dense thrombus involving the proximal superficial femoral vein extending into the common femoral, external and common iliac veins. 12 mg of alteplase was infused into the thrombus. Subsequently, an AngioJet catheter was passed through the veins. This led to a resolution of thrombus in the superficial and common femoral veins, but there was significant residual stenosis and thrombus in the left common and external iliac veins. Angioplasty of the left common and external iliac, superficial and common femoral veins was performed. Catheter directed therapy with alteplase at 0.5 mg/hr was infused overnight. The following day, angiography showed patency of the left femoral and external iliac veins, but no forward flow in the left common iliac vein. IVUS revealed a residual thrombus and extrinsic compression of the common iliac vein from the crossing artery. A diagnosis of May Thurner Syndrome was made. Stents were placed in the common and external iliac veins, after which there was no residual irregularity, and a forward flow into the IVC was achieved. There were no further complications and she was discharged on long-term oral anticoagulation therapy with warfarin.

IMPACT: In patients with extensive and recurrent DVT of the lower extremities, May Thurner Syndrome should be considered. A high index of clinical suspicion is required to make the diagnosis both in inpatient and outpatient settings. This case supports the literature regarding the management of this condition, which includes a combination of anticoagulation and interventional approach.

DISCUSSION: May Thurner Syndrome occurs when the left common iliac vein is compressed between the overlying right common iliac artery and the lumbar spine. It is a cause of DVT in 2–3% of cases. Management includes anticoagulation, catheter-directed thrombolysis, and/or intravascular stenting. Hence, May Turner Syndrome should be included in the differential diagnosis in order to prevent recurrent DVT and additional complications, such as pulmonary emboli, iliac vein rupture and chronic venous stasis.

MECKEL'S DIVERTICULUM, NOT JUST A PEDIATRIC DIAGNOSIS Claire L. Jansson-Knodell; Dante Schiavo. Mayo Clinic, Rochester, MN. (Control ID #2706704)

LEARNING OBJECTIVE #1: Diagnose Meckel's diverticulum as a cause of obscure gastrointestinal bleeding in an adult.

LEARNING OBJECTIVE #2: Recognize the changing differential diagnosis for hematochezia based on age.

CASE: A 19-year-old male with a history of spondylosis and asthma presented with upper respiratory symptoms, fever and headache and had been using daily NSAIDs for symptom relief. He was found to have *Fusobacterium* bacteremia

likely related to sinusitis. During his hospitalization, he had persistent headaches and imaging revealed a cavernous sinus thrombosis that required anticoagulation. Prior to antithrombotic therapy, he developed severe hematochezia with output of 1.5 L of bloody stool over a few hours. Physical exam showed vitals of HR 94/min and BP 99/57 mmHg. The abdomen was soft, diffusely tender, not distended with normal bowel sounds. Bright red blood was seen on rectal exam. Laboratory studies showed a significant hemoglobin drop from 14 g/dL to 6.9 g/dL. He required 3 units of packed RBCs for resuscitation in addition to vasopressors for septic shock. EGD and colonoscopy including intubation of the terminal ileum were unremarkable. CT enterography revealed a thickened, blind-ending segment of small bowel extending from the ileum concerning for Meckel's diverticulum. An open surgical resection was performed. Pathology revealed a 2-cm diverticulum with focal ulceration and gastric heterotopia. The ulceration and bleeding were likely related to his heavy NSAID use before admission. After the procedure his bleeding resolved and he was able to initiate warfarin as treatment for his cavernous sinus thrombosis.

IMPACT: Meckel's diverticulum is an important part of the differential diagnosis for GI bleeding, particularly in patients under age 40. The differential of hematochezia changes based on age. In older individuals angioectasias and diverticulosis are common. IBD, Dieulafoy lesions, neoplasia, and polyposis syndromes also need to be considered in young adults. This case serves as a reminder that congenital anomalies extend beyond the scope of pediatrics and have clinical relevance in adult practice.

DISCUSSION: While Meckel's diverticulum ranks as the most common congenital anomaly of a child's gastrointestinal tract, it is somewhat rare for it to become clinically significant in an adult. Meckel's diverticulum is notable in medical texts for the rule of 2's: 2% of the population, symptomatic before age 2, length of 2 inches, 2 feet from the ileocecal valve, and 2 types of heterotopic mucosa. Epidemiologic studies estimate actual prevalence to be 1.2%. Approximately 6% of those with a diverticulum will develop a complication such as bleeding, which requires surgery. This case highlights the role of age in causes of hematochezia and the need to consider a traditionally pediatric pathology manifesting later in adulthood.

MEDICAL MANAGEMENT OF AN INFECTED BRONCHOGENIC CYST PRIOR TO SURGERY: AN ALTERNATIVE TO MECHANICAL DRAINAGE

Hadas Reich[1]; David Wei[2]. [1]New York University, NEW YORK, NY; [2]New York University, New York, NY. (Control ID #2706575)

LEARNING OBJECTIVE #1: Diagnose and manage an infected bronchogenic cyst

CASE: A 35 year old man without any past medical history presented with 1 week of cough, associated with blood-tinged sputum and subjective fevers and night sweats. He emigrated from Mexico 12 years prior and had been living in a shelter for 1 year. He had a 10 pack-year history but had quit 10 years prior to presentation. On exam, he had normal vital signs with a mild decrease in breath sounds over the left middle lobe, but an otherwise unremarkable physical exam. Chest X-ray demonstrated a 9cm lesion with an air fluid level in the left hemithorax, with subsequent chest computed tomography demonstrating a thin-walled cystic lesion. He was ruled out for tuberculosis with 3 negative sputum samples. Due to his mild infectious symptoms, we decided to treat with empiric antibiotics. Interval imaging showed a persistent thin-walled cavity without a fluid level. He underwent video-assisted thoracic surgery (VATS) guided wedge resection; pathology confirmed a bronchogenic cyst.

IMPACT: Our patient presented with mild symptoms and a large bronchogenic cyst. Most case reports involve mechanical drainage of the cyst prior to surgery. Our case demonstrates that medical management may be an alternative to mechanical cyst drainage prior to resection.

DISCUSSION: Bronchogenic cysts are congenital lesions caused by outpouchings of the foregut during development. They have been described in multiple locations, including the mediastinum, diaphragm, neck, and abdomen, with 15–20% found in the lung.(Jiang et al. 2015) They can vary in size, with different reviews reporting average sizes of 4–6cm.(Patel et al. 1994, Jiang et al. 2015) Bronchogenic cysts are often incidentally diagnosed in asymptomatic patients, however the literature suggests most will eventually become symptomatic. Symptoms develop if a cyst becomes large enough to compress contiguous structures (such as the esophagus, IVC, or trachea), or if the cyst becomes infected. Symptoms can include cough, dyspnea, fever, chest pain, or dysphagia, and can progress to respiratory distress.(St-Georges et al. 1991) When a cyst becomes infected, most are treated by either early surgical excision, or by drainage (through endoscopy, bronchoscopy, mediastionoscopy, or percutaneously), followed by surgical resection.(Kawaguchi et al. 2014) Surgical resection is needed for definitive cure, prevention of recurrence, and pathologic diagnosis. Excision of asymptomatic bronchogenic cysts is controversial, but is typically recommended to prevent subsequent infection and complications. There have not been many reports in the literature of treatment with antibiotics as a means of emptying the cyst. In our case, given that the patient was clinically well, empiric antibiotics were used to treat the infection, which led to subsequent drainage of the cyst. Our patient underwent VATS excision after a course of antibiotics to prevent recurrence.

MESALAMINE-INDUCED EOSINOPHILIC PNEUMONIA

Elizabeth Bonarigo[2]; Matthew Schaikewitz[1]; Jon-Emile Kenny[1]; Veevek Agrawal[1]; Erica Grabscheid[2]. [1]Mount Sinai Beth Israel, Passaic, NJ; [2]Mount Sinai Beth Israel, New York, NY. (Control ID #2697515)

LEARNING OBJECTIVE #1: Ulcerative colitis (UC) can have extra-intestinal manifestations and present as new onset pulmonary disease. Patients who suffer from UC are commonly treated with mesalamine, which has been reported to rarely cause mesalamine-induced lung disease (MILD). An objective of this clinical vignette is to present a case in which it is important to recognize the possibility for MILD in patients with UC who present with new onset lung disease.

CASE: A 27 year old male with ulcerative colitis (UC) and childhood asthma presented with a dry cough, fever and weight loss for 6 weeks. One and a half years prior to admission, he was diagnosed with UC for which he was started on oral mesalamine 1.2 g/day. Prior to admission, he visited an outpatient clinic because of shortness of breath. CXR demonstrated bilateral upper lobe opacities that subsequently did not respond to a 7 day course of antibiotics. Physical examination on admission: Temp100°F, BP 112/95, HR 126, RR 20, O_2 sat of 94% RA and decreased lung sounds at the bases bilaterally. WBC 14.8K/uL (nl 4.5-10.8) with repeat peripheral eosinophils 1.0K/uL ($x < 0.9$). CT chest demonstrated dense peripheral opacities in both upper lobes. Blood, fungal and resp cultures were negative. TB, HIV, Legionella, Histo, Coccidio, Aspergillus and stool O + P tests were negative also. A transbronchial lung biopsy disclosed increased eosinophils, fibroblastic tissue and foamy macrophage accumulation consistent with eosinophilic pneumonia. There were no viral

cytopathic changes, granulomas or malignancy noted. Broncho-alveolar lavage cytology showed increased eosinophils. Eosinophilic pneumonia secondary to mesalamine was suspected. With the discontinuation of mesalamine and subsequent treatment with steroids, the patient's symptoms resolved. Repeat CBC 2 weeks after treatment revealed normal WBC and eosinophils. Repeat CXR showed clearance of pneumonia.

IMPACT: This clinical vignette provides a case in which MILD was suspected. Once mesalamine was discontinued, symptoms almost immediately improved. MILD should be considered in any patient that presents with respiratory symptoms on such medication. Medication discontinuation will provide symptom improvement.

DISCUSSION: Sulfasalazine is an important drug in the treatment of inflammatory bowel disease (IBD). Unfortunately it is known to cause pneumonitis and, rarely, an eosinophilic pneumonia. Mesalamine contains the active ingredient (5-ASA) in Sulfasalazine but without the sulfa moiety, it is associated with less side effects and allergic reactions. Mesalamine's common side effects include headache, nausea, abdominal pain and diarrhea. Only scattered case reports exist regarding Mesalamine-induced lung disease (MILD) and its pathogenesis remains unclear. It appears that in MILD, pulmonary symptoms (usually fever, cough and dyspnea) appear within 5 days to 44 months of drug initiation. It is more common in women than men and is not dose dependent. Also peripheral eosinophilia and CXR findings are variable.

METASTATIC BREAST CANCER PRESENTING AS PANCREATITIS

Chandana Shekar; Niralee Patel; Arundati Rao. University of Connecticut School of Medicine, Farmington, CT. (Control ID #2706689)

LEARNING OBJECTIVE #1: Recognising a rare complication of malignancy as the presenting symptom.

CASE: A 33 year old female with no significant medical problems presented to our hospital with severe epigastric pain, radiating to the back for 3 days. Pertinent positive history included nausea, vomiting and constipation. She had intermittent abdominal pain and nausea for a month which had now worsened. She had been prescribed proton pump inhibitors by her primary care physician, but with no relief. There was no history of any other medication use, alcohol use or hyperlipidemia. Physical examination revealed tachycardia with a heart rate of 110 beats per minute and tenderness to palpation in the epigastric area of the abdomen. Rest of the examination was within normal limits. Lab investigations showed a leucocytosis of11,600/mL, total calcium of 15.4 mg/dl and ionized calcium of 2.02 mmol/L. The rest of complete blood count and chemistries were normal. Other abnormalities included lipase 1376 U/L, total bilirubin 4.2mg/dL, direct bilirubin 3.1 mg/dL, alkaline phosphatase of 414 U/L, aspartate transaminase of 351 U/L, alanine transaminase of 160 U/L and triglycerides 153 mg/dL. Hepatitis and iron panel were normal. Computed tomography scan of the chest and abdomen revealed right axillary lymphadenopathy, innumerable hypodense lesions scattered throughout the liver parenchyma and innumerable lytic lesions throughout the thoracic and lumbar spine. Pancreas was unremarkable and no cholelithiasis was noted. Given the pattern of metastases, mammogram and ultrasound of the breasts were done. They revealed multiple irregular right breast masses concerning for malignancy with a multifocal pattern and multiple abnormal right axillary lymph nodes most compatible with metastatic disease. Right breast biopsy showed invasive mammary carcinoma with mixed ductal and lobar features. Receptors were ER and PR positive and HER-2 negative. Liver biopsy showed metastatic carcinoma with features similar to the breast malignancy. She was managed with supportive care, zoledronic acid and calcitonin for the hypercalcemia induced pancreatitis. She also received chemotherapy with Adriamycin and cyclophosphamide and follows up with Oncology.

IMPACT: This case reiterates the fact that we should not be overcome by tunnel vision and have a wide differential diagnosis will eliminate the human error of missing a diagnosis, even a fatal one.

DISCUSSION: Acute pancreatitis induced by cancer-related hypercalcemia has been rarely reported. Reviewing related references between 1990 and 2013, we came across only 8 reported cases; mostly from T-cell leukemia or multiple myeloma and 1 from metastatic breast cancer. A single case of autoimmune pancreatitis secondary to breast cancer has also been reported in the past, however IgG4 was negative in our patient. Pancreatitis being the presenting symptom without warning signs of cancer is furthermore rare. The pathophysiology of acute pancreatitis induced by hypercalcemia still remains unclear.

METASTATIC LESIONS IN LUNG AND BRAIN DUE TO NOCARDIA ENDOCARDITIS SEPTIC EMBOLI

Krista N. Larson; Cecil A. Rambarat; Denise C. Schain. University of Florida, Gainesville, FL. (Control ID #2704045)

LEARNING OBJECTIVE #1: Recognize endocarditis with septic emboli can present like metastatic disease

LEARNING OBJECTIVE #2: Reassess cases frequently without a diagnosis and from different perspectives to avoid cognitive bias

CASE: An 80-year-old Caucasian male with a past medical history of CAD, ICD placement, DM type II, thrombocytopenia, stage 1 adenocarcinoma of the colon in 2012, squamous cell carcinoma of the left arm in 2015, colitis treated with prednisone 10 mg PO daily, and a 40 lb unintentional weight loss over the last year presented with an acute episode of dsyarthia. CT head found left parietal and left cerebellar masses consistent with metastatic disease. IV dexamethasone was administered and patient's speech returned to baseline. CT chest/abdomen/pelvis showed two cavitary lesions in his right lung concerning for metastatic disease. Transthoracic biopsy was non-diagnostic. Bronchoscopy was not able to reach the lesions for biopsy and BAL was performed. Cytology was negative for malignancy, fungal, and AFB organisms; bacteria, fungi, and AFB cultures were negative. Given the history of stage I adenocarcinoma of the colon, an EGD/colonoscopy was performed and was negative for cancer. A second CT chest to further evaluate the cavitary lesions showed multiple new septic emboli. Transesophageal echocardiogram revealed vegetations on the mitral valve and on the ICD leads. Antibiotics were started and the ICD was removed. Brain biopsy was performed removing copious purulent material; cultures grew *Nocardia cyriacigeorgica*/*asteroids*. Antibiotic coverage was narrowed based on susceptibility testing. The patient began medically improving in response to treatment.

IMPACT: Our case highlights an unusual presentation of Nocardia endocarditis with septic emboli. It also emphasizes the importance of keeping an open differential diagnosis throughout the diagnostic evaluation of the patient.

DISCUSSION: Nocardia typically causes infections in immunocompromised hosts and most commonly presents as pulmonary nocardosis[1]. Most cases of reported Nocardia endocarditis involve prosthetic valves[2]. A few cases of Nocardia endocarditis in native valves have been described following a dental extraction[3], a Nocardia skin/soft tissue infection[4]; and, a case in an IV drug

user[2]. Our case occurred in an elderly man on long term prednisone presenting with dysarthria and weight loss, a history of two primary cancers, and no symptoms to suggest infection. This case highlights an unusual presentation of a rare diagnosis and the importance of keeping an open differential diagnosis throughout evaluation to prevent cognitive bias. 1. Wilson JW. Nocardosis: Update and Clinical Overview. Mayo Clin Proc. 2012 Apr;87(4):403–407 2. Watson A et al. Nocardia asteroides native valve endocarditis. Clin Infect Dis. 2001 Feb;32(4):660–1 3. Lazo Torres AM et al. Nocardia endocarditis in a native mitral valve. Rev Esp Cardiol.2004 Aug;57(8):787–8 4. Dhawan VK et al. Native valve endocarditis due to a Nocardia-like organism. Clin Infect Dis.1998 Oct;27(4):902–4

METHAMPHETAMINE CARDIOMYOPATHY WITH A SHOWERING OF PULMONARY EMBOLI

Ali Al-Hilli; Joanna Pluta; David Heegeman. Marshfield Clinic, Marshfield, WI. (Control ID #2703058)

LEARNING OBJECTIVE #1: Recognize that cardiomyopathy from abusing Amphetamines Type Stimulants (ATS) can mimic various pathologic processes, thereby presenting a diagnostic challenge.

LEARNING OBJECTIVE #2: Be aware that ATS abuse and related complications are on the rise.

CASE: A 35-year-old male presented to the Emergency Department with a 2-week history of progressive dyspnea and a 3-day history of hemoptysis. He also complained of fatigue, cough, pleurisy, chest pain, calf pain with swelling and erythema. He denied any recent trauma, infection, long distance travel, surgery, immobilization, fever, chills, weight loss, or orthopnea. His past medical history is significant for deep venous thrombosis (DVT) 1 year ago, treated for 6 months with warfarin. He works as a driver for the local Amish community. He is a light smoker and occasionally drinks alcohol. He admitted to using intravenous methamphetamine in the past, but none in the last 6 months. His mother suffered from DVTs. He takes no medications. On examination, the patient was afebrile, tachycardic at 117 beats per minute, normotensive, in moderate respiratory distress but saturating 94% on room air. Jugular venous pressure was elevated, an S3 gallop was heard, lung sounds were clear and abdominal exam was unremarkable. The calves were symmetric bilaterally with 1+ pitting edema to mid shins and apparent stasis dermatitis. Point of Care Ultrasound (POCUS) showed a dilated inferior cava and a severely reduced left ventricular ejection fraction (LVEF) visually estimated to be less than 20%. This warranted admission to hospital. Laboratory studies showed a mildly raised troponin, and a high B-type Natriuretic Peptide (BNP). ECG revealed sinus tachycardia. Chest X-Ray demonstrated cardiomegaly without pulmonary edema. Transthoracic echocardiography (TTE) showed an LVEF of only 10%. Chest Computed Tomography (CT) was notable for multiple acute bilateral pulmonary emboli. A pericarditis panel and hypercoagulable workup were negative. Cardiac catheterization revealed clean coronary arteries. A urine drug test was positive for methamphetamine. In light of this result, he admitted to a recent methamphetamine binge. He left the hospital against medical advice shortly thereafter.

IMPACT: This is the second reported case of methamphetamine cardiomyopathy presenting with multiple pulmonary emboli. However, it is the first in the literature to describe such a markedly depressed LVEF of 10%.

DISCUSSION: Nonischemic cardiomyopathies due to ATS abuse are becoming increasingly prevalent owing to the widespread availability of such drugs. Common cardiac manifestations from methamphetamine-driven sympathetic activity include hypertension, arrhythmias, acute coronary syndromes and sudden cardiac death. Cardiac dysfunction is thought to be related to vasospastic and ischemic changes, direct drug toxicity, and sympathetic effects of catecholamines on the myocytes. When unexplained cardiomyopathy is encountered, ATS abuse should be considered in the differential diagnosis.

MIGRATING PARASITES!

Sreelakshmi Panginikkod[3]; Venu Pararath Gopalakrishnan[3]; Pratyusha Bollimunta[3]; Niyati M. Gupta[2]; Malav P. Parikh[1]. [1]Cleveland Clinic Foundation, Cleveland, OH; [2]Cleveland Clinic Foundation. Grant Medical College and Sir J.J. Group of Hospitals.., Cleveland, OH; [3]Presence Saint Francis Hospital, Evanston, IL. (Control ID #2706904)

LEARNING OBJECTIVE #1: Recognize Neurocysticercosis (NCC) as a cause of headache and seizure

LEARNING OBJECTIVE #2: Recognize the appropriate management of NCC

CASE: A 63-year-old male immigrant from Ecuador was brought to Emergency Department after a seizure episode. He endorsed headache, abdominal pain, and nausea with scanty non-bilious vomiting for 1 week prior to presentation. He had travelled to Ecuador 1 year ago, and also enjoys eating raw pork. Physical examination including neurological exam was normal with stable vitals. Laboratory investigations revealed normal hemoglobin, leukocytosis with eosinophilic predominance (1500) and a normal comprehensive metabolic panel. Autoimmune panel and tests for HIV and hepatitis panel were negative. Computed tomography of brain showed multiple nodular calcified and cystic lesions throughout the brain parenchyma with surrounding edema. Furthermore, magnetic resonance imaging (MRI) of brain reveled multiple intra-axial CSF intensity masses, with associated rim enhancement, calcifications, and perilesional edema with mass effect, compatible with Neurocysticercosis (NCC) in colloidal vesicular and granular nodular stages. Plain X-Ray of all extremities did not reveal any lesions in the soft tissues and a subsequent serum cysticercus antibody test with ELISA was positive with high titres. Fundoscopic examination ruled out ocular cysticercosis. He was treated with albendazole for 2 weeks, levetiracetam and tapering dose of dexamethasone. His symptoms resolved and was discharged after 7 days. On a 2 month follow up, he was asymptomatic and repeat MRI brain showed interval improvement in edema and also replacement of cystic lesion to granular stage that suggests resolution of infection.

IMPACT: With ever increasing worldwide migration, the diagnosis of NCC is more common. Treatment includes anti-parasitic, anti-epileptic, or anti-inflammatory treatments and surgery. Careful fundoscopy and plain film radiology are mandatory for all in whom the diagnosis is suspected

DISCUSSION: NCC is one of the seven neglected endemic zoonosis targeted by the World Health Organization. Sufferers often experience a long asymptomatic period, and can present with a variety of neurological manifestations, including focal neurological deficits, headache, and seizures. Extra-neurological manifestations include ocular deposition and skeletal muscle nodules. Management of NCC needs to be individualized. Treatment with albendazole and praziquantel may be associated with severe adverse reactions, which result from a massive release of antigens. Use of a corticosteroid would likely decrease the incidence of such complications. Cysticidal therapy should not be used in cases with markedly elevated intracranial pressure or in intraocular NCC, to avoid any worsening of intracranial pressure and damage to the eye, respectively. Steroids alone are used in these situations. Cysticidal therapy is of no use for calcified lesion. The patient will need repeat imaging after several months to ensure complete eradication.

MIND ALTERING ANTIBODIES: A TREATABLE CAUSE OF ALTERED MENTAL STATUS Alyson Michener[1]; Jill Huded[2]. [1]Case Western Reserve University, Cleveland, OH; [2]Cleveland VA Medical Center, Cleveland, OH. (Control ID #2706803)

LEARNING OBJECTIVE #1: Consider an important differential diagnosis for a patient presenting with altered mental status

CASE: WM is an 80-year-old male with past medical history of dementia who presented to the ED after he sustained a witnessed fall at home. Prior to losing his balance he appeared to be trembling but did not lose consciousness. The patient endorsed generalized weakness but denied any other complaints. His wife reported worsening of the patient's "dementia" over the prior two months with increased confusion. At time of presentation, the patient was febrile and tachycardic. His neurological exam was nonfocal. Labs were notable for a white blood cell count of 9.95 and 92% neutrophils. CT head and neck showed only multilevel degenerative disc disease. MRI brain revealed enhancement along the left insular cortex. CSF analysis revealed negative gram stain, normal glucose, protein of 95, and no white blood cells. EEG showed intermittent delta slowing over the posterior temporal area. The patient was started on leviteracetam due to concern for seizures and treated empirically for herpes encephalitis with IV acyclovir. He also received a three-day prednisone burst as limbic encephalitis remained on the differential. Shortly after discharge, the medical team was contacted by an outside laboratory and informed that the patient's autoimmune encephalitis antibody was positive for anti-leucine-rich glioma inactivated-1 (LGI1) antibody. The patient was readmitted for five days of IVIG, which he tolerated without complication. At one month follow up, the patient and his wife reported improvement in his functional status

IMPACT: Limbic encephalitis is a treatable cause of altered mental status and should be included in the differential for older patients presenting with behavioral and memory disturbances.

DISCUSSION: Limbic encephalitis is a subacute disturbance in memory and behavior which is often accompanied by seizures. When it occurs in elderly patients who have underlying cognitive impairment, it may be difficult to identify or differentiate from chronic dementia or acute delirium from other causes. Because our patient had baseline dementia, his family initially believed that his subacute clinical deterioration was progression of his underlying cognitive disease. It was not until he presented with a fall suggestive of a seizure that further investigation revealed the true diagnosis. Limbic encephalitis, which typically presents with memory disturbance, confusion, neuropsychiatric features, and seizures, may be autoimmune or paraneoplastic. Autoimmune encephalopathies are associated with antibodies, such as anti-LGI-1, that target extracellular epitopes of cell-surface or synaptic proteins. Once a diagnosis of limbic encephalitis is established, treatment may be initiated with immunotherapy. As many as 90% of patients with anti-LGI1 encephalitis respond favorably treatment, emphasizing the point that clinicians should be aware of this relatively rare but treatable cause of altered mental status.

MISSING POUNDS; MISSED DIAGNOSIS Rachel Solomon[2]; Ariela Holmer[1]; Aparna Sarin[1]. [1]Mount Sinai, New York, NY; [2]Mount Sinai Medical Center, New York, NY. (Control ID #2707127)

LEARNING OBJECTIVE #1: Identify early satiety as a symptom of dyspepsia and H. pylori infection

CASE: A 65 year-old female smoker with diabetes, distant IV drug use on methadone, and dyspepsia treated with ppi for over 10 years presented to clinic with unintentional 30-pound weight loss over a year. She denied abdominal pain, bleeding, melena, fevers, night sweats, and cough. There was breast cancer in her mother and gastrointestinal cancer in a grandfather. Pap smear was up to date; mammogram and colonoscopy were overdue. No abnormalities were noted on exam. Initial diagnostics - cbc, cmp, TSH, HIV, HCV, ESR, CRP and chest x-ray - were unremarkable. A1c was low, 5.8. Screening mammogram showed breast asymmetry that was not reproduced on diagnostic test. CT chest, abdomen, pelvis, revealed dilated common bile duct diagnosed as choledochal cyst on MRCP. She deferred colonoscopy. 5 months later, she described "forcing" herself to eat to combat poor appetite and early satiety. Weight was stable. Chart review found low B12 (198) three years prior attributed to metformin. She had never been tested or treated for Helicobacter pylori. Serum antibody returned positive. Following 14-days of triple therapy, the patient's appetite returned. She regained 10 pounds in 2 months and is awaiting endoscopy.

IMPACT: When evaluating unintentional weight loss, assessing for early satiety and accounting for dyspepsia history may provide direction and prevent excess testing and patient stress.

DISCUSSION: Unintentional weight loss presents commonly in primary care. Incidence is 5–7%, but risk increases with age, smoking, and poor reported self-health. Association with increased mortality demands prompt attention. Absent suggestive findings, guidelines support casting a wide diagnostic net. Where diagnostic clues are sparse, initial evaluation must incorporate reexamination of standing diagnoses and medication histories - particularly as regards dyspepsia and chronic ppi use - to guide appropriate work-up. Dyspepsia, defined by postprandial fullness, early satiety, *and/or* epigastric pain, impacts 25% of the population. H. pylori is an organic cause of dyspepsia and, untreated, linked to peptic ulcer disease and malignancy. Though more common in the developing world, prevalence in the US is 30–40%. The ACG recommends *testing and treating* patients in prevalence areas over 10% who are under 55 without alarm symptoms. Urea breath and fecal antigen tests are preferred; the serum antibody test is an alternative in untreated patients. Despite 10 years of ppi therapy and unexplained vitamin B12 deficiency, our patient had not been tested. Given the history, had early satiety been identified at current presentation, our patient would have been sent for early EGD. Because this was missed, EGD was delayed by red-herrings identified on excess diagnostic imaging. Where there is delay or difficulty in accessing EGD, using less invasive tests to assess for H.pylori infection is an important first step in making an intervenable diagnosis.

MMIND THE GAP: FLIMSY FOLLOW-UP LEADS TO TOXIC THYROID Zieanna Chang. University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2703213)

LEARNING OBJECTIVE #1: Describe the initial treatment and definitive therapy of toxic multinodular goiter

LEARNING OBJECTIVE #2: Manage thyrotoxic periodic paralysis

CASE: A 58-year-old woman presented to the emergency department with one week of generalized muscle weakness characterized by difficulty walking, multiple falls, and inability to prepare meals. She also reported a new tremor in her hands. She denied fevers, palpitations, dyspnea, nausea, diarrhea, or abdominal pain. Examination revealed marked weakness and prolonged 3+

reflexes in all four extremities. Thyroid palpation was unremarkable without thyromegaly, nodularity, or tenderness. EKG showed sinus tachycardia to 118bpm with exaggerated P waves, J point depression, and possible U waves. Laboratories were remarkable for a potassium level of 1.4mMol/L. TSH was undetectable, and free T4 was elevated to 1.83ng/dL. The patient was started on methimazole (MMI) 20mg daily and atenolol 50mg daily. She received 100 milliequivalents of potassium repletion daily for 48–72 h, and her weakness improved. Careful history revealed that the patient had a known history of multinodular goiter and was previously maintained on methimazole. Her endocrinologist had moved away one year ago, and she ran out of medication. Repeat thyroid ultrasound revealed two stable nodules as large as 1.6cm. Two months after hospitalization, she underwent successful total thyroidectomy.

IMPACT: This case emphasizes that primary care and specialty providers have an important role in communicating the potential severity of chronic diseases that require maintenance therapy. Thyrotoxic periodic paralysis is a rare but dramatic complication of uncontrolled hyperthyroidism that should also be recognized and treated early.

DISCUSSION: Physical exam findings of hyperreflexia, tremor, and tachycardia are suggestive of hyperthyroidism. This patient's weakness resulted from an uncommon complication of hyperthyroidism known as thyrotoxic periodic paralysis. Often associated with severe hypokalemia, it typically improves with potassium repletion and appropriate management of hyperthyroidism. The mainstay of therapy for hyperthyroidism is a beta blocker (atenolol or propranolol) to reduce the thyroid hormone's sympathetic-activating effects. Methimazole is used concomitantly to inhibit thyroid hormone synthesis. Propylthiouracil can cause agranulocytosis and liver injury, but it is the safer agent in the first trimester of pregnancy. Toxic multinodular goiter is the second most common cause of hyperthyroidism in the United States, second only to Graves disease. Definitive treatment requires either radioiodine ablation or thyroidectomy, neither of which were performed prior to this patient's acute presentation. Therefore, the importance of follow up and definitive treatment must be emphasized to avoid complications of untreated hypothyroidism such as thyroid storm.

MOLLARET'S MENINGITIS: AN ATYPICAL PRESENTATION WITH HYPOGLYCORRHACHIA

Natalie Klar[1]; Shelly Kakar[1]; Amar Kohli[2]. [1]UPMC, Pittsburgh, PA; [2]UPMC, Mars, PA. (Control ID #2702874)

LEARNING OBJECTIVE #1: Detail the diagnostic criteria and treatment for Mollaret's meningitis (MM) in patients with recurrent and non-specific neurological symptoms.

LEARNING OBJECTIVE #2: Define hypoglycorrhachia and recognize the differential diagnosis that may cause this.

CASE: A 67 year-old male with history of IDDM type II, OSA and obesity presented with worsening occipital headaches, blurred vision and ataxia. He had a 6 month history of intermittent confusion and syncopal episodes which would resolve spontaneously. Pertinent exam findings included papilledema, positive Babinski, waddling gait, and no signs of meningismus. ECHO, carotid dopplers and head CT and MRI were unremarkable. Lumbar puncture (LP) showed 315 WBC (73% lymphs, 27% monocytes), glucose 5 mg/dl (serum 101), opening pressure 38 cm H20 and total protein 154 mg/dl. Given his hypoglycorrhachia, increased intracranial pressure and lymphocytic pleocytosis, fungal or TB meningitis was highest on the differential. He was started on amphotericin with minimal clinical improvement. Histoplasmosis antigen (serum, urine and CSF), Cryptococcus antigen (serum and CSF), TB (CSF PCR and QuantiFERON) were negative in addition to negative CSF gram stain, India ink and AFB culture. CSF VZV, CMV, EBV, HSV-1, HHV-6, Lyme and VDRL were all negative. CSF HSV-2 PCR and serum HSV-2 IgG returned positive. MM was diagnosed with these findings and bi-lobulated lymphocytes in CSF cytology. The patient reported genital herpes 40 years ago without recent recurrences or lesions. Repeat LP, following 7 days of Acyclovir, showed 202 WBC (82% lymphs), glucose 62 mg/dl (serum 177), opening pressure <40 cmH20 and total protein 151 mg/dl. The patient noted resolution of headaches, blurred vision and LP showed resolving hypoglycorrhachia.

IMPACT: This unique case highlighted non-specific neurological symptoms and CSF findings consistent with MM which improved with Acyclovir. This case illustrated hypoglycorrhachia can be seen in MM and can improve with Acyclovir.

DISCUSSION: MM is a rare entity with <100 cases published making it a challenging diagnosis. MM is defined as benign recurrent lymphocytic meningitis characterized by repeated episodes of headaches, photophobia, mental status changes, and meningismus. These episodes last 2–7 days and resolve on their own followed by symptom-free intervals. MM is diagnosed with lymphocytic pleocytosis and positive CSF HSV-2 PCR. Features in MM include hypercellularity with pleocytosis and atypia with deeply lobulated/cleft nuclei. Hypoglycorrhachia is defined as CSF glucose <40mg/dl with CSF/serum glucose ratio <0.6. Hypoglycorrhachia is typically seen in bacterial, fungal, TB meningitis and malignancy. It has been reported, although rare, with HSV-2 meningitis and typically never <25mg/dl. MM treatment is controversial with recommendations ranging from no treatment to 7–10 days to 14–21 days of IV Acyclovir to lifelong prophylactic PO Acyclovir.

MORE COMPLICATED THAN ASTHMA AND ALLERGIES

Joseph M. Rocco; Lee Rabinowitz. University of Pittsburgh, Pittsburgh, PA. (Control ID #2698945)

LEARNING OBJECTIVE #1: Recognize the clinical features in asthma that increase the risk of underlying vasculitis

LEARNING OBJECTIVE #2: Diagnose Eosinophilic Granulomatosis with Polyangiitis (EGPA) in the setting of asthma, peripheral eosinophilia and evidence of vasculitis

CASE: A 65-year old woman with a history of asthma and pansinusitis presents with fever and hypoxemia. Over the last year, she had recurrent hospitalizations for pneumonia and received multiple courses of antibiotics and steroids. She also noted a new non-blanching rash on the ankles. Her asthma was adult-onset and had been chronically difficult to control. Exam noted a new oxygen requirement and palpable purpura on all extremities. Labs showed leukocytosis with a 30% eosinophilia. Chest CT noted scattered ground-glass opacities. The next day, patient developed flash pulmonary edema and TTE revealed diffuse hypokinesis. Due to multi-organ involvement, both EGPA and hypereosinophilic syndrome were considered. IgE was significantly elevated but ANCA was negative. Skin biopsy after steroids was non-specific. Bone marrow biopsy had normal hematopoiesis. Cardiac MRI demonstrated subendocardial fibrosis in multiple coronary distributions consistent with vasculitis. Final diagnosis of EGPA was made and treatment with steroids and rituximab led to resolution of symptoms. Repeat TTE after discharge showed improved EF and normal ventricular function.

IMPACT: Failing to recognize EGPA early can lead to significant mortality however with prompt treatment the 5-year survival rate is over 90%. I plan to

monitor asthma patients with risk factors for vasculitis more closely and initiate evaluation for EGPA earlier should these patients develop systemic symptoms.
DISCUSSION: Both asthma and chronic sinusitis are common disease processes, whereas systemic vasculitides, such as EGPA, are extraordinarily rare. Recognizing risk factors for EGPA is important due to the risks of delaying treatment. Patients with EGPA often have adult-onset asthma which is difficult to control. Sinusitis is almost universally present and associated with nasal polyps. Peripheral eosinophilia can be an early clue, as this is rare in asthma alone. EGPA classically progresses through a prodromal allergic phase, an eosinophilic phase and a vasculitic phase. However, most patients do not follow this classic progression. EGPA is difficult to diagnose and although a biopsy is needed to confirm vasculitis, the final diagnosis remains clinical. Common lab abnormalities include an absolute eosinophilia and elevated IgE. RF is positive in 50% of cases, whereas ANCA is only present in 38%. ANCA-negative cases characteristically have more cardiac and lung manifestations. The ACR diagnostic criteria have a high sensitivity and specificity, however these can only be applied after a vasculitis is confirmed. The ACR criteria include asthma, paranasal sinusitis, peripheral eosinophilia, migrating pulmonary infiltrates, neuropathy and tissue eosinophilia; they are positive when 4 of the 6 standards are present.

MORE THAN MEETS THE EYE Annelys Roque; L. E. Goldman. University of California, San Francisco, San Francisco, CA. (Control ID #2706170)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of intraocular tuberculosis
LEARNING OBJECTIVE #2: Diagnose intraocular tuberculosis in a patient without pulmonary symptoms
CASE: A 64-year-old male with a PMH of bilateral cataracts presented to primary care clinic to establish care. The patient had been out of care for 2 years and had been evaluated but never treated for his cataracts. On presentation, his vision was 20/200 bilaterally. At that time, he was referred to ophthalmology. In ophthalmology clinic, he was found to have cataracts likely secondary to chronic bilateral anterior uveitis. The patient had labs drawn that were significant for a non-reactive RPR, negative PPD, and a normal ESR, lysozyme level, and ACE level. A chest x-ray showed an unchanged 5mm left costophrenic angle nodule that could represent a granuloma. The patient was born in Thailand, immigrated to the United States over 40 years ago, but frequently returned to visit. He had always lived on the West Coast and worked as a cook. He did not have a history of incarceration and was housed in an apartment. The patient was seen in primary care clinic for a follow-up two months after being seen by ophthalmology. He continued to endorse poor vision but denied cough, night sweats, hemoptysis, weight loss, and fatigue. Labs drawn were significant for a positive quantiferon gold and positive ANA with a 1:40 titer. The patient was referred to Tuberculosis Clinic. An AFB sputa and stain were positive for Mycobacterium tuberculosis. The patient was started on RIPE therapy shortly thereafter. In a follow-up appointment with ophthalmology two months after being started on therapy, the patient had no evidence of uveitis.
IMPACT: This patient's case changed my practice by broadening my differential of a patient presenting with chronically poor vision from an endemic TB area. Given the self-reported history of bilateral cataracts, I fell into the cognitive error of premature closure and attributed his poor vision to cataracts from advanced age.
DISCUSSION: The presentation of intraocular tuberculosis includes a wide spectrum of pathologies. Among these are: anterior granulomatous uveitis, choroiditis, retinal vasculitis, panuveitis, and chronic anterior uveitis. By the time patients seek treatment for uveitis, most do not show overt evidence of systemic TB disease although it develops from hematogenous spread from a primary focus. The lack of systemic symptoms and the difficulty of obtaining a microbiological diagnosis from ocular tissues/fluids makes establishing the diagnosis of intraocular tuberculosis very difficult. The accepted approach, and the one used in this case, first involves the exclusion of other etiologies of chronic granulomatous disease such as infectious or systemic inflammatory diseases. After exclusion of other etiologies, suggestive ocular findings and evidence of systemic tuberculosis is enough to establish the diagnosis. In this case, the patient had evidence of Mycobacterium tuberculosis in his lungs.

MORE THAN MEETS THE EYE: IDIOPATHIC CENTRAL RETINAL ARTERY OCCLUSION IN A YOUNG WOMAN Lan Jin. UCSF, San Francisco, CA. (Control ID #2700129)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of retinal artery occlusion
LEARNING OBJECTIVE #2: Generate an age appropriate differential for retinal artery occlusion
CASE: A 20 year-old healthy woman presented with acute left lower quadrant vision loss. She reported a similar episode 1 week prior after which her vision recovered, as well as a month-long history of left-sided temporal headaches associated with photosensitivity. Review of systems was positive for episodic paresthesias of bilateral forearms, hands, and feet. She denied constitutional symptoms, rash, joint pain, and drug use of any kind. Family history was remarkable for father with ocular migraine, and grandparents with rheumatoid arthritis and neurosarcoidosis. Exam revealed a left monocular lower quadrantanopsia, normal venous pulsations, no cherry red spot and a normal neurological exam. An extensive rheumatic and infectious workup was negative, including a hypercoaguability panel, antinuclear antibody, ESR, CRP, and hemoglobin evaluation. A brain MRI/MRA without contrast showed patent bilateral ophthalmic arteries. Face and neck MRI with contrast, transthoracic echocardiography with bubble study, electromyography, as well as nerve conduction studies were all unremarkable. Given the negative workup, the presumable etiology was thought to be vasospasm with migraine. She was started on low dose aspirin for secondary stroke prevention, and propranolol for migraine prophylaxis.
IMPACT: This case highlights the clinical manifestations of retinal artery occlusion, as well as the possible etiologies of retinal artery occlusion. Workup should be tailored to an age appropriate differential.
DISCUSSION: Overall, central and branch retinal artery occlusions (CRAO and BRAO) are rare with an incidence of approximately 1 to 10 in 100,000, with an affected mean age of 60–65 years. The etiology varies with age, with carotid artery atherosclerosis being most common overall, as high as 70%; however, for patients less than 40 years of age, cardiogenic embolism is much more likely. Therefore, workup for younger patients should be focused on evaluating for sources of cardiogenic embolism such as arrhythmias, murmurs, congenital heart disease, and substance abuse. For older patients, temporal arteritis should be ruled out. Vascular diseases such as fibromuscular dysplasia, radiation injury, or hematologic diseases including sickle cell anemia, hypercoagulable states, and hyperviscosity syndrome can affect all ages and should

be investigated if other causes are excluded. Rare causes of CRAO/BRAO include infections due to Bartonella, toxoplasmosis, and varicella; ocular surgery; fat or amniotic fluid embolism; and vasospasm with or without migraine, which is a diagnosis of exclusion. There have only been case studies describing CRAO associated with vasculitis.

MORPHEUS STROKE: AN ANATOMICAL VARIANT CAUSING BILATERAL THALAMIC INFARCTIONS

Philip Brandt. Baystate Medical Center, Broad Brook, CT. (Control ID #2705946)

LEARNING OBJECTIVE #1: Describe the clinical and radiological presentation of bilateral thalamic stroke from an occlusion of the artery of Percheron.
LEARNING OBJECTIVE #2: Identify differential diagnosis for bilateral thalamic stroke

CASE: A 62 year old male with a past medical history of paroxysmal atrial fibrillation, hypertension, and obstructive sleep apnea was found unresponsive in his bathroom by his wife. The patient's wife noticed that her husband managed to get up to use the bathroom but was then alerted to the sound of him snoring. She found him slumped over the toilet, unconscious and with facial asymmetry. In the ED he was found to be obtunded with a GCS of 7. Vital signs were within the normal limits and EKG was negative for arrhythmia. Physical examination was notable for a fixed lateral gaze as well as his altered mental status. CT of the brain did not show any evidence of hemorrhage and thrombolytic therapy was initiated. Patient rapidly regained consciousness with a GCS of 15/15 without focal neurological deficits. The patient was then transferred to the ICU and an MRI was performed which is seen in Figure 1. Ischemia involving the bilateral median thalami suggested an occlusion of common artery caused by an anatomical variant called the artery of Percheron.

IMPACT: Infarctions of the anatomical variant, artery of Percheron, are characterized by a triad of gaze palsy, memory impairment and a low GCS or comatose state. Early recognition and conventional medical management of this type of cerebrovascular accident can significantly reduce morbidity and mortality in patients with this anatomical variant. Other differentials can include "top of the basilar" syndrome, deep cerebral venous thrombosis, venous sinus thrombosis from occlusion of the internal cerebral veins, most notably the straight sinus

DISCUSSION: The thalamus is located between the cerebral cortex and midbrain. It is responsible for processing and relaying sensory information to other centers of the brain in addition to regulating activities like sleep and wakefulness. Usually the thalamus is supplied by paired arteries which are perforating divisions of the posterior cerebral artery. Occasionally an anatomical vascular variant exists where one unpaired artery supplies perforating branches to both medial thalami and midbrain. An insult that occludes or interrupts the blood supply to the artery of Percheron usually presents with 3 characteristic symptoms: gaze palsy, memory impairment, and coma. In our case our patient presented with an obtunded state and a gaze palsy was noted. In patients found to have a new disorder of consciousness with high clinical suspicion of a cerebrovascular accident we should consider an infarction of the bilateral thalami from occlusion of the artery of Percheron. Quick interventional or pharmacological therapies should be undertaken to reduce the immediate and long term morbidity that can be associated with the location of this disease.

MULTIFOCAL, SYNCHRONOUS, BILATERAL NECK MASSES

Paul Millner; Casey Zelus; Erica Cichowski. Creighton University Medical Center, Omaha, NE. (Control ID #2687390)

LEARNING OBJECTIVE #1: To illustrate a unique presentation of Warthin Tumor in the primary care setting
LEARNING OBJECTIVE #2: To identify the possible diagnoses associated with head and neck masses

CASE: A 65-year-old male presented to our primary care clinic after going without health care for twenty years. He presented with bilateral masses located near the mandible that had been slowly increasing in size for the past five years. He reported a 100 pack-year smoking history. Physical exam showed nontender, bilateral parotid masses and suspected lymphadenopathy including multiple chains from preauricular down to the supraclavicular regions. Computerized tomography showed multiple, bilateral heterogenous parotid and periparotid masses. On the right, a dominant mass measuring 4.5 × 3.1 cm with areas of necrosis was found along with multiple smaller nodules. Similar small soft tissue nodules were present in the left parotid and periparotid regions, the largest measuring 2.0 × 1.5 cm. Additionally, a small cluster of left supraclavicular lymph nodes were present concerning for possible metastatic lymphadenopathy. Malignancy was suspected, however, it was unclear whether these findings were due to synchronous, bilateral primary parotid tumors, one primary parotid tumor with contralateral metastasis, or metastasis from a primary tumor not of parotid origin. After ultrasound guided core needle biopsy, a right superficial parotidectomy with facial nerve dissection was performed. The final diagnosis was synchronous, bilateral, multifocal Warthin tumor.

IMPACT: Bilateral, synchronous, multifocal is a rare and unique presentation of Warthin tumor. The bilateral and multifocal nature, including the possible lymph node involvement noted on imaging were initially concerning for a malignant process. Primary care physicians must keep a wide differential diagnosis when evaluating head and neck masses in the outpatient setting.

DISCUSSION: Warthin's tumor, also called cystadenolymphoma, are benign lesions of the head and neck. It is the second most common neoplasm of the parotid gland, with only pleomorphic adenomas being more common. Warthin's tumor occur almost exclusively in the parotid glands and periparotid regions. Representing about 2–15% of all parotid neoplasms, Warthin's tumor classically presents in adult, male smokers as a slow growing unilateral mass, while simultaneous and bilateral findings are unusual. Previous studies have found bilateral tumors in 7–10% of cases and multifocal Warthin's tumors in 2% of cases. Extra-parotid involvement is exceedingly rare in the literature. Previously, it was thought to be a neoplastic condition. Analysis by Honda et al. have since shown polyclonal cellular populations, consistent with a benign, tumor-like condition. Although unusual, warthin tumor can occur simultaneously with lymphoma or pleomorphic adenoma which are other possible diagnoses in the evaluation of head and neck masses. Treatment is typically partial or total parotidectomy with sparing of the facial nerve.

MULTIPLE MYELOMA ASSOCIATED SYSTEMIC AL AMYLOIDOSIS WITH PREDOMINANT CARDIAC INVOLVEMENT

Aditya Kotecha; Joel Appel; Geetha Krishnamoorthy. Wayne State University/Detroit Medical Center, Detroit, MI. (Control ID #2702669)

LEARNING OBJECTIVE #1: Understand that rapidly progressive LVH with diastolic dysfunction along with biatrial enlargement and right heart failure can be due to cardiac amyloidosis

LEARNING OBJECTIVE #2: Recognize that multiple myeloma can cause concomitant AL amyloidosis

CASE: A 56-year-old male with a recent diagnosis of HFpEF presented with dyspnea on exertion. ECHO from five months ago showed normal LV size and wall thickness with a restrictive filling pattern, normal atria and RV function. A repeat ECHO from 2 months prior to admission showed increased LV wall thickness, normal cavity size, LA and RA dilatation, RV dilatation and failure. EKG showed RBBB with low voltage QRS complexes disproportionate to the LV thickness. This rapid onset of restrictive cardiomyopathy with biatrial dilatation and LV size/QRS voltage mismatch led us to suspect cardiac amyloidosis. Cardiac catheterization showed a dip and plateau LV tracing and concordance of RV and LV filling pressures ruling out constrictive pericarditis. Strain ECHO showed apical sparing with impaired basal strain, characteristic of cardiac amyloidosis. Further workup revealed elevated serum FLC (free light chains) with abnormal ratio of $\kappa:\lambda < 0.01$. Fat pad biopsy showed apple green birefringence with Congo red staining and tandem mass spectrometry analysis confirmed AL (lambda) type amyloidosis.There were normal levels of calcium, creatinine, hemoglobin, serum total protein and albumin and he had no proteinuria (urine protein 270 mg/24hours). Bone marrow (BM) biopsy showed 25% plasma cells with cytogenetics: 45, XY,t(11;14)(q13;q32) translocation. Serum protein electrophoresis and immunofixation showed lambda chains. PET-CT showed increased uptake in the left clavicle. Patient was diagnosed with active MM with AL amyloidosis and was referred to myeloma clinic for further management.

IMPACT: Rapid progression of LVH with HFpEF and absence of usual risk factors like hypertension should raise the suspicion for infiltrative diseases of the heart such as amyloidosis. Patients with untreated cardiac amyloidosis have a median survival of six months from the onset of heart failure.Therefore, early recognition and prompt referral for treatment is critical.

DISCUSSION: Management is dual: treatment of HFpEF and the plasma cell dyscrasia. The mainstay of management of HFpEF is diuretics; BB, ACEi, ARB and CCB should be avoided in cardiac amyloidosis since they may cause hypotension. Atrial fibrillation is difficult to manage since AV nodal blocking agents are not tolerated and digoxin may lead to toxicity from digoxin binding to the amyloid. Amiodarone or AV nodal ablation with pacemaker maybe needed for managing the atrial fibrillation. Variety of options exists for treatment of plasma cell dyscrasia which includes chemotherapy, stem cell and cardiac transplant. AL amyloidosis with > 10% BM plasma cells and cardiac involvement irrespective of CRAB (hypercalcemia, renal failure, anemia and lytic bone lesion) damage portends poor prognosis.

MYOCLONUS FROM GABAPENTIN TOXICITY IN THE SETTING OF ACUTE KIDNEY INJURY Crystal Zheng. Montefiore Medical Center, NEW YORK, NY. (Control ID #2706919)

LEARNING OBJECTIVE #1: Recognize myoclonus as an adverse effect of gabapentin

LEARNING OBJECTIVE #2: Consider medication toxicity in the differential diagnosis, especially when acute kidney injury is present

CASE: A 74 year old female presented with three days of worsening tremors of the hands, arms, head, and jaw. Her past medical history included diabetes with neuropathy, heart failure, and ventral hernia repair one month ago. Her medications were gabapentin 900 mg daily, furosemide, and lisinopril. On exam she exhibited a severe multifocal myoclonic tremor of the upper extremities, and her surgical wound was foul smelling with purulent discharge. Her laboratory studies were notable for white blood cell count of 14.6 k/uL, creatinine of 3.8 mg/dL and blood urea nitrogen of 28 mg/dL. Notably, her kidney function was normal when she was discharged after her surgery one month ago. The suspected cause of her tremors was gabapentin toxicity in the setting of acute kidney injury. During the hospitalization, gabapentin, furosemide, and lisinopril were discontinued, and she underwent incision and drainage of the abdominal wound. Her creatinine improved to 2.1 mg/dL on discharge and her tremors resolved with discontinuation of gabapentin.

IMPACT: This case highlights the importance of keeping medication toxicity in the differential, especially in the presence of acute kidney injury. Additionally, this case adds to the literature demonstrating myoclonus as an adverse effect of gabapentin.

DISCUSSION: Gabapentin is a medication frequently prescribed by general internists for a variety of indications including diabetic neuropathy and neuropathic pain. Clinicians are generally familiar with dizziness and drowsiness as adverse effects of gabapentin; myoclonus, though less common, has also been described. While the differential diagnosis of any presenting symptom should always include medication toxicity, this is especially true in the setting of acute kidney injury. Because gabapentin is exclusively excreted by the kidneys, its toxicity is more apparent with renal failure. In this case, the patient had remained on a stable dose of gabapentin for two years without side effects until its toxicity was unmasked by an acute insult to her renal function. Gabapentin should be used with caution in patients at risk for renal failure. The prevalence of chronic kidney disease is roughly 14% of the U.S. population. Considering that gabapentin is often used in patients with poorly controlled diabetes, the prevalence of renal failure among patients prescribed gabapentin is likely even higher. Patients with decreased renal function on gabapentin should be monitored closely for toxicity, and if present the medication should be dose-reduced or discontinued. Generalists and specialists alike will all take care of patients prescribed gabapentin. The widespread use of gabapentin and the prevalence of kidney disease underscore the need for clinicians to be aware of the side effect profile of this medication and its relationship with renal function.

MYXEDEMA COMA AND THE T3 CONUNDRUM Spencer Hodgins; Jasmine Paadam. Baystate Medical Center, Longmeadow, MA. (Control ID #2704195)

LEARNING OBJECTIVE #1: Recognize rare complications of myxedema coma

LEARNING OBJECTIVE #2: Learn how to manage a patient with myxedema coma

CASE: 32-year-old man with history of cervical gunshot wound resulting in quadriplegia, recurrent UTIs, stage IV decubitus ulcer, initially presented to emergency department with slurring of speech and vomiting. In the ED the patient was found to be bradycardic in 40's, afebrile and maintaining oxygen saturations. His labs showed hyponatremia with a sodium of 99, hyperkalemia with K of 5.7. TSH was also elevated at 79 with fT3 0.5 and fT4 0.26. CXR was clear, UA revealed >182WBC. Anti-TPO Ab was found to be 3,042 IU/mL and Antithryroglobulin Ab was elevated at 21,413 IU/mL. Renal was consulted for hyponatremia and he was started on 3% NS. He was admitted to ICU for further management. Na levels slowly improved with 3% saline. Endocrinology was consulted for hypothyroidism and concern for myxedema coma. He was started on IV levothyroxine and transferred to an ICU step-down

unit the same day. Further in the hospital stay he was noted to be hypotensive with BP in 70's and hypothermic and he was started on broad-spectrum antibiotics for empiric treatment of UTI. Bradycardia persisted and he began having frequent desaturations with worsening mental status and increased work of breathing in the setting of mucus plugging. Eventually the patient went into asystole secondary to hypoxia but was intubated and quickly resuscitated. The pulmonary and MICU team felt that the cause of his respiratory issues was most likely due to diaphragmatic weakness from myxedema coma. The patient failed to improve and liothryonine was started via NG. Within 24 hrs there was significant improvement in mental status and other symptoms and he was successfully extubated the following day. He was eventually discharged home following full recovery.

IMPACT: This case shows the significant complications which can occur during myxedema coma. It further strengthens the argument for the use of liothyronine when response is not significant to levothyroxine.

DISCUSSION: This case illustrates some of the complications of myxedema coma. He was initially severely hyponatremic, which is a more rare but significant complication of myxedema coma. One proposed mechanism is that severe hypothyroidism causes a reduction in GFR and CO leading to an increase in ADH production (Reynolds et al. 2004). He also experienced respiratory muscle weakness, which has been shown to occur in a linear fashion corresponding to Thyroid hormone levels and improve with treatment (Siafakas et al. 1992). When managing patients with myxedema coma the backbone of therapy is T4. T3 may also be used and may have a more rapid onset with significant clinical improvement in 24 hours (Matthews et al. 2006). This needs to be balanced against potential cardiac adverse effects (Yamamoto 1999). This case report illustrates the importance of considering the use of T3 when marked improvement is not achieved with levothyroxine.

MYXEDEMA COMA WITH LARGE PLEURAL EFFUSION

Preeyanka R. Sundar; Jonila Murati; Sylvia V. Alarcon; Gabriela A. Ciofoaia; Brian Phillps. Berkshire Medical Center, Pittsfield, MA. (Control ID #2671641)

LEARNING OBJECTIVE #1: Early recognition of myxedema coma signs and symptoms with atypical presentations

CASE: A 74 year old female with severe hypothyroidism presented with profound general weakness, mental status changes, anorexia, constipation and urinary frequency in the setting of poor compliance with thyroid hormone replacement therapy. On physical exam she was found to be somnolent, hypothermic, hypotensive, hypoxic, with a mildly enlarged thyroid gland, pretibial non pitting edema and delayed deep reflexes response. Labs revealed macrocytic anemia, leukopenia, thrombocytopenia, a remarkably high TSH 214 uIU/mL, free T4 0.14 ng/dl and free T3 < 50 pg/dl. Urinalysis revealed pyuria. Chest x-ray showed a large right sided pleural effusion. Pleural fluid was consistent with transudate. Blood and pleural fluid cultures were negative. She was initially treated with ceftriaxone for urinary infection and intravenous levothyroxine, liothyronine and hydrocortisone for thyroid replacement. Despite initiation of treatment her respiratory status continued to deteriorate leading to worsening hypoxia and hypercapnia requiring use of noninvasive ventilation and later intubation. After a few days of intensive care treatment with ventilatory support, central venous pressure monitoring, appropriate fluid management, steroid treatment and thyroid hormone replacement her overall status improved.

IMPACT: Myxoedema coma is a severe presentation of profound decompensated hypothyroidism with a 25-60% mortality rate despite treatment. It can be precipitated by hypothermia, systemic infections cerebrovascular accidents, cardiac disease, trauma, drugs (anaesthetics, sedative, narcotics, amiodarone and lithium), untreated hypothyroidism.

DISCUSSION: Myxoedema coma has an incidence rate of 0.22 per million per year. Presentation includes decreased mental status, hypothermia, dry skin, delayed tendon reflexes, macroglossia, non-pitting edema, goiter, hypoventilation, bradycardia, hypotension, pleural and pericardial effusions, bundle branch blocks, hypoglycemia, hyponatremia, and confirmed by elevated TSH and low free T4. There are cases in literature describing myxedema associated with minimal pleural effusions, but large pleural effusions are uncommon.The pathogenesis of pleural effusion is hypothesized to be related to increase in capillary permeability. Myxoedema coma is a true medical emergency requiring a multifaceted approach in critical care settings with ventilator support, adequate fluid management, steroid treatment and intravenous thyroid hormone replacement which is the mainstay in therapy. Standard IV thyroid supplementation includes a loading dose, followed by 1.6 mcg/kg daily, with liothyronine 10 mcg Q8hours and Hydrocortisone 100mg IV. Early recognition and therapy are essential due to high mortality rate despite of adequate thyroid replacement and it should be initiated even without laboratory confirmation if clinical suspicion remains high.

NATURAL PROGRESSION OF PLASMODIUM FALCIPARUM AND SIDE EFFECTS OF QUININE

Simi Sharma[1]; Shelby Lee[1]; Jennifer Schmidt[2]. [1]Saint Louis University School of Medicine, Saint Louis, MO; [2]Saint Louis University, Saint Louis, MO. (Control ID #2688998)

LEARNING OBJECTIVE #1: Recognize and discuss the life cycle and pathogenesis of Plasmodium falciparum.

LEARNING OBJECTIVE #2: Assess appropriate individual Plasmodium falciparum treatment and manage side effects of treatment (with adjustments as necessary).

CASE: We discuss a previously healthy 60-year-old Caucasian female who presented to an urgent care clinic with fever of 103°F, intermittent nausea, vomiting, diarrhea, fatigue, and myalgias following recent travel to Burkina Faso. After blood testing, patient presented to the emergency department with findings of: a protozoal load of 6.3%, elevated creatinine levels, elevated total bilirubin levels, thrombocytopenia, anemia, and confusion. Patient was admitted to the Medicine service and treated with doxycycline and quinidine sulfate. After two days of treatment, patient's QTc interval was noted to be 608ms (from 494ms) so quinidine sulfate was changed to quinine sulfate. After three days of therapy, patient reported decreased hearing and "underwater sensation." On exam, she was unable to hear finger rub bilaterally. Quinine sulfate was discontinued for ototoxicity and replaced with artemether-lumefantrine to complete therapy. The patient's hearing subjectively and objectively (normal finger rub test) improved following cessation of quinine sulfate.

IMPACT: This case demonstrates the importance of a broad differential diagnosis as well as awareness of toxicities for an uncommonly used medication. As clinicians, we must remain vigilant of the potential side effects and issues of these medications. It is critical to monitor for drug side effects to mitigate permanent effects and determine appropriate alternative courses of action as a pre-emptive, rather than reactionary, response.

DISCUSSION: Plasmodium falciparum is responsible for the most medically severe and rapidly fatal malaria, causing 50% of malarial infections. Infection

begins with an infected Anopheles mosquito bite, where sporozoites quickly invade hepatocytes and begin to differentiate and reproduce for the next two weeks. Merozoites burst from each hepatocyte and invade RBCs, continuing the reproductive cycle. Rupture and release of the merozoites cause anemia, hemolysis, fever, chills, and nausea; adherence of RBCs to endothelial cells (due to chemical nature of parasital trophozoites) lead to cerebral malaria by preventing adequate cerebral oxygenation. Artemisin-based combination therapies are recommended first-line therapy of uncomplicated malaria; however, treatment may also involve a tetracycline in addition to quinine therapy. Significant side effects of quinidine can include cinchonism, ototoxicity, granulomatous hepatitis, and torsades de pointes; significant side effects of quinine include immune thrombocytopenic purpura (ITP) and cinchonism. Treatment involves cessation of the offending agent and side effects are often reversible if medications are discontinued promptly.

NAVIGATING ANCHORING BIAS: AN UNUSUAL PRESENTATION OF VON WILLEBRAND'S DISEASE Suegene Lee; Jason S. Schneider. Emory University School of Medicine, Atlanta, GA. (Control ID #2706801)

LEARNING OBJECTIVE #1: Differentiate the diagnosis of inherited and acquired von Willebrand disease

CASE: The patient is a 66 year old male who was admitted with gastrointestinal bleeds resulting in hemoglobin as low as 2g/dL. He experienced epistaxis as a child and began having bright red blood per rectum at age 13. He denied any excessive bleeding with tooth extractions and underwent major surgery without any complications. A comprehensive work-up was performed, but no source of bleeding was found.After an elevated PTT, his VWF antigen level was 14, Factor VIII 10%, VWF ristocetin cofactor assay <20. A VWF multimer study showed decrease in intermediate, large molecular weight multimers and VWF propeptide was normal. Given these findings and his childhood history, he was diagnosed with inherited von Willebrand disease, likely type 2A, and began receiving infusions of antihemophilic factor/VWF complex. Meanwhile, after an abnormal SPEP, a bone marrow biopsy revealed monoclonal gammopathy of undetermined significance. Despite these infusions, his Factor VIII and ristocetin cofactor levels remained low. As he was not responding after 12 days and considering his biopsy results, acquired VWD was suspected. IVIG was infused and patient's factor VIII level increased to 205 and ristocetin cofactor level to 220. Following discharge, his exon 28 testing results returned confirming that patient was negative for VWD type 2A.

IMPACT: Given his experience of multiple bleeding episodes as a child, this patient was assumed to have inherited VWD. Clinicians oftentimes fixate on the first piece of information provided, leading to missing the diagnosis and appropriate treatment. In this case, due to his lack of response to the standard therapies for inherited VWD, we re-evaluated the patient with a fresh pair of eyes and arrived at IVIG, used for patients with acquired VWD, specifically in whom an immune mechanism is responsible.

DISCUSSION: Acquired VWD is suspected in patients with negative family history, late-onset of bleeding and a known associated underlying disease. Common pathologies include lymphoproliferative disorders, such as MGUS. In these patients, paraproteins bind to VWF, leading to low circulating levels of VWF. Patients with acquired VWF have low VWF antigen levels, just as those with inherited VWF, but have markedly lower levels of VWF activity (i.e. ristocetin cofactor assay). In inherited VWF, the ristocetin cofactor/antigen ratio is approximately 1, whereas a ratio of <0.6-0.7 implies inhibitory antibodies are present. The underlying disorder must be treated in patients with acquired VWD, as this may reverse the bleeding. If the underlying disease is lymphoproliferative or autoimmune, IVIG appears to be the most effective management and can correct VWF activity for 2–3 weeks.Acquired VWD, although uncommon, must be considered in an elderly patient with a new diagnosis of VWD. The associated disease should also be determined and if an immune mechanism is suspected, a trial of IVIG is warranted.

NERVOUS TIC: A CASE OF LYME DISEASE ASSOCIATED TRIGEMINAL NEURALGIA Matthew Basciotta; Jared Grochowsky. BIDMC, Brookline, MA. (Control ID #2705753)

LEARNING OBJECTIVE #1: Recognize clinical features of early and late disseminated Lyme disease

LEARNING OBJECTIVE #2: Diagnose and treat early disseminated Lyme disease

CASE: A 49 year old man presented with a submandibular enlarged non-tender lymph node and 1 day of sharp lightening like headache in the left temple. He noticed a left neck mass 1 week prior to presentation. He then had sharp, zinging pains that rapidly worsened. Each episode lasted 8 s at 10/10 intensity with associated conjunctival injection and watering. Denied travel, animal exposure, sick contacts. PMH/SH/FH: Childhood asthma. Single with five children. Drinks alcohol and smokes marijuana daily with tobacco. Father with throat cancer, Mother with DM. Medications: None Vitals: Afebrile and normotensive, obviously anxious and in pain. There was a soft 2 × 3 cm L submandibular mass without fluctuance. No dental abnormalities noted. Remainder of exam normal. Labs identified WBC 3.2 with normal differential. CT scan showed lymph nodes measuring up to 2.2 cm within the left sublingual, submandibular and supraclavicular regions without fluid collection. He was treated with carbamazepine for trigeminal neuralgia and his pain and lymphadenopathy rapidly improved. MRI did not identify focal trigeminal nerve entrapment. A range of infectious and auto-immune tests were sent and all were negative or pending at time of discharge. 1 week later he presented to his PCP for follow up. At that time, his Lyme serology had resulted with positive IgM and negative IgG consistent with early Lyme. Pain and lymphadenopathy were improved. He recalled being bitten by an insect on his head 1 month ago. He did not recall a rash and was treated with doxycycline for 21 days and continued carbamazepine for 3 months. His only current symptom is occasion forehead twinges.

IMPACT: While a majority of patients with localized Lyme disease present with erythema migrans, up to 20–30% do not. When not treated, progression to disseminated disease is common. 60% will have joint involvement, 15% neurologic involvement and 5% cardiac involvement. After this case I am more likely to consider Lyme in patients with symptoms consistent with disseminated disease, even without rash or tick bite.

DISCUSSION: This was a patient with trigeminal neuralgia secondary to early disseminated Lyme disease. He did well with near complete resolution of symptoms following a course of doxycycline and carbamazepine. Lyme disease is the most common tick borne illness in the US with 300,000 Americans diagnosed each year. Clinical manifestations can occur from days to months or years following exposure and involve multiple organ systems. This makes it both common but potentially easy to miss. Clinical features can be characterized into early localized, early disseminated and late disseminated disease. Stage and organ system involvement determines antibiotic choice and duration. Lyme disease is a common but complex illness that general medical practitioners should recognize and feel equipped to diagnose and treat.

NEUROSYPHILIS PRESENTING AS STROKE Kathryn Rice[1, 2]; Heather Abraham[1, 2]; Michael Pezzillo[2]. [1]WSU-DMC, Detroit, MI; [2]Wayne State University School of Medicine, Detroit, MI. (Control ID #2687519)

LEARNING OBJECTIVE #1: Recognize neurosyphilis as a strong risk factor for cerebral vascular incidents in adults with few or no other identifiable risk factors for stroke.

CASE: A 54 year-old African American man with no past medical history was brought to the emergency department due to altered mental status. In the ED, the patient was found to be nonverbal, with weakness of the right upper and lower extremity. Given these focal findings, stroke was suspected, and a CT scan performed, demonstrating old lacunar infarcts in the left internal capsule. A follow up MRI showed a large acute to subacute non-hemorrhagic infarct in the left cerebral hemisphere involving the left middle cerebral arterial territory. Given that the patient had limited identifiable risk factors for stroke, further workup was performed and he was found to be HIV positive. Treponemal testing with syphilis EIA was >70, with an RPR reactive to 1:64. A lumbar puncture was performed due to high suspicion for neurosyphilis and confirmed the diagnosis with CSF VDRL reactive at 1:4. Penicillin G 4 million units every four hours was started to treat neurosyphilis.

IMPACT: This case report will help clinicians to have a higher degree of suspicion for infectious etiologies, such as neurosyphilis, as the causative factor for stroke in an otherwise healthy individual.

DISCUSSION: Syphilis is transmitted through sexual intercourse, when a sexual partner has direct contact with an infectious lesion. The transmission rate after exposure to an infectious lesion is approximately 30 percent.[4] CNS infection with T. *pallidum* can lead to neurosyphilis. Many neurologic symptoms of neurosyphilis can be attributed to acute or subacute meningitis.[5] CNS infections with T. pallidum can cause arteritis of any size vessel, leading to possible infarction or thrombosis. HIV-infected patients develop neurosyphilis more frequently and in earlier stage than do HIV-negative persons. Additionally, the risk of neurosyphilis correlates with a low CD4 count.[6] REFERENCES 1. Newman L, Rowley J, Vander Hoorn S, et al. Global Estimates of the Prevalence and Incidence of Four Curable Sexually Transmitted Infections in 2012 Based on Systematic Review and Global Reporting. PLoS One 2015; 10:e0143304. 2. Three Episodes of Brain Stroke as a Manifestation of Neurosyphilis in an HIV-infected Man. Acta Derm Venereol, 216–256. 6. Int J STD AIDS. 2016 Aug 10. pii: 0956462416665029. [Epub ahead of print] Stroke in a young patient with neurosyphilis and HIV.

NON CONVULSIVE STATUS EPILEPTICUS: HIDING IN PLAIN SIGHT Michael Korsmo[2]; Ashley Vachon[1]; Amy H. Farkas[1]. [1]UPMC, Pittsburgh, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2706684)

LEARNING OBJECTIVE #1: Recognize NCSE in altered mentation
LEARNING OBJECTIVE #2: Ackowledge cognitive biases

CASE: A 62-year-old male with history of alcohol dependence and seizure was transferred from another facility for altered mental status. A week earlier, he was found unconscious and brought to an outside hospital where CT brain, UDS, TSH, NH3, CMP, and CBC were normal. EEG showed diffuse slowing without epileptiform activity. MRI showed T2 hyperintensities in bilateral hippocampi interpreted as nonspecific. He had a witnessed seizure that was treated with lorazepam and levetiracetam. He continued to be altered and psychiatry prescribed risperidone for delirium. He was transferred to our facility for management of delirium. On admission, he was confused, not oriented, had marked memory impairment, and frequently confabulated. Due to his waxing and waning levels of consciousness and cognitive impairment, acute delirium and prolonged post ictal period following alcohol withdrawal seizures were the leading diagnoses. Two days later, the patient's mental status deteriorated further and EEG obtained showed left posterior non-convulsive status epilepticus.

IMPACT: Non Convulsive Status Epilepticus (NCSE) is varied in its presentation, typically without obvious signs and symptoms. The veiled nature of NCSE in conjunction with the milieu of social factors, medical comorbidities, and provider bias can make inclusion of this condition in the differential a challenge.

DISCUSSION: Subtle alterations in consciousness and cognition may be the only presenting sign of complex partial NCSE. Keys to making the diagnosis involve lowering the diagnostic threshold for obtaining an EEG when a patient with a history of seizure presents with alterations in consciousness. In this case, EEG was considered early on, but deferred as there had been no witnessed seizure activity since transfer and was previously done. Confirmatory and availability bias were likely part of the non-analytical mental processes. Confirmatory bias is defined as looking to confirm a diagnosis rather than reject. This patient's history of alcoholism and withdrawal lure a provider into confirming withdrawal or delirium rather than systematically rejecting them. Availability bias involves assessing probability of a diagnosis based on ease of retrieval from memory strongly influenced by recent events. In this case, a provider who commonly treats patients suffering from alcohol withdrawal will likely retrieve that diagnosis from memory first. Because of this, they are likely to unconsciously weigh the probability of simple alcohol withdrawal more strongly than usual. Unrecognized bias can lead to a common diagnostic error known as premature closure. Premature closure can stop further workup of altered mental status in favor of a diagnosis we are biased towards. There is yet an effective method of removing bias from the process of the differential diagnosis. The best we can do is be aware of them and work to recognize when they are affecting our judgement.

NON-ISCHEMIC CARDIOMYOPATHY PRESENTING AS CONGESTIVE HEPATOPATHY Logan J. Hostetter[1]; Rebecca Johnson-Paben[4]; Joseph A. Simonetti[2, 3]. [1]University of Colorado, Aurora, CO; [2]University of Colorado School of Medicine, Denver, CO; [3]Denver VA Medical Center, Denver, CO; [4]University of Colorado, Denver, CO. (Control ID #2698385)

LEARNING OBJECTIVE #1: Recognize hepatic congestion as a sign of cardiac dysfunction.

LEARNING OBJECTIVE #2: Recognize indications for cardiac defibrillator implantation in heart failure and outcomes specific to non-ischemic cardiomyopathy.

CASE: Three weeks prior to admission, a healthy 37-year-old male developed watery diarrhea, vomiting, and abdominal pain after attending a picnic.

He was diagnosed with viral gastroenteritis; returning 4 days later with worsening symptoms and dyspnea. Due to hyperbilirubinemia and leukocytosis on labs, a RUQ ultrasound was obtained revealing hepatomegaly. A HIDA scan was scheduled. One week later, he presented to the ED with orthopnea, DOE, and leg swelling. Vitals: afebrile, HR 120 and regular, RR 22, BP 114/83. He was diaphoretic, sitting upright, appearing short of breath. He had scleral icterus, an S3 heart sound, pulmonary rales, and 2+ pitting edema. Labs revealed Cr 1.4mg/dL, ALK phos 58U/L, AST 303U/L, ALT 289U/L, total bilirubin 4.1mg/dL, INR 1.4, and BNP 10,000pg/mL. A TTE showed four-chamber dilatation with a 10-15% EF. He developed non-sustained ventricular tachycardia (VT) and was transferred to another facility for advanced therapies and transplant evaluation given severe, inotrope-dependent heart failure. Evaluation to determine the etiology of his cardiomyopathy (CM) was unrevealing, including L/R heart catheterization with biopsy, and evaluation for infection, infiltrative diseases, and thyroid disorders. His final diagnosis was non-ischemic cardiomyopathy (NICM), likely due to a viral infection.

IMPACT: Cardiomyopathy symptoms result from reduced cardiac output and volume overload and include DOE, fatigue, reduced exercise tolerance, orthopnea, and PND. When LV dysfunction leads to congestive hepatopathy, patients may have abdominal pain (usually RUQ), hepatomegaly, jaundice and liver dysfunction. Avoiding anchoring bias when patients with cardiomyopathy present atypically is crucial for the early diagnosis and treatment.

DISCUSSION: NICM represents 15-40% of all heart failure in the US. Causes include viral, bacterial and parasitic infections, persistent tachycardia, immunologic and metabolic disorders, infiltrative diseases, toxins, and genetics. The etiology is never identified in 50% of patients. First-line treatment includes a beta-blocker, ACE-inhibitor, diuretics, and an aldosterone antagonist (if EF < 35%). Inotropic support, ventricular assist devices, cardiac resynchronization, and transplant are options for those with refractory LV dysfunction and resting symptoms. Prophylactic implantable cardiac defibrillator (ICD) placement is indicated for patients with ischemic or non-ischemic CM and EF <35%. However, a recent RCT found that ICD placement was not associated with reduced mortality among NICM patients receiving maximal medical therapy; many of whom had cardiac resynchronization therapy (Kober et al. *N Engl J Med* 2016; 375:1221–1230). Whether ICD placement may benefit younger patients with NICM remains unknown.

NOT ALL WHEEZING IS ASTHMA - A CASE OF SEVERE MITRAL STENOSIS. Gabriel S. Vidal[1]; Dr. Ali Yousif[1]; Dr. Sunil Mathew[1, 2]. [1]University of Oklahoma College of Medicine, Oklahoma City, OK; [2]Oklahoma City VA Medical Center, Oklahoma City, OK. (Control ID #2706838)

LEARNING OBJECTIVE #1: Recognize mitral stenosis (MS) as part of the differential diagnosis for wheezing.

LEARNING OBJECTIVE #2: Discuss the importance for prompt recognition of rheumatic mitral valve disease.

CASE: A 62 year-old man with a history of asthma, hypertension, hyperlipidemia, and diabetes presented to a rural emergency department (ED) with suspected asthma exacerbation. The patient was an avid golfer, but stopped playing six month prior due to significant dyspnea on exertion. Patient and family members contributed his symptoms to worsening asthma. In the ED he was treated with bronchodilators with symptomatic improvement and was discharged home. Patient collapsed while walking to his vehicle in the parking lot. After multiple rounds of ACLS, patient had return of spontaneous circulation. He was intubated on scene, initiated on hypothermia protocol, and transferred to our hospital for further care. On presentation, patient was intubated, had distended jugular veins, distant heart sounds, and bibasilar rales. Chest x-ray showed bilateral pulmonary edema. First degree AV Block seen on ECG otherwise no ischemic changes. Transthoracic Echocardiogram (TTE) showed reduced ejection fraction 45-50%, rheumatic mitral and aortic valve disease significant for severe mitral stenosis with severe mitral regurgitation and moderate aortic regurgitation. Prior TTE several years prior showed mild mitral valve stenosis. The patient was started on aggressive diuresis, weaned off mechanical ventilation, and extubated two days later. Pulmonary function tests showed mild obstructive lung disease. Coronary angiogram showed normal coronaries. Patient was referred for valve surgery and underwent successful mechanical mitral valve replacement.

IMPACT: This case emphasizes the importance of history taking and physical examination in determining etiology of wheezing.

DISCUSSION: Here we describe a case of symptomatic MS misdiagnosed as asthma exacerbation. Internists and emergency room physicians are often confronted with the task of identifying the etiology of wheezing in a patient. Commonly identified etiologies for wheezing include asthma or COPD, however, MS can manifest as wheezing and should be considered in the differential diagnosis of wheezing. The most common cause of MS is rheumatic heart disease. Dyspnea on exertion and decreased exercise tolerance are most common clinical manifestations. The pathophysiology of wheezing in mitral stenosis, is increased left ventricular filling pressure leading to pulmonary edema and cardiac wheezing. Obtaining thorough history especially childhood illnesses and physical examination is pivotal for rheumatic MS diagnosis. Echocardiography will help confirm diagnosis and assess disease severity. Rheumatic MS is a progressive disease, hence, prompt recognition is important because of initiation of prophylactic antibiotic and treatment of symptoms improves morbidity and mortality associated with this condition.

NOT ANOTHER ACS RULE OUT Ryan Nelson; David Spruill. Tulane University, New Orleans, LA. (Control ID #2705321)

LEARNING OBJECTIVE #1: Recognize Sarcoidosis as a possible diagnosis in patients with recurrent typical chest pain

LEARNING OBJECTIVE #2: Identify the classic MRI findings of Cardiac and Neurosarcoidosis

CASE: A 50-year-old African-American woman with diabetes, hypertension, and hyperlipidemia presented with progressively worsening chest pain, exacerbated by activity and relieved by rest. She also endorsed unintentional weight loss and dysphagia. On exam, she was dysarthric with left-sided Bell's palsy. Her troponin values were normal and an EKG showed T-wave inversions in leads I and aVL. On echocardiography, her ejection fraction was 45% with antero-lateral hypokinesis. She was treated for NSTEMI. An angiogram showed 95% stenosis of the right coronary artery. A modified barium swallow study showed weak swallowing with aspiration of thin liquids. An MRI of the brain demonstrated scattered T2/FLAIR hyper-intense foci in the subcortical white matter and focal meningeal thickening. ANA, dsDNA, ANCA, and Lyme antibodies were all negative. A chest CT showed hilar lymphadenopathy. Cardiac MRI demonstrated scattered foci of delayed enhancement in the mid-myocardium and sub-epicardium without infarction. An endobronchial biopsy of hilar lymph nodes showed two small epithelioid granulomas, consistent with

sarcoidosis. She was started on high-dose corticosteroids with rapid improvement. Her dysphagia, dysarthria and Bell's palsy resolved after several days of therapy. A repeat echocardiogram demonstrated recovered ejection fraction of 55% with improved wall motion in the septum and apex.

IMPACT: This case illustrates the widespread impact sarcodiosis can have on a patient. Sarcoidosis can affect multiple organ systems. In this case, both cardiac sarcoidosis and neurosarcoidosis is demonstrated.

DISCUSSION: Symptomatic myocardial involvement in sarcoidosis is relatively rare, affecting 5% of patients. Usually, cardiac sarcoidosis presents as conduction abnormalities with arrhythmia rather than acute coronary syndrome (ACS). Our patient had multiple risk factors for coronary artherosclerosis, including diabetes, hypertension and hyperlipidemia; however, sarcoidosis creates an inflammatory environment that can independently generate and accelerate coronary artherosclerosis. In this case, our patient's weight loss, dysphagia, and Bells' Palsy alerted us to an underlying rheumatologic, vasculitic, or infiltrative process. Sarcoidosis is associated with specific findings on both cardiac and brain MRI. Cardiac sarcoidosis is characterized by subepicardial and mid-myocardial nodules. Neurosarcoidosis typically manifests as granulomatous infiltrates within the dura mater. On MRI, these lesions appear as pachymeningitis, or patchy thickening of the dura mater. To our knowledge, this report is the third case of multi-organ Sarcoidosis presenting as ACS. This case also depicts the simultaneous presentation of neurologic, pharyngeal, pulmonary, and cardiac sarcoidosis.

NOT ANOTHER BILATERAL CELLULITIS Erin M. Noren; Edward Ha. University of California Los Angeles, Los Angeles, CA. (Control ID #2706986)

LEARNING OBJECTIVE #1: Recognize the clinical features of cryoglobulinemic vasculitis (CGV).

LEARNING OBJECTIVE #2: Recognize the importance of the United States Preventive Services Task Force (USPSTF) screening guidelines to prevent sequelae of chronic hepatitis C infection (HCV).

CASE: A 75 year-old woman with a history of protein S deficiency, stroke, and anemia presented with 5 days of fevers and a lower extremity rash. She first noticed swelling in her ankles, followed by daily fevers up to 103 F and development of a rash on both legs. She had constant pain in the distribution to her rash that worsened with standing. She had a similar rash 2 years prior that self-resolved. She also reported nausea and 6 pound weight loss. On presentation, she was febrile to 101 F and tachycardic at 105 bpm. Her exam showed a non-blanching erythematous maculopapular rash on both lower extremities that was tender to palpation. She had no scleral icterus, lymphadenopathy, or joint effusions. Laboratory tests showed elevated inflammatory markers, leukopenia, anemia, and mild transaminitis. She had been started on antibiotics for presumed cellulitis in the emergency room. Skin biopsy revealed medium-vessel vasculitis with no evidence of infection. The differential diagnosis was narrowed to include rheumatologic disease, cryoglobulinemia (CG) and lymphoma. Autoimmune studies were inconclusive. PET scan was negative for malignancy. HCV antibody was positive with a viral load of 1.6 million IU/L. Serum cryoglobulin test (Cryocrit) was positive, confirming the diagnosis of CGV. Treatment with prednisone 40 mg daily resolved the rash and fevers. She had no history of drug use or tattoos but later recalled receiving blood products after childbirth in the 1970s. She was seen by Hepatology and began direct-acting antiviral (DAA) treatment.

IMPACT: This case highlights the need for a centralized effort to implement HCV screening. Primary care physicians need to play a more active role in this capacity, as patients without obvious risk factors have the potential for infection, and the benefits of early detection, treatment and surveillance have far-reaching benefits.

DISCUSSION: CG is a frequent complication of HCV infection. An estimated 2.7-3.9 million people in the United States have chronic HCV, but many are undiagnosed. The prevalence of CG among HCV patients is approximately 50%, though less than one-third have symptoms. The risk for CG increases with the duration of HCV infection, with an annual incidence of 3%. Definitive therapy is to treat the HCV, and the majority of patients with sustained viral response have resolution of CG. This case reinforces the importance of the USPSTF screening guidelines for HCV. Despite the ease of testing, rates of screening remain undesirably low. In one 2014 study of a HCV screening program, physician adherence rates were as low as 36%, and there was wide variation between individuals. An improved focus on HCV screening in primary care is imperative to prevent serious sequelae of chronic infection.

NOT EVERY ORTHOPNEA MEANS HEART FAILURE Nabil Mesiha[2]; Noorain Mazhar[2]; Stephen Tieku[1]; Saba A. Hasan[1]; Daniel Goldsmith[1]. [1]Capital Health Regional Medical Center, Trenton, NJ; [2]Capital health Regional Medical Center, Trenton, NJ. (Control ID #2698382)

LEARNING OBJECTIVE #1: To demonstrate that positional PFT's can help establish the diagnosis of myopathy when there is significant worsening of volumes in the supine position.

CASE: Orthopnea is defined as dyspnea that occurs while lying down. The mechanism is redistribution of body fluids, which is tolerated in patients with normal cardiac function, but in those with heart failure, the heart is unable to accommodate the minimal extra fluid in the lung. Orthopnea is often associated with heart failure, but can be observed with other, less obvious diagnoses. A 61 year old woman presented with gradual onset of dyspnea, orthopnea, paroxysmal nocturnal dyspnea for 2 months. On physical exam she was slightly tachycardic, oxygen saturation was 96% on room air while sitting but she desaturated to 89% on supine position. Lung exam showed fine crackles bilaterally but there was no leg swelling. Initial diagnosis was heart failure, and she required non-invasive mechanical ventilation especially at night. Lab testing revealed mildly elevated LFTs, normal troponins. Chest X-ray revealed bibasilar subsegmental atelectasis versus infiltrate. Furosemide resulted in no significant improvement in symptoms. Echocardiogram was normal. BNP was not elevated. Review of the chest X-ray showed small lung volumes and on further questioning she reported mild dysphagia. Neurologic exam revealed mildly decreased proximal muscle strength in the upper and lower extremities. PFTs in the sitting and supine position showed that in the sitting position, the FVC was 1.12 liters (46% predicted) while in supine position FVC was 0.56 liters (24% predicted). Sitting FEV-1 was 0.97 liters (52% predicted) while supine FEV-1 was 0.42 (23% predicted) showing moderate restrictive ventilatory impairment worse in the supine position. ABG showed hypercapnia and hypoxemia. Additional lab testing showed elevated CK, ANA titer 1:160, elevated aldolase 25.2 U, negative acetylcholine receptor antibody test, and negative anti-MUSK antibodies. EMG showed acute myopathy. Muscle biopsy was consistent with mild, active myopathy. Prednisone resulted in significant improvement in her symptoms. Patient was discharged home with no ventilatory support.

IMPACT: To consider myopathy in patients with dyspnea and orthopnea, when heart failure is less likely the correct diagnosis. EMG and muscle biopsy should be considered to confirm the diagnosis.

DISCUSSION: Myopathy is a systemic disease that can affect all muscles of the body including chest wall and diaphragm, resulting in dyspnea and orthopnea especially during supine position. Arriving at the correct diagnosis starts with high clinical suspicion, supported with high level of CK, aldolase, and transaminases. EMG and muscle biopsy confirm the diagnosis. Positional PFT's can help establish the diagnosis of myopathy when there is significant worsening of volumes in the supine position, and should be considered in certain patients with dyspnea and orthopnea, when heart failure is less likely the correct diagnosis.

NOT GIST A STOMACH MASS: WHY DIAGNOSING GASTROINTESTINAL STROMAL TUMORS CAN BE CHALLENGING Ali Shami. Baystate Medical Center, Springfield, MA. (Control ID #2707173)

LEARNING OBJECTIVE #1: To distinguish the endoscopic diagnostic modalities for a gastrointestinal stromal tumor (GIST)

LEARNING OBJECTIVE #2: To review the anatomical origin of GISTs

CASE: A 64 year old female of Thai descent presented with nausea, vomiting and bloating for several days. She had recently felt loss of appetite but denied any weight loss. She also reported two years of dull, intermittent abdominal discomfort. On physical examination she was found to have a palpable tender mass in the left upper quadrant of her abdomen without other exam findings. She underwent computed tomography (CT) scan of the abdomen with contrast which revealed a large gastric mass with both intraluminal and extraluminal components measuring at least 18cm × 14.6cm × 12cm in size. The patient underwent an esophagogastroduodenoscopy (EGD) for biopsy of the mass. EGD showed a fungating 5cm × 4cm mass in the stomach body, suspicious for malignancy and several biopsies of the lesion were obtained. However histology results were negative, revealing only gastric mucosa. For further characterization of the mass, endoscopic ultrasound (EUS) was performed during which the mass appeared to protrude from the submucosal layers of the stomach wall with an overlying layer of normal appearing gastric mucosa. Needle aspiration biopsy of the mass was performed and results were consistent with a gastrointestinal stromal tumor (GIST). The patient is currently awaiting multidisciplinary management of the GIST with oncology and surgery involvement.

IMPACT: For histological diagnosis of large gastric masses, EGD may appear the most intuitive diagnostic option. However, for GISTs the diagnostic yield is low (20-30%) due to the fact that these malignant tumors are submucosal rather than arising from the gastric mucosal layer and therefore may not be accessed by biopsies obtained by EGD. This is an important consideration as GISTs are often found as sizeable masses in the stomach and small intestine.

DISCUSSION: GISTs represent only 1-3% of all gastrointestinal malignancies. However they are the most common mesenchymal tumors of the gastrointestinal tract, originating from the interstitial cells of Cajal (ICC) in the submucosal layers. They commonly manifest as large masses in the stomach or small intestine, which may be picked up on imaging in a patient presenting with nonspecific abdominal symptoms. EGD is often the first modality pursued for histological diagnosis of gastric masses; however, for GISTs the diagnostic yield with biopsy obtained by EGD is 20-30%. This is due to the fact that most GISTs originate from the submucosal layers and many grow extraluminally outside the gastric wall. Consequently, standard EGD biopsies often access only the topmost mucosal layer and therefore reveal normal findings on histology. Endoscopic ultrasound with fine needle aspiration (EUS-FNA) offers better access to submucosal layers and is a superior method for tissue diagnosis. This technique has proven between 80-100% accurate for GIST diagnosis in several studies.

NOT YOUR TYPICAL PANCREATITIS: A PSOAS PSEUDOCYST
Shelly Kakar[4]; Carl Manzo[4]; Sophie M. Hapak[3]; Jana Al Hashash[4]; Amar Kohli[2]; Edgar Raymund Ramirez[1]. [1]UPMC, Pittsburgh, PA; [2]UPMC, Mars, PA; [3]University of Pittsburgh, Pittsburgh, PA; [4]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2705518)

LEARNING OBJECTIVE #1: Recognize an unusual presentation of a pancreatic pseudocyst.

LEARNING OBJECTIVE #2: Identify the management for a retroperitoneal fluid collection and the impact of advanced imaging.

CASE: A 54 year-old, previously healthy female, presented to the emergency department with a 2 week history of left flank pain radiating to her left leg. She described the pain as a constant ache that worsened with movement. Social history was pertinent for heavy alcohol and tobacco use. Physical exam revealed a drowsy, cachectic patient in acute pain. Patient was afebrile and hemodynamically stable. Left lower quadrant, left flank, and left thigh were tender to palpation. A positive psoas sign was elicited on the left side. Laboratory data was significant for sodium of 127mEq/L, potassium 3.2mEq/L, and calcium 7.5mg/dL. Albumin was 2.1g/dL. ALT and AST were normal. WBC count was 3.7k/mm^2, hemoglobin 10.6g/dL, and MCV 97.7fL. Amylase was 54U/L and lipase 94U/L. Contrast-enhanced CT scan of the abdomen and pelvis showed a large (8.6cm × 11.4cm) rim-enhancing fluid collection within the entire left psoas muscle, extending from the iliac fossa into the left upper quadrant displacing the kidney and the pancreatic tail anteriorly. This was suspicious for a psoas abscess. The patient also had punctate calcifications in the pancreas and mild dilation of the pancreatic duct suggestive of chronic pancreatitis. She was started on IV vancomycin and piperacillin/tazobactam for the presumed abscess. The collection was percutaneously drained and ~1L was aspirated. Fluid analysis revealed an amylase rich fluid (6,696U/L). Repeat CT 3 days later showed the collection had decreased in size. MRCP demonstrated a direct communication between the pancreatic duct and the fluid collection.

IMPACT: Retroperitoneal fluid collections are rare, it is important to differentiate the primary source as it can lead to poor prognosis if not managed correctly. A broad differential should remain with any presentation of retroperitoneal fluid collections.

DISCUSSION: Pseudocysts are a known complication of pancreatitis with the highest incidence occurring in patients with chronic alcohol related pancreatitis. Very rarely do pseudocysts form in the retroperitoneum and along the psoas muscle as seen in our case. Complications include infection, abscess formation, fistula formation, and rupture into the peritoneal cavity. In both acute and chronic pancreatitis, pseudocysts do not require intervention unless they are enlarging quickly or symptomatic. Case management includes simple drainage of the cyst verses laparoscopic excision. In our patient, CT demonstrated chronic pancreatitis changes and MRCP delineated a direct communication between the pancreatic duct and the fluid collection, suggesting what was originally thought to be a psoas abscess was actually a pancreatic pseudocyst. In our case, a MRCP was

necessary to further delineate the communication between the pancreas and collection which allowed us to accurately manage the patient

NOW YOU SEE ME, NOW YOU DON'T Eric S. Miller; Rachel Sandler. Hennepin County Medical Center, Minneapolis, MN. (Control ID #2698511)

LEARNING OBJECTIVE #1: Review the differential diagnosis for neutrophil-predominant cerebrospinal fluid (CSF)

LEARNING OBJECTIVE #2: Identify alternative diagnostic testing for bacterial meningitis

CASE: Ms. S is a twenty three-year-old woman with a history of migraines who presented to the hospital with left-sided headache associated with fever, chills, nausea, confusion and photophobia that began six hours prior. She did not report any recent travel, animal or insect bites, sexual partners, or sick contacts. On physical exam, she was febrile to 104°F and tachycardic. She appeared somnolent, but was arousable to voice. Neurologic exam was pertinent for nuchal rigidity and pain with neck flexion without focal neurologic findings. Initial labs were remarkable for serum WBC $21x10^3/mm^3$ with 94% neutrophils. CSF showed cloudy pink fluid with 2000 RBC/mL, 8600 WBC/mL with 93% neutrophils, protein 221 mg/dL, and glucose 45 mg/dL. The initial gram stain was negative. She was empirically started on broad-spectrum antibiotics for bacterial meningitis and admitted to the hospital. On day 3, CSF cultures returned negative. 16S ribosomal RNA testing and repeat routine CSF studies were obtained. Repeat routine CSF studies were unremarkable and the 16S ribosomal RNA was negative. Antibiotic therapy was stopped after 7 days.

IMPACT: Recognizing the differential diagnosis for neutrophil-predominant CSF and utilizing alternative diagnostic testing allows for further diagnostic clarification and judicious use of antibiotics in cases of suspected bacterial meningitis.

DISCUSSION: Bacterial meningitis is suspected when CSF reveals a neutrophilic WBC count greater than 1000/mL, low glucose, and high protein. Elevated protein and CSF WBC of greater than 100 cells/mL have been seen in over 90% of patients with acute community-acquired bacterial meningitis. Neutrophilic predominant CSF can also be seen with viruses, such as *West Nile* virus and *Herpes Simplex* virus and *Mycobacterium tuberculosis*. Immunodeficiency can alter commonly seen patterns and complicate diagnosis. While CSF culture is the gold standard for diagnosis of bacterial meningitis, culture-negative cases do occur. Most often such cases occur if studies are drawn after antibiotics have been administered. Blood cultures can be a useful adjunct in these cases. Rapid PCR testing for common meningitis pathogens is now possible and has been shown to have very high sensitivity, specificity, and positive and negative predictive value. Alternatively, 16S ribosomal RNA gene testing is available and if positive, indicates the presence of bacteria. CSF lactate concentration can also be used to distinguish bacterial from aseptic meningitis with greater than 90% sensitivity and specificity. In cases of meningitis where CSF results are either equivocal or culture-negative when suspecting bacterial meningitis, re-examining the different diagnosis and knowledge of alternative testing is key for accurate diagnosis and appropriate treatment.

NSAID RESISTANT PERICARDITIS: THE CASE FOR KEEPING YOUR PATIENT CLOSE Jerry N. Centeno; Chris Lee; Harshil Patel. New York Presbyterian Queens, Queens, NY. (Control ID #2706527)

LEARNING OBJECTIVE #1: Recognize the clinical presentation, rare complications, and diagnosis of systemic inflammatory disease.

LEARNING OBJECTIVE #2: Recognize the importance of monitoring clinical response and establishing close follow up in patients with serositis.

CASE: A 22 year old African American male with a history of Raynaud's phenomenon, presented with worsening chest discomfort and shortness of breath for one month. He described a sharp chest pain which increased while supine and decreased when upright. Upon further investigation, he reported being treated with NSAIDs at a previous hospitalization elsewhere for pericarditis, but with a gap in follow up prior to presentation. On physical exam, vital signs were heart rate 112bpm, blood pressure 101/60mmHg, and Respiratory rate 25. On auscultation there were distant heart sounds with bilateral crackles in the lower lung fields. Laboratory work up showed elevated creatinine (2.54mg/dl) and inflammatory markers (CRP 10.57mg/dl, ESR 83mm). Chest x-ray revealed bilateral vascular congestion with an enlarged cardiac silhouette. EKG showed sinus tachycardia with diffuse PR segment depressions. Echocardiogram revealed a large circumferential pericardial effusion with fibrin stranding, but no sign of tamponade physiology. Laboratory studies revealed decreased C3 < 38mg/dl, C4 < 9mg/dl, ANA titer 1:2560 with coarse speckled pattern, dsDNA titer 1:320, smith Ab >8, and ribonucleoprotein antibody >8. Pericardiocentesis drained 900cc of exudative fluid by Lights criteria and he was started on high dose methylprednisolone 40mg IV q12 hours to treat pericarditis secondary to active systemic lupus. Hospital course was uncomplicated and patient was discharged with outpatient follow up. He was started on a steroid taper and azathioprine was added for steroid sparing therapy. Patient remains asymptomatic while adhering with therapy and follow up appointments.

IMPACT: This case highlights the importance of monitoring medical management in order to prevent rare, but life threatning complications from systemic inflammatory disease.

DISCUSSION: Systemic lupus erythematosus is a disease which is highly prevalent among African American females and typically presents earlier than in Caucasians [2]. Pericarditis is a common manifestation of lupus, however, these patients are often asymptomatic, and it rarely causes hemodynamic instability or tamponade. Our patient presented with unstable vital signs due to a significant pericardial effusion secondary to lupus pericarditis resistant to NSAID therapy. Lab work and imaging studies raised suspicion of systemic disease which promptly led to a diagnosis, proper management, and close outpatient follow up. This case highlights the importance of aggressive follow-up to rule-out systemic etiologies in young patients with serositis, in order to prevent complications from systemic autoimmune disease.

OBSTRUCTED LARYNGEAL PROSTHESIS CAUSING TAKOTSUBO'S CARDIOMYOPATHY AND TORSADES DE POINTES Teresa Ratajczak[2]; Brian Cothern[2]; Ahmed El-Moghraby[2]; Rey F. Arcenas[1]. [1]Dayton VA, Dayton, OH; [2]Wright State University, Dayton, OH. (Control ID #2703556)

LEARNING OBJECTIVE #1: Recognize Takotsubo's cardiomyopathy in the differential diagnosis for a prolonged QT interval.

LEARNING OBJECTIVE #2: Understand the impact of Takotsubo's cardiomyopathy.

CASE: A 64-year-old male with history of Stage IV squamous carcinoma of the pharynx, status post laryngectomy and larytube implantation presented to the emergency department in respiratory distress. He was found to have an acutely obstructed larytube causing hypoxic respiratory failure and

subsequently underwent urgent surgical stabilization with larytube exchange. He was admitted for monitoring. Laboratory results were remarkable for a troponin of 0.457 ng/ml (reference < 0.045 ng/ml) without associated chest pain. Electrocardiogram (ECG) showed sinus rhythm, a known right bundle branch block and corrected QT (QTc) interval of 539ms (baseline 480ms). An electrolyte panel was within normal limits. Over the next several hours, the patient developed deeply inverted T waves in the anterior, lateral and inferior leads as well as accelerated lengthening of his QTc to 668ms on serial ECGs. Etiology of the QTc prolongation was unclear. Citalopram, which he had been taking daily for ten years was stopped. Short runs of TdP developed. Due to unstable hemodynamics, ECG changes and troponin elevation, he underwent an urgent cardiac catheterization which revealed nonobstructive coronary artery disease and apical ballooning. A diagnosis of Takotsubo CMP was made. A temporary pacemaker was placed and set at 100bpm to prevent further TdP. After a few days, QTc decreased to 570ms with gradual improvement of T wave changes and resolution of TdP. He was seen in clinic a month later and his ECG showed normalization of T waves and a return of QTc to baseline of 480ms (reference < 460 ms). It was proposed that the physical and emotional stress from of an obstructed larytube triggered the patient to develop Takotsubo CMP, prolonging his QTc and causing TdP.

IMPACT: Prolonged QT interval is a common finding in the hospital. Often it is caused by medications, however it can also be precipitated by Takotsubo cardiomyopathy (CMP). Although rare in this setting, some patients can develop torsades de pointes (TdP) ventricular tachycardia.

DISCUSSION: Takotsubo CMP is an important differential diagnosis of acute coronary syndrome due to the similar clinical presentation. Catecholamine surge due to physical or emotional stressors causes a temporary myocardial stunning, with a good prognosis. The mechanism of prolonged QTc is not known, and TdP is rarely seen with 0.5–3% reported in literature. Overdrive pacing is often required. A common cause of QTc prolongation is medication. Our patient had been taking citalopram for over ten years with only mild prolongation of baseline QTc, thus its contribution to the development of TdP is probably small in comparison to that of Takotsubo CMP.

OBSTRUCTIVE UROPATHY PRESENTING AS ALTERED MENTAL STATUS Vishal Shah[1]; joshua smith[2]; Chio Yokose[1]. [1]NYU, Long Island City, NY; [2]NYU Langone Medical Center, New York, NY. (Control ID #2704933)

LEARNING OBJECTIVE #1: Recognize that a bladder mass causing obstructive uropathy is an uncommon entity than can lead to Acute Kidney Injury

CASE: A 94 year-old male presented with altered mental status for one day. Patient's history is notable for diabetes mellitus for which he takes glimepiride. Exam was notable for disorientation and a distended bladder. His finger stick glucose was 59mg/dL and serum blood urea nitrogen and creatinine were elevated at 113mg/dL and 5.6mg/dL, respectively. Renal ultrasound revealed bilateral hydroureteronephrosis. Urinary catheterization was performed with 700ml of urine drained. He was started on subcutaneous octreotide for sulfonylurea overdose. The patient's mental status improved, however, his serum creatinine continued to rise over the next 24 hours. Further imaging with computed tomography revealed an abnormal soft tissue mass in the urinary bladder. He then underwent bilateral nephrostomy tube placement with rapid recovery of his renal function. The bladder mass was presumed to be bladder cancer, and the patient was discharged with plan for outpatient follow up.

IMPACT: In men, obstructive uropathy is not synonymous with prostatic enlargement. In addition to prostate pathology, pelvic masses, renal and ureteral stones can also cause obstruction. When a patient's renal function does not improve after initial bladder decompression, it is important to consider more proximal sources of obstruction.

DISCUSSION: In any patient presenting with acute kidney injury (AKI), it is important to consider obstructive causes, as timely intervention can lead to improvement of renal function. Elderly men and patients with a single functioning kidney or intra-abdominal malignancy are particularly vulnerable to obstructive nephropathy. In one study of etiologies of AKI, 10% were due to urinary tract obstruction. The incidence of obstructive nephropathy increases with age. In another study, obstruction was the cause of AKI in 7, 11, and 20% of those aged <65, 65–79, and >80 years-old, respectively. In men, the most common site for urinary tract obstruction is the prostate. However, obstruction may occur at any site from the renal papilla to the urethra. In cases of suspected obstructive uropathy, ultrasonography should be performed to evaluate for hydroureter and/or hydronephrosis, and if demonstrated, it would be advisable to scan the bladder. A non-distended bladder in the setting of hydroureter or hydronephrosis may indicate an obstructing ureteral stone or bladder mass. Our patient had two sites of obstruction: prostate and bladder. The prostatic obstruction was promptly relieved with insertion of a urinary catheter, but renal function did not improve as expected. This led us to further imaging which revealed an obstructing bladder mass. While prostatic enlargement is the most common cause of obstructive nephropathy in elderly men, other etiologies must remain on the differential, especially when renal function fails to improve after bladder decompression.

OCCLUSION OF RIGHT MIDDLE CEREBRAL ARTERY AS INITIAL PRESENTATION OF THROMBOTIC THROMBOCYTOPENIC PURPURA Andrea Tufano[1]; Ryan Sugarman[1]; Rebecca Nejat[2]; Johnson Liu[1]; Kyle Katona[1]. [1]Hofstra Northwell School of Medicine, Woodbury, NY; [2]Weill Cornell, New York, NY. (Control ID #2699239)

LEARNING OBJECTIVE #1: To recognize large cerebral artery occlusion (LCAO) as a rare presentation of thrombotic thrombocytopenic purpura (TTP).

LEARNING OBJECTIVE #2: To manage LCAO secondary to TTP with plasma exchange, and in select cases, to consider the use of thrombolytic therapy as well.

CASE: A 67-year-old right-handed female presented to the Emergency Department with a chief complaint of slurred speech. Physical exam revealed a partial right gaze palsy, left arm motor drift, dysarthria, and right-sided neglect, consistent with National Institute of Health Stroke Score of 7. Workup revealed elevated creatinine and severe thrombocytopenia, which precluded the use of tissue plasminogen activator (tPA). Noncontrast computed tomography (CT) of the head revealed no ischemia or hemorrhage, however CT angiography revealed an occlusion of the right middle cerebral artery. A peripheral smear was performed and schistocytes were identified. The diagnosis of TTP was later confirmed with ADAMTS13 assay. Therapeutic plasma exchange (TPE) and high dose corticosteroid therapy was initiated. The patient was discharged to rehabilitation with a diagnosis of TTP as the cause of stroke. One year later, the patient remains wheelchair bound with persistent right hemiparesis.

IMPACT: To our knowledge, this is the first reported case of LCAO as the initial presentation of TTP confirmed by ADAMTS13 assay.

DISCUSSION: TTP is an uncommon disease characterized by the classic pentad of thrombocytopenia, microangiopathic hemolytic anemia, acute kidney

injury, fever and neurologic symptoms. TTP results from inherited deficiency or acquired inhibition of the enzyme ADAMTS13. Reversible neurologic involvement is common in TTP, however, it is very rare to have permanent neurologic deficit secondary to LCAO. Prognosis is generally good when diagnosed early and treated with TPE. After extensive literature review, we could only identify nine cases in the literature that reported LCAO in the context of clinical TTP. In two of these cases the patient received thrombolytic therapy with tPA. In the first case, the patient had a normal platelet count at the time of tPA administration and was diagnosed with TTP later in the hospital course. This patient had residual arm weakness. In the second case, documented by Boattini, et al., administration of tPA and TPE was done in the setting of a platelet count of 27×10^9/L and the patient had full neurologic recovery. Our case illustrates that TTP can cause large vessel infarct, and plasma exchange should not be delayed for ADAMTS13 assay result. Thrombolytic therapy should only be considered in select cases where the benefit of treating large vessel stroke outweighs the risk of life threatening bleed in the setting of severe thrombocytopenia.

OCTREO-TRIED IN THE TREATMENT OF IDIOPATHIC CHRONIC INTESTINAL PSEUDO-OBSTRUCTION REEM E. AOUN[2]; Lydia Assioun[2]; Jennifer Schmidt[1]. [1]Saint Louis University, Saint Louis, MO; [2]Saint Louis University, St Louis, MO. (Control ID #2698377)

LEARNING OBJECTIVE #1: Octreotide could be useful in patients with idiopathic chronic intestinal pseudo-obstruction

CASE: A 67-year-old woman with history significant for Parkinson coming with nausea, vomiting, abdominal distention, and a 40-pound weight loss over 3 months is admitted for failure to thrive. During an outside hospital admission 4 weeks prior to presentation, CT scan, endoscopy, and exploratory laparotomy showed dilated bowels without mechanical obstruction. Repeat imaging during her current admission showed similar results. A colonoscopy with an intestinal biopsy was normal. Thus the workup was unrevealing of an underlying obstructive etiology. The patient was subsequently diagnosed with chronic intestinal pseudo-obstruction (CIPO). She was started on bethanecol, promethazine, and a trial of erythromycin without symptom improvement. She was unable to tolerate enteral feeds and was subsequently initiated on parenteral feeds for nutritional support. As traditional treatments had failed, the patient was started on octreotide nightly injections. The patient's symptoms improved; she was tolerating tube feeds at goal rate and was able to transition to oral intake. Her abdominal distention decreased and parenteral feeds were discontinued. The patient was discharged on a clear diet, tube feeds, and octreotide injections. On outpatient follow up 3 weeks post-discharge, the patient remained symptom free and was tolerating a general diet.

IMPACT: Chronic intestinal pseudo-obstruction is a rare disorder in which the patient exhibits symptoms and signs of intestinal obstruction in the absence of a mechanical block. Its treatment remains challenging with the limited literature available. We present a case of CIPO that failed treatment with prokinetics but resolved upon treatment with octreotide.

DISCUSSION: CIPO is a syndrome of small or large intestinal dysmotility characterized by bowel dilatation without evidence of physical obstruction. The literature on disease treatment is limited due to the rarity of the disease; thus treatment is typically based on clinical experience. Most intestinal prokinetics such as erythromycin or metoclopramide do not have proven benefit but are commonly used due to their theoretical role in improving gut motility. While caring for this patient, a literature search resulted in two small studies where octreotide had shown benefit on intestinal motility. Studies were limited however, to patients with scleroderma or to patients given a combination of octreotide and erythromycin. This case demonstrates the usefulness of octreotide in a patient with severe idiopathic CIPO after failing treatment with other prokinetics. In conclusion, octreotide could be a treatment option in dysmotility disorders when traditional treatments fail.

OH BABY! A CASE OF SEVERE HYPERNATREMIA AND EXTRAPONTINE MYLENOLOSIS SECONDARY TO GESTATIONAL DIABETES INSIPIDUS Serena M. Ogunwole. University of Texas Health Science Center San Antonio, San Antonio, TX. (Control ID #2703990)

LEARNING OBJECTIVE #1: Identify gestational diabetes insipidius as a cause of polyuria and severe hypernatremia.

LEARNING OBJECTIVE #2: Recognize an uncommon complication of overcorrection of hyponatremia.

CASE: An 18 year old G1P0 female (at 33 weeks gestation) with a history of obstructing nephrolithiasis presented to the ED with dysuria and abdominal pain. She was admitted for concern for urinary tract infection and recurrent obstructing nephrolithiasis. She was started on broad spectrum antibiotics and was made NPO at midnight for percutaneous nephrostomy tube placement. On hospital day 2 fetal heart sounds were noted to be absent and the patient was diagnosed with intrauterine fetal demise. Shortly after, the patient began to have changes in mental status. The Medicine consults team was called to evaluate the patient. Upon review of the flowsheet it was noted that the patient had 9L of urine output in the preceding day. A basic metabolic panel was drawn that revealed a serum sodium of 188 (a 40 point increase from admission). The patient was transferred to the Intensive Care Unit and Nephrology was consulted. She was started on a D5W drip and DDAVP. She had slow correction of her hypernatremia. MRI done on hospital day 4 showed pontine and extrapontine myelnolysis. The patient continued to recover motor and cognitive skills and was later sent to inpatient rehab.

IMPACT: GDI is a rare cause of polyuria and hypernatremia. Symptoms of GDI are benign and usually well tolerated when the sensation of thirst and access to water are not altered. Hospitalized patients often have a change in their access to free water for various reasons. Careful evaluation of intake and output can lead to immediate recognition of polyuria and prompt diagnostic and therapeutic interventions. It is important to recognize polyuria early, as the complication of acute severe hypernatremia may have devastating consequences.

DISCUSSION: GDI is estimated to occur in 2 to 6 cases per 100, 000 pregnancies. It can occur at any stage of gestation, but it generally occurs at the end of the second or during the third trimester of a first pregnancy and sometimes after delivery. The syncytiotrophoblast of the human placenta is known to play an important role in the production of vasopressinase which quickly degrades ADH and oxytoci. In gestational diabetes insipidus there is thought to be an increase in vasoppresinase activity. Administration of intranasal DDAVP is the treatment of choice in GDI. Unlike natural vasopressin, DDAVP, a synthetic analogue of vasopressin, resists degradation by vasopressinase.

OH SHIPP Juan C. Avila[2]; Kanapa Kornsawad[1]. [1]University of Texas Health Science Center, San Antonio, TX; [2]University of Texas Health Science Center at San Antonio, San Antonio, TX. (Control ID #2701738)

LEARNING OBJECTIVE #1: Recognize medications associated with and the clinical features of drug-induced lupus.

LEARNING OBJECTIVE #2: Develop a proper treatment plan for drug-induced lupus.

CASE: A 59-year-old woman presented with progressive dyspnea for four months. She was previously treated for pneumonia, but her symptoms continued to progress. On review of systems, she denied fevers, night sweats, weight loss, hemoptysis, and hematuria, but endorsed intermittent dry cough. Past medical history was significant for hypertension for five years treated with hydralazine and chronic kidney disease stage IV. She denied a prior smoking history. On physical exam, she had bibasilar crackles, no heart murmurs, rubs, or gallops, and no bilateral extremity edema. Serum laboratory studies were significant for a positive p-ANCA (titer of 1:640) and a positive histone antibody. Chest CT scan showed diffuse ground glass opacities. Bronchoscopy was noted to have significant erythematous and friable tissue with pulmonary hemorrhage. Bronchoalveolar lavage pathology revelead numerous hemosiderin-laden macrophages consistent with diffuse alveolar hemorrhage. Given these findings and long-standing use of hydralazine, the patient was diagnosed with hydralazine-induced vasculitis. Hydralazine was discontinued. In addition, she was started on high dose steroids with tapering. She wil be started on Rituximab infusions as an outpatient.

IMPACT: With the assistance of electronic medical records, it is convenient to obtain a medication history without having to inquire the patient directly. However, this can be problematic as one may overlook when a particular medication was started and, consequently, be unable to clinically correlate it with the presentation of the patient. With this in mind, I will be more diligent in my clinical practice by routinely taking a thorough medication history and being cognizant of medication side effects.

DISCUSSION: Specific drugs are known to induce an autoimmune response with the production of autoantibodies. Common drugs known to induce lupus include sulfasalazine, hydralazine, isoniazid, procainamide, and penicillamine (which are easily remembered by the mnemonic "SHIPP"). Drug-induced lupus is diagnosed when clinical features consistent with systemic lupus erythematosus are evident and autoimmune antibodies are present in the serum. This patient did not exhibit signs of myalgia, arthralgia, or rash, but rather pulmonary manifestations (i.e., diffuse alveolar hemorrhage). Anti-histone antibodies have been shown to be present in 95-percent of patients with hydralazine-induced lupus. Furthermore, p-ANCA antibodies have been shown to be markedly elevated in cases of hydralazine-induced vasculitis. In such cases, typical management involves complete withdrawal of hydralazine and administration of immunosuppressive therapy, as demonstrated with this patient.

ORBITAL APEX MASS (OAM) FROM GRANULOMATOSIS WITH POLYANGIITIS (GPA) AFTER INHALED PARTICLE EXPOSURE

Morgan Cronin; Sarah Schaeffer. University of California, San Francisco, San Francisco, CA. (Control ID #2701220)

LEARNING OBJECTIVE #1: Recognize the broad differential diagnosis for OAM, including GPA

LEARNING OBJECTIVE #2: Consider environmental exposures as risk factors for ANCA-associated vasculitides

CASE: A 65-year-old woman with a history of diabetes presented to our hospital with left eye vision loss, ophthalmoplegia, and MRI finding of left OAM. Six months prior, the patient's home roof collapsed and she was exposed to particulate matter during repair. She developed left sided headaches, eye pressure, intermittent diplopia, and bloody rhinorrhea that failed to improve with antibiotics. Out of concern for temporal arteritis, she was prescribed steroids which resolved her headaches. Temporal artery biopsy was negative, steroids were discontinued, and her headaches recurred. Five months after the collapse, she developed progressive left eye vision loss. An MRI confirmed a left OAM and she was admitted to our hospital for evaluation. Exam of the left eye showed ophthalmoparesis, minimally reactive pupil, and vision limited to light perception. Right eye exam was normal. Exam and testing of all other organ systems, including pulmonary and renal, were normal. Evaluation was performed for the broad differential causes of OAM, including neoplastic, infectious, and inflammatory conditions. Testing returned positive for elevated Anti-PR3 antibody and biopsy noted inflammatory features compatible with GPA. All other testing returned negative. The patient was diagnosed with GPA limited to the orbit and referred to rheumatology for further management.

IMPACT: This case highlighted the need to think beyond common presentations of GPA and to consider the role of environmental exposures as potential triggers for disease processes.

DISCUSSION: When evaluating a patient with OAM, internists must consider a broad differential of infectious, neoplastic, and inflammatory conditions. Orbital involvement has been reported in up to 50% of patients with GPA. Orbital disease may present as the first symptom of systemic GPA or as the only manifestation of limited GPA. As this case highlights, is it important to consider GPA in a patient with OAM, even in the absence of pulmonary or renal disease. The onset of disease symptoms after exposure to roofing debris is also notable. Many construction materials, including roofing, contain silica, a substance that has been associated with increased risk of GPA and other autoimmune diseases. Case control studies of roofing and construction workers have found positive association between silica exposure and risk of GPA. In this case, the patient experienced months of non-occupational exposure to similar materials. While knowledge of the pathophysiology is limited, it is important to note the connection. Recognizing the role of environmental exposure could lead to earlier consideration of GPA in patients like this with vision loss from orbital apex mass.

OROLINGUAL ANGIOEDEMA AFTER TISSUE PLASMINOGEN ACTIVATOR ADMINISTRATION: A CASE REPORT

Matthew Schilling; Kenneth Raney; Gregg Shalan. Methodist Hospital Dallas, Dallas, TX. (Control ID #2701870)

LEARNING OBJECTIVE #1: Recognize a potentially life-threatening side effect of tissue plasminogen activator therapy

CASE: An 88-year-old African American male with past medical history of chronic kidney disease stage IV, hypertension, atrial fibrillation, and gout presented to Methodist Dallas Medical Center emergency room on May 13, 2015 with acute onset right hemiparesis, numbness, right sided facial droop and slurred speech. Patients last known normal was 1.5 hours prior to arrival at ER. Code stroke was activated and teleneurology service was consulted. Stat CT scan was obtained, which showed no intracranial bleed. Teleneurologist and family agreed to administration of tPA. tPA was administered 1 hour after arrival to ER. Patient was admitted for observation in the neuro critical care ICU after administration of tPA. Patient was found to have moderate improvement in speech and minimal improvement in right sided weakness

immediately after administration. Patient was examined 6 hours after administration of tPA and was found to have right sided lower lip swelling. No tongue swelling or stridor was found on exam. Patient was started on methylprednisolone 40mg IV Q6h and was closely monitored. Orolingual angioedema resolved without further complications within the next 2 hours. Patient had overall improved strength in right lower extremity and speech but had significant residual right upper extremity weakness. Transesophageal echo was performed which showed vegetation on posterior mitral valve leaflet. Blood cultures were obtained to rule out endocarditis and resulted negative. Patient was sent to a rehab facility, and was subsequently started on xarelto for anticoagulation.

IMPACT: This case serves as a reminder of the need for increased awareness and caution in regards to post-tPA monitoring. Routine inspection of the lips and oral cavity is necessary during and after the administration of tPA in stroke patients.

DISCUSSION: Orolingual angioedema is a rare side effect of Tissue Plasminogen Activator (tPA) administration, with incidence per literature search to be between 1–5%. With increasing use of tPA for treatment of stroke, awareness needs to be raised regarding this potentially life threatening complication.

OROPHARYNGEAL DYSPHAGIA: RARE PRESENTING SYMPTOM OF STATIN-INDUCED HMG COA REDUCTASE NECROTIZING AUTOIMMUNE MYOPATHY Vatsal Y. Bhatt; Clifford Stermer; Vivien Hsu; Ranita Sharma. Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ. (Control ID #2702031)

LEARNING OBJECTIVE #1: To recognize an atypical presenting symptom of Statin Induced Necrotizing Autoimmune Myopathy.

LEARNING OBJECTIVE #2: To distinguish a rare case of treatment refractory disease process.

CASE: A 79 year old male presented with four weeks of progressive dysphagia to solids and liquids, a 25lb weight loss and fatigue. He denied odynophagia, vomiting, dyspnea, fevers, skin changes, or arthralgias. No recent vaccinations were administered. Over time he reported pain with weakness in bilateral lower extremity proximal muscle groups. Increased effort was needed to rise from the sitting position. Once upright, he could ambulate. He denied tobacco or alcohol use. He had diabetes treated with metformin, hypertension controlled with medications and hyperlipidemia treated with daily atorvastatin 40 mg for the past 2 years. Age appropriate cancer screening was completed. On exam HR was 96, BP was 137/65 and RR was 18 without hypoxia. He was thin with notable temporal wasting and gargled speech. No neck masses were detected. Cardiopulmonary and abdominal exam were normal. Rashes were absent. Neurological exam revealed intact cranial nerves, no tremors, fasciculations or muscle wasting, no difficulty in raising arms above his head but visible difficulty rising from a chair with a subsequent normal gait and sensory testing. Labs included CPK of 8185, aldolase of 346 (normal < 8), AST/ALT of 176/395 (subsequently normalized), normal renal function, and a hemoglobin of 10. TSH and B12 levels were normal. HIV, T-SPOT, Hepatitis B/C were negative. Vitamin D levels were low. A barium swallow confirmed cricopharyngeal paralysis. MRI brain was normal. Atorvastatin was discontinued for a suspicion of statin induced myopathy but CPK levels remained elevated. Myopathy workup was pursued. Myositis panel antibodies including Jo-1, MI-2, SRP, U2-snRNP, U1-RNP, NXP-2, and TIF1 were all negative. Anti-HMGCR antibodies were markedly elevated at > 200 (normal < 20). Biopsy revealed muscle fiber necrosis, phagocytosis, macrophages with minimal inflammation. Despite steroids, IVIG and Rituximab, the patient's clinical condition deteriorated with inability to ambulate and continued need for PEG feeding.

IMPACT: This was a unique presentation of statin induced Necrotizing Autoimmune Myopathy that required a thorough investigation before reaching the diagnosis. Because patient presented with dysphagia as the primary symptom with no initial muscle weakness, myopathy was not initially high on our differential. However, this case highlights that in individuals with statin exposure and elevated CPK levels, oropharyngeal dysphagia should warrant a myopathy workup.

DISCUSSION: We highlight two variations to descriptions of statin-induced HMGCR NAM: oropharyngeal dysphagia replacing the classic presentation of proximal muscle weakness and progression of disease despite immunosuppression. It is imperative to exercise early recognition of statin induced NAM to allow for prompt immunosupressive therapy, leading to better clinical outcomes.

OUCH MY LEG! ATYPICAL PRESENTATION OF BURKITT LYMPHOMA WITH PERSISTENT LACTIC ACIDOSIS AND HYPOGLYCEMIA Sophie Korzan; Rooma Nankani; Michael Thompson; Shiromini Herath. University of Connecticut, Farmington, CT. (Control ID #2707380)

LEARNING OBJECTIVE #1: Recognize the rare association of Burkitt Lymphoma with lactic acidosis and hypoglycemia

LEARNING OBJECTIVE #2: Distinguish and be able to provide appropriate work-up and pain evaluation in difficult patient populations

CASE: 47 year old Hispanic male with a medical history of IV drug abuse with opiate dependence, HIV not adherent with ART, untreated Hepatitis C and Diabetes Mellitus presenting with worsening left lower extremity (LLE) pain of two years duration. He visited various Emergency Departments with no conclusive diagnosis only receiving various antibiotics for suspicion of infection and prescription pain medications. The pain was described as a crushing, burning sensation in his left buttock and thigh rated 10/10 on the severity pain scale, with associated swelling and general weakness. Other symptoms included fever, chills, night sweats, nausea, decreased oral intake, dizziness and confusion. No chest pain, shortness of breath, sensory or neurologic deficits. On exam he was ill-appearing, restless and combative. Examination of the LLE revealed a circumferential area of erythema on the thigh with diffuse edema, induration, tenderness to light palpation and limited range of motion. Laboratory studies revealed hypoglycemia and lactic acidosis. LLE doppler was negative for deep venous thrombosis. Computer Tomography (CT) and Magnetic Resonance Imaging (MRI) of the LLE showed a large medial compartment soft tissue mass. He was evaluated by surgery for compartment syndrome as well as necrotizing fasciitis and underwent an urgent fasciotomy. Throughout the hospital stay he had persistent hypoglycemia and lactic acidosis complicated by tachycardia and tumor lysis syndrome with worsening of symptoms into the

periscrotal area. CT guided biopsy of left thigh revealed a diffuse aggressive B-cell Non-Hodgkins lymphoma infiltrating skeletal muscle. Given the patient's underlying immunosuppression, the patient was deemed unsuitable for chemotherapy and was transitioned to inpatient hospice. Autopsy revealed extensive involvement of the heart, iliopsoas musculature, and brain by aggressive Burkitt Lymphoma.

IMPACT: This is a rare presentation of Burkitt Lymphoma with primary localization in the LLE musculature. Associated metabolic features of combined lactic acidosis and hypoglycemia have been reported in only three documented cases.

DISCUSSION: Combined lactic acidosis with hypoglycemia in the setting of malignancy can be explained by the Warburg effect whereby neoplastic cells undergo glycolysis and produce lactate even in aerobic conditions. This phenomenon can be disrupted by chemotherapy in certain lymphomas. It is also important to be aware that as physicians we may be biased towards difficult patients like the IV drug user who appears to be pain-seeking. To avoid delay in appropriate management of rare pathology, thorough diagnostic work up and attention should be provided regardless of socioeconomic background.

OVERLOOKED CAUSE OF DYSPNEA IN A PATIENT WITH GLAUCOMA Jean M. Lenz; Denise Dupras. Mayo Clinic, Rochester, MN. (Control ID #2706849)

LEARNING OBJECTIVE #1: Recognize topical ophthalmic beta blockers as a cause of chronotropic incompetence and bronchoconstriction.

CASE: BF was a 74-year-old woman with a history of RA, hypertension, remote smoking history, chest radiation for breast cancer 24 years ago, cataracts, and open angle glaucoma who presented initially with acute episodic shortness of breath, atypical chest discomfort, and dyspnea on exertion. She was doing well until several days after cataract surgery, when she began to notice wheezing and shortness of breath with minimal exertion. She was evaluated in the emergency department where vital signs were stable. Labs were notable for hemoglobin 14.2, WBC of 13.6, and a negative troponin. ECG was normal and CT angiogram of the chest showed only mild inflammatory changes consistent with bronchiolitis. She was discharged home. In follow up 2 weeks later, her symptoms were improving but still present. Exercise ECG was negative for ischemia, but maximum heart rate achieved was only 109 bpm. Pulmonary function testing showed an increase in residual volume and airway resistance with an FEV1/FVC ratio 82% of predicted and a positive bronchodilator response. Echocardiogram was within normal limits. A trial of albuterol improved her symptoms. Detailed evaluation of her medication list revealed that she had been prescribed high doses of timolol and latanoprost eye drops post operatively, corresponding to the time of her symptom onset. Additionally, she was taking timolol eye drops at the time of her exercise stress test, explaining her chronotropic incompetence. As the doses of her timolol drops were tapered, her shortness of breath and wheezing improved. The CT findings were thought to be related to her underlying connective tissue disorder, and her immunosuppressive medications were continued. Ultimately, the etiology of her shortness of breath was considered multifactorial, likely related to medication effect from the topical beta blocker and deconditioning.

IMPACT: This case illustrates the importance of a careful history and review of the medication list, including often overlooked topical medications. Eye drops can have systemic effects, as seen in this case.

DISCUSSION: Beta blockers are well known to cause bronchoconstriction and bradycardia. Bronchoconstriction has even been reported with topical ophthalmic administration of timolol. Dyspnea and PFT abnormalities have also been reported. In general, topical timolol therapy is contraindicated in patients with asthma or severe COPD. Cardiovascular effects of topical timolol have also been well described. Bradycardia, complete heart block, and precipitation of acute heart failure have all been reported with topical timolol use.

PAN-SINUSITIS: AN UNUSUAL PRESENTATION OF INFECTION IN MULTIPLE FACIAL CAVITIES Bernard Partiula; Vladimir Ornstein. Northwell Health Lenox Hill Hospital, Brooklyn, NY. (Control ID #2705045)

LEARNING OBJECTIVE #1: Recognize an unusual presentation of sinusitis.

LEARNING OBJECTIVE #2: Understand the potential lethal complications of severe bacterial sinusitis.

CASE: An 18 year old male presented with a throbbing headache for 1 week, associated with fevers to Tmax 102 F, neck stiffness and photophobia. He also admitted to a recent sore throat which had since improved and a mechanical fall onto the back of his head 3 weeks ago. He presented to another hospital prior, had a lumbar puncture (LP) performed which was negative, and was discharged with a diagnosis of muscle strain. On physical exam, he had marked photophobia, mild neck stiffness, negative Kernig's and Brudzinski's signs, and mild bilateral maxillary sinus/temporal bone tenderness. He was febrile on admission and had a leukocytosis to 30 K/uL. Suspecting meningitis, broad spectrum antibiotics were administered and another LP was performed, which was negative for any growth. His fever curve down-trended and antibiotics were stopped. A CT neck ruled out a fracture/abscess, given the recent fall he sustained. Another LP was performed and ruled out a possible autoimmune cause for his symptoms. An MRI brain, followed by a CT sinuses, then showed complete opacification of the left and right sphenoid sinuses and abnormal extensive enhancement along the lateral left cavernous sinus, along with bilateral ethmoid sinusitis and left mild mastoiditis, extending to the apex of the orbital bones. He was immediately started on Zosyn and otolaryngology took the patient for a functional endoscopic sinus surgery with drainage of massive amounts of pus. The patient was continued on IV antibiotics for several days and was discharged with all symptoms having resolved.

IMPACT: This case represents an unusual presentation of sinusitis and changes the way we should think about facial cavity infections. Initially this patient seemed to fit the bill for a diagnosis of meningitis but it's important to see that severe sinusitis can mimic and overlap with other diseases. Going forward, it would behoove health care providers to consider facial sinusitis as part of the differential in young patients presenting with fevers, headache, facial pain, and neck stiffness in the setting of a recent URI.

DISCUSSION: The majority of cases of acute rhinosinusitis is due to viral infection with superinfection with bacteria being a common complication. Our patient presented with fevers, neck stiffness, photophobia, and severe headache after experiencing a recent URI. He was initially suspected to have meningitis, however further workup showed extensive inflammation/infection in multiple facial sinuses. This case illustrates the extent of overlap between signs and symptoms of meningitis and facial sinus infection. It is imperative to have a high suspicion for this disease as the complications may be devastating and can include

periorbital/orbital cellulitis, subperiosteal abscess, meningitis, intracranial/epidural abscess, osteomyelitis of the sinus bones, and septic cavernous sinus thrombosis.

PANCREATITIS ASSOCIATED WITH A NEW HAART Amro Ilaiwy[2]; Nitya Ramreddy[1]; Ravi George[3]. [1]University of Miami Miller School of Medicine at Holy Cross Hospital, Fort Lauderdale, FL; [2]University of Miami Miller School of Medicine at Holy Cross Hopsital, Fort Lauderdale, FL; [3]Holy Cross Hospital, Fort Lauderdale, FL. (Control ID #2706784)

LEARNING OBJECTIVE #1: Acute pancreatitis is a condition characterized by systemic inflammation of the pancreas. Common etiologies in general population include alcohol abuse and choleodocolithiasis. The incidence of acute pancreatitis in HIV infected individuals is known to be higher than general population, and epidemiologic studies suggest it might be as high as 40%. Many HAARTs have been reported to cause pancreatitis. In this case report, we present a possible side effect of newly FDA proven medication, Genvoya

CASE: This patient is a 65 year old gentleman with past history significant for HIV infection on HAART (started on Genvoya 4 weeks ago) and non hodgkin lymphoma two decades ago presented with new onset abdominal pain over six hours. Pain was stabbing, 10/10 in severity, increased with movement and decreased while lying still. Patient was unable to provide detailed history during first encounter due to severe pain. Physical exam was performed after administering intravenous morphine, Patient was hypertensive 180/80 mmHg, despite a negative prior history of hypertension. Severe epigastric tenderness was appreciated, with active bowel sounds on abdominal exam. Pertinent lab workup on admission revealed elevated lipase 607 IU/l, mildly elevated LFTs with no leukocytosis. Patient was managed with IV fluids, NPO diet (Genvoya was held) and pain control. Gastroenterology were consulted. CT scan of the abdomen without contrast was done and did not reveal any acute findings. Both MRI abdomen and HIDA scan were done 8 days prior to admission and did not reveal any evidence of cholelithiasis. Patient denied any alcohol use, which was supported by ALT/AST ratio >1. Calcium and triglyceride levels were within normal limits. On the next day, Lipase levels increased to 1396 IU/l. Patient continued to improve clinically and liquid diet was advanced. Genvoya was not given. On third day of admission, lipase levels returned to normal, and patient was tolerating full diet with no issues. Patient was later discharged with appropriate follow-up with his primary and infectious disease physicians to consider adjusting HAART regimen.

IMPACT: Despite the well established association between many HIV medications and acute pancreatitis, no data has yet been published in regards of Genvoya use and incidence of acute pancreatitis.

DISCUSSION: Genvoya is a new HAART approved by FDA in November 2015 for eligible HIV infected individuals. It is composed of Elvitegravir (integrase strand transfer inhibitor), Cobicistat (CYP3A inhibitor), Emtricitabine (NRTI) and Tenofovir alafenamide, which is a novel phosphonoamidate prodrug of Tenofovir used for the first time in HAART. To our knowledge, this is the first documented case report that links inititation of Genvoya therapy to acute pancreatitis.Other possible etiologies of acute pancreatitis, including choledocholithiasis, alcohol use, hypercalcemia, and hypertriglyceridemia have been ruled out before making the diagnosis.

PARANEOPLASTIC MEMBRANOUS NEPHROPATHY IN A DIABETIC PATIENT Nathan C. Nowalk[1]; June Kampangkaew[1]; Glynda Raynaldo[2]. [1]Baylor College of Medicine, Houston, TX; [2]Michael E. DeBakey VA Medical Center, Houston, TX. (Control ID #2706137)

LEARNING OBJECTIVE #1: Recognize the existence of non-diabetic glomerular disease in the diabetic patient.

LEARNING OBJECTIVE #2: Acknowledge the association between membranous nephropathy and malignancy.

CASE: 63 year-old male with history of Diabetes Mellitus Type 2 (DMT2) presented with diffuse swelling and dyspnea on exertion for one month. Outpatient labs showed progression of Chronic Kidney Disease from Stage 2 to Stage 4 over the last 4 months. Paradoxically, the patient noted an unintentional weight loss preceding new swelling. The patient's DMT2 had been well-managed on oral hypoglycemic drugs and he displayed no evidence of retinopathy or neuropathy. Admission labs showed creatinine of 2.4 mg/dL, serum albumin of 1.1 g/dL, and proteinuria of 16g/dL. Following unrevealing serologic work-up for secondary causes of proteinuria, the patient underwent renal biopsy showing membranous nephropathy (MN). Admission chest x-ray revealed incidental 1.4 cm nodular opacity. While he underwent diuresis for anasarca, a CT-Thorax demonstrated 1.8 cm Right Middle Lobe nodule. A follow-up PET/CT again recognized the suspicious nodule, but lesion was absent FDG-avidity. Given high clinical suspicion for malignancy, the patient underwent biopsy confirming Stage 1A Lung Adenocarcinoma. Currently, the patient is scheduled for lobectomy.

IMPACT: As DMT2 is a common cause of proteinuria, his providers were reluctant to pursue renal biopsy. Ultimately, he underwent biopsy as he met characteristics of non-diabetic glomerular disease. The general hospitalist should continue to recognize non-diabetic glomerular disease in diabetics. An established association between MN and malignancy exists. Given this association and the reported weight loss before edema accumulation, an aggressive approach was taken for an incidental pulmonary nodule.

DISCUSSION: Nephrotic syndrome is defined by heavy proteinuria (>3.5 g/day), hypoalbuminemia (<3 g/dL), and peripheral edema. MN is the 2nd most common cause of primary nephrotic syndrome. Diagnosis is established by renal biopsy. Recognized characteristics that should prompt biopsy in a diabetic patient include: absence of other end-organ damage from DMT2 and faster progression to overt proteinuria in weeks-to-months, rather than years. Etiologies of MN can be divided into primary (idiopathic) or secondary causes. These causes include: Drugs (NSAIDs, Anti-TNF Therapy), Hepatitis B or C infection, Systemic Lupus and malignancy. In a review of 240 patients with MN, the prevalence of cancer was 10%. In this cohort, the diagnosis of cancer and MN was often made within 1 year of one another. In patients with cancer-associated MN, a strong relationship between cancer remission and reduction in proteinuria has been observed. Patients with MN warrant more aggressive evaluation of unexplained weight loss or anemia, particularly in the population greater than 65 years old.

PATIENT WITH ACUTE SHORTNESS OF BREATH, DRY COUGH, ARTHRALGIA AND FEVER Smita Y. Bakhai. SUNY at Buffalo, Buffalo, NY. (Control ID #2692645)

LEARNING OBJECTIVE #1: Recognize clinical features of antisynthetase syndrome

LEARNING OBJECTIVE #2: Diagnose interstitial lung disease (ILD) in patients with polymyositis (PM)

CASE: 54 year old nonsmoker male consulted primary care physician (PCP) for acute onset of dyspnea, fever, dry cough and arthralgia. PMH was significant for positive PPD. Physical examination revealed a sick male, dyspnea at rest, absence of rales and otherwise normal. Chest x-ray and CT chest were performed in the emergency room (ER) one day prior to visit showed bilateral pneumonia and patient was started on antibiotic. PCP suspected rheumatology disorder with lung involvement. Rheumatology work up was ordered including HIV. Creatine kinase (CK) was elevated at 1026. PCP consulted with a rheumatologist; clinical diagnosis of acute onset of ILD with simultaneous onset of inflammatory myopathy (PM) was suspected; Jo-1 antibody was ordered. Patient had multiple ER visits for worsening of dyspnea with respiratory failure, requiring 2 Liter of oxygen. Rheumatologist evaluated patient for worsening dyspnea, proximal muscle weakness, arthritis and Raynaud's syndrome. Diagnosis of anti-synthetase syndrome was confirmed based on inflammatory myopathy, acute interstitial pneumonitis and arthritis, with elevated CK level of 1537 and positive Jo-1 antibody at 540. Patient was started on high dose prednisone and INH after muscle biopsy. Pulmonary function tests (PFT) and lung biopsy were consistent with interstitial lung disease.CT chest at one month showed classic ILD. ILD was steroid responsive, resulting into clinical improvement in dyspnea, hypoxemia, and PFT. Patient's muscle weakness got worse while trying to taper prednisone. Cyclophosphamide was added, patient responded well to the treatment. CK level paralleled disease activity, peaked at 1657 at one month, trended down to 80 within one month of therapy. CT Chest performed at 5 months showed improvement. PM symptoms continued to worsen at one year, requiring repeat muscle biopsy which confirmed changes compatible with PM.

IMPACT: History and physical examination skills are very crucial to recognize any disease. Coordination of care and communication between PCP and specialists are cornerstone in prompt diagnosis and treatment of a life threatening condition. When patient's CK is lowered, but strength is not improved, muscle biopsy should be performed to exclude steroid induced myopathy. Awareness of anti-synthetase syndrome is important, because early diagnosis and management of ILD may prevent morbidity and mortality.

DISCUSSION: Antisynthetase syndrome is a rare autoimmune disease, characterized by anti-Jo1 antibody and presence of one or more components of the triad: inflammatory myopathy; dermatomyositis (DM), and PM, ILD and polyarthritis. With variable presentations of PM and ILD, it poses a major diagnostic challenge. High resolution CT chest and PFTs are sensitive tools to detect early ILD. Recognition is critical to prevent morbidity and mortality from ILD.

PEN CAP: FOREIGN BODY ASPIRATION FROM INTRANASAL DRUG ABUSE CAUSING EMPYEMA Crystal Singleton; Faris Galambo; Alexandra Strauss; Kellee Oller. University of South Florida, Tampa, FL. (Control ID #2700208)

LEARNING OBJECTIVE #1: Recognize foreign body aspiration as a potential cause of serious pulmonary disease

LEARNING OBJECTIVE #2: Assess intravenous drug users for risk factors of foreign body aspiration

CASE: A 38-year-old previously healthy male presented to the emergency department with sudden onset, right-sided back pain worse with movement. He also reported 1 month of progressive dyspnea, malaise, productive cough with purulent sputum, and 15-pound unintentional weight loss. He had a 15 pack-year smoking history, daily marijuana use, and current intravenous (IV) drug use. On initial physical exam, he was uncomfortable and had tachypnea with an oxygen saturation of 92% on room air. Breath sounds were decreased over the right lung field. Initial labs demonstrated respiratory alkalosis, mild leukocytosis, normocytic anemia, and a mild protein gap. Computed tomography (CT) of the chest demonstrated consolidation of the right lower lobe with a trace right pleural effusion. He was admitted to medicine and started on ceftriaxone and azithromycin for community-acquired pneumonia. When his symptoms did not improve, a thoracentesis was performed. The 800 ml of pleural fluid was found to be exudative by Light's criteria, and a chest tube was placed. He underwent right thoracotomy for a decortication on hospital day 7. Given his minimal post-operative improvement, a bronchoscopic alveolar lavage (BAL) was performed which identified a foreign body in the right lower lobe bronchus, which had the appearance of an endobronchial valve. He denied prior pulmonary interventions in the past but recalled accidentally "inhaling a pen" while snorting methamphetamine 3 years prior. Repeat bronchoscopy removed the foreign body, which was confirmed to be a pen tip. He was to receive 4 weeks of IV antibiotics, but he left the hospital AMA.

IMPACT: In patients unresponsive to treatment for community-acquired pneumonia, further investigation is required to identify the cause. CT of the chest or bronchoscopy can assist in identifying etiologies such as an empyema or endobronchial lesions. This case highlights a rare consequence of intranasal drug abuse - foreign body inhalation and the delay in which it can manifest.

DISCUSSION: Foreign body aspiration (FBA) is an uncommon diagnosis in the healthy adult patient. Documented risk factors include age over 75, alcohol or sedative use, and impaired mental status and swallow reflex. Presentations can range from acute cough and asphyxiation to severe long-term complications including persistent pneumonia and empyema. Patients with inhalation illicit drug use should be considered as a risk factor. Our case demonstrates the potential for serious long-term pulmonary complications in the adult patient with unrecognized FBA, and the value of a complete history in arriving at the diagnosis.

PERICARDIAL EFFUSION AS A RARE INITIAL PRESENTATION OF AN EXTRA-GONADAL MIXED GERM CELL TUMOR

Dhruv Mahtta; William Paul Skelton IV; Samantha Leigh Welniak; Long Dang. University of Florida, GAINESVILLE, FL. (Control ID #2702477)

LEARNING OBJECTIVE #1: Recognize the importance of a thorough work up of atypical chest pain after ruling out acute coronary syndrome (ACS)

CASE: A 26-year-old construction worker with no medical history presented to the emergency department with chest pain. After acute coronary syndrome was ruled out, his symptoms were attributed to musculoskeletal chest pain, likely costochondritis. On re-evaluation two months later, a transthoracic echocardiogram (TTE) was obtained for suspected post-infectious myocarditis which showed a large pericardial

effusion without tamponade physiology. Pericardiocentesis was performed with placement of a pericardial drain. On hospital day two, worsening respiratory distress prompted a CT angiogram of the chest to evaluate for pulmonary embolism; imaging revealed a large (10.5 cm) mediastinal mass compressing the right pulmonary artery. Pericardial fluid cytology was consistent with a malignant effusion. The patient underwent emergent radiation therapy for size reduction and CT guided biopsy. Pathology resulted as mixed malignant germ cell tumor with yolk sac, embryonal, and mature teratomatous components. Subsequent staging CT abdomen/pelvis and scrotal ultrasound were negative, confirming the diagnosis of an extra-gonadal mixed germ cell tumor (EGCT). The patient completed 4 cycles of chemotherapy with bleomycin, etoposide, and cisplatin, which he tolerated well.

IMPACT: After ruling out ACS, chest pain in a young patient without risk factors is challenging and often attributed to musculoskeletal etiologies; thorough workup to evaluate for other etiologies is imperative. Metastasis to anterior mediastinum has been well described as the presentation of EGCT. However, erosion into the pericardium with subsequent malignant pericardial effusion is a rare presentation and serious complication.

DISCUSSION: Musculoskeletal chest pain is a common etiology of chest pain, especially in young patients without risk factors. In addition to thorough cardiac workup to evaluate for life threatening etiologies of chest pain, imaging with TTE and CT scan are important in identifying pericardial pathology or mediastinal mass lesions, such as thymoma, lymphoma, teratoma, and germ cell tumor, the latter of which is most commonly found in males in the third decade, as in our case. Of primary mediastinal germ cell tumors, malignant nonseminomatous tumors are far less common than their seminomatous and benign teratomatous counterparts, and when present, rarely cause pericardial involvement. They often carry a distinctly worse prognosis, making early diagnosis imperative. In this patient, thorough workup with imaging and pericardial fluid analysis allowed for early diagnosis of a rare nonseminomatous EGCT with pericardial involvement. The patient promptly underwent appropriate therapy with curative intent and resolution of symptoms.

PERIPHERAL NEUROPATHY AS A COMPLICATION OF LIVEDOID VASCULOPATHY Augustin Joseph; Adam P. Sawatsky. Mayo Clinic, Rochester, MN. (Control ID #2678895)

LEARNING OBJECTIVE #1: Recognize manifestations of livedoid vasculopathy

LEARNING OBJECTIVE #2: Diagnose peripheral neuropathy as a complication of livedoid vasculopathy

CASE: A 67-year-old female presented with painful, petechial-like rashes on her lower extremities. After several months the lesions ulcerated, with increasing pain and paresthesias in her feet bilaterally. Her physical examination revealed atrophic, porcelain white macules with peripheral telangiectasias and circumferential erythematous patches. A punch biopsy showed occlusive vasculopathy. Work-up ruled out underlying rheumatologic and hypercoagulable conditions. She was diagnosed with of livedoid vasculopathy and started on warfarin. After one month her ulcers began healing. She continued to have significant pain and swelling in her feet and underwent a course of hyperbaric oxygen therapy. Two months after starting warfarin her wounds healed, her swelling resolved, and her pain improved. She developed a new burning band-like pain across the top of her foot and ankle that limited her walking. An EMG demonstrated a mild length-dependent axonal peripheral neuropathy, which was treated with gabapentin and lidocaine patches.

IMPACT: Livedoid vasculopathy is a rare condition that presents similar to vasculitis, but is caused by intravascular thrombosis and not vascular inflammation. This case highlights the importance of obtaining a biopsy to confirm appropriate diagnosis and management.

DISCUSSION: Livedoid vasculopathy is a thrombotic, noninflammatory skin condition that causes chronic recurrent painful lesions of the lower extremities, most commonly in young and middle-aged women. It is thought to be mediated by a dysfunction of coagulation or fibrinolysis. Livedoid vasculopathy can manifest as a primary disease or secondary to underlying hypercoagulability or rheumatologic condition. Patients present with small, erythematous, telangiectatic, purpuric areas, with scattered petechiae at the margins. Many patients experience pain, burning, or itching from their rash. Small superficial sharply punched-out ulcerations are common. Ulceration healing can require up to six months. Ankle edema and pain can precede the onset of clinical lesions. To confirm the diagnosis, a skin biopsy deep enough to include muscular vessels must show segmental hyalinizing vasculopathy and thrombus formation in blood vessels of the middle to deep dermis. Management includes wound care, analgesia, and avoidance of predisposing risk factors to thrombosis. Small observational studies suggest antiplatelet, anticoagulant, or fibrinolytic therapies may be effective in controlling the disease. Our patient responded to warfarin and hyperbaric oxygen, with wound healing and diminished pain. As a sequela of her primary livedoid vasculopathy, our patient developed peripheral neuropathy, a rare complication. Peripheral neuropathy is thought to be caused by ischemia from vascular thrombotic insults of the vasa nervorum.

PERIPHERAL NEUROPATHY ASSOCIATED WITH HEPATITIS C INFECTION Kristen S. Lee. Boston University School of Medicine, Boston, MA. (Control ID #2702074)

LEARNING OBJECTIVE #1: Recognize peripheral neuropathy as an extrahepatic manifestation of hepatitis C (HCV) infection.

LEARNING OBJECTIVE #2: Distinguish peripheral from central neuropathy based on history and physical exam in patients with neurological symptoms.

CASE: A 45-year-old woman with HCV genotype 1b with a viral load of 670,000 IU/mL was evaluated for numbness and tingling of her hands and feet after a fall. She denied trauma. On physical exam, she had decreased sensation to pinprick and light touch on bilateral upper and lower extremities up to her ankles with a positive Romberg. Computed tomography angiogram identified two intracranial aneurysms. She underwent stent placement and suffered no post-operative complications. There were no cerebellar or vertebral artery lesions on imaging studies. However, her paresthesias significantly worsened over one month causing difficulty with ambulation and inability to bathe and dress herself. She denied skin rash or joint pain. Physical exam showed proximal extension of her sensory deficit and absence of lower extremity reflexes. There was no palpable purpura or abnormal joint findings. Vitamin B12, hemoglobin A1c, and thyroid stimulating hormone levels were within normal limits, rapid plasma reagin test was non-reactive, and HIV was

negative. Cryoglobulin was positive with decreased level of complement C4 level. A twelve-week course of HCV treatment with ledipasvir-sofosbuvir was initiated. At three months after treatment completion, she achieved sustained virologic response (SVR) and her neurological symptoms resolved except for residual paresthesia of her right toes. She fully recovered the ability to perform all her activities of daily living.

IMPACT: Clinical data are not yet available for optimal treatment of HCV related peripheral neuropathy with direct-acting antiviral agents (DAA). However, given favorable side effect profiles and SVR rates, DAAs are an attractive option for this condition.

DISCUSSION: Peripheral neuropathy, both motor and sensory, is the most common neurologic complication of HCV infection. The pathophysiology of the neuropathy is not definitively known but proposed mechanisms include cryoglobulin deposition in the vasa nervorum and HCV-mediated vasculitis. This is evidenced by the prevalence of peripheral neuropathy among people with HCV infection and mixed cryoglobulinemia which is close to 90%. The optimal treatment for HCV-related peripheral neuropathy has not been established. For severe neuropathy, immune modulatory therapy should also be considered. This case demonstrated the importance of a good history and physical exam to prompt consideration of most likely diagnosis in a patient who presented with neurological symptoms. In this case, two intracranial aneurysms were incidental findings. Her clinicians recognized that her symptoms were more consistent with peripheral neuropathy and her symptoms largely resolved with DAA treatment.

PERNICIOUS ANEMIA CAN BE A BLAST: PERNICIOUS ANEMIA PRESENTING WITH PANCYTOPENIA AND LEUKOERYTHROBLASTIC CHANGES Audrey Sigmund; Matthew Sullivan; Jennifer Woyach. The Ohio State University, Columbus, OH. (Control ID #2704063)

LEARNING OBJECTIVE #1: Nutritional deficiencies should be considered early in the work-up of new pancytopenias in order to avoid unnecessary invasive testing and harmful treatment.

LEARNING OBJECTIVE #2: Pernicious anemia can present with features on blood smear that are often found in myelodysplastic disorders, hemolytic processes, and acute leukemia including pancytopenia, increased LDH, decreased haptoglobin, and blasts.

CASE: A 41-year-old African American female with a history of Crohn's disease and hypothyroidism presented with progressive fatigue, melena, and an episode of syncope. Labs were notable for hemoglobin of 3.1 with a MCV of 105.8, WBC of 2.14 with 41.5% neutrophils, and platelets of 24. Initial physical exam showed tachycardia and mild tachypnea with positive hemoccult test on rectal exam. Further work-up revealed TSH of 29.33, reticulocyte count of 3% with a reticulocyte index of 0.3, lactate dehydrogenase (LDH) of 3322 with haptoglobin of <30, vitamin B12 of 158 (ref range 180–914 ng/L) and folic acid of 3.63 (normal ≥ 4.0 mcg/L). Peripheral blood smear showed leukopenia with absolute neutropenia, rare circulating blasts, occasional elliptocytes, circulating nucleated red blood cells, and hypersegmented neutrophils. Gastroenterology was consulted and she underwent upper esophagogastroduodenoscopy (EGD) and colonoscopy to evaluate for a source of bleeding and to perform biopsies. EGD showed diffuse mild atrophic gastric mucosa but did not identify any endoscopic source of bleeding. Colonoscopy was notable only for thrombosed external hemorrhoids. Biopsies of the gastric mucosa were consistent with autoimmune metaplasia atrophic gastritis and serum intrinsic factor antibody was positive, which led to the diagnosis of pernicious anemia. She was started on daily parenteral vitamin B12 supplementation with improvement in her blood counts.

IMPACT: This presentation is a unique case because it demonstrates the diverse hematologic abnormalities that can be seen with pernicious anemia. While it classically presents with isolated anemia, it can, as in this case, also present with pancytopenia. This patient also presented with signs of hemolysis including increased LDH and decreased haptoglobin as well as leukoerythroblastic changes.

DISCUSSION: Pernicious anemia is a megaloblastic anemia that results from vitamin B12 deficiency due to lack of intrinsic factor. Diagnostic criteria include megaloblastic anemia, low serum vitamin B12, gastric body mucosal atrophy, and antibodies to intrinsic factor. Peripheral blood smear findings and laboratory work-up of the anemia are essential in evaluation. While it classically presents with megaloblastic anemia, pancytopenia, signs of hemolysis, and leukoerythroblastic changes can also be seen. These findings often can be mistaken for myelodysplastic disorders, hemolytic processes, and even acute leukemia. Thus, it is important to consider nutritional deficiencies early in the work-up of new pancytopenias in order to avoid unnecessary invasive testing and harmful treatment.

PERSONALIZED PHARMACOTHERAPY IN A PATIENT WITH CYTOCHROME P450 2D6 POLYMORPHISM Sheeba Paul[1]; Celia Lu[2]; Lauren Block[1]. [1]St. Johns University, Queens, NY; [2]Northwell Health, Lake Success, NY. (Control ID #2702736)

LEARNING OBJECTIVE #1: Pharmacogenomic testing should be considered for patients on multiple psychiatric medications due to the complexity of each individual's metabolism of these drugs

LEARNING OBJECTIVE #2: Poor metabolizers of CYP2D6 may be at increased risk for serotonin syndrome as well as other adverse events related to polypharmacy

CASE: A 47 year old woman with a history of depression, migraine headaches, urticaria, and an eating disorder presented to her primary care physician with palpitations, night sweats, and hot flashes as well as occasional tremors for 2 weeks. Her medications at the time included vortioxetine 5 milligrams three times daily, duloxetine 30 milligrams three times daily, and sertraline 125 milligrams daily, which are substrates of the cytochrome P450 2D6 enzyme. Laboratory testing including blood count, thyroid function, and metabolic panel were normal. No infectious etiology was found and the patient reported adequate fluids intake. An electrocardiogram showed sinus tachycardia at 110 beats per minute, which had increased from 60 three months prior. The patient noted palpitations the following afternoon, took her own heart rate, and found it to be 190. She was hospitalized for further management of her sinus tachycardia and found to meet clinical (Hunter) criteria for serotonin syndrome. Results of her genetic testing indicated that patient is a poor metabolizer of cytochrome P450 2D6, increasing her risk of serotonin syndrome on her current medications. Withdrawal of her serotonergic medications resulted in complete resolution of her symptoms.

IMPACT: Due to the great deal of psychiatric medications metabolized by cytochrome P450 2D6 and the widespread availability of tests for genetic polymorphisms, pharmacogenomic testing should be considered in patients taking multiple medications that are substrates of the enzyme and in patients considering escalating psychotherapy with multiple serotonergic agents.

DISCUSSION: The CYP2D6 enzyme metabolizes about 25% of current medications, including opioids, antidepressants, antiarrhythmics, and antiemetics. There is large variation in enzyme activity within the population, and 5–10% of Caucasian patients are poor metabolizers. This patient's CYP 2D6 polymorphism predisposed her to abnormal metabolism, increasing her likelihood of developing serotonin syndrome. The new discovery of the patient's genetic makeup and history of serotonin syndrome posed a great challenge in providing appropriate medications to treat her multiple chronic conditions. Although pharmacogenomic testing for CYP2D6 polymorphism is now widely available and covered by most insurances, cost-effectiveness data has not supported routine use in patients with depression or schizophrenia. More studies are needed to determine the clinical impact of CYP2D6 polymorphism in patients with psychiatric polypharmacy, as well as the cost-effectiveness of pharmacogenomic testing in this subset of patients.

PLASMODIUM VIVAX MALARIA IN A PATIENT WITH LONG QT SYNDROME Srikanth Tammali[1]; Sai Prasad Gadapa[2]. [1]Kakatiya Medical College, Hyderabad, India; [2]Presence Saint Francis Hospital, Evanston, IL. (Control ID #2707466)

LEARNING OBJECTIVE #1: 1) Only medication licensed for elimination of hypnozoites of Plasmodium Vivax and Plasmodium Ovale is Primaquine.

LEARNING OBJECTIVE #2: 2) Treatment becomes challenging in a patient with Plasmodium Vivax infection, history of Long QT syndrome, and significant family history of sudden cardiac death.

CASE: We report a case of 45 yo female with past history of hypertension on metoprolol 50 mg twice daily presenting with high grade continuous fever more in the evening associated with night sweats, nausea, headache, malaise, myalgias and dizziness since past 1 week. She moved to USA from Pakistan 10 months ago. Review of systems was negative except above. She has strong family history of sudden cardiac death, her sister died at the age of 30, her son died at the age of 16, her other son received AICD 6 years ago. On examination her BP was 142/60 mm of Hg, HR 97/min, RR 20/min, Oral Temperature 102 F, Spo2 97% on room air. General and systemic examination was unremarkable. Significant findings on investigations include thrombocytopenia 87 k/mm cu; normal leukocyte count with 14% bandemia, procalcitonin was 45 ng/mL, and CRP 6 mg/dL. EKG showed 507 msec on admission. She was admitted and started on broad-spectrum antibiotics. She developed transient episode of palpitations and low blood pressure, cardiac monitor showed Torsades de pointes for 8 s. During her hospitalization her blood cultures were negative, received AICD and was eventually discharged after her symptoms improved. She was admitted again after one month with similar complaints. This time Malaria preparation was sent which showed 10% malaria parasitemia. she was treated with Atovaquone and Proguanil 1000/400 mg daily for 3 days. Her blood sample was sent to CDC for identification of species. She was found to be infected with Plasmodium Vivax species. She has no G6PD deficiency. She received Primaquine 45 mg weekly for 8 weeks with close follow up with cardiologist. She successfully finished her treatment without complications.

IMPACT: This is the rare case report of Malaria and Long QT syndrome. Our options of treating this patient were very limited as most of the drugs used to treat malaria has an adverse effect of QT prolongation. Termination of Plasmodium Vivax hypnozoites with primaquin was challenging.

DISCUSSION: Primaquine 45 mg weekly for 8 weeks is used in patients with borderline G6PD deficiency, we used the same regime in this patient.

PLASTIC BRONCHITIS (PB) COMPLICATED WITH PNEUMOMEDIASTINUM AND PNEUMOPERICARDIUM IN A YOUNG FEMALE: A RARE COMPLICATION OF STATUS ASTHMATICUS Kushal A. Shah; Maliha Naseer; Sarwan Kumar. Wayne State University, Rochester, MI. (Control ID #2707622)

LEARNING OBJECTIVE #1: Plastic Bronchitis is a rare condition with heterogeneous presentation associated with formation of extensive endobronchial casts.

CASE: A 23 years-old female with history of asthma presented with complains of worsening shortness of breath accompanied with productive cough, chest tightness, sinus congestion and wheeze which started a week ago. The patient denied history of fever, chills, chest pain, palpitations, exposure to sick contacts and travel history. Vitals showed RR of 35, HR in 120-130s with an SO2 of 88%. Examination revealed crepitations on palpation of the neck area and chest. Auscultation was significant for scattered rhonchi and wheezing bilaterally and diminished heart sounds. X-ray and CT Chest showed extensive pneumomediastinum and pneumopericardium, subcutaneous emphysema and ground glass opacities in the bilateral lower lobes. Labs showed anion gap metabolic acidosis with lactate level of 3.7 (0.5-2.2), and WBC: 14700. The patient was admitted to the ICU and started on prednisone, albuterol and IV levofloxacin. Subsequently the patient developed acute respiratory failure and became hemodynamically unstable. Bedside ECHO was done to rule out cardiac tamponade. Left sided chest tube was placed because of presence of pneumothorax and patient was taken to OR for left anterior thoracotomy with pericardial window and mediastinotomy. Later bronchoscopy revealed several mucus plugs tracking the airway in the L upper and lower lobe and R upper lobe. Chest X-ray post bronchoscopy showed left lung re-expansion. She had improved respiratory function, decreased ventilator requirement. Bronchial wash sample tested negative for aspergillus antibody, cystic fibrosis screening and gene mutation, serology for histoplasmosis, blastomycosis and coccidiomycosis. IgE level was in normal limits. Cytology was negative for malignant cells but revealed dense mucoid material with abundant mixed neutrophils, eosinophils and reactive respiratory epithelial cells. Gram stain showed respiratory flora. The patient was extubated and discharged home on steroids and inhaler.

IMPACT: We present an otherwise healthy, 23 years-old female diagnosed with Plastic bronchitis complicated with pneumopericardium and pneumomediastinum.

DISCUSSION: It has been hypothesized that asthma, ABPA, mucoid impaction and plastic bronchitis are based on a common allergic response involving the bronchial mucosa. PB often present as an acute life-threatening emergency if mechanical obstruction of major airways occurs. In plastic bronchitis casts are differentiated into type I, inflammatory casts, or type II, acellular casts. The type I inflammatory casts are often associated with bronchial disease and often have an acute presentation. Our patient presented with a Type I Plastic bronchitis complicated with pneumopericardium and pneumomediastinum. This case shows diagnostic evaluation and the need for suspicion by the physician to consider Plastic bronchitis (PB) as a differential diagnosis in respiratory distress.

PLOT TWIST: A STORY OF HEMODIALYSIS INITIATION Ihsan Yassine. UTHSCSA, San Antonio, TX. (Control ID #2706369)

LEARNING OBJECTIVE #1: Recognize the importance of maintaining a wide differential diagnosis when a patient is not progressing appropriately
CASE: Patient is a 57 year old man with PMH of diabetes, hypertension, chronic kidney disease stage V (baseline Cr ~ 3.5) who presented with 1 day history of acute onset nausea, vomiting, fatigue and dizziness. On admission, patient was noted to have BP of 214/163; exam otherwise unremarkable, without signs of volume overload. Labs were significant for Cr 6.0, BUN 52 with normal electrolytes. He was diagnosed with acute renal insufficiency, secondary to hypertensive emergency. His BP improved with nicardipine drip. Although patient continued to make sufficient urine output, his Cr/BUN peaked at 7.4/71. Nephrology determined this was progression of CKD in setting of medication noncompliance. Physical therapy noted significant imbalance with ambulation. Three days after admission, patient was initiated on hemodialysis due to persistent uremic symptoms. His symptoms and objective findings by PT did not improve. His son became concerned that his father was limited in activity due to dizziness and imbalance and did not feel he was safe to return home. With the patient not progressing as expected with dialysis initiation, a CT head was ordered 10 days after admission to assess for other causes. It revealed a recent left cerebellar infarct in the posterior inferior cerebellar artery distribution. A neurological exam revealed ataxic gait, impaired finger-to-nose, poor rapid alternating movements, and difficulty with heel-to-shin movements. Neurology determined patient's presenting symptoms were in fact due to the large cerebellar stroke, specifically with vermis involvement. Etiology of stroke was thought to be atherosclerosis. Patient was optimized on aspirin and statin. Scopolamine patch was started for vertigo. He was eventually discharged to rehabilitation with focus on vestibular rehabilitation.
IMPACT: This case highlights the importance of keeping a wide differential diagnosis when evaluating a patient, particularly when symptoms are non-specific. It is also important to continuously re-evaluate a patient throughout the hospitalization, especially if they are not progressing as expected. The case also shows the importance of looking beyond the labs and numbers and performing a thorough exam, particularly neurological in this case. Lastly, the patient's family's opinion is an important factor in assessing the patient.
DISCUSSION: Uremia due to renal failure is a common indication for the initiation of dialysis and can be seen at BUN level > 50 mmol/L but is usually seen at higher levels. Symptoms of uremia, such as nausea, vomiting, fatigue, pruritus, tremors, anorexia and altered mental status, are non-specific. Because they can be present in other illnesses, uremia must be a diagnosis of exclusion. A thorough history and physical exam should look for other causes of presentation, such as a cerebellar infarct, as in this case.

PLUGGING THE FILTER: THROMBOSED INFERIOR VENA CAVA FILTER CAUSING ACUTE RENAL FAILURE Warda Zaman; Sandrine Lebrun; Melissa P. Hershman; Gary Orin. Lenox Hill Hospital, New York, NY. (Control ID #2679342)

LEARNING OBJECTIVE #1: Diagnose renal failure from thrombosis
CASE: Current guidelines recommend retrievable inferior vena cava filters when both the risk of recurrent pulmonary embolism and the risk of bleeding with anticoagulation are high. The substantial burden of filter thrombosis warrants their removal once it is safe to resume anticoagulation therapy. We present a unique case of extensive filter thrombosis resulting in acute renal failure. An 86 year-old obese African American female presented with acute lower back pain, bilateral lower extremity swelling, and decreased urine output over two days. Her medical history included hypertension, hyperlipidemia, diastolic congestive heart failure, untreated deep vein thrombosis one year prior and remote bilateral PE complicated by diverticular lower gastrointestinal bleeding, requiring placement of an infrarenal IVC filter. Physical examination was notable for bilateral asymmetric pitting lower extremity edema up to the thighs. Abnormal laboratory results included: Sodium 133 mmol/L, BUN 33 mg/dL, and Creatinine 1.84 mg/dL. Urinalysis showed hematuria without red cell casts, trace proteinuria, fractional urea excretion below 35%, and urine osmolarity below 350 mosmol/kg. Renal ultrasound was unremarkable. Despite fluid resuscitation, the patient remained oliguric with progressive renal failure with creatinine peaking at 8.20 mg/dL. A noncontrast abdominal CT revealed extensive edematous changes in the proximal upper thighs bilaterally extending to the lower pelvis, suspicious for DVT involving the IVC and iliac veins. Doppler ultrasound confirmed venous thrombosis both proximal and distal to the IVC filter. After initiating intravenous heparin, intraoperative venogram showed thrombosis proximal to the IVC filter to the level of right ovarian vein and at the origin of right renal vein and left renal vein. Tissue plasminogen activator injection into both renal veins with subsequent Angiojet mechanical thrombectomy successfully restored patency. The patient was discharged on coumadin therapy, and required hemodialysis therapy for one month with return of renal function her baseline.
IMPACT: Current literature estimates filter thrombosis varies from 2.7 to 28%, typically lowest with Greenfield filter. To date, there is no data estimating the incidence of renal failure secondary to bilateral renal vein thrombosis in permanent IVC filters, though limited case reports involving both suprarenal and infrarenal filters noted a similar constellation of lower extremity edema, back pain, proteinuria and hematuria.
DISCUSSION: Though iliocaval thrombosis extending to renal veins is a rare complication of IVC filters, our case demonstrates the need for providers to maintain a high index of suspicion when diagnosing this unique cause of renal failure for which outcomes can range from reversible to fatal. As shown, CT imaging and doppler ultrasound may both adequately achieve diagnosis, with combination anticoagulation and thrombectomy proving effective therapy.

PNEUMOCEPHALUS SEEING MOUNT FUJI ON FILM Woody Chang[1]; Sinthana Umakanthan[2]; Fred Rubin[3]. [1]University of Pittsburgh Medical Center, Prebysterian-Montefiore, Pittsburgh, PA; [2]University of Pittsburgh Medical Center- Shadyside, Pittsburgh, PA; [3]UPMC Shadyside– Senior Care, Pittsburgh, PA. (Control ID #2707440)

LEARNING OBJECTIVE #1: To review the etiology of pneumocephalus
LEARNING OBJECTIVE #2: To definte treatment options for pneumocephalus
CASE: A 79-year-old female with mild dementia with biochemical workup being unremarkable presented to her primary care physician with worsening memory problems following a mild head trauma noted about 7 months prior to the visit. Her primary care physician ordered a brain MRI which showed a left

sided subdural hemorrhage with subfalcine herniation and rightward midline shift. She was transferred to the neurology unit where she then underwent a surgical evacuation of the hematoma with craniotomy, which was complicated by pneumocephalus, as noted on head CT with the "Mount Fuji sign," with a lowered level of consciousness. She was transferred to the ICU to be observed, though no intervention was undertaken. Serial head CTs showing improvement and gradual return to her baseline mental status over the next three days. She was discharged with outpatient follow up with neurosurgery.

IMPACT: Pneumocephalus, or the presence of intracranial gas, is a common postsurgical complication of neurosurgical procedures such as craniotomies. The gold standard of diagnosis is a head CT for the detection of air, with the "Mount Fuji sign" being a common finding for air that has compressed the frontal lobes. The majority of pneumocephalus cases are treated conservatively by preventing the increase of intracranial pressure, resulting in reabsorption of air within weeks of diagnosis. Severe cases require emergent relieving of intracranial pressure.

DISCUSSION: This case illustrates pneumocephalus, a complication of neurosurgical procedures as a result of intracranial air. The mechanism thought to involve either the introduction of air through cerebralspinal fluid leakage causing a ball valve effect, or fluid drainage causing a negative intracranial pressure with subsequent pressure equilibration by air replacement. The diagnostic gold standard to detect air intracranially is a head CT. The "Mount Fuji sign" that was seen on CT in this case indicates a more severe case of pneumocephalus, likely reflecting the amount of blood that was drained. Using conservative treatment of avoiding increased intracranial pressure, providing pain control, and using osmotic diuretics, 85% of pneumocephalus cases result in reabsorption of the air such as in this case. However, had there been any acute changes in consciousness or signs of intracranial hypertension, it would have necessitated surgical decompression.

PORT-A-CATH ASSOCIATED CEREBRAL GAS EMBOLISM Monica Thim[1]; Linda Shehu[2]; Abigail Orenstein[2]. [1]Baystate Medical Center, Broad Brook, CT; [2]Baystate Medical Center, Springfield, MA. (Control ID #2707015)

LEARNING OBJECTIVE #1: Assess a unique and rare case of cerebral gas embolism (CGE) as a port-a-cath complication

CASE: 29 year-old male with a history of CVID, pulmonary telangiectasia with shunting s/p lung transplant, and ITP s/p total splenectomy presented with focal neurologic deficits, seizure, and encephalopathy. Recently, he had been admitted for streptococcus viridans bacteremia for which he was discharged home on penicillin G via port-a-cath. On presentation, he was found unresponsive with chest wall trauma with seizure like activity. On ED arrival, he was intubated for airway protection with admission to the medical ICU. Laboratory data showed leukocytosis with left shift, acute kidney injury, lactic acidosis, CPK 1112, and myoglobinuria. CT Head showed no acute abnormalities. For possible meningoencephalitis, emergent LP was completed; and, he was given IV dexamethasone and broad-spectrum antibiotics. However, CSF fluid studies and culture were negative. MRI Brain on hospital day two showed ischemic changes of the left MCA and PCA territories. Repeat review of CT Head/Brain on presentation did reveal two foci of air in the left frontal lobe, concerning for CGE. TTE with bubble study confirmed the presence of PFO. EEG, completed for seizure concerns, was unrevealing after which Neurology recommended depakote for myoclonus. At discharge, all neurologic deficits had nearly resolved.

IMPACT: CGE is an iatrogenic, complication often associated with the insertion, removal, or manipulation of central venous catheters in the ICU. The increased outpatient use of long-term central venous devices, such as subcutaneous ports, can increase the risk of CGE, due to manipulation by inexperienced individuals. Increased recognition of CGE as a potential complication of these devices will be important to avoid high mortality.

DISCUSSION: Most reported cases of CGE have been associated with nontunneled central venous catheters and procedures such as laparoscopic or cardiothoracic surgeries. We present a rare case of CGE associated with port-a-cath use. Most common complications of their use are infection, thrombosis, mechanical failure, migration, port separation with extravasation, and hematoma. However, CGE is also a possible complication that should be considered as well. A high level of suspicion must be maintained to detect CGE, due to mimicry of ischemic stroke and high mortality of 1/5. Early detection is important as there has been some literature on the use of hyperbaric oxygen therapy for favorable outcomes. Patients with PFOs as our patient may be at higher risk of CGE with central venous devices. Thus, this may be an important consideration prior their use. Due to the increased outpatient use of subcutaneous ports, CGE should be recognized as a possible long-term complication. Judicious use, increased training, and monitoring of these devices should be considered for the prevention of CGE due to high mortality.

POSITIVELY CHARGED: RECURRENT HYPERCALCEMIA AS A COMPLICATION OF AIDS AND DISSEMINATED MAC INFECTION

Cesar Taborda; Schuyler D. Livingston. Emory University School of Medicine, Decatur, GA. (Control ID #2701182)

LEARNING OBJECTIVE #1: Distinguish the causes of hypercalcemia by contrasting key differences in the clinical and laboratory evaluation.

LEARNING OBJECTIVE #2: Outline the pathophysiology of hypercalcemia in the setting of granulomatous diseases such as mycobacterial infections.

CASE: A 40 year old male with a history of HIV/AIDS and disseminated mycobacterium avium complex (dMAC) presented to clinic with two weeks of fatigue, fevers, anorexia, and weight loss. Combined antiretroviral therapy (cART) had been initiated approximately three weeks prior, two weeks before the diagnosis of dMAC. Physical exam revealed a cachectic male with fever and tachycardia. On initial presentation, the patient was found to have moderate hypercalcemia (corrected serum calcium, 12.4 mg/dL). Further laboratory evaluation revealed suppressed parathyroid hormone (PTH), undetectable PTH-related peptide, and increased levels of 1,25 dihydroxyvitamin D (128 pg/mL). The clinical and laboratory data were consistent with hypercalcemia due to dMAC. Given the recent initiation of cART, the development of hypercalcemia was likely due to paradoxical worsening of dMAC due to immune reconstitution inflammatory syndrome (IRIS). He required inpatient care including hydration, intravenous pamidronate, and initiation of high dose steroids. Three months later, the patient again developed symptomatic hypercalcemia (corrected calcium, 13.1 mg/dL), shortly after tapering to low doses of prednisone. Approximately one year after his initial presentation, despite consistent therapy for dMAC and HIV, he developed recurrent hypercalcemia (corrected calcium, 14.5 mg/dL), again with highly elevated calcitriol levels.

IMPACT: Hypercalcemia has long been recognized as a potential serious complication of granulomatous disease. This is well-described in the setting of sarcoidosis and tuberculosis. Only rare case reports have documented hypercalcemia with elevated calcitriol levels in the context of AIDS and

dMAC. Among these rare cases, only one occurred in the setting of immune reconstitution.

DISCUSSION: Hypercalcemia is a common electrolyte abnormality in both primary care and hospital settings. Primary hyperparathyroidism, the most common etiology, is mild and gradual in onset, and typically asymptomatic. Hypercalcemia of malignancy tends to be more acute, with higher levels of serum calcium (>13 mg/dL), often leading to severe symptoms and complications. Elevated, or inappropriately normal, levels of PTH are consistent with primary hyperparathyroidism and familial hypocalciuric hypercalcemia. Low levels of PTH are highly concerning for malignancy, such as squamous cell carcinoma or lytic bone lesions. In some cases, measurement of vitamin D metabolites may be necessary to secure the diagnosis. High levels of $1,25(OH)_2D_3$ suggest granulomatous disease, in which macrophages convert $25(OH)D_3$ to its active form via the enzyme 1 α-hydroxylase.

POST COLONOSCOPY BLEEDING IT'S NOT ALL EXTERNAL

Clifton Davis[1]; Timothy E. Sommerville[1]; Michael Smith[2]. [1]Wright State University, Dayton, OH; [2]Wright State University, Fairborn, OH. (Control ID #2706303)

LEARNING OBJECTIVE #1: Recognize that splenic injury resulting in hemoperitoneum is a known but rare complication of colonoscopy.

CASE: A 60 year old female with past medical history of major depression, osteoarthritis, hyperlipidemia, and remote breast cancer treated with mastectomy presented for routine screening colonoscopy. The patient was admitted from the endoscopy suite after vomiting and aspiration concerns during the procedure. Per the colonoscopy report there was a normal distal colon but the exam was limited and abruptly terminated due to concern for aspiration. The patient was stable, requiring 2-3L of oxygen but resting comfortably in observation. The next morning, the patient was saturating well on room air. Less than 48 hours post-procedure, patient developed pleuritic chest pain and left upper quadrant pain. A computerized tomography angiogram was negative for pulmonary embolism, but revealed a 2.7 × 4.8 cm perisplenic hematoma. A CT abdomen and pelvis was performed showing a grade 3 splenic hematoma and hemoperitoneum. Pain worsened with the development of an acute abdomen on exam and vitals deteriorated to a blood pressure of 92/60, heart rate of 107, and oxygen saturation of 94% on room air. The patient was taken for an exploratory laparotomy. A splenectomy was done after finding a grade 4 splenic injury and an estimated blood loss of 500 mL. The patient received two units of packed red blood cells, one unit of fresh frozen plasma, and a quad pack of platelets while in the operating room. The patient's clinical status improved following the splenectomy, and eventually discharged home in stable and improved clinical condition after a nine day hospital stay.

IMPACT: With the frequency of colonoscopy in practice it is important to have an appreciation for splenic injury and other post procedural complications so that timely recognition can decrease delays in proper management.

DISCUSSION: Colonoscopies are a vital tool to the medical community and are utilized by internists, surgeons, and specialists alike. With the implementation of colorectal cancer screening practices, the number of colonoscopies performed each year will likely continue to grow. Predictably, the number of complications due to colonoscopy will also rise each year. The most notable serious complications of colonoscopy include perforation and hemorrhage which are reported at a rate of 0.1-0.3 and 0.1-0.6% respectively. Studies have shown that the incidence of splenic injury may be as low as 0.001%, with a third of patients being asymptomatic until a full 24 hours following the procedure. The delay in presentation not only delays the diagnosis, but also hinders timely management, including a surgical evaluation.

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME ASSOCIATED WITH METHADONE OVERDOSE

Polina Trachuk; Paul Magda; Gary Bernardini. New York-Presbyterian/Queens, Flushing, NY. (Control ID #2698378)

LEARNING OBJECTIVE #1: Recognize that high-dose methadone may be the cause of the endothelial dysfunction seen in PRES

LEARNING OBJECTIVE #2: Recognize that methadone is not detectable on routine urine opioid screening as it is a synthetic opioid

CASE: A 55 year-old woman with a history of depression presented with acute onset of unresponsiveness, hypotension, acute renal insufficiency, fever and leukocytosis. A CT head and lumbar puncture were both negative for any significant findings. A video EEG showed no epileptiform activity. She was treated with IV fluids, IV antibiotics and pressors, subsequently showing clinical improvement. Initial urine drug toxicology screen was negative. However, on further questioning, the patient admitted to a suicide attempt by taking an overdose of methadone (30 pills). A methadone urine drug level performed 6 days after admission was markedly elevated at 560 (normal < 100ng/mL). On the same day, the patient began complaining of headache then had generalized tonic-clonic seizure. Upon awakening from the seizure, she complained of transient bilateral visual loss. A complete neurological exam was significant for only left proximal arm weakness. Initial MRI of the brain revealed bilateral subcortical fronto-parieto-occipital and watershed region FLAIR hyperintensities. MRA of the head and neck were normal. Follow-up laboratory testing showed normal creatinine, electrolytes, ANA and RF. Blood pressures had remained normal or only mildly elevated for the 5 days leading up to patient's seizure. Follow-up MRI FLAIR images 7 days later showed improvement in signal abnormalities. Follow-up neurological examination showed only the persistent predominantly proximal left arm weakness. Given the clinical scenario and the suggestive radiological features, she was diagnosed with PRES.

IMPACT: PRES is usually associated with malignant hypertension, blood pressure fluctuations, eclampsia, renal failure, autoimmune conditions or immunosuppressant medication use, none of which were found in our patient. This suggests the possibility that high-dose methadone may have been the precipitating factor that resulted in endothelial dysfunction. Our patient also highlights the interesting fact that methadone, as a synthetic opioid, is not detectable on routine urine opioid screening.

DISCUSSION: PRES is a clinical-radiological syndrome related to acute disruption of brain auto-regulation and endothelial dysfunction, leading to cerebral hyperperfusion and vasogenic edema. It typically presents with some combination of encephalopathy, headache, seizures, visual disturbances. Bilateral sub-cortical MRI abnormalities are common and can be associated with small watershed region ischemic or hemorrhagic strokes. Previously unreported, this is a rare case of PRES likely secondary to methadone overdose. If suspected, healthcare providers should keep in mind that methadone does not show up on routine urine toxicology.

PRIMARY EFFUSION LYMPHOMA: A MASS-LESS DISEASE WITH MASSIVE EFFECTS

Nina Nguyen[1]; Ana I. Velazquez[1]; Natalie Berger[1]; Ilan Shapira[2]. [1]Mount Sinai Beth Israel, New York, NY; [2]The Beth Israel Medical Center, New York, NY. (Control ID #2706062)

LEARNING OBJECTIVE #1: Recognize primary effusion lymphoma as a rare HIV-related disease

LEARNING OBJECTIVE #2: Distinguish primary effusion lymphoma from other types of lymphoma

CASE: A 44 year-old man with HIV on antiretroviral therapy (ART) with CD4 359 presented with a three month history of progressive bilateral lower extremity swelling, increasing abdominal girth, and dyspnea. He reported a 20-pound unintentional weight loss over the last year, associated with fatigue, drenching night sweats for three months and denied fever, headaches, abdominal pain, or changes in bowel habits. Physical examination revealed tachycardia and a pale cachectic man with cervical and axillary lymphadenopathy. He had a distended tense abdomen with palpable spleen and fluid wave, 2+ pitting lower extremity edema, and scrotal edema. Initial laboratory evaluation was significant for normocytic anemia 6.5g/dL, thrombocytopenia 126k/uL, and hypoalbuminemia 1.6g/dL. Further testing showed positive EBV and HHV-8 antibodies. CT-scan showed axillary, mediastinal and retroperitoneal lymphadenopathy, moderate right-sided pleural effusion, small bowel mass, splenomegaly, and ascites. Multiple lymph node biopsies were non-diagnostic. Thoracentesis was performed for worsening dyspnea and showed atypical cells positive for HHV-8, BOB-1, CD30, CD45 and negative for CD20 and PAX5, consistent with primary effusion lymphoma (PEL). Ascitic fluid cytology was also consistent with PEL. The patient was diagnosed with HIV and HHV-8-associated PEL. Given his poor performance status, ECOG 4, treatment with bortezomib and valganciclovir was started. Despite initiation of chemotherapy, the patient continued to deteriorate and comfort measures were eventually pursued.

IMPACT: HIV infection results in impaired cellular immunity leading to an increased incidence of a wide range of malignancies. Hospitalists should consider HIV-associated malignancies in the differential of HIV+ patients with nonspecific complaints. This case exhibits an additional rare differential diagnosis that should be considered in HIV+ patients who present with effusions of unknown etiology.

DISCUSSION: PEL is a rare and aggressive subtype of HIV-associated non-Hodgkin lymphoma (NHL) that only accounts for 1-4% of NHL cases. PEL manifests as malignant effusions without extracavitary involvement. Symptoms are related to fluid accumulation, such as dyspnea from pleural or pericardial effusions, and abdominal distension from ascites. PEL is associated with EBV+, however it is distinguished from all other lymphomas by its HHV-8 positivity. Due to its rarity, there is no therapeutic standard of care for PEL. Current options are based on case reports or in vitro data for which currently PEL remains a diagnosis with extremely poor prognosis. Aggressive chemotherapy with EPOCH or CHOP in combination with ART in patients has shown the most success with a median overall survival of 6-months. However, as in our case, therapy selection is limited by patient's performance status and side effect tolerance.

PRIMARY HYPERPARATHYROIDISM AND EWING'S SARCOMA IN AN ELDERLY MALE, A RARE COMBINATION. Maria D. Garcia-Jimenez[1]; Ali Hadi[2]; Monica Gupta[1]. [1]NYU School of Medicine, New York, NY; [2]New York University School of Medicine, New York, NY. (Control ID #2670791)

LEARNING OBJECTIVE #1: Recognize the co-existence of primary hyperparathyroidism and Ewing's sarcoma in patients with asymptomatic hypercalcemia.

LEARNING OBJECTIVE #2: Recognize that though rare, Ewing's sarcoma and primary hyperparathyroidism can be seen in an elderly male.

CASE: A 60 year-old man was diagnosed with Ewing's sarcoma of the left scapula after biopsy of a lytic lesion seen on computed tomography of the left shoulder. At time of diagnosis he had metastatic disease, a calcium of 11.6 mg/dL, parathyroid hormone (PTH) of 177.8 pg/mL, and parathyroid hormone related peptide (PTHrP) of <0.74 pmol/L (normal <2). Renal function, 25-vitamin D, and phosphate were normal. He received zoledronic acid and began chemotherapy. At a routine oncology appointment a year later laboratory studies showed calcium of 14 mg/dL. Though he was asymptomatic, this dangerously high level prompted his admission for treatment and monitoring. Vital signs, thyroid, neck, and lymph node exam were normal. A 10x10 cm fixed, non-tender mass extended down his left trapezius muscle and pain limited abduction of his left shoulder. Admission labs were notable for calcium of 14 mg/dL, PTH 376.6 pg/mL, PTHrP <0.74 pmol/L, 25-Vitamin D 18.4 ng/mL, and phosphate 1.8 mg/dL. Laboratory studies were consistent with primary hyperparathyroidism. He received intravenous (IV) fluids, IV furosemide, and pamidronic acid. His calcium improved to 11.2 mg/dL at discharge.

IMPACT: This case changed our thinking regarding the well-taught approach of medicine through Occam's razor, with a gaze toward the simplest, single explanation for pathology. It emphasized the need for thoughtful re-evaluation of common findings at points of transition of care. Additionally it highlighted a need for vigilance in patients with hypercalcemia, as they can remain asymptomatic at high levels.

DISCUSSION: Malignancy and primary hyperparathyroidism (PHPT) are the leading causes of hypercalcemia. In this patient malignancy was the initial hypothesized etiology of hypercalcemia. Paraneoplastic phenomena were considered, but PTHrP was undetectable and the osteosarcoma was not stained for release of PTH secretion given labs consistent with primary hyperthyroidism. The patient was left with diagnoses of both PHPT and Ewing's sarcoma, an unusual combination in an elderly male. PHPT is most common in females 50–60 years old, and not typical in elderly males. The incidence of Ewing's sarcoma is 4–5 cases per million, with the highest occurrence in men ages 10–20. There are four reported cases of concomitant PHPT and osteosarcoma; all females ages 34–69. These reports postulated elevated PTH led to development of osteosarcoma. However, lack of temporal association between diagnoses made this difficult to establish. The combination of PHPT and Ewing's sarcoma occurring simultaneously in an elderly male is rare. Recognizing the possibility of two concomitant diagnoses is crucial to ascertaining curative therapy of hypercalcemia, even when asymptomatic, as well as for further monitoring.

PRIMARY LIVER NEUROENDOCRINE TUMORS DO EXIST Anup Shah; Lily L. Yung; Kevin Andujar; Krystle Hernandez; Praneet Korrapati; Angela Chiang; Erica Grabscheid. Mount Sinai Beth Israel, Icahn School of Medicine, New York, NY. (Control ID #2688947)

LEARNING OBJECTIVE #1: Recognize the rapid progression of liver NET's.

LEARNING OBJECTIVE #2: The most frequent signs/symptoms of primary liver NET's are pain, jaundice, abdominal distention and a palpable mass as many NET's are endocrinologically silent.

CASE: A 51 yo male with a PMH of HIV CD4 494 on HAART and CABG one month prior presented with right sided abdominal pain and weight loss for 3 weeks. The patient appeared jaundiced with tender hepatomegaly. Blood work revealed elevated LFT's: Total Bili 10.4 mg/dL (nl 0.1-1.2), Direct Bili 7.3 mg/dL (x < 0.9), ALP 1318 U/L (38–126), AST 220 U/L (x < 36) and ALT 151 U/L (x < 46). Abdominal CT showed replacement of the majority of the liver parenchyma with innumerable rim enhancing hepatic lesions; the pancreas/ducts were unremarkable. To note, one month earlier the patient had normal LFT's. Chest CT prior to CABG revealed small vague hypodensities in the liver not pursued then due to the emergent nature of cardiac surgery and lack of abdominal symptoms. Although the pt was afebrile (VSS) and without leukocytosis, empiric antibiotics were started to cover potential liver abscesses. Blood and ascites fluid cultures, hepatitis, tuberculosis, entamoeba and echinococcus tests returned negative. AFP tumor marker was negative. CT chest revealed only a post-CABG hematoma. Serum chromogranin A was high at 3148 ng/mL (x < 95), but the urine 5-HIAA and octreotide scan were normal. Liver biopsy confirmed: small cell neuroendocrine tumors (NET's). The patient developed multi-organ failure, rendering him a poor candidate for chemo. Pt expired on LOS day 29. Autopsy revealed small cell NET's associated with intrahepatic lesions.

IMPACT: This case presents a very rare presentation of small cell NET of primary liver origin and highlights the rapid progression of which NET's can present. Octreotide scans and Urine 5-HIAA studies may fail to localize and diagnose NET's. Due to diagnostic challenges, small cell NET's in the GI tract are usually found at a late stage, characterized by extensive metastasis.

DISCUSSION: Neuroendocrine tumors have a low annual incidence of 2–5 cases per 100,000 people in the US. Although commonly arising from the lung and GI tract (e.g. pancreas), the liver as a primary source of small cell NET's is tremendously rare, with less than 20 cases described worldwide. Prevalence is higher among females; mean age of diagnosis is near 70 years. Frequently endocrinologically silent, the most frequent signs/symptoms are based on mass effects such as pain, jaundice, abdominal distention and a palpable mass. Chromogranin A levels are usually elevated in 80% of patients and can relate to illness burden. Octreotide scans often fail to localize tumors, as poorly differentiated NET's rarely express somatostatin receptors. Urine 5-HIAA testing has a low sensitivity in NET's without carcinoid features. Treatment involves radiotherapy/chemotherapy and may, if the tumor is localized, involve resection. Survival is poor - from 6 to 18 months in treated, or weeks in untreated patients.

PROGRESSIVE CUTANEOUS DISEASE FOLLOWING A DIAGNOSIS OF RHEUMATOID ARTHRITIS: UNCOVERING DISSEMINATED MYCOBACTERIUM MARINUM Cristina Garcia; Erika Abel; Kellee Oller; Charurut Somboonwit; Jose Montero. University of South Florida Morsani College of Medicine, Tampa, FL. (Control ID #2707450)

LEARNING OBJECTIVE #1: Identify risk factors for *Mycobacterium marinum*

LEARNING OBJECTIVE #2: Recognize cutaneous manifestations of disseminated *M. marinum*

CASE: 50 year-old man with a history of treated Hepatitis C initially presented with a progressive rash, digital swelling, and joint pain. He was diagnosed an inflammatory polyarthritis and was started on prednisone and eventually etanercept. Labs obtained at that time included a mildly positive rheumatoid factor, negative cyclic citrullinated peptide antibody, and an elevated C-reactive protein. Despite therapies, he experienced progression of synovitis and developed small, suppurative, nontender nodules of several joints as well as ulceration of his digits. Five months after his initial symptoms he presented to our facility. Upon interview he reported being an avid fisherman, with a trip the Bahamas prior to the start of his symptoms. He was febrile and mildly hypertensive. Erythematous rash was present on all extremities with multiple suppurative nodules and ulcerations on his forearms and fluid filled blisters on his feet. Tips of his digits had deep ulcerations. Remainder of the physical exam was unremarkable. Laboratory findings were significant for the following: WBC 12.4 K/UL, albumin 2.0 g/dL, ALT 73 IU/L, C-reactive protein 3.9 mg/dL, and ESR 18 mm/hr. Skin biopsy was performed, acid-fast blood cultures were obtained and incubated at 30°C specifically to evaluate for *M. marinum*. Skin biopsy demonstrated filamentous branching rods. Acid-fast smears were positive. He was started on intravenous minocycline with oral rifabutin and ethambutol. *M. marinum* was cultured from both his skin biopsy and his acid-fast blood cultures. Following sensitivity testing he was discharged home on a prolonged course of clarithromycin, rifabutin, and ethambutol. Steroids were tapered and his skin lesions completely resolved 5 months later.

IMPACT: Clinical features of *M. marinum* should be suspected when patients with known aquatic exposure. The diagnosis can escape recognition when presenting atypically or without reported exposure history.

DISCUSSION: Diagnosis is often delayed; the average time from symptom onset to diagnosis has been reported to be 17 months. Diagnostic dilemma may be made more challenging by the difficulty in growing *M. marinum* at standard blood culture temperatures. In this case, growth was achieved by decreasing the incubation temperature to 30°C. Immunosuppressed patients typically present with disseminated and progressive disease. Treatment of disseminated disease is not clearly defined, and is often based on multiple antibiotics until sensitivity testing is completed. As medication resistance and relapse is common, therapy may need to be prolonged and averages 11.4 months. Evidence based guidance for empiric treatment of *M. marinum* bacteremia is scarce. *Mycobacterium marinum* should be consider in the differential of skin and joint pathology to prevent delays in diagnosis that could lead to severe disseminated infection.

PROGRESSIVE DYSPHAGIA, COUGH, AND RECURRENT ASPIRATION IN A PATIENT WITH ZENKER'S DIVERTICULUM Brittany Glassberg; Mackenzie Naert; Matthew Spindler; Joseph Truglio. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2706278)

LEARNING OBJECTIVE #1: Recognize presenting symptoms of Zenker's Diverticulum.

LEARNING OBJECTIVE #2: Identify potential pulmonary complications of Zenker's Diverticulum in complex patients.

CASE: IB is a 31-year-old woman with Juvenile Idiopathic Arthritis (JIA), prior pulmonary embolism and Zenker's Diverticulum who presented with progressive DOE, cough, and intermittent fever of 2 week's duration. The patient takes albuterol as needed for SOB, prednisone (5 mg) once daily, nystatin (15g) as needed, esomeprazole (1000 units) once daily for gastroesophageal reflux, and Rituximab in sodium chloride 375mg/m2 by

intravenous route for JIA every three months. The initial differential diagnosis included aspiration pneumonia from Zenker's diverticulum, *Pneumocystis jirovecii* due to chronic immunosuppression, and interstitial lung disease (ILD) related to Rituximab. On exam she was afebrile, had a heart rate of 104 and an oxygen saturation of 100% on room air. A d-dimer was 2.10 ug/ml (patient's baseline 3–5 ug/ml) with a WBC count of 17.2. A CT scan showed patchy ground-glass densities in the right upper, middle, and lower lobes of the lung, consistent with atypical pneumonia vs ILD. She was initially treated with azithromycin for pneumonia, with improvement in symptoms. A follow-up CT documented near resolution of the initial opacities post-antibiotics, but the presence of smaller, new ground-glass opacities. She subsequently developed intermittent cough with chest pain, along with progressive dysphagia and positional choking. A videoesophagram demonstrated that the pharyngeal outpouching had grown from 2cm to 5cm since 2011. She was referred to ENT for surgical correction.

IMPACT: A Zenker's diverticulum often results in dysphagia with resultant weight loss. It also causes aspirations presenting as pneumonitis and pneumonia (Ferreira, et al., 2007). While a rare and often asymptomatic condition, in patients with recurrent aspiration or dysphagia, a Zenker's diverticulum should be considered. In patients with a known Zenker's diverticulum, progressive symptoms may indicate growth in size.

DISCUSSION: A Zenker's diverticulum is a pseudodiverticulum of the mucosa of pharynx above the crichopharyngeal muscle. It usually presents in patients over 40 years old and can manifest as dysphagia, aspiration and weight loss. Management focuses on speech and swallow therapy, with endoscopic or surgical correction for refractory cases. Our patient is complex, with multiple potential causes of cough and dyspnea. Her JIA created an inflammatory state placing her at risk for recurrent PE. Rituximab is recognized as potential cause of ILD (Alexeeva, et al., 2011). Chronic immunosuppression placed her at risk for atypical pneumonias. Finally, her Zenker's diverticulum may have grown, resulting in aspiration pneumonia, as was ultimately diagnosed. This highlights the need for a high index of suspicion for a new Zenker's or progression of a previously asymptomatic Zenker's in patients with dysphagia, cough and aspiration.

PROGRESSIVE METABOLIC ACIDOSIS OR MEASUREMENT ERROR: A CHALLENGING CASE OF DKA Max M. Brock; Steven C. Borkan; Shu-ling Fan. Boston University Medical Center, Boston, MA. (Control ID #2706644)

LEARNING OBJECTIVE #1: Distinguish and assess measurement error for discordant lab values.

LEARNING OBJECTIVE #2: Recognize causes for a falsely low serum bicarbonate measurement.

CASE: A 54-year-old man with newly diagnosed diabetes mellitus presented to his primary care clinic. Routine serum venous blood testing revealed a blood glucose 446 mg/dl, carbon dioxide of 27 mmol/L, and an anion gap of 27 mmol/L. UA revealed 3+ urine ketones prompting the clinical diagnosis of mild DKA In the ED, a VBG showed acidemia with pH of 7.28, PCO_2 of 39.4 mmol/L and a carbon dioxide of 17.7 mmol/L supporting the clinical suspicion of DKA. On the Medical floor, basal and bolus insulin was started. Despite no untoward symptoms, his morning labs, revealed a serum venous carbon dioxide of 7.0 mmol/L and an anion gap of 21 mmol/L. Repeat serum venous testing 3 hours later showed a carbon dioxide of 5.0 mmol/L and an increasing anion gap of 24 mmol/L. This data prompted urgent transfer to the MICU. In the MICU, both IV insulin and isotonic bicarbonate infusions were initiated. However, a VBG before the insulin infusion revealed a pH 7.30, PCO_2 35 mm Hg and carbon dioxide 15 mmol/L, a much less profound academia. Repeat VBGs consistently showed a carbon dioxide level that was 8–10 mmol/L higher than the carbon dioxide levels in serum venous blood. A profound hypertriglyceridemia of 2,179 mg/dl was detected. During treatment with an insulin drip, his triglycerides level fell to <1000 mg/dl, at which time his bicarbonate discrepancy disappeared. He transitioned to basal/bolus insulin and fenofibrate.

IMPACT: Bicarbonate is not widely known to be falsely measured or affected by interfering substances. There are scant, if any, similar case reports. This vignette will add "pseudo-hypobicarbonatemia" as possibility to providers, as well as serve as warning to others to avoid unnecessary ICU transfers/ treatment.

DISCUSSION: In our case, the term "pseudo-hypobicarbonatemia" is apt. Serum sodium measurements are known to be affected by interfering substances and is commonly referred to as "pseudo-hyponatremia." This was first described with serum sodium measurements performed by flame photometry, requiring a dilution step. Since our chemistry lab utilizes a photometric method to measure carbon dioxide, a dilution step is not required. Our patient with DKA exhibited a consistent, 8–10 mmol/L discrepancy between the measured serum carbon dioxide and the blood gas carbon dioxide calculated by the Henderson-Hasselbach equation. When there is a discrepancy between these two lab values, it is common to accept the measured value from the venous chemistry, rather than the calculated blood gas estimate. This practice prompted an unnecessary MICU transfer and isotonic bicarbonate drip. Interestingly, as the triglyceride level fell to < 1000 mg/dl, the discrepancy between the serum and venous blood gas carbon dioxide disappeared, implicating the triglyceride or a substance that tracks in parallel with triglycerides as the interfering substance.

PROGRESSIVE SUPRANUCLEAR PALSY Veronica Johnson[1]; Irene Grundy[2]. [1]Tulane University, New Orleans, LA; [2]Veterans Affairs/Tulane University SOM, New Orleans, LA. (Control ID #2705196)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of progressive supranuclear palsy (PSP)

LEARNING OBJECTIVE #2: Identify therapies available to treat PSP

CASE: A 57 year-old man presented with altered mental status following an un-witnessed fall. He denied any loss of consciousness, syncope, headache, vision changes, or weakness. The family reported a six-month history of recurrent falls, memory loss, and slurred speech. He was afebrile on presentation. Cardiopulmonary exam was normal. His neurologic exam was significant for wide-based unsteady gait, bradyphrenia and slowed saccadic movement in horizontal plane with vertical gaze palsy. Mini-mental state examination (MMSE) was 24. TSH, folate and vitamin B12 were all within normal limits. MRI of the brain was performed and showed atrophy of the midbrain. He was diagnosed with "probable" progressive supranuclear palsy (PSP). He was started on a trial of carbidopa-levodopa, which was titrated up to maximum dose to aid in improvement in gait. He was eventually discharged to skilled nursing facility for further rehabilitation.

IMPACT: With an aging population, internists are diagnosing and managing dementia with increasing frequency. Recognition of the cause of dementia can

allow for appropriate treatment and a chance to slow the progression of dementia if possible.

DISCUSSION: PSP is a rare, neurodegenerative syndrome of mild dementia, supranuclear gaze palsy, progressive axial rigidity, and pseudobulbar palsy. The NINDS (National Institute of Neurological Disorders and Stroke) diagnosis criteria for “probable” PSP describes a gradual progressive disorder with an age of onset over 40 years, falls within the first year, vertical supranuclear gaze palsy or slowing of vertical saccades. “Definite” PSP is diagnosed pathologically with the presence of tau-positive neurofibrillary tangles on postmortem brain biopsy. Patients often require multiple clinical presentations to diagnose definitively. MRI is obtained in all patients to rule out alternative etiologies such as tumors, cerebrovascular accident, and hydrocephalus. Common radiographic findings consist of signal increase and atrophy of the midbrain (ie the Hummingbird Sign), thinning or smudging of the substantia nigra, atrophy of the putamen, atrophy and signal increase of globus pallidus and atrophy of the red nucleus. Our patient has PSP-Richard Syndrome (PSP-RS) characterized by dementia with impaired balance, movement slowness, subtle personality changes, bulbar symptoms, and impaired oculomotion. Close to 50% of patients with PSP have this form. PSP-Parkinsonism is the second most common form. It presents with asymmetric limb bradykinesia as opposed to symmetric limb involvement in Parkinson’s disease. The management of PSP is mainly supportive. Most patients are given a trial of carbidopa-levodopa. Patients are referred for multidisciplinary care to support the progression of the disease. The average time from symptom onset to death is usually 7 years.

PROLONGED QTC AND CARDIAC ARREST: QUESTIONS TO HONE FOR METHADONE Himani Divatia[2]; Terry Horton[1]. [1]Christiana Care Health Services, Wilmington, DE; [2]Christiana Care Health System, Newark, DE. (Control ID #2693232)

LEARNING OBJECTIVE #1: Assess patient factors in choosing methadone versus buprenorphine in the setting of opioid dependence

LEARNING OBJECTIVE #2: Transition patients from methadone to buprenorphine when continuing methadone is not feasible

CASE: C.L. was a 30 y/o F with a history of anorexia nervosa and heroin use disorder on methadone treatment who presented with syncopal episode. On EMS arrival, she was in ventricular fibrillation and was resuscitated within 10 min. Upon admission to the ICU, her potassium was found to be 2.0 and EKG revealed a QTc of 688. After correction of potassium to 4.0, a repeat EKG demonstrated a QTc of 414 and she was transferred to a medicine floor on her usual daily dose of 75 mg of methadone to avoid opioid withdrawal. Due to the elevated risk of recurrent QT prolongation in the setting of multiple comorbidities, a decision was made to transition her from methadone, however current standards of care preclude direct induction to buprenorphine for doses of Methadone greater than 40mg due to the risk of precipitated withdrawal. Her methadone was cut down to 30 mg and then discontinued 48 hours thereafter. With the guidance of an Addiction Medicine Specialist, the team utilized a ‘morphine bridge.’ She was initially transitioned to 60 mg of oral morphine over 4 days. On the fourth day, all opioids were stopped and she was monitored for opiate withdrawal using the Clinical Opiate Withdrawal Scale, with successful induction to 16 mg of daily buprenorphine within 24 hours of opioid cessation. Three days after discontinuation of methadone, the patient’s corrected QT level was 388. Upon discharge, she continued on daily buprenorphine at her drug treatment program.

IMPACT: This case demonstrates the need for thorough history taking, medication reconciliation, and enhanced evidence-based guidelines for the Internist in managing complex opoid dependence patients with multiple comorbidities.

DISCUSSION: For 50 years, Methadone, a mu-receptor opioid agonist, has been one of the most effective options for the management of opioid use disorders. Though generally safe under usual supervised administration, studies show a significant risk of QT prolongation and fatal arrhythmias when used with other QT prolonging agents or electrolyte abnormalities. Buprenorphine, a partial mu-receptor agonist is likewise an effective treatment of opioid withdrawal with less risk of QT prolongation. The case highlights the challenge of continuing mu agonist therapy when QTc prolongation occurs and the need to consider a patient’s many risk factors when choosing care. Though opioid addiction and fatal overdose is an epidemic, the literature does not provide guidance for bridging from one therapy to the other. We describe one method for transitioning from high dose methadone to buprenorphine utilizing a ‘morphine bridge’ in the inpatient setting. As a result, the patient was able to continue on long term agonist therapy preventing her risk of a fatal overdose while reducing her risk of a recurrent fatal arrhythmia.

PROLONGED USE OF INHALED PROSTAGLANDIN IN UNILATERAL ADULT RESPIRATORY DISTRESS SYNDROME AND SEVERE REFRACTORY HYPOXEMIA Olga Tarasova; Roozbeh M. Ghavami; Syeda Bokhari; Manish Gugnani. Capital Health Regional Medical Center, Trenton, NJ. (Control ID #2702122)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of adult respiratory distress syndrome (ARDS)

LEARNING OBJECTIVE #2: Management of refractory hypoxemia in severe ARDS

CASE: We describe a case of patient who presented to our ICU with unilateral ARDS and required 10 days of epoprostenol. A 49-year- old Caucasian male with active IV heroin use presented to the hospital with shortness of breath, cough and hypoxia that resulted in respiratory failure. The patient was intubated and admitted to ICU where antibiotics were started. Vital signs on admission were - BP104/68 HR 122, RR 37, and SpO2 76% on ambient air. Laboratory data was significant for elevated D-dimer, hemoglobin of 7.5 g/dL, WBC 9,300/L and unremarkable chemistry panel. Chest x-ray showed a patchy increased density within the left lung and a right perihilar infiltrate. Due to the elevated D-dimer and the refractory hypoxemia that was out of proportion to the chest X-ray findings, IV heparin was initiated as empiric treatment for pulmonary embolus despite negative lower extremity duplex for acute DVT. CTA chest could not be performed due to elevated creatinine and unstable clinical condition. Echocardiogram was not able to visualize the right ventricle due to poor acoustic windows. The patient remained hemodynamically unstable despite pressors and tPa was given. The following day, the patient continued to deteriorate and chest X-ray showed complete left lung opacification. Different modes of ventilation were tried including APRV without success. He remained hypoxemic with a PaO2/FiO2 ratio of 50 and trans-esophageal echocardiogram suggested no evidence of pulmonary hypertension. At this point, aerosolized epoprostenol was initiated and there was improvement of PaO2/FiO2 ratio to 112 within the first hour, and to 145 within 2 hours. Oxygenation progressively improved, however we were not able to wean off epoprostenol for 10 days due to hypoxia on weaning trials. During the

hospital stay, the patient required thorocostomy and eventually Video-assisted thoracoscopic surgery for a complicated right-sided pleural effusion. The patient was successfully extubated on Day 26 and transferred out of ICU and eventually discharged to a rehabilitation center.

IMPACT: There are not many reports showing use of prostaglandins for more than 24 hours. We present a case of prolonged use of inhaled prostaglandin in a patient with ARDS and severe refractory hypoxemia when extracorporeal membrane oxygenation (ECMO) was not readily available.

DISCUSSION: Adult respiratory distress syndrome (ARDS) presents as a rapidly progressive disease occurring in critically ill patients characterized by severe hypoxemia, systemic inflammatory response, and high hospital mortality. Inhaled vasodilators selectively dilate vessels that perfuse well-ventilated lung zones. This results in improved oxygenation due to improved ventilation/ perfusion matching. There are few reports on unilateral ARDS and prolonged use of inhaled prostaglandins available in current medical literature.

PROTEIN-LOSING ENTEROPATHY AND NECROTIZING PNEUMONIA: A RARE PRESENTATION OF DISSEMINATED TUBERCULOSIS Monica Maalouf; Rajkishen Narayanan. New York University, New York City, NY. (Control ID #2705917)

LEARNING OBJECTIVE #1: Recognize sepsis with multi-organ system involvement as a presentation of TB in an immunocompetent patient.

LEARNING OBJECTIVE #2: Recognize colitis and enteritis as manifestations of extrapulmonary TB.

CASE: A 55 year old woman with no past medical history presented with four days of disabling, lower extremity edema and one month of watery diarrhea. She also endorsed three months of chronic cough with intermittent sputum production and progressive dyspnea. Review of systems was notable for a ten pound weight loss over this period and night sweats. She immigrated from Peru 25 years ago and denied any travel outside of the US since. She works as a nanny in Manhattan. On admission, her vital signs revealed a temperature of 102°F, a heart rate of 125bpm,and a blood pressure of 91/ 46mmHg. Her oxygen saturation was 90%.Physical exam was notable for tachycardia, diffuse crackles in bilateral lungs, diffuse tenderness to palpation of the abdomen, and profound anasarca. Admission laboratory testing showed a white blood cell count of 11g/dL, a hemoglobin of 10g/dL and a venous lactate of 3.8. Her total protein count was 4.0g/dL with an albumin of 1.5g/dL. Chest CT scan revealed extensive, bilateral, infiltrates consistent with a multifocal necrotizing pneumonia as well as evidence of past granulomatous disease. Abdominal CT scan showed distended, edematous small bowel loops with air fluid levels as well as colonic wall thickening. She was initially treated with broad spectrum antibiotics and aggressive fluid resuscitation. Her infectious work up revealed negative routine blood cultures, negative urine cultures and a negative HIV test. Sputum smears for acid fast bacilli were positive on day two. Stool smears were also positive for acid fast bacilli. PCR confirmed the diagnosis of disseminated mycobacterium tuberculosis (mTB). She was promptly started on isoniazid, rifampin, pyrazinamide, and ethambutol along with methylprednisolone given her disease burden. She underwent CSF testing which was negative for mTB. She was hospitalized at Bellevue for twelve weeks and was discharged home once her sputum smears were negative for mTB.

IMPACT: This case highlights the variable and often severe manifestations of mTB. It reiterates the importance of always keeping TB on the differential, especially in patients from endemic regions, and reminds me to have a low threshold for placing patients on respiratory isolation while a diagnostic workup is underway.

DISCUSSION: Patients who present with constitutional symptoms and pathology in multiple organ systems can pose a diagnostic dilemma. MTB is not an uncommon bacterial disease that can have varied extrapulmonary manifestations, even in the immunocompetent patient. A high index of suspicion is required to make the diagnosis. Enteritis causing protein wasting is a rare sequelae of abdominal mTB. Early diagnosis and initiation of anti-tuberculous therapy is essential, as severe cases may require surgical intervention and are associated with high morbidity and mortality.

PSEUDO LEMIERRE'S Gray Jodon[2]; Chi Zheng[1]; Timothy Miller[3]. [1]Denver Health, Denver, CO; [2]University of Colorado, Denver, CO; [3]University of Colorado School of Medicine, Loveland, CO. (Control ID #2706757)

LEARNING OBJECTIVE #1: Diagnose malignancy in spontaneous internal jugular vein thrombosis

CASE: A 59 year old man with no significant past medical history presented with 3–5 days of left-sided neck pain and swelling. Physical exam was notable for enlargement of the left side of his neck that was tender to palpation from the anterior neck to the inferior margin of the mandible. He had no fever, dental carries, pharyngeal erythema, cervical nor supraclavicular lymphadenopathy. Laboratory analysis was notable for a white blood cell count of 9,400/μL. A neck CT showed left internal jugular vein thrombosis with surrounding inflammation suggestive of septic thrombophlebitis, also known as Lemierre's syndrome. The patient was admitted to the hospital and started on IV antibiotics. Due to his lack of typical signs of infection, there was concern for spontaneous and, particularly malignancy-associated, thrombosis. He was also found to have a non-occlusive thrombosis in his opposite subclavian vein and an elevated CA 19–9. The patient was discharged on anticoagulation and IV antibiotics. Despite this, he returned to the hospital 2 weeks later with a pulmonary embolism. Due to concern for occult malignancy, the patient was referred to oncology and a PET-CT revealed multiple hypermetabolic lymph nodes without pancreatic involvement. A cervical lymph node excision ultimately revealed metastatic germ cell malignancy.

IMPACT: Our decision for anticoagulation in this patient as part of treatment for suspected Lemierre's was controversial; as was our decision to pursue further hypercoagulability work-up. However, due to his atypical presentation of a rare disease, our concern for malignancy associated hypercoagulability led us to start anticoagulation and ultimately to the definitive diagnosis and treatment. Atypical presentations of rare diseases should prompt a search for more common disease processes.

DISCUSSION: Spontaneous internal jugular vein thrombosis (IJVT) is rare, occurring in less than 1 in 25,000 individuals annually. It is most commonly associated with central venous access devices (CVADs), but can also be caused by deep neck infections, IV drug abuse, trauma, or hypercoagulability due to malignancy. Lemierre's syndrome is rare, with the incidence estimated to be 1 per 1,000,000, and is most commonly caused by a peritonsillar or tonsillar infection with anaerobic bacteria. 83% of cases present with fever and sore throat, and 78% have leukocytosis. On the other hand, malignancy in general has a much higher incidence than Lemierre's syndrome, with testicular cancer alone having an incidence of 4.84 per 100,000. Malignancy increases the risk

of VTE, with a 400% increase in risk of DVT or PE. In isolated spontaneous IJVT, up to 10.8% of cases will be diagnosed with a malignancy within one year. In cases of IJVT without evidence of CVADs, IV drug use, trauma or infection, screening for malignancy should be considered to provide an accurate diagnosis and timely treatment.

PSEUDOSEPTIC ARTHRITIS AS THE INITIAL PRESENTATION OF RHEUMATOID ARTHRITIS Hye Gi Shim; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (Control ID #2706686)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of early rheumatoid arthritis (RA)

CASE: A 78-year-old woman with well-controlled hypertension presented with severe pain and swelling in the right shoulder for 3 days. Arthrocentesis showed 20 ml of purulent fluid, a white blood cell count of 210,000 cells/uL with 95% neutrophils, and absent crystals; gram stain was negative. For presumed septic arthritis, she underwent irrigation and debridement and was started on Vancomycin. Four sets of synovial fluid culture and blood culture showed no growth after 5 days. She was discharged home with a plan to continue Vancomycin for 4 weeks. She returned to the hospital 3 days later, with new onset of pain and swelling in the left ankle and bilateral finger joints for 1 day. Physical exam at this time showed erythema, warmth, and tenderness of the left ankle; the right 2nd, 3rd, and 4th metacarpophalangeal (MCP) and 4th proximal interphalangeal (PIP) joints; left 2nd, 3rd, and 4th MCP and 3rd PIP joints. Rheumatoid factor was negative but cyclic citrullinated peptide antibody (CCP Ab) was greater than 500 U/ml. Nuclear antibody screen, anti-streptolysin O antibody, Parvovirus serologies, viral hepatitis serologies, and Lyme titers were negative. The patient fulfilled the 2010 ACR/EULAR criteria for RA. She was started on prednisone with resolution of her joint inflammation in 2–3 days.

IMPACT: Pseudoseptic arthritis as the initial presentation of rheumatoid arthritis–which typically presents with indolent polyarthritis rather than an acute monoarthritis–is uncommon but increasingly recognized.

DISCUSSION: Pseudoseptic arthritis is an entity describing an acute inflammatory monoarthritis with purulent but sterile synovial fluid. It is a diagnosis of exclusion. In a retrospective study of patients with presumed septic arthritis and negative microbiological results, 14% subsequently developed a variety of rheumatic diseases. Mean time to diagnosis of rheumatic disease was 6 months, suggesting that such patients require close follow-up to exclude rheumatic disease. It is appropriate to start antibiotics until clinical and microbiological evaluation is complete. The decision whether to continue antibiotics if culture results are negative should be individualized, given the low combined sensitivity (81% in a retrospective series) of synovial fluid and blood cultures. In this patient, the subsequent development of a symmetric small joint polyarthritis, with a highly specific (96 percent) CCP Ab level, and the rapid improvement with steroid administration, supported the diagnosis of rheumatoid arthritis as the cause of this pseudoseptic arthritis.

PSORIASIS FLARE WITH ADALIMUMAB USE FOR PSORIATIC ARTHRITIS TREATMENT Anandita Arora[1]; Alaa Elkhider[1]; Mohamed Mohamed[2]; Ahmed Kadhim[1]; Marie-Claire Maroun[2]. [1]Detroit Medical Center, Farmington Hills, MI; [2]Detroit Medical Center, Detroit, MI. (Control ID #2702459)

LEARNING OBJECTIVE #1: Recognize worsening of cutaneous psoriasis after TNF inhibitor therapy and consider alternate therapies

CASE: A 55 year old woman with psoriasis and diabetes was seen in clinic for psoriatic arthritis. She was being treated for psoriasis with topical therapy and methotrexate by dermatology. Her last psoriatic arthritis flare up was 2 months ago with pain in multiple joints. Her Methotrexate was decreased from 20mg to 15mg weekly and Adalimumab was added 8 weeks ago. She reported worsening skin rash in palms and soles since she started Adalimumab. Due to concern for anti TNF induced worsening psoriasis, we discontinued her Adalimumab and placed her back on Methotrexate 20mg. After 2 months she reported marked improvement in her joint pain and skin rash. Methotrexate was continued at 20mg and Ustekinumab 45mg IV every 4 weeks was added as an alternative biologic agent for the palmoplantar psoriasis related to TNF use.

IMPACT: Using alternative therapies to TNF inhibitors early on in the treatment for Psoriatic arthritis can prevent paradoxical side effects.

DISCUSSION: A paradoxical adverse effect being increasingly reported is new onset or worsening psoriasis with TNF inhibitors like Adalimumab. This may occur any time after initiation of TNF antagonist therapy and the skin lesions usually resolved with TNF discontinuation. Retrospective studies noted psoriasis occurring during anti-TNF therapy to be mostly de novo psoriasis and less an aggravation of a pre-existing psoriasis. Although this side effect has been reported as a 'class-effect' of TNF-alpha antagonists, one study suggested that the deterioration of psoriasis is an adverse reaction seen mainly with drugs used specifically for the treatment of psoriasis and not with any anti-TNF agent. This might indicate a poor understanding of the pathogenesis of psoriasis itself or of the mechanism of action of the drugs used for treatment. One study recommended the combined use of topical therapy with high-strength corticosteroids and vitamin D analogs for patients with de novo psoriasis. If this does not control the episode and it is necessary to continue the anti-TNF agent (because it adequately controls the patient's underlying non-dermatologic disease without serious side effects), then partial control of the skin lesions with topical therapy may be acceptable with addition of photo or systemic therapies. If it is not essential to continue the anti-TNF drug, then it is best to substitute the implicated agent with a drug that does not act by inhibiting TNF. In patients with a change in the morphology of the psoriasis, the most widely used initial option is to continue using the same drug at the same dose and to prescribe additional topical therapy. If this does not control the episode, it is recommended to substitute the first agent by another drug, preferably one with a different mechanism of action, as in cases of new onset psoriasis.

PULMONARY ARTERY INTIMA SARCOMA MASQUERADING AS PULMONARY EMBOLISM shahistha hameed; Dipen Khanapara. montefiore medical center, Bronx, NY. (Control ID #2707639)

LEARNING OBJECTIVE #1: Recognize symptoms and imaging of pulmonary arterial intimal sarcomas mimic pulmonary thromboembolism

CASE: A 43 year old man with hypertension presented with 1 month worsening dyspnea, dry cough, and left-sided pleuritic chest pain. He also had 20-pound weight loss. He presented with hypoxia, tachycardia, and a grade 3 systolic murmur with clear lungs. Chest X ray revealed right upper lobe consolidation. Given the clinical picture and elevated d-dimer, pulmonary embolism was considered. CT chest revealed a 7x5 cm right mediastinal mass with invasion into the pulmonary artery, SVC, and right mainstem bronchus,

and a large pulmonary embolism within the right and left main pulmonary arteries. Anticoagulation was not started due to the invasion of the mass into the pulmonary artery and risk of bleeding. He was transferred to ICU and intubated for clinical worsening, followed shortly by cardiac arrest and death despite resuscitation. At autopsy, the mass was diagnosed as pulmonary artery intima sarcoma, which was occluding the pulmonary artery bifurcation and invading the right bronchus, SVC, and pericardium.

IMPACT: Pulmonary artery intima sarcoma (PAIS) is rare and very difficult to diagnose. PAIS should be considered in differential diagnosis of a patient presenting with chest pain, dyspnea, and filling defect within the pulmonary arteries. Distinguishing PAIS from thromboembolic events is imperative in order to hasten the initialization of surgical resection and chemotherapy.

DISCUSSION: PAIS was first described at autopsy in 1923 and since then approximately 200 cases have been reported. The usual features are endoluminal growth, vessel obstruction, seeding of distal emboli; rarely retrograde extension to right ventricle occurs. Diagnosis is often delayed due to long asymptomatic course. There is female predominance with mean age of 48 years. Symptoms of pulmonary hypertension and right heart failure can occur. Diagnostic imaging of choice is contrast-enhanced chest CT, as it can reveal some features of sarcoma, such as mild contrast enhancement and extravascular spread. However, definitive diagnosis is made postoperatively or at autopsy. It is frequently misdiagnosed as thromboembolism, which can lead to inappropriate anticoagulation or thrombolysis. Surgical resection of the tumor decreases symptoms and prolongs survival. The role of chemotherapy and radiotherapy remain undefined. Prognosis is poor with median survival of 12–18 months after surgery. In conclusion, pulmonary artery intima sarcoma is a rare lethal tumor which requires a high degree of suspicion for diagnosis, even with advanced imaging technology

PULMONARY CEMENT EMBOLISM Calvin Ngai; Arun Manmadhan; Nathan Teich; joshua smith. NYU Langone Medical Center, New York, NY. (Control ID #2704197)

LEARNING OBJECTIVE #1: Assess the need for anticoagulation in patients with pulmonary cement embolism

LEARNING OBJECTIVE #2: Manage the complications of cement embolism caused by kyphoplasty

CASE: A 79 year-old woman with recent T12/L1 compression fractures presented with left leg pain for 2 weeks. Five months prior to presentation, she underwent an uncomplicated kyphoplasty for T12/L1 compression fractures. Two weeks prior to presentation the patient began to experience left leg pain with ambulation without associated sensory loss or urinary/fecal incontinence. A computed tomography (CT) scan of the thoracic and lumbosacral spines showed prior T12 and L1 kyphoplasty with extravasation of cement into the surrounding vasculature and bilateral pulmonary arteries. A CT angiogram showed central cement pulmonary emboli extending from the pulmonary artery bifurcation into the left main pulmonary artery. A transthoracic echocardiogram did not reveal evidence of right heart strain. As the patient was asymptomatic and clinically stable with normal cardiac function post-procedurally for 5 months, initiation of anticoagulation was deferred.

IMPACT: This case emphasizes considering pulmonary cement embolism in the risk and benefit profile of kyphoplasties for intractable pain due to fractures secondary to metastases or osteoporosis.

DISCUSSION: Percutaneous kyphoplasty (PKP) is a minimally invasive procedure where polymethylmethacrylate (PMMA) is injected into damaged vertebral bodies for pain relief. Pulmonary cement embolism (PCE) is a known complication of PKP with a reported incidence of 3.5 to 23%. Currently, there are no published guidelines to guide the management of PCE. One proposed schema, based on expert opinion, is to risk-stratify patients with PCE by symptoms. Patients with symptomatic PCE typically present peri-procedurally with chest pain, dyspnea, tachycardia and/or cough. In patients with central, symptomatic PCE, some authors suggest surgical removal as pharmacologic intervention may be insufficient. In patients with symptomatic, peripheral PCE, CHEST guidelines on thrombotic pulmonary emboli recommend initial intravenous heparin followed by at least 3 months of oral anticoagulation. It is important to note, however, that there is no data to suggest that PMMA is itself thrombogenic either *in vitro* or *in vivo*. Given numerous case reports of recovery from symptomatic PCE with anticoagulation, many clinicians hypothesize that anticoagulation prevents thrombus formation while the cement is endothelialized. PCEs in asymptomatic individuals are typically discovered incidentally. The true incidence of PCE may be much higher than what is reported as many patients are asymptomatic. In asymptomatic individuals, it may be reasonable to avoid further intervention and instead monitor longitudinally. In one study of 11 asymptomatic patients with PCE identified post-procedurally, none developed symptoms during 1-year follow-up. Given the paucity of prospective data to direct management of PCEs, further research is warranted.

PULMONIC VALVE VEGETATION IN A DIALYSIS-DEPENDENT MALE WITH MORAXELLA OSLOENSIS BACTEREMIA Emily E. Jones[2]; Christopher Ghiathi[3]; Yana Thaker[3]; Nancy Simon[1]. [1]UWMC, Seattle, WA; [2]University of Washington, Burlington, WA; [3]University of Washington, Seattle, WA. (Control ID #2671037)

LEARNING OBJECTIVE #1: Recognize and evaluate atypical organisms causing endocarditis.

CASE: A 23-year-old male with ESRD status-post failed living-donor renal transplant due to medication nonadherence presented to an outside hospital with a week of dyspnea, productive cough, and ankle swelling after a missed dialysis appointment. The transplanted kidney was removed in 2011, and he had been off all immunosuppressant medications since that time. At presentation, he was hyperkalemic, febrile, and profoundly fluid overloaded, with subsequent blood cultures growing *Moraxella osloensis*. Physical exam revealed a 2/6 blowing murmur at apex and axilla likely transmitted from AV fistula without sequelae of infective endocarditis, and imaging revealed a left lobar consolidation. He was transferred for urgent hemodialysis and his dyspnea and cough improved on ceftriaxone and azithromycin. On hospital day one, a TTE obtained for evaluation of cardiac function showed a 6mm × 3mm mobile mass on the pulmonic valve without associated regurgitation or septal defects; this was not present on echocardiogram two months prior. The patient had no history of IVDU but had a dental extraction 1 month prior; he was broadened to cefepime for improved coverage of gram-negative rods. Additional infectious evaluation, including in-house blood cultures, was negative. AVF duplex US of left upper extremity revealed a non-occlusive, non-infectious basilic vein thrombosis. The patient met one major (valvular vegetation) and two minor (fever, bacteremia with atypical organism) Duke's Criteria. Given the possibility of infective endocarditis and concurrent basilic

vein thrombosis, he was initiated on a 4 week course of ceftazidime 1g on hemodialysis days and discharged home with infectious disease follow up.

IMPACT: This case illustrates a novel presentation for *Moraxella osloensis*, an organism that has been associated with endocarditis in only three patients, all of whom were immunocompromised. This is the first published case of *Moraxella osloensis* endocarditis in an immunocompetent patient, and also the first involving the pulmonic valve.

DISCUSSION: *M. osloensis* is a gram-negative coccobacillus known to cause peritonitis, pneumonia, meningitis, and infective endocarditis. The majority of cases of *osloensis* infection have occurred in immunosuppressed patients. Though somewhat immunocompromised due to ESRD, our patient was not on any immunosuppressant therapy and no longer had a transplanted organ. The presence of the vegetation on the pulmonic valve in a structurally sound heart adds to the novelty of presentation. Because M. *osloensis* is an infrequently encountered organism with established association with endocarditis, bacteremia with this pathogen warrants evaluation with TTE.

PURPLE SPOTS AND POLKA DOTS! A RARE CASE OF ADULT ONSET HENOCH-SCHONLEIN PURPURA (HSP)

Kyle Gobeil; Shakil Shaikh. Baystate Medical Center, Suffield, CT. (Control ID #2706517)

LEARNING OBJECTIVE #1: Highlight the association between age and rapid renal impairment in the adult HSP population

LEARNING OBJECTIVE #2: Identify an approach to treatment in adults with HSP

CASE: A 47 year-old-male with coronary artery disease presented with 5 days of abdominal pain. CT abdomen was notable for perforated sigmoid diverticulum, for which he was appropriately treated with antibiotics. Hospital course was complicated by renal deterioration and a new onset palpable purpuric rash. Serum creatinine was found to increase to 5.1, up from normal baseline. Initial workup included hepatitis and rheumatoid panels with urine analysis, which was significant for hematuria and proteinuria. Skin biopsy was revealing for necrotizing vasculitis. Kidney biopsy was ultimately preformed, which showed IgA dominant necrotizing and focal crescentic glomerulonephritis. HSP was suspected given dermatologic findings and rapid progressive renal disease with renal biopsy confirming this diagnosis. Our patient was initially treated with high dose steroid therapy. Once HSP was confirmed, patient was started on cyclophosphamide and plasmapheresis was initiated. Fortunately, plasmapheresis and immunotherapy prevented the progression to dialysis. By discharge, creatinine had improved, however, renal function was persistently impaired.

IMPACT: While primarily a pediatric illness, I developed an understanding that HSP can affect the adult population, often with severe consequences. Given the right clinical scenario, it is important to identify HSP and initiate early treatment to prevent progression of renal compromise.

DISCUSSION: HSP, a systemic vasculitis, is as a common vasculitic reaction primarily affecting the pediatric population with 90% of cases occurring between the ages of 3–15 years. Within the pediatric population, HSP is generally self-limited, however, adults have a higher prevalence of hematuria and renal impairment. In general, clinical manifestations are similar among both demographics, although, a higher incidence of renal involvement and eventual progression to end stage renal disease is seen in adults. In an adult French cohort, 11% of patients reached end-stage renal failure and 13% progressed to severe renal failure. Initial treatment typically includes high dose glucocorticoid therapy. Various immunosuppressive therapies have been trialed with no good data supporting a positive correlation between their use and renal outcomes. Plasmapheresis has been shown to independently improve renal function in those with severe renal dysfunction. Therefore, it is vital to promptly identify patients at risk of developing renal dysfunction and recognize the utility of high dose steroids with plasmapheresis. Our case highlights the importance physical examination in identifying the purpuric lesions of HSP in the setting of renal dysfunction. Once diagnosis is confirmed, plasmapheresis has proved beneficial, while selection of immunotherapy should be made on an individual basis as data supporting their utility is limited.

PURPURA FULMINANS FROM STREPTOCOCCUS PNEUMONIAE IN AN ASPLENIC PATIENT

Steven L. Register. Carolinas Medical Center, Ch, NC. (Control ID #2707627)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of purpura fulminans

LEARNING OBJECTIVE #2: Raise awareness of vaccination in alspenic patients

CASE: Patient was a 50 year old male with a history of COPD and prior splenectomy following traumatic splenic rupture who presented with fever, altered mental status, and somnolence. He was subsequently intubated and transferred to the ICU, at which time his wife was able to report that since splenectomy he had experienced two episodes of pneumococcal meningitis in the past few years. Following the second bout of meningitis he had undergone proper vaccination with both Prevnar 13 and Pneumovax one year prior to his presentation. On exam, he was noted to have a temperature of 103.7, heart rate of 126, and BP of 109/63. He was initially noted to have retiform purpura diffusely spread over his body with a dark, dusky appearance of the nose, ears, eyelids, bilateral hands and feet, and tip of the penis. These areas eventually became pulseless and developed necrosis. His labs were remarkable for a WBC of 47,000, platelets of 34,000, PT of 16.1, INR of 1.5, PTT of 58.7, and fibrinogen of 185. Schistocytes were noted on peripheral blood smear. Two sets of blood cultures were positive for pneumococcus. The diagnosis of purpura fulminans from Pneumococcus was made. Despite being on appropriate antibiotics and maximal supportive care, the patient developed multisystem organ dysfunction and was eventually transitioned to a comfort care approach and passed away shortly after.

IMPACT: This case helped to raise awareness of an uncommon, yet devastating disease. This case also points out that, though not as commonly recognized, organisms other than Neisseria meningitidis can be associated with purpura fulminans. We are also reminded of the importance of routine vaccination in susceptible patients.

DISCUSSION: Pupura fulminans is an acute, potentially fatal thrombotic disorder that is commonly associated with DIC and presents as widespread retiform purpura that can rapidly lead to skin necrosis. It may progress rapidly to multi-organ failure due to thrombotic occlusion of small and medium-sized blood vessels. Although this disease can occur in congenital or acquired protein C and S deficiencies, it is typically recognized with sepsis, oftentimes from Meningococcus. While providing blood products to help treat coagulopathy and surgical intervention to remove dead tissue can be employed, initial therapy is focused on aggressive supportive measures and removing the offending cause. This case is interesting in the fact that our patient developed invasive pneumococcal disease despite being properly vaccinated and having

no other immunodeficiencies. It also raises the question of the prevelance of nontypable strains of Pneumococcus, which our patient may very well have had.

PYODERMA GANGRENOSUM MIMICKING NECROTIZING FASCIITIS: A CASE OF ANCHORING BIAS

Jefferson Berryman[1, 3]; Rachael Hilton[1, 3]; Katrina Handoyo[1, 2]. [1]Presbyterian/St. Luke's Medical Center, Denver, CO; [2]University of Colorado, Denver, CO; [3]Colorado Health Foundation, Denver, CO. (Control ID #2702871)

LEARNING OBJECTIVE #1: Diagnose pyoderma gangrenosum in patients with necrotizing soft tissue wounds

LEARNING OBJECTIVE #2: Recognize the importance of anchoring bias in clinical decision making

CASE: A 28-year-old female presented to the ED with abdominal wound complications seven days after undergoing a cesarean section. Upon admission she had a low grade fever and her scar was erythematous and tender with surrounding purple discoloration. Within several hours the discoloration had extended well outside of the originally marked boundaries and a diagnosis of necrotizing fasciitis (NF) was promptly made. The patient was started on broad spectrum antibiotics, hyperbaric oxygen, and underwent multiple aggressive debridements of the wound in the ensuing weeks. Initial pathology showed "sheets of necrosis consistent with NF," and wound cultures were initially positive but persistently negative thereafter. Despite treatment her condition worsened, and her wound grew to encompass her entire abdomen, extending to the peritoneum. Additional questioning of the patient revealed a family history of pyoderma gangrenosum (PG) in her grandmother with a remarkably similar presentation. Dermatopathologists were asked to re-evaluate surgical specimens and determined that the case was more consistent with PG given the clinical history and lack of microscopic bacteria. The patient's condition quickly improved with high dose steroids and a gradual recession of her wound was observed. She is now undergoing permanent skin grafting before discharge.

IMPACT: Post cesarean section PG, though rare, has occasionally been described in the literature (Banga *et al.*). However, the condition is extremely uncommon in the absence of other pathergy and when no underlying condition is present. Additionally, the clinical presentation of our patient mimicked NF more closely than many previously described occurrences, with specialists in numerous different fields initially agreeing with the diagnosis.

DISCUSSION: PG is a rare and often recurring chronic neutrophilic dermatosis which typically occurs in the lower extremities of patients with inflammatory and hematologic disorders. The disease lacks specific clinical and histologic findings and diagnosis often requires a high index of suspicion. This case demonstrates the difficulty in diagnosing PG and differentiating it from NF. In medicine we frequently "anchor" to more typical or common diagnoses, often to the exclusion of other possibilities. Although this can provide efficiency, it can also result in significant error. Before the correct diagnosis was made in our patient, she suffered from an AKI, upper-extremity DVT, profound anasarca, and extensive surgical interventions, all of which were potentially avoidable. Additionally, this case is an important reminder of the role of a medicine physician in orchestrating patient care amongst different specialists, as well as the value of thoroughly investigating a complete patient and family history to aid in correct diagnosis.

QUIT BREAKING MY HEART; 5-FLUOROURACIL ASSOCIATED CARDIOMYOPATHY

Sabina Zawadzka; Upendra P. Hegde. University of Connecticut, Farmington, CT. (Control ID #2706108)

LEARNING OBJECTIVE #1: Recognize the clinical features of 5-fluorouracil associated cardiomyopathy

LEARNING OBJECTIVE #2: Execute appropriate work-up and management of 5-fluorouracil associated cardiomyopathy in the inpatient setting

CASE: A 47 year-old male with recurrent squamous cell carcinoma of the left tongue presented for induction chemotherapy. He was a lifetime non-smoker with occasional alcohol use, with no personal or family history of cardiac disease. Treatment was started with paclitaxel, cisplatin and 5-fluorouracil (TPF). One day after receiving 1 dose of 5-fluorouracil (5-FU), he developed severe sudden onset, crushing, substernal chest pain associated with dypsnea and a syncopal episode. 5-FU was immediately discontinued. An EKG showed diffuse ST elevation. Cardiac enzymes were negative. The patient underwent an urgent cardiac catheterization demonstrating normal coronary anatomy and no evidence of coronary artery disease. An initial echocardiogram showed an ejection fraction (EF) of 55–65% with no wall motion abnormalities. The following day there was moderately reduced left ventricular systolic function, an EF of 35% with moderate diffuse hypokinesis. Clinically and based on echocardiogram studies, the patient was diagnosed with 5-FU-associated cardiomyopathy, specifically myopericarditis. He was conservatively treated for myocardial inflammation in the absence of ischemia. Repeat echocardiogram 3 days later showed an improved ejection fraction of 45% with persistent diffuse hypokinesis. Five days after the initial event, echocardiogram showed continued systolic improvement with an EF of 50%. A repeat EKG showed resolution of the ST elevations. The patient's subsequent chemotherapy cycles were modified from the TPF regimen without further cardiac symptoms. He was followed by an outpatient cardiologist and monitored with routine echocardiograms, with his EF returning back to baseline and hypokinesis resolved.

IMPACT: This case is notable for the degree of severity of toxicity, especially with regard to left ventricular systolic dysfunction after a short exposure to 5-FU. Rapidly worsening systolic dysfunction after 5-FU exposure with resolution after stopping the drug is a typical feature in the setting of 5-FU cardiomyopathy. 5-FU cardiotoxicity is now the second most common cause of chemotherapy induced cardiotoxicity, with incidence ranging from 1.2 to 18%. A majority of cases occur in patients with no cardiac history and it is difficult to predict which individual will be adversely affect by the drug. Physicians should be vigilant in monitoring for cardiac symptoms after initiating 5-FU.

DISCUSSION: The patient's first dose of 5-FU was complicated by myopericarditis. While cardiotoxicity has been reported with 5-FU use, myopericarditis is a relatively uncommon complication. Treatment of 5-FU cardiotoxicity consists of stopping the drug and replacing it with another chemotherapy agent. Repeated exposure to 5-FU carries a recurrence rate of 82-100%.

RAISE YOUR INDEX OF SUSPICION FOR SYPHILIS

Zachary Quinn[2]; Deepa Bhatnagar[1]. [1]Tulane University, New Orleans, LA; [2]Tulane University Health Sciences Center, New Orleans, LA. (Control ID #2703628)

LEARNING OBJECTIVE #1: Identify infectious causes of psychiatric symptoms

LEARNING OBJECTIVE #2: Review diagnosis of neurosyphilis in HIV co-infection

CASE: A 31 year-old man with a history of HIV (CD4 count of 7) and schizoaffective disorder presented from home after a reported seizure. Three weeks prior, he was evaluated with multiple painless ulcers including a clean-based, penile ulcer. He was diagnosed with secondary syphilis. He received one dose of IM penicillin G. His wife reported a change in cognition and personality with decreased sleep. He had discontinued his carbamazepine recently. On exam, he displayed disorganization, bizarre thought processes, distractibility, pressured speech, and bizarre automatisms. MRI with contrast was performed which was negative for any masses or abnormalities in enhancement. Two separate EEGs were consistent with normal sleep wake cycles. A lumbar puncture demonstrated a protein level of 41 mg/dl, glucose 41 mg/dl, WBC count of 3, RBC count of 0. VDRL titers were non-reactive, but FTA-ABS antibodies were present. Further workup for medical delirium included normal electrolytes, liver function tests, and a normal serum ammonia level. Blood, urine, and CSF cultures were negative. He was transferred to inpatient psychiatry for treatment of uncontrolled schizoaffective disorder. After receiving psychiatric treatment for ten days, a repeat lumbar puncture was performed. Both FTA-ABS and VDRL titers were positive. A diagnosis of neurosyphilis was confirmed. Due to a penicillin allergy, he successfully underwent desensitization with ceftriaxone. He subsequently received 2 weeks of IV therapy. His mental status significantly improved to his cognitive baseline.

IMPACT: Acute change in mental status is a complaint for which a definitive diagnosis can often be elusive for internists. When symptoms persist without discovery of an underlying cause, physicians consider undiagnosed medical condition or new onset of primary psychiatric disorder.

DISCUSSION: Neurosyphilis can present with a variety of symptoms, which include auditory or ocular hallucinations. Acute psychosis is a documented phenomenon and is uncommon. There is no gold standard for diagnosis, but a positive blood treponemal serology and a reactive CSF VDRL typically justify a diagnosis. The sensitivity of CSF VDRL is poor, averaging near 50% positive in confirmed cases of neurosyphilis. CSF FTA-ABS is a highly sensitive marker for neurosyphilis; but false positives occur often, especially in setting of serum cross contamination. CSF pleocytosis or elevated protein levels can assist the diagnosis in absence of a reactive VDRL titer; however these findings alone can be seen in HIV without syphilis co-infection. There are no current guidelines for when to repeat a lumbar puncture in setting of inconclusive CSF analysis. This case demonstrates that when clinical suspicion is high and laboratory data does not initially support the diagnosis, repeating a lumbar puncture is a valid approach in the diagnosis of neurosyphilis.

RAPID-ONSET DIABETES: AN OMINOUS SIGN? Sara Jane Cromer. New York Presbyterian Hospital - Columbia University Medical Center, New York, NY. (Control ID #2672682)

LEARNING OBJECTIVE #1: Recognize rapid-onset diabetes as a possible early sign of pancreatic cancer

LEARNING OBJECTIVE #2: Consider pancreatic imaging for older adult patients with new-onset of diabetes

CASE: A 58 year-old woman with history of polysubstance use (tobacco and intranasal cocaine), peptic ulcer disease, hypertension, and recent diagnosis of diabetes presented to the emergency department (ED) with one week of non-bloody, non-bilious vomiting and right upper quadrant (RUQ) cramping abdominal pain improved with drinking water. She had subsequently developed constipation and a heavy, cramping sensation in her legs bilaterally. Review of systems revealed polyuria, polydipsia, blurred vision, and a 10-pound weight loss in the past week. Exam was significant for dry mucous membranes and epigastric tenderness without rebound or guarding. Initial labs revealed creatinine 2.77 mg/dL (baseline 1.8–2.2 mg/dL), glucose 686 mg/dL, anion gap 10, and urinalysis with 3+ glucose and no ketones. Hemoglobin A1c on admission was 13.3%, increased from 7.7% one month prior to admission. Liver function tests were normal except for lipase 374 u/L (normal range 3–43 u/L). She was treated for hyperosmolar non-ketotic syndrome with fluid resuscitation and insulin. Abdominal ultrasound, MRI, and subsequent endoscopic ultrasound revealed a cystic mass in the pancreatic head invading the superior mesenteric vein with associated mild dilation of the main pancreatic and common bile ducts. CA 19–9 was elevated at 119 u/mL (normal range 0–37 u/mL). One week later, she returned to the ED for worsening severe RUQ pain and new-onset pruritis, as well as yellowing of her eyes and darkening of her urine. Exam confirmed scleral icterus, and labs revealed total bilirubin 7.2 mg/dL, direct bilirubin 3.8 mg/dL, AST 195 u/L, ALT 379 u/L, and alkaline phosphatase 467 u/L. Repeat ultrasound revealed an interval increase in the size of the pancreatic mass and the degree of ductal dilatation. Endoscopic retrograde cholangiopancreatograophy (ERCP) was performed with sphincterotomy and stent placement to relieve ductal obstruction. Biopsy at that time confirmed well- to moderately-differentiated pancreatic adenocarcinoma.

IMPACT: Rapid-onset diabetes in adults over age 50 should prompt consideration of an inciting cause.

DISCUSSION: Early diagnosis of pancreatic cancer is critical as localized disease can sometimes be cured surgically; however, the disease often remains asymptomatic until an advanced stage. Multiple studies now reveal that as many as 40-80% of patients with pancreatic cancer have hyperglycemia which precedes symptoms and diagnosis of pancreatic cancer. Further, patients aged >50 with new-onset diabetes have up to an 8-fold higher risk of pancreatic cancer than age-matched controls. While widespread screening for pancreatic cancer is not recommended due to the low incidence of the disease, more research is needed to determine the cost-benefit of screening adult patients with new-onset hyperglycemia or diabetes.

RAPIDLY PROGRESSIVE BULLAE IN A CRITICALLY ILL PATIENT David T. Broome[1]; Ceena Neena Jacob[2]; Ellen Wurm[1]; Alok Vij[1]; Cassandra Calabrese[1, 1]; Carlos Isada[1]. [1]Cleveland Clinic Foundation, Cleveland, OH; [2]Government Medical College, Kottayam, India. (Control ID #2679683)

LEARNING OBJECTIVE #1: Diagnose Bullous Pyoderma Gangrenosum

LEARNING OBJECTIVE #2: Recognize cognitive bias while diagnosing rare conditions

CASE: A 63-year-old woman presented to an outside hospital with toxic megacolon with unclear etiology, refractory to multiple antibiotics (vancomycin, piperacillin/tazobactam, and metronidazole) that resulted in colectomy with end ileostomy placement. On postoperative day five, she was transferred for papules at the surgical incision site that rapidly expanded and coalesced

with a surrounding red-purple violaceous border and superimposed bullae. The Nikoslky sign was positive, and Asboe Hansen sign was negative. These lesions appeared on her abdomen around the surgical incision, her right thigh where the foley was anchored, and her right neck where she had an interjugular catheter. Given that the patient had recent trials of antibiotics with the development of a rash, the patient had a presumptive diagnosis of stevens-johnson syndrome prior to being transferred. When she presented to our hospital, the differential diagnosis was broad, including stevens-johnson syndrome, sweet's syndrome, infections, malignancies, and vasculitides.The patient had localized blisters at sites of trauma, not in dependent areas, which were consistent with pathergy. Skin biopsy displayed a sub-epidermal split, hemorrhage, and a dense neutrophil-rich infiltrate extending full thickness through the dermis. Upon extensive chart review, it was found that she had been diagnosed with ulcerative colitis previously and had been non-adherent to therapy. In the setting of pathology-confirmed ulcerative colitis with toxic megacolon, paired with pathergy and the biopsy findings, pyoderma gangrenosum became the clear diagnosis. A final diagnosis of bullous pyoderma gangrenosum secondary to an ulcerative colitis flare was made and the patient was started on IV methylprednisolone with adjuvant intravenous immunoglobulin and rapid improvement was noted within days.

IMPACT: It is common to encounter type 1 cognitive errors in treating critically ill patients with acute skin manifestations. This patient had denied a previous history of ulcerative colitis, leading the outside hospital to conclude that this patient had stevens-johnson syndrome and led to diagnostic momentum. When reanalyzing this case, a type 2 analytical thinking approach was employed and eventually led to the correct diagnosis of bullous pyoderma gangrenosum.

DISCUSSION: Bullous pyoderma gangrenosum is a rare manifestation of inflammatory bowel disease that may manifest in the critically ill patient. It is important to distinguish this diagnosis utilizing type 2 analytical thinking, discern it in the light of opposing diagnostic momentum, and treat it appropriately. Surgical debridement is contraindicated in bullous pyoderma gangrenosum, and if used may cause significant morbidity and mortality. When treated with steroids and biologic agents, rapid improvement is noted within days, and significant morbidity and mortality may be avoided.

RARE CASE OF NEUTROPENIC DIVERTICULITIS Meghana Vellanki[1]; Sajiv Sethi[1]; Sowmya Nanjappa[2]; John N. Greene[2]. [1]University of South Florida, Tampa, FL; [2]Moffitt, Tampa, FL. (Control ID #2707404)

LEARNING OBJECTIVE #1: The aim of our case is to describe occurrence of diverticulitis in patients with prolonged neutropenia to help guide future diagnosis and treatment.

LEARNING OBJECTIVE #2: Recognize that having a higher index of suspicion for neutropenic diverticulitis may lead to earlier intervention and improved outcomes.

CASE: Patient was a 52-year-old female with history of AML and recurrent diverticulitis who presented with gradually worsening left lower quadrant abdominal pain. She was hospitalized three times within the past two months, twice for diverticulitis. On admission, patient was noted to be pancytopenic with ANC 150. CT of the abdomen and pelvis showed persistent extensive wall thickening with pericolonic inflammation involving the descending and sigmoid colon reflecting diverticulitis. Patient was discharged with IV antibiotics. Unfortunately, patient remained neutropenic with ANC 40 and was readmitted for recurrent diverticulitis with small focal abscesses that were too high risk to be drained. She eventually deteriorated after developing neutropenic fever and sigmoid colonic abscess and passed away 21 days after admission.

IMPACT: Importantly, one should have a higher index of suspicion for neutropenic diverticulitis in patients with a prior history of diverticulitis as familiarity with severe outcomes of neutropenic diverticulitis including abscess formation and perforation indicates a need for identifying and aggressively managing their controllable risk factors.

DISCUSSION: The course of diverticular disease in patients who are immunosuppressed may significantly differ from those with competent immune systems. Mortality for immunosuppressed patients with prior history of diverticulosis is higher with mortality rates of 25% for all patients with diverticulitis who were treated either conservatively or surgically, significantly higher than for the general population at 1-5% [2]. For example patient was not a surgical candidate but had multiple admissions for diverticulitis and patients with complicated diverticulitis may benefit from early resection, which could have been an early consideration in a patient with refractory diverticulitis [3]. Diagnosis of neutropenic diverticulitis requires a history specifying gastrointestinal symptoms in the setting of neutropenia. Often, patients will have a past history of diverticulosis and CT is an extremely useful tool in diagnosis. Treatment involves conservative therapy with antibiotics or even drainage or surgery. As patients who are immunosuppressed have higher complication rates, elective sigmoid resection is currently a Grade 1C recommendation for immunosuppressed patients after one episode of acute left sided colonic diverticulitis, but studies have not been done isolated to neutropenic patients [5]. This disease pattern necessitates provider familiarity for diagnosis with clinical history and CT, conservative versus aggressive therapeutic options, the role of surgical drainage, and patient outcomes in the setting of prolonged neutropenia.

RARE CASE OF OLANZAPINE INDUCED HYPOGLYCEMIA, BRADYCARDIA, AND HYPOTHERMIA Waleed Al-Darzi[2]; Mehnaz Rahman[3]; Sonya Sandhu[1]; Joyce Philip[2]; Vinay Shah[2]. [1]Wayne State School of Medicine, Detroit, MI; [2]Henry Ford Hospital, Detroit, MI; [3]Louisiana State University Health Sciences Center, New Orleans, LA. (Control ID #2687621)

LEARNING OBJECTIVE #1: Recognizing that Olanzapine can induce hypoglycemia. Although Olanzapine is known to cause hyperglycemia and new onset diabetes, there are few case reports of Olanzapine induced hypoglycemia.

CASE: 65 year old female with history of schizophrenia, hypertension and hyperlipidemia presented for dizziness. She has had multiple ER evaluations for similar complaints with a largely negative evaluation including normal orthostatic vitals and lack of events on implanted loop monitor. During this presentation she was noted to be in sinus bradycardia, hypothermic at 35.3 C and hypoglycemic at 49 mg/dl. Initial symptoms subsided with supplemental glucose, device interrogation of her loop recorder demonstrated sinus bradycardia with multiple PAC's and sinus pauses. Intracranial imaging with CT and MRI did not reveal acute pathology and EEG was negative for epileptiform activity. She had repeat neuroglycopenic episodes with altered mentation during her hospitalization with blood glucose levels repeatedly in the 50's mg/dl despite appropriate dietary intake. Endocrinology was consulted with

extensive evaluation yielding negative results for potential etiologies including hypothyroidism, adrenal insufficiency, insulinoma, sulfonylurea toxicity. Abdominal CT did not show evidence of adrenal or pancreatic mass. On review of her medications, Olanzapine was identified as the iatrogenic cause of her symptoms. After discontinuation of the drug, patient had gradual improvement remaining normothermic and with normal blood glucose levels throughout the rest of her inpatient visit.

IMPACT: Olanzapine can cause glucose dysregulation whether hypoglycemia or hyperglycemia. Hypoglycemia can produce bradycardia and hypothermia.

DISCUSSION: Olanzapine is a commonly used atypical antipsychotic medication. It has well documented side effects of dyslipidemia and hyperglycemia, often resulting in new onset diabetes in patients. However, there are very rare reported cases of hypoglycemia with this medication. The mechanism for glucose dysregulation in general is poorly understood. Hypoglycemia is proposed to be a result of insulin hypersecretion due to systemic increases in insulin resistance. In patients with prior risk factors for hypoglycemia, previous episodes of unexplained syncope, obesity or pre-existing diabetes, prescribing physician to re-evaluate the role of Olanzapine over another agent with similar efficacy in treatment as an antipsychotic.

RARE DOUBLE BACTEREMIA WITH STREPTOCOCCUS PNEUMONIAE AND CAPNOCYTOPHAGA SPUTIGENA

Reiko Sakama[1]; Mizuki Uchiyama[1]; Yuichi Takahashi[1]; Taiju Miyagami[1]; Hiromizu Takahashi[2]; Yuki Uehara[1]; Toshio Naito[1]. [1]Juntendo University, Tokyo, Japan; [2]Juntendo university, Tokyo, Japan. (Control ID #2701779)

LEARNING OBJECTIVE #1: An immunocompromised patient with double bacteremia can have a lethal clinical course.

CASE: A 75-year-old man with a history of type 2 diabetes mellitus and alcoholic hepatitis was admitted to our hospital due to a high fever and dyspnea. Two months prior to admission, he had been diagnosed with T3 stage esophageal cancer after evaluation for dysphagia. Three days before admission, he became feverish and developed dyspnea that brought him to our emergency room. On admission, he was alert and oriented. His temperature was 38°C, blood pressure 152/85 mmHg, heart rate 109/min, respiratory rate 26/min, and percutaneous arterial oxygen saturation was 90% with 6 L/min of oxygen by mask. Heart sounds were normal. Coarse crackles were heard over the right lung. Chest X-ray and CT scan showed bilateral pleural effusions and consolidation. He was admitted for severe pneumonia with immediate initiation of meropenem, but he became unconscious with severe hypoxemia in a few hours. Mechanical ventilation was started. Two sets of blood cultures on admission yielded *Streptococcus pneumoniae* and *Capnocytophaga sputigena* after 11 hours and 65 hours of incubation, respectively. Based on antimicrobial susceptibility testing, meropenem was switched to ceftriaxone. The high fever persisted with no evidence of abscess formation and deep vein thrombosis on whole body enhanced CT. No vegetations were found on transthoracic echocardiography. He recovered temporarily and was extubated. He again became unconscious and hypoxemic a week later, and noninvasive positive pressure ventilation was started. Multiple hemorrhagic infarct lesions on head MRI and acute myocardial infarction of the left inferior wall were found. He was re-intubated, but he died the following day.

IMPACT: This is the first report of double bacteremia with *Streptococcus pneumoniae* and *Capnocytophaga sputigena*. Bacteremia with these two pathogens in an immunocompromised patient could cause rapid deterioration, multiple embolic phenomena, and a fatal outcome even with adequate treatment.

DISCUSSION: We experienced a treatment challenge in an immunocompromised patient who was undergoing evaluation for esophageal cancer and had untreated type 2 diabetes mellitus. This patient showed rapid deterioration of consciousness and dyspnea within a few hours. The patient was started on antimicrobials quickly, but multiple emboli, possibly septic, occurred, along with endovascular damage and coagulopathy. Invasive streptococcal infection is known for its high mortality rate in patients with comorbidities and age older than 65 years. *Capnocytophaga* species are generally known as invasive pathogens in immunosuppressed patients, though *Capnocytophaga sputigena* is part of human oral flora, and the clinical course of infection has not been well described. Bacteremia with these two pathogens could show a lethal clinical course. Thus, further studies of bacteremia with multiple pathogens are needed.

RARE PANCREATIC MASSES

Stephen Catalya; Sunil Tulpule; Sabrina Arshed; Qiang Nai. Raritan Bay Medical Center, Rahway, NJ. (Control ID #2701729)

LEARNING OBJECTIVE #1: Recognize atypical presentations of tuberculosis.

CASE: Here is an 86 year old male who presented with abdominal pain, nausea, vomiting, and malaise for 5 days. His past history was significant for taking cyclosporine (known to reactivate tuberculosis) for a skin rash and immigrating from the Philippines in infancy. A computerized tomography scan of his abdomen done during the course of his stay showed a 2.2cm × 3.8cm cystic mass in the tail of the pancreas. Initially the mass was thought to be malignant; however a biopsy done as an outpatient showed no malignant cells. Ascitic fluid sampled was negative for acid fast bacilli. However, further testing, including polymerase chain reaction, revealed the presence of tuberculosis protein. This led to the diagnosis of pancreatic tuberculosis. He was started on rifampin, isoniazid, pyrazinamide, and ethambutol. However, due to worsening renal failure and failure to thrive from poor PO intake, his condition continued to deteriorate as an outpatient. A pleural effusion developed leading to respiratory failure. Given the poor prognosis, care was withdrawn two weeks after readmission (without the effusion being sampled) and the patient then died.

IMPACT: He was born in a country endemic with tuberculosis but moved to the US at a young age and then developed symptoms decades after his last known exposure. The lesion was also located in a location rarely documented in the literature, the tail. Given its scarcity, pancreatic tuberculosis does not appear in most differential diagnosis of a pancreatic mass. Usually, the first thought is malignancy when seeing a mass. Adding to the confusion is the fact that most tuberculous lesions appear as a mass on imaging, causing a dangerous delay in diagnosis. Evaluation of such masses, especially if fluid is present in the area along with suspected tuberculosis, should include polymerase chain reaction testing as the assay is highly specific and can give a true positive result when other results including acid fast bacilli smears are negative. Acid fast bacilli smears are only positive in 20-40% of cases.

DISCUSSION: As a clinical entity pancreatic tuberculosis is very rare and the presentation here is atypical compared to published cases. Even in countries endemic with tuberculosis, isolated pancreatic tuberculosis accounts for less than 5% of total cases. A review of case reports shows a dearth of cases in the US, and one study found that cases are usually young adults who are recent immigrants from countries endemic with tuberculosis. Furthermore, published reports show that the pancreatic masses found to be tuberculous are located in

the head, not in the tail of the pancreas. This case does not fit the typical profile outlined in that study and other published case reports raising the absolute need to be aware of both from epidemiological and clinical standpoints. What appears to have been overlooked is that this patient was taking cyclosporine, predisposing him to tuberculous infection.

RARE TRANSUDATIVE CHYLOTHORAX IN THE SETTING OF CIRRHOSIS Jonathan Dewald[1]; Benjamin Verzi[1]; Anil Singh[2]; Trey La Charité[1]. [1]Univerity of Tennessee Medical Center Knoxville, Knoxville, TN; [2]University of Tennesee, Knoxville, TN. (Control ID #2704855)

LEARNING OBJECTIVE #1: Chylothorax is typically an exudative process secondary to trauma or malignancy. We present a case of a transudative chylothorax in a female patient with cirrhosis. This case will help recognize pleural effusions with underlying cirrhosis, and assess for chylothorax which requires different management than a typical transudative pleural effusion.

CASE: A 62-year-old female with history of cirrhosis secondary to nonalcoholic steatohepatitis (NASH) with ascites (SAAG 2.5–2.9 g/dL) and diabetes mellitus type 2 presented with 3 days of worsening dyspnea on exertion and right sided pleuritic chest pain. Initial chest radiograph noted a moderate right-sided pleural effusion. Patient underwent thoracentesis with alleviation of dyspnea. Pleural fluid was milky white with slight pink tinge. Pleural fluid studies indicated a lymphocyte predominant transudative effusion based on Light's Criteria with a triglyceride level of 431 mg/dL and cholesterol level of 39, diagnostic for chylothorax. Cytology was negative for malignant cells. AFB and fungal cultures were negative. There was no history of thoracic surgery or trauma and lymphocintigraphy was performed with no evidence of chylous leak. CT scan of the thorax and abdomen was negative for lymphadenopathy or masses. In view of liver cirrhosis, this transudative chylothorax was attributed most likely to liver cirrhosis. Diuretic therapy, along with low fat, medium-chain triglyceride diet was initiated. Patient remained asymptomatic over the next 24 hours and discharged home.

IMPACT: Transudative chylothorax is rarely associated with liver cirrhosis and should be considered in differential diagnosis as this can change the workup as well as treatment plan.

DISCUSSION: Chylothorax is a rare cause of pleural effusion most commonly caused by trauma or neoplastic interruption of the thoracic duct. Transudative chylothoraces is exceptionally rare with few cases reported thus far in the literature associated with liver cirrhosis. Management involves reduction of portal hypertension with medical management and thoracentesis for symptomatic relief. Octreotide has been used in case series with variable responses, and is not considered standard of care at this time. Transjugular intrahepatic portosystemic shunt (TIPS) is reserved for refractory cases. Tube thoracostomy drainage is contraindicated as this may lead to significant loss of nutrients and results in immune suppression.

RECENT ADVANCES IN THE TREATMENT OF CHRONIC TOPHACEOUS GOUT.

Niyati M. Gupta[1, 2]; Sreelakshmi Panginikkod[3]; Harsh Rawal[4]; Sahil Gehlot[2]; Malav P. Parikh[1]. [1]Cleveland Clinic Foundation, Cleveland, OH; [2]Grant Medical College and Sir J.J. Group of Hospitals, Mumbai, OH; [3]Presence Saint Francis Hospital, Evanston, IL; [4]University of Illinois at Urbana Champaign, Champaign, OH. (Control ID #2694673)

LEARNING OBJECTIVE #1: Recognize the role of Pegloticase and Anakinra in treatment of chronic tophaceous gout

CASE: A 55-year-old male with a history of chronic tophaceous gout (CTG) presented to the hospital with debilitating pain related to polyarticular gout flare. He has been previously treated with allopurinol, for which he developed resistance and had adverse reaction to Febuxostat. The patient noted no improvement on colchicine and low dose prednisone. Due to severe CTG affecting the activities of daily living and articular loss of motion, patient was deemed eligible for a trial drug, "Pegloticase". Initial infusions of Pegloticase were well tolerated, however he developed severe flare after fourth infusion requiring hospitalization. He reported 10/10 pain in bilateral knees, hands, elbows and shoulders. On examination, tophi were present at bilateral wrists, elbows and knees along with joint swelling, tenderness and erythema. He was afebrile with a WBC count of 8.4k/uL and serum uric acid levels of <0.2mg/dL. The patient was thought to have acute gout flare related to Pegloticase infusion. He was treated with 2 doses of Anakinra 100mg QD, showing marked symptomatic improvement within few hours. The swelling, pain and erythema of the joints improved significantly and he was able to ambulate around the room.

IMPACT: How did this case change my practice? Pegloticase is a recently approved agent for the treatment of chronic tophaceous gout. In the initial phase of treatment, it can cause gouty flare related to uric acid mobilization. Anakinra can be an effective agent for management of gout attack in these situations. It is also a good alternative for treating gouty arthritis in patients for whom conventional therapies are ineffective or contraindicated.

DISCUSSION: Gout is an inflammatory arthritis characterized by self-limiting but excruciatingly painful acute attacks. Hyperuricemia is the most important risk factor for developing gout. Colchicine, nonsteroidal anti-inflammatory drugs (NSAIDS) and corticosteroids are standard approaches for terminating the acute gouty attack. Xanthine oxidase inhibitors or uricosuric drugs are effective as a chronic suppressive therapy. However, additional therapy is required in patients with resistant CTG. Pegloticase is a recombinant, uricase enzyme, which metabolizes uric acid into soluble allantoin for the excretion by kidney. This results in lytic decrease of serum uric acid, leading to dissolution of tophi. It is intended for use in resistant CTG. It has been reported that about 77% of patients treated with Pegloticase experience gout flares in the initial three months related to urate mobilization. Monosodium urate (MSU) crystals induce tissue inflammation and gout flare via induction of IL-1. This led to investigation weather IL-1 blockade could inhibit inflammation provoked by MSU. Anakinra is one such IL-1 inhibitor and has shown rapid relief of inflammatory gout symptoms in patients where conventional therapies are ineffective or contraindicated.

RECOGNIZING OSTEOARTHRITIS WITH CHRONIC CALCIUM PYROPHOSPHATE DIHYDRATE CRYSTAL DEPOSITION (CPPD) AS A DIFFERENTIAL AND ASSOCIATED THERAPIES IN ELDERLY PATIENT WITH KNEE PAIN Priya Vijayvargiya[2]; Adam P. Sawatsky[1]. [1]Mayo Clinic, Rochester, MN; [2]Mayo clinic, Rochester, MN. (Control ID #2707608)

LEARNING OBJECTIVE #1: Include osteoarthritis with CPPD in the differential for knee pain

LEARNING OBJECTIVE #2: Consider alternative therapies in this patient population that is commonly treated similarly to osteoarthritis.

CASE: The patient is a 77-year-old female with a past medical history significant for chronic low back pain, peripheral neuropathy, and chronic left knee pain, presumed to be osteoarthritis and treated with meloxicam. Given the risks of long-term meloxicam use in elderly patients, she discontinued the medication and underwent a course of acetaminophen, quadriceps strengthening exercises and topical diclofenac sodium gel. She presented 1 month later with acute worsening of her chronic left knee pain, with no fevers, chills or night sweats. At that encounter, she had difficulty with ambulation and the physical exam of her left knee demonstrated a joint effusion, but no erythema, restriction of movement, or joint laxity. Left knee radiograph demonstrated degenerative arthritis with moderate medial compartment narrowing, genu varus alignment, chondrocalcinosis, and a moderate-sized joint effusion. Knee aspiration revealed a cell count of 276 with microscopy findings of intracellular CPPD crystals. Based on this evaluation, we made the diagnosis of OA with CPPD. She received intra-articular steroids with complete resolution of her knee pain. Within a month, her pain started to resume and started ibuprofen with stable pain control for 1 year. She then developed an acute flair of left knee pain and effusion, currently being treated with colchicine.

IMPACT: OA and CPPD have similar physical exam findings: joint enlargement, effusion, crepitus and restricted movement. CPPD diagnosis is based on imaging studies or joint aspiration. With an accurate diagnosis, alternative treatment options can be made available, impacting disease progression and patient quality of life.

DISCUSSION: CPPD is diagnosed later in life, the average age of diagnosis being 72 years with no significant gender difference.(1) Approximately 50% of patients with CPPD have evidence of OA. OA with CPPD commonly affects the knees, followed by wrists. Presentation either follows intermittent flairs or proceeding with the natural progression of OA. (2, 3) Non-invasive diagnostic tests include: radiographs, ultrasound (US), and dual energy CT scan. Knee radiographs have been reported to only recognize 40% of clinically relevant chondrocalcinosis. Recent studies report US has > 80% sensitivity of detecting chondrocalcinosis as compared to radiography alone. Dual energy CT scan is predominantly utilized in research studies. The diagnosis of OA with CPPD helps with treatment when the patient has recurrent episodes of flairs not resolved with steroid injections or conservative therapy. In these patients, we recommend US followed by radiography, depending on availability.(4) Treatment for OA with CPPD flairs includes NSAIDs, intra-articular steroids, colchicine and systemic steroids, and require small dose of NSAIDs for maintenance therapy. (2,3)

RECURRENT PERICARDIAL EFFUSION IN THE SETTING OF UNCONTROLLED HYPOTHYROIDISM Ekta Kakkar; Nalini Ram. Baylor College of Medicine, Houston, TX. (Control ID #2706280)

LEARNING OBJECTIVE #1: It is important to treat uncontrolled hypothyroidism to prevent many cardiac complications including pericardial effusions, heart failure, and reduced contractility.

CASE: A 43-year-old female presented to the emergency room with a history of progressive dyspnea on exertion for 3 months. Bedside echo confirmed the presence of a large pericardial effusion with RV collapse consistent with tamponade. Transthoracic echo showed preserved ejection fraction. The patient had been diagnosed with autoimmune hypothyroidism during her pregnancy about 9 years prior to presentation and was found to have a large pericardial effusion on imaging by CT scan. At that time she complained of shortness of breath, weight gain, and fatigue. She had declined pericardiocentesis and was subsequently lost to follow up. She was on levothyroxine till 4 years ago and had stopped it due to weight loss and itching. At current presentation, she endorsed diffuse hair loss, menorrhagia, cold intolerance, intermittent constipation, weight gain, and fatigue. Physical exam was notable for delayed relaxation phase of deep tendon reflexes, distant heart sounds, JVD, and a displaced PMI. She did not however have evidence of hemodynamic instability. Her TSH was elevated to 53 uIU/mL (normal 0.36–3.74 uIU/mL), free T4 was 0.16 ng/dL (0.76–1.46 ng/dL), and total T3 was <10 ng/dL (normal 60–181 ng/dL). Her thyroid peroxidase antibody was positive. Emergent pericardiocentesis was performed and 1600cc of pericardial fluid was removed and sent for analysis. She was started on levothyroxine. Cytology, cultures, and cell count of the pericardial fluid were negative for infection or malignancy. Repeat transthoracic echo showed resolution of the effusion. Importance of compliance with levothyroxine was emphasized, and the patient was discharged with significant improvement in her symptoms.

IMPACT: Pericardial effusion is a rare complication of hypothyroidism with an incidence of 3–6%. Tamponade in a patient with a large effusion due to uncontrolled hypothyroidism is even rarer. It is important to have a high suspicion of hypothyroidism in patients with pericardial effusions with unclear etiology. Thyroid replacement hormone is sufficient for resolution of such pericardial effusions except in the setting of tamponade when emergent pericardiocentesis must be performed.

DISCUSSION: Hypothyroid patients have increased systemic capillary permeability which can lead to the development of a pericardial effusion. In previous case reports, the pericardial fluid in patients with uncontrolled hypothyroidism has also been shown to have an elevated cholesterol level due to the role of thyroid hormone in lipid metabolism; however, this is not the case in our patient. Studies have shown that reduced serum T3 levels are a strong predictor of cardiovascular mortality. The heart relies on hepatic conversion of T4 to active T3. Cardiac contractility and cardiac output are dependent on T3. Thus, it is important to treat hypothyroidism.

RECURRENT PNEUMOCYSTIS PNEUMONIA CAN DEVELOP IN A HUMAN T-CELL LYMPHOTROPIC VIRUS TYPE-1(HTLV-1) CARRIER Motoshi Fujiwara[2, 1]; Yoshinori Tokushima[1]; Naoko E. Furukawa[1]; Masaki Tago[1]; Yoshiaki Nakahara[2]; Shu-ichi Yamashita[1]. [1]Saga University Hospital, Saga, Japan; [2]Yuai-kai foundation and Oda Hospital, Kashima, Japan. (Control ID #2700007)

LEARNING OBJECTIVE #1: To know the causes of recurrent opportunistic infections such as Pneumocystis pneumonia.

CASE: A 49-year-old Japanese woman without significant medical history admitted with shortness of breath. She had cough and dyspnea with gradual exacerbation for three weeks. The physical examination revealed slight fine crackles in her both lungs without systemic lymphadenopathy. Chest CT showed bilateral diffuse ground-glass opacity. Laboratory findings were as follows; white blood cell count was 10.000/μl without abnormal lymphocyte, β-D glucan was over 300pg/ml, KL-6 was 1780U/ml, HIV antibody was negative and HTLV-1 antibody titers were elevated of 1:256. Systemic administration of glucocorticoid and trimethoprim- sulfamethoxazole were effective for her symptoms. Therefore, we diagnosed Pneumocystis pneumonia

occurred in a HTLV-1 carrier. She got a follow-up observation and experienced dry cough 10 months later again. Chest radiography revealed ground glass opacity. Once normalized β-D glucan after first admission rose to over 300pg/ml again. Broncho alveolar lavage (BAL) and transbronchial lung biopsy (TBLB) were performed which revealed the presence of pneumocystis cysts with Grocott methenamine silver staining. The patient improved with the same treatments as before.

IMPACT: What does this case add to the literature? HTLV-1 without developing lymphoma or leukemia could lead to subclinical immunodeficiency state that could cause opportunistic infections such as Pneumocystis pneumonia.

DISCUSSION: Representative endemic regions of HTLV-1 are southwestern part of Japan, sub-Saharan Africa, South America, the Caribbean area, several parts in Middle East and Australo-Melanesia. Among them, southwestern part of Japan is one of the most highly endemic regions, and the number of Japanese HTLV-1 carriers was estimated to be at least 1.08 million in 2011. Although infection with HTLV-1 causes adult T-cell leukemia/lymphoma (ATLL), which has four subtypes, acute, lymphomatous, chronic, and smoldering, most patients remain asymptomatic career. Naturally, ATLL tends to cause immune-deficient state. However, even asymptomatic career could be complained with opportunistic infections, such as strongyloidiasis. Although Pneumocystis pneumonia(PCP) is reported to be a rare complication of HTLV-1 career, our patient shows the importance of asymptomatic careers as one of the causes of PCP, and furthermore, the necessity of examination of the presence of HTLV-1 infection in the patient with PCP without causes of immunodeficiency.

RECURRENT PRIMARY HYPERPARATHYROIDISM IN MULTIPLE ENDOCRINE NEOPLASIA TYPE 1 Hyon Kim; beatrice wong; Xiangbing Wang. Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ. (Control ID #2707092)

LEARNING OBJECTIVE #1: Manage Multiple Endocrine Neoplasia Type 1 (MEN1) complicated by recurrent primary hyperparathyroidism (PHPT)

CASE: A 34-year-old woman originally presented with persistent headaches, blurry vision, galactorrhea and amenorrhea. Magnetic resonance imaging (MRI) of her brain showed a large pituitary mass with compression of the optic chiasm. Laboratory studies confirmed a prolactinoma with an elevated prolactin level of 3767 ng/mL. She was treated with partial hypophysectomy, bromocriptine, cabergoline, and external beam radiation. She was also found to be hypercalcemic (10.6-11 mg/dL) with lab studies consistent with PHPT: intact parathyroid hormone (iPTH) 93 pg/mL (normal 15–75 pg/mL) and urine calcium 384 mg/24h. Thyroid ultrasound and Sestamibi scan revealed parathyroid adenomas that were resected surgically. Post-operatively, her calcium (up to 11.4 mg/dL) and iPTH levels (up to 142 pg/mL) remained consistently elevated. Repeat thyroid ultrasound identified another 1.8 × 0.6 × 1.8 cm parathyroid adenoma leading to a second parathyroidectomy. Despite these interventions, hypercalcemia recurred again. A third parathyroidectomy was performed with implant of the last parathyroid gland into her forearm. Subsequently, she developed severe hypocalcemia and resultant hyperparathyroidism that has been difficult to manage with calcium and vitamin D supplementation. Genetic testing for MEN1 confirmed a heterozygous mutation of exon 10 codon 468. She also had a synaptophysin and chromogranin A positive pancreatic islet cell tumor removed with a spleen-saving distal pancreatectomy.

IMPACT: The optimal management of patients with MEN1 is an evolving conversation limited by the lack of randomized trials due to its rare prevalence. This case highlights some of the challenges in managing these patients and the importance of coordination of care across multiple specialties.

DISCUSSION: MEN1 is a rare autosomal dominant disorder associated with an increased risk of premature death usually from related complications. This patient had recurrent PHPT disease that was difficult to manage despite three separate parathyroidectomies. The optimal surgical management of PHPT in MEN1 patients is controversial. A conservative surgical approach has been advocated to reduce the risk of permanent hypoparathyroidism and hypocalcemia, in particular with sporadic PHPT. However, multiple parathyroidectomies are associated with poor prognosis in MEN1. There is growing literature supporting initial 3.5-gland subtotal parathyroidectomy or total parathyroidectomy with autotransplantation due to particularly high rates of recurrent PHPT in MEN1. This case lends support to more aggressive initial surgical management of PHPT in MEN1.

RECURRENT RHEUMATOID PLEURAL EFFUSIONS COMPLICATED BY MYCOBACTERIUM HECKESHORNENSE INFECTION
Daniel J. Howell[2]; Benjamin T. Galen[1]. [1]Albert Einstein College of Medicine, Bronx, NY; [2]Montefiore Medical Center, Bronx, NY. (Control ID #2706070)

LEARNING OBJECTIVE #1: Recognize the challenges and complications of treating rheumatoid pleural effusions

LEARNING OBJECTIVE #2: Diagnose and treat nontuberculous mycobacterial pulmonary infection

CASE: A 41 year old man with a history of rheumatoid arthritis (RA) presented with dyspnea and tachycardia. During the ten months prior to admission he had developed recurrent pleural effusions, which did not improve with adalimumab. Over the course of several hospital admissions, multiple thoracenteses were performed, which resulted in hydropneumothorax on the right and loculated pleural effusion on the left. A pleural fluid specimen eventually grew *Mycobacterium heckeshornense*. He began long-term rifampin, azithromycin, and ethambutol for nontuberculous mycobacterial (NTM) infection and was discharged to a rehabilitation facility. On this admission, he was markedly cachectic and dyspneic. Lung examination revealed dullness to percussion and reduced air entry at both bases. Serum albumin was 2.9 g/dL (3.7–5g/dL) and Rheumatoid Factor (RF) was elevated to 957 IU/ml (0–22IU/ml). Antibodies to CCP and Ro were positive. A chest tube was placed and pleural fluid analysis showed 560,000 RBCs, Protein 6.1 g/dL, LDH 2456 U/l, Cholesterol 67 mg/dl, pH 8.0 and glucose 2 mg/dl, Despite intrapleural fibrinolytic therapy, repeat chest CT showed persistent left-sided loculated pleural effusion and lung entrapment. He was discharged for rehabilitation and continued anti-NTM therapy

IMPACT: This case highlights the challenge of treating symptomatic pleural disease in RA especially in the setting of NTM infection.

DISCUSSION: Fewer than 5% of patients with RA develop rheumatoid pleural effusions (RPE), but risk factors include male sex and a high RF titer. Typical RPE are small and asymptomatic but they can be severe. RPE may be present in the absence of synovitis. The pleural fluid is typically exudative and straw colored, but can be bloody. Pleural fluid protein is usually high (>4g/dL), glucose levels low (<60mg/dl), ph < 7.20, with elevated LDH (>700 IU/L) and high cholesterol (>65 mg/dL). Treatment options include disease modifying anti-rheumatic drugs (DMARDs), systemic or intrapleural steroids, biologic

agents, or surgical drainage. Complications of RPE include infection, lung entrapment, fibrothorax, and persistent pneumothorax. Patients treated with anti-TNF medications like adalimumab are also susceptible to NTM infections. *Mycobacterium heckeshornense* was first identified in 2000. Spondylodiscitis due to *Mycobacterium heckeshornense* has been reported in a patient with RA on etanercept, but pleural infection due to this species has not previously been reported. There are no specific guidelines on the treatment of Mycobacterium heckeshornense infection and drug choices are based on case reports and susceptibility testing. NTM infection therefore presented a barrier to the medical management of RPE.

RECURRENT STROKE DUE TO VASCULAR STEAL FROM EATING LUNCH Andrew Kelly; Bryden Considine. University of Connecticut, Hartford, CT. (Control ID #2706901)

LEARNING OBJECTIVE #1: Outline a rare occurence and management strategies for a patient with vascular steal causing a clinical picture consistent with recurrent ischemic stroke.

CASE: An 82 year-old male with history of coronary artery disease status post bypass, prior stroke 30 years prior, hypertension and heart failure presented to the hospital due to multiple episodes of dysarthria with left upper and lower extremity weakness. The patient had an endoscopy and a colonoscopy a week prior to admission and went home, developing slurred speech one day later. His family thought it was due to the prior day's anesthesia however when it happened on consecutive days he was brought to the hospital. A head CT was negative for acute findings. A CT angiogram revealed bilateral vertebral artery stenosis (no flow in right vertebral artery with atherosclerotic disease and possible narrowing at craniovertebral junction in the left vertebral artery). A cochlear implant precluded obtaining any magnetic resonance imaging. While in hospital the patient developed recurrent epsiodes of left arm and leg weakness with dysarthria always around noon. A stroke activation was called four days out of seven, all around lunch time. Each time, a head CT was obtained without any evidence of changes. His systolic BPs at those times were all in the 140–145 mmHg range, much lower than 170–180 mmHg where his blood pressure ran normally. His symptoms would resolve over an hour when given boluses of 1 liter of normal saline. It was believed that the patient had recurrent episodes of vascular steal from blood shunting and redistributing to the gastrointestinal tract after his lunch, his biggest meal of the day.

IMPACT: This case provides a rare opportunity to individualize blood pressure management and develop management strategies for a patient with severe vascular disease developing stroke-like symptoms due to vascular redistribution of blood and relative hypotension.

DISCUSSION: Vascular steal is a well-known phenomena and occurs commonly in arterial systems that have known stenosis. It has been documented in subclavian steal syndrome where symptoms of upper extremity ischemia occur due to subclavian stenosis. Similarity, vascular access steal can occur when blood flow distal to an AV fistula in a dialysis patient becomes compromised and can cause limb pallor. This case outlines a unique occurrence where a patient with extensive vascular disease and stenosed vertebral arteries developed recurrent steal from a relative change in distribution of blood flow to the gastrointestinal tract after his main meal of the day. At first the symptoms resolved with fluid boluses to increase blood pressure. It was hoped that eventually the body would be able to adapt to this and be able to preferentially increase blood flow to the brain, but a management strategy the patient had to rely on was smaller more frequent meals throughout the day instead of one main meal at lunch and also positional changes when symptoms developed including lying down.

RECURRENT SYNCOPE IN A 23-YEAR-OLD: NOT THE USUAL SUSPECT Natasha Adlakha; Ala Eltom M.D.; Chad Kliger; Robert Glatter. Lenox Hill Hospital, New York, NY. (Control ID #2702922)

LEARNING OBJECTIVE #1: Diagnose a unique presentation of an atrial septal defect (ASD)

LEARNING OBJECTIVE #2: Recognize cardiac and vasovagal syncope can co-exist

CASE: A 23-year-old female with no medical history presented after witnessed loss of consciousness of 1 min while sitting down during eyebrow waxing. She experienced multiple syncopal episodes triggered by pain, stress, or blood, starting as early as seven years old, and occurring monthly for the last six months. She reported excessive fatigue, dyspnea with one flight of stairs, and recalled syncope more than once while climbing stairs without premonitory symptoms. She had fixed splitting of S2 on exam. Electrocardiogram showed normal sinus rhythm, right axis deviation and an incomplete right bundle branch block. Transthoracic and transesophageal echocardiograms showed elevated right ventricular (RV) end-diastolic pressure, right atrium and ventricular dilation, a large 2.6cm ostium secundum ASD with significant left to right shunt, Qp:Qs 4:1, and mild pulmonary hypertension. The structural heart disease team performed percutaneous closure of the defect and she has been asymptomatic since intervention.

IMPACT: We present a unique diagnosis of ASD with recurrent syncope. ASDs often present with fatigue, dyspnea, right heart failure but rarely syncope. There are only three case reports that associate ASD with syncope. Two are written in native language of Japanese and German. The third is from 1958 and associates syncope in a 22-year-old with undiagnosed ASD secondary to latent heart block. This case raises physician awareness of syncope as an uncommon and rarely documented symptom for ASD presentation.

DISCUSSION: Atrial septal defect (ASD) is one of the most common congenital heart disease anomalies in adults. Very small ASDs (<5mm diameter) are clinically insignificant and >10mm are symptomatic in the third decade of life. Symptoms on diagnosis include dyspnea, fatigue, dysrhythmias, or right heart failure. This patient presents with both vasovagal and cardiac syncope. The mechanism of vasovagal syncope is triggering a sympathetic response from stress, dehydration, or vasodilation from warm environment. This leads to hyperdynamic contractions and activates a paradoxical vagal response of vasodilation and relative bradycardia with a transient decreased cardiac output, perfusion to the brain and subsequent loss of consciousness. A significant ASD shunt results in right sided overload, ventricular enlargement, and septal shift towards the left ventricle (LV) during diastole. This impairs LV filling, causing reduced LV stroke volume, cardiac output and increased left to right shunting. Our patient had a sizeable, hemodynamically significant shunt and was subject to reduced stroke volume and cardiac output. During vasovagal episodes, cardiac output was reduced further with extreme sensitivity to hemodynamic changes and lower threshold for syncope. The significant shunt also resulted in poor exercise tolerance and sudden loss of consciousness on exertion.

REFRAMING REFRACTORY ANOREXIA NERVOSA AS A CHRONIC ILLNESS: A PALLIATIVE APPROACH Mina F. Tanaka. Massachusetts General Hospital, Boston, MA. (Control ID #2705607)

LEARNING OBJECTIVE #1: Explain the morbidity & mortality associated with eating disorders (ED).

LEARNING OBJECTIVE #2: Recognize role of palliative care in broad range of life threatening illnesses and identify patients who would benefit from palliative care referral.

CASE: 50F w/h/o anorexia nervosa (AN) since age 14 w/multiple involuntary admissions on the ED unit was admitted to general medicine unit w/electrolyte disarray, bradycardia, hypotension, and failure to thrive. ROS: 20lb wt loss in last few months. PMH: AN, depression. SH: lives alone but brother is court-appointed guardian. Meds, FMH, allergies: non-contributory. Of note, during previous admission for FTT, she had two PEA arrests, hypoxemic respiratory failure s/p trach and decannulation, and malnutrition requiring PEG. Exam notable for emaciated appearance. Labs K 2.6, CO2 33; SBPs 60s, HRs 40s–50s, BMI 13. Her metabolic disarray, hypotension, and bradycardia responded well to aggressive repletion and fluid resuscitation. She declined transfer to an inpatient ED unit, though this was thought to be necessary to achieve wt gain goal. Ethics committee, psychiatry, and palliative care conceptualized her illness as "end stage AN" due to continued self-restrictive eating w/severe complications despite repeated treatments. After multiple family meetings, patient was transitioned to DNR/DNI and discharged with bridge to hospice with focus on palliative options. This was seen as an ethical choice by all parties, including the patient, given the low likelihood of full meaningful recovery. Eight months later, she is followed closely by her PCP and psychiatrist and has avoided further hospitalizations.

IMPACT: This case illustrated that as those in the front lines, general practitioners must be able to recognize patients appropriate for prompt referral to palliative care specialists no matter the underlying condition.

DISCUSSION: Although AN is relatively rare, those afflicted with the disorder are faced with a wide range of complications, from GI to cardiac dysfunctions. Patients who suffer from ED have 2x higher all-cause mortality compared to the general population. Less than 50% of those who survive recover from their disorder. Despite the dismal prognosis, there has been little focus on palliative care and hospice as viable options for patients with chronic ED. Center for Advance Palliative Care proposes set of criteria that can help clinicians identify patients who would benefit from general palliative assessment, with primary criteria (probable death w/in 12 months, frequent admissions for same condition, admission for difficult-to-control symptoms, complex care requirement, decline in function/feeding/weight) and secondary criteria (admission from long-term care facility, older cognitively impaired patient with hip fracture, metastatic/locally advanced incurable cancer, chronic home O2 use, out-of-hospital cardiac arrest, current/past hospice program enrollee, limited social support, no history of completing an advance care planning document).

RENAL INVOLVEMENT IN ANAPLASMOSIS

Sylvia V. Alarcon; Jonila Murati; Gabriela A. Ciofoaia; Preeyanka R. Sundar. Berkshire Medical Center, Pittsfield, MA. (Control ID #2707072)

LEARNING OBJECTIVE #1: Patients with anaplasmosis can developed a broad range of renal manifestations.

LEARNING OBJECTIVE #2: Early recognition and treatment of anaplasmosis is essential in preventing severe renal complications.

CASE: Case 1. A 62 year-old man presented with fever, chills, fatigue, shortness of breath, cough, anorexia, abdominal bloating and diarrhea. Labs revealed thrombocytopenia, elevated venous lactate, elevated liver enzymes, mild elevated creatinine kinase and acute kidney injury. Urine microscopy showed granular casts consistent with acute tubular necrosis. Renal ultrasound showed no abnormalities. Peripheral blood smear showed inclusion bodies suggestive of anaplasmosis, which was confirmed by DNA PCR. During hospital course his renal function declined rapidly, but improved with aggressive hydration and doxycycline. Case 2. A 69 year-old male presented with fever, sweating, headache, increased urinary frequency annd diarrhea. Labs showed thrombocytopenia, elevated liver enzymes, elevated LDH, elevated venous lactate and acute kidney injury. Peripheral blood smear suggested anaplasmosis, later confirmed by DNA PCR. Microscopic urianalysis was suggestive of acute tubular necrosis. There was no sonographic evidence of hydronephrosis, and the remaining tests indicated there were no other sources of infection. His renal function continued to rapidly deteriorate; he became oliguric, developed worsening azotemia, metabolic acidosis, and fluid overload requiring hemodyalisis. His renal function recovered following a month of hemodialysis and anaplasmosis treatement.

IMPACT: Anaplasmosis can present with renal involvement from mild azotemia to renal failure therefore prompt diagnosis and treatment is necessary to prevent serious complications.

DISCUSSION: Anaplasmosis is a tick-borne disease caused by obligate intracellular bacteria of the genera Anaplasma, in the Northeast and upper Midwest United States. Typically the clinical manifistations of anaplasmosis vary from asymptomatic to nonspecific symptoms such as fever, confusion, general weakness and gastrointestinal symptoms; however, it can cause severe complications such as renal dysfunction. Common laboratory findings are thrombocytopenia, leukopenia and elevated liver enzymes. Severe complications develop in 3% of patients with anasplasmosis; of those complications 20% are attributed to renal dysfunction. Renal involvement can occur in various degrees. Most of the cases are mild azotemia; however renal failure has rarely been reported. The pathophysiology of renal dysfunction is unknown but cytokine activation, sepsis, intravascular volume depletion, acidosis, renal vasoconstriction and nephrotoxins may contribute to acute kidney injury. The range in severity of complications can be explained by genetic differences in the A phagocytophilum strains. The recommended treatment for anaplasmosis is doxycycline 100mg twice daily for 10 days. Prompt recognition and treatment of disease is necessary to prevent serious complications such as renal failure.

REVERSIBLE METHAMPHETAMINE-ASSOCIATED CARDIOMYOPATHY (MAC) Brigitte N. Sallee[2]; Muhammad R. Nazir[1]; Larissa Verda[1]. [1]Weiss Memorial Hospital, Chicago, IL; [2]Weiss Hospital, Chicago, IL. (Control ID #2688954)

LEARNING OBJECTIVE #1: Recognizing MAC as an increasing cause of new onset cardiomyopathy.

CASE: A 54 year old man with a history of HIV on highly active antiretroviral therapy with no prior personal or familial cardiac history presented with

progressively worsening dyspnea on exertion and dry cough for a few days. Physical exam findings were consistent with classic acute heart failure: diffuse lung crackles, tachycardia, and S3 gallop. EKG revealed sinus tachycardia with nonspecific changes, and a chest x-ray demonstrated mild cardiomegaly and redistribution of the pulmonary vasculature in addition to perihilar haziness. Systolic dysfunction was suspected and confirmed by echocardiogram which revealed a low ejection fraction of 15-20% with diffuse hypokinesis. Laboratory findings were remarkable for a mild creatinine elevation and mild troponin elevation. Urine toxicology analysis was positive for methamphetamine, a finding consistent with the patient's social history of regular intravenous crystal methamphetamine use. He underwent a cardiac catheterization which revealed mild non-obstructive coronary artery disease. Standard heart failure management including a diuretic, β-blocker, angiotensin-converting enzyme inhibitor, and spironolactone was initiated. The patient improved symptomatically and was discharged home after extensive counselling on drug use and compliance with medications. The patient subsequently ceased using methamphetamine. Twenty-two months later, he again underwent a cardiac workup where he was found to have an ejection fraction of 55% with normal wall motion despite being non-compliant with his medical therapy for one month prior. Considering the patient's history and fast improvement, the most likely cause of his systolic heart failure was determined to be his use of methamphetamine.

IMPACT: Due to the increasing incidence of methamphetamine use in the general population this should be considered as an important risk factor for new onset cardiomyopathy.

DISCUSSION: The mechanisms of methamphetamine induced cardiomyopathy are poorly understood. Suggested etiologies include catecholamine excess, coronary vasospasm and ischemia, changes in myocardial metabolism, increases in reactive oxygen species, mitochondrial injury, and direct toxic effects. Case reports have previously indicated similarities in clinical presentations between MAC and Takotsubo cardiomyopathy. Withdrawal of adrenergic stress with drug abstinence and β-blocking agents (though precautions are suggested in active users) may result in resolution of left ventricular systolic dysfunction in MAC, as similar results have been noted in patients with stress-induced cardiomyopathies and pheochromocytomas. The potential for early reversibility of MAC, therefore, has significant medical and social implications.

REVERSING OPIATES IN A FLASH: INTRANASAL NALOXONE-INDUCED PULMONARY EDEMA Clark A. Veet; Nicholas Vu; Amar Kohli. UPMC, Pittsburgh, PA. (Control ID #2675561)

LEARNING OBJECTIVE #1: List indications and side effects of naloxone

LEARNING OBJECTIVE #2: Differentiate diagnostic criteria of cardiogenic and non-cardiogenic pulmonary edema on chest radiography

CASE: A 27 year old man with chronic neck pain and polysubstance abuse is found unresponsive with shallow breathing at a party. At the scene, paramedics administered 3 sprays of intranasal naloxone (6 mg) with improvement in mental status and respirations. In transit, he was hypertensive and hypoxemic requiring intubation. Exam revealed course bilateral crackles. Chest radiograph showed diffuse bilateral infiltrates. Cardiac ultrasound showed normal heart function without wall motion or valvular abnormalities. Labs showed leukocytosis to 14,200 and mixed respiratory failure with ABG of 7.33/58/37/29. Drug screen was positive for oxycodone. Treatment with IV furosemide yielded rapid improvement and subsequent extubation. A diagnosis of naloxone-induced pulmonary edema was made.

IMPACT: Naloxone use is increasing in the setting of a national opiate epidemic. Often first responders administer naloxone, however Internists should be aware of the potential downstream effects. This vignette is novel and expands the current understanding of adverse reactions, as it is one of the first accounts of intranasal naloxone causing pulmonary edema.

DISCUSSION: Naloxone is an opiate antagonist used to reverse the effects of opiates by competitively binding mu receptors in the central nervous system. The agent provides value in healthcare settings where rapid reversal of opiates is desired after anesthesia or overdose. Naloxone is available in IV, IM, SC, and intranasal formulations. Indications include opiate overdose, reversal of respiratory depression with therapeutic opiate use, and opioid-induced pruritus. Side effects include CNS disturbances such as seizure and hallucination, cardiac syndromes including arrhythmia and cardiac arrest, and pulmonary syndromes including pulmonary edema. Many of these side effects are dose dependent. After naloxone administration, the patient's chest radiograph showed extensive airspace consolidations involving all lobes of both lungs without cardiomegaly. On day 2, a repeat radiograph showed resolution of pulmonary edema. Pulmonary edema, either cardiogenic or non-cardiogenic, can be identified on chest film by diffuse infiltrates that demonstrate a bilateral alveolar filling pattern. The distinction between the two types can be made based on the presence of cardiomegaly, apical vascular redistribution, or Kerley "B" lines suggesting interstitial edema, which are typically features of cardiogenic edema. Previously published cases have identified rapid catecholamine surge resulting in acute neurogenic pulmonary edema following naloxone administration. Treatment includes respiratory support, diuresis, and pulmonary vascular vasodilation. This case serves as a reminder for physicians to use naloxone in the smallest possible dose and to monitor closely for side effects.

RHABDOMYOLYSIS FOLLOWING EXERCISE COMBINED WITH A SPORTS SUPPLEMENT CONTAINING MULTIPLE PHARMACEUTICAL STIMULANTS Chin Ho Fung; Pieter Cohen. Cambridge Health Alliance, Cambridge, MA. (Control ID #2705681)

LEARNING OBJECTIVE #1: Recognize sports supplements as a source of hidden pharmaceutical stimulants

LEARNING OBJECTIVE #2: Assess safety information of supplements through the FDA's MedWatch alerts

CASE: A 23-year-old male with past medical history of epilepsy and anabolic steroid use presented with vertigo and bilateral leg soreness after a 60-min weightlifting workout. Prescription medication included divalproex 500mg twice daily. Patient also routinely used 3 sports supplements–Black Mamba Hyperrush, Mega-size BCAA, and SARM YK-11. He denied anabolic steroids use for the past two years. He denied smoking, alcohol, or recreational drug use. Physical exam revealed a well-appearing muscular young male, afebrile, heart rate 102/minute, blood pressure 148/82 mmHg. Neurological exam was normal. Moderate tenderness noted on bilateral thighs with intact distal pulses. Serum labs were significant for creatinine kinase 11,241 IU/L (normal 39–308 IU/L), creatinine 0.9 mg/dL, thyroid stimulating hormone 1.97 uIU/mL, and normal electrolyte levels. Urine drug screen was negative for amphetamines, cocaine metabolites, opiates, barbituates, benzodiazepines, cannabinoids, and ethanol. Patient was diagnosed with rhabdomyolysis and treated

with intravenous fluid. Patient's unused supplements were sent for analysis (NSF International, Ann Arbor, MI) using liquid chromatography-mass spectrometry. Black Mamba Hyperrush contained various pharmaceutical stimulants including oxilofrine, 1,3-dimethylamylamine (DMAA), along with trace amounts of beta-methylphenylethylamine (BMPEA), amphetamine, and multiple other stimulants. No banned substances were identified in Mega-size BCAA or SARM YK-11. We reported these results to the FDA's MedWatch program.

IMPACT: Over half of US adults use dietary supplements, which do not require pre-market approval by the FDA. Such products may contain undisclosed pharmaceutical agents and thus may inflict harm to a significant population.

DISCUSSION: We present a case of rhabdomyolysis after consumption of a sports supplement containing multiple stimulants. A search of the FDA's list of tainted supplements revealed previous reports of Black Mamba Hyperrush adulterated with banned ingredients sibutramine and phenolphthalein. While we did not detect sibutramine and phenolphthalein in our samples of Black Mamba Hyperrush, significant dosages of undisclosed synthetic stimulants were instead identified, which might have contributed to patient's rhabdomyolysis. We suspect that the standard urine drug screen used in this case lacked the sensitivity to detect these compounds. Physicians should be aware that sports supplements may contain pharmacologically active agents and that the FDA has identified more than 750 brands of adulterated supplements. Physicians should refer to the FDA website for more information and report all potential related adverse events to the MedWatch program. We strongly advise our patients to avoid sports supplements as they may contain pharmaceutical drugs linked with serious adverse outcomes.

RHABDOMYOLYSIS IN A PATIENT WITH LEGIONELLA PNEUMONIA Vijay Bhat; Aviva Cohn; Gargi Patel; Laura R. Willett. Rutgers Robert Wood Johnson Medical School, North Brunswick, NJ. (Control ID #2706080)

LEARNING OBJECTIVE #1: Recognize rhabdomyolysis as a complication of legionella pneumonia

CASE: A 63 year old male with a history of hypertension and treated Hepatitis C, presented with a 1 week history of malaise and worsening generalized weakness leading to a mechanical fall at home. On admission, physical exam was significant for new onset atrial fibrillation with heart rates in the 130s, high fevers, and hypoxia requiring 3 liters of supplemental oxygen. He was lethargic, tachypneic, with bibasilar rales on lung exam. There was marked weakness in the lower extremities. Initial workup revealed leukocytosis of 20, hyponatremia with serum sodium of 127, elevated creatinine of 1.4, and urinalysis with 3+ blood and 4 red blood cells. Imaging including chest radiograph revealed multifocal infiltrates. A CT angiogram of the chest showed no evidence of pulmonary embolism. The patient's clinical picture and imaging raised concerns for atypical pneumonia and therefore, urine legionella antigen was sent for testing, which resulted in a positive test. In addition, given the patient's acute kidney injury (AKI), muscle weakness, and evidence of blood with few red blood cells on urinalysis, a creatinine phosphokinase (CPK) level was checked, and was markedly elevated at 48,765. The patient was treated with aggressive intravenous hydration for rhabdomyolysis, and a 14 day course of Levofloxacin for legionella pneumonia. Fever curve improved and the patient had gradual resolution of weakness, dyspnea, and AKI with treatment.

IMPACT: Critically ill patients often present with multi-organ involvement. In this case, the patient's cardiac, pulmonary, renal, and musculoskeletal systems were affected; the multi-organ dysfunction could have easily been attributed entirely to sepsis. It is, however, important to consider and test for rhabdomyolysis as a possible etiology of musculoskeletal and renal injury in patients who present with sepsis, particularly in cases of legionella infection.

DISCUSSION: A current literature review demonstrates that legionella is a known but rare cause of rhabdomyolysis. The biochemistry is unclear, however theories include a possible bacterial invasion of muscle fibers. Particularly in these patients, severe cases of rhabdomyolysis can lead to metabolic derangements and renal failure. This case highlights the importance of recognizing the association between legionella infection and rhabdomyolysis, as prompt treatment including aggressive intravenous fluid administration, trending CPK levels, and frequent electrolyte monitoring can lead to good outcomes in this population.

RING ENHANCING LESION IN AN AIDS PATIENT WITH NEGATIVE TOXOPLASMA ANTIBODIES Alejandro Lemor[3]; Farid Gholitabar[2]; Joseph Sassine[4]; Georgina Osorio[1]. [1]Mount Sinai, New York, NY; [2]Mount Sinai St Luke's and West, New York, NY; [3]Mount Sinai St Lukes and Mount Sinai West Hospital, New York, NY; [4]Mount Sinai St. Luke's & Mount Sinai West, New York, NY. (Control ID #2687532)

LEARNING OBJECTIVE #1: Demonstrate the limitations of Toxoplasma serologies in diagnosing CNS toxoplasmosis in AIDS patients

CASE: A 35-year-old man with history of HIV/AIDS was brought to the ER for a witnessed generalized tonic-clonic seizure. On exam he was drowsy but no focal signs, reactive pupils, no neck rigidity, normal reflexes, rest of systems within normal limits. His lab work showed anemia (hemoglobin 9.2), normal white blood cells (7.3K/uL) and normal platelets (400 K), elevated ESR (>150) and CRP (1.8). CT head showed an area of lucency in the left frontal lobe; and MRI showed two ring-enhancing lesions in the left frontal lobe (21 and 6 mm in diameter). He was started on empiric toxoplasmosis treatment with trimethoprim-sulfamethoxazole, as pyrimethamine was not readily available. His CD4 was 239 (11%) cells/mL, viral load 16,686 copies/mL and both Toxoplasma IgM and IgG antibodies were negative. Blood cultures, rapid plasma reagin (RPR), cryptococcal antigen, and quantiferon TB gold were negative. On hospital day 3, thallium scan was negative for primary CNS lymphoma. Brain biopsy showed extensive necrosis and chronic inflammatory infiltrate with predominantly CD68+ macrophages. On H&E possible toxoplasma tachyzoites were seen and toxoplasma immunostains confirmed the diagnosis of cerebral toxoplasmosis. He will complete 6 weeks of trimethoprim-sulfamethoxazole and an MRI brain is planned to assess for improvement.

IMPACT: In most cases Toxoplasma serology will be positive in HIV/AIDS patients with CNS toxoplasmosis; however, immunocompromised patients may have low antibody production. Therefore, when clinical suspicion is high, a negative serology for toxoplasmosis should not preclude empiric treatment.

DISCUSSION: In AIDS patients, neurologic signs and symptoms warrant imaging with CT or MRI. The differential diagnosis of intracranial mass includes *Toxoplasma gondii*, *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, *Treponema pallidum*, as well as CNS lymphoma. A reliable diagnostic approach involves obtaining a CD4 count, chest X-ray, serum Toxoplasma IgG level, CSF india ink smear, cryptococcal antigen, cytology,

PCR for *M. tuberculosis*, bacterial, AFB, fungal cultures and serum and CSF syphilis serologies; coupled with characteristics of the lesion(s) and other imaging (PET or Th-SPECT) for suspected CNS lymphoma. In a study of 268 HIV patients with *T. gondii* infection, the antibody level was not biased by anti-retroviral treatment or prophylaxis for *T. gondii*. There were fluctuations in levels based on the degree of infection. A negative serology in a patient with toxoplasmosis is explained by primary infection, reactivation of latent disease in a patient who cannot generate antibodies, or false negative result. This shows the limitation of serological testing in determining the stage and predicting of reactivation of toxoplasma in HIV/AIDS patients.

RISING TSH IN A CASE OF GRAVES Melissa Rusli[1]; Adam Law[2]. [1]New York Presbyterian-Weill Cornell Medical College, New York, NY; [2]Cayuga Medical Center, Ithaca, NY. (Control ID #2705808)

LEARNING OBJECTIVE #1: Recognize lab errors when test results do not fit the clinical picture/story.

LEARNING OBJECTIVE #2: Review types of immunoassay interferences due to endogenous antibodies and initial investigations to pursue.

CASE: 75 yo woman PMH Crohn's disease presented to endocrine clinic with "shakiness", palpitations, insomnia, 30 lbs weight loss, and hoarseness. On exam, HR 108 bpm, thin, warm skin, and 30g thyroid goiter with right hemithyroid nodules. TSH was initially <0.03 U/ml (nl 0.34–5.6 U/ml), FT4 3.82 ng/dl (nl 0.61–1.12 ng/dl), TT3 2.03 ng/dL (nl 0.87–1.78 ng/dL), Thyroid-Stimulating-Immunoglobulin (TSI) 3.0 (nl <1.5), consistent with diagnosis of Grave's disease thyrotoxicosis. She was started on methimazole and achieved clinical and laboratory euthyroidism by the third month of treatment. She remained clinically euthyroid, however at the ninth month of treatment her TSH was elevated disproportionately to her clinical exam and other thyroid hormone levels: euthyroid, TSH 11.95 U/ml, FT4 1.14 ng/dl, TT3 2.42 ng/dL. The following month, TSH further rose to 26.09 U/ml. Serial dilutions were performed and revealed nonlinearity of TSH levels, suggesting immunoassay interference. Sendout studies were sent to the Mayo Clinic to further work-up the etiology of immunoassay interference. She remained clinically euthyroid despite rising TSH, and her hyperthyroidism management is based off of her clinical presentation and FT4 levels.

IMPACT: This case is a reminder to keep a high level of skepticism when blood results do not match the clinical story. With certain diseases, such as thyroid dysfunction, it is easy to fall into the habit of treating a single lab value. However, as clinicians, we must remember to treat the patient in front of us using additional clinical tools and clues to investigate our skepticism.

DISCUSSION: Immunoassays are quick and accurate tests to measure the concentrations of many common proteins. They rely on the binding of antibodies in analyte to epitopes of target compounds. Immunoassays are subject to several types of interferences, such as the presence of endogenous antibodies: heterophile antibodies, anti-animal antibodies, autoantibodies, or therapeutic antibodies. A serial dilution test is a common initial study to request if interference is suspected. If the test result is accurate without interference, it is expected that the concentration would decrease respectively to the corresponding dilution. If the concentration does not, it is considered nonlinear and interference is suspected. To further identify the etiology of the interfering endogenous antibody, the following tests can be requested: repeat assay using a different analyte, use of heterophile antibody blocker tubes, test for human anti-mouse antibody (HAMA), removal of interfering antibodies by polyethylene glycol precipitation.

RIVAROXABAN DRUG HYPERSENSITIVITY PRESENTING AS PALPABLE PURPURA Michael Del Rosario; Keyan Matinpour; Richard Loftus. Eisenhower Medical Center, Rancho Mirage, CA. (Control ID #2702119)

LEARNING OBJECTIVE #1: Assess an adverse drug reaction using the Naranjo nomogram

LEARNING OBJECTIVE #2: Diagnose rivaroxaban drug hypersensitivity reaction presenting as palpable purpura

CASE: A 60-year-old male presented with a rash of two days. 15 days prior to presentation, the patient was placed on rivaroxaban for left lower leg deep venous thrombosis and pulmonary embolism provoked from driving across the country. He had a similar event in 2005 treated with warfarin. His past medical history included HIV with a CD4 count of 541 and undetectable viral load. The patient had no known allergies. His medications include atorvastatin and tenofovir/emtricitabine. Rivaroxaban was the most recent medication started on his list. He denied using any vitamin/mineral supplements. Family history was noncontributory. He denied smoking, drinking, and recreational drug use. Review of systems was unremarkable. On physical exam, the patient had bilateral hand and foot palpable purpura (Figure 1). The rash was scattered consisting of dark purple-red lesions with the largest under 3mm in size. The rest of the physical examination was unremarkable. The patient was advised to stop rivaroxaban and was started on warfarin 5mg daily with INR goal of 2.0–3.0. The patient was bridged with enoxaparin injections twice daily for the first 5 days of warfarin administration. Labs including CK, ESR, CRP, CBC, CMP, TSH were all within normal limits. He was referred to a dermatologist with subsequent biopsy showing evidence of a bullous hypersensitivity reaction. The patient's rash completely dissipated within 1 week. Rivaroxaban was added to this patient's allergy list and the patient completed his warfarin therapy to completion without adverse events.

IMPACT: To our knowledge, this is the first reported episode of rivaroxaban drug hypersensitivity reaction presenting as palpable purpura. This case also highlights that healthcare providers need to be aware of potential drug adverse effects beyond bleeding with the newer anticoagulants and to be vigilant in making changes to their patients' anticoagulant regimen when necessary.

DISCUSSION: The Naranjo nomogram (Figure 2) is used to classify the probability that an adverse event is related to drug therapy. Based on the answers to the questionnaire, the patient's score was 6, making this a probable adverse drug reaction to rivaroxaban use. Ackroyd et al. demonstrated that purpura as an immunological response is likely due to a formation of a drug-platelet compound which stimulates antibodies. These antibodies, in turn, lyse the platelets and form the vascular lesion. To manage this case, we switched from factor Xa inhibitors to warfarin with enoxaparin bridging until anticoagulation. In conclusion, this is the first reported case of rivaroxaban drug hypersensitivity reaction presenting as palpable purpura. Physicians should be aware of this potential drug reaction, and at most be able to think outside the scope of bleeding as a complication of the newer anticoagulation therapies.

SARCOIDOSIS: CHALLENGING OUR DIAGNOSTIC THOUGHT PROCESS

Benjamin C. Hofeld[1]; Tonia Qaisar[1]; Sarah Nickoloff[1, 2]. [1]Medical College of Wisconsin, Milwaukee, WI; [2]Zablocki VA Medical Center, Milwaukee, WI. (Control ID #2699674)

LEARNING OBJECTIVE #1: Review the importance of maintaining a broad differential diagnosis for an unknown disease.

LEARNING OBJECTIVE #2: Recognize the variety of demographics, symptoms, and lab abnormalities in sarcoidosis.

CASE: A 61-year-old Caucasian male presented to his primary care physician for a routine check-up. He complained of generalized fatigue, body and joint aches, and new dyspnea with exertion for the last 2–3 months. Over the last 1.5 years he had a 20-pound unintentional weight loss. He had no other complaints. Relevant medical history included alcohol abuse (10 beers daily) and rheumatoid arthritis. Family history was non-contributory. Medications included cholecalciferol and as needed calcium carbonate. Physical exam was unremarkable. Initial labs showed new normocytic anemia (hemoglobin 9.2 g/dL), corrected calcium of 11.6 mg/dL, and acute renal failure with serum creatinine 4.29 mg/dL. Urinalysis revealed non-nephrotic range proteinuria and no casts. Given the laboratory findings, initial concern was for multiple myeloma; however, further workup revealed normal serum and urine protein electrophoresis, minimally elevated kappa-lambda ratio, and normal bone scan. Renal biopsy showed evidence of calcium induced renal injury, but was otherwise unremarkable. Chest CT was suggestive of vasculitis but bronchoscopy revealed foci of non-caseating granulomas, diagnostic of sarcoidosis. He was subsequently started on high dose corticosteroids, with improvement in his lab parameters and symptoms.

IMPACT: Preliminary workup was focused primarily on multiple myeloma, given the constellation of laboratory and clinical findings. The patient's vitamin D and calcium use broadened the differential to include supplement overdose, and differential was later expanded to include malignancy, vasculitis, and granulomatous disease. Expanding the differential following negative lab/ imaging results was more challenging to our medical reasoning than starting with a broad differential and reconsidering it daily.

DISCUSSION: Reassessment of the differential was critical, especially given this epidemiologically rare presentation. Demographic epidemiological studies show a 3-fold higher annual incidence of sarcoidosis in African Americans vs Caucasians. By organ system, the literature reports calcium dysregulation and renal involvement occurring in only 4-7 and 1% of all-comers, respectively. By these data this patient was an epidemiologic outlier for sarcoidosis, but had typical demographics and classic signs of multiple myeloma. Thus, in diseases that are both systemic and multi-demographic, epidemiology must be integrated with all other clinical information. This case highlights the importance of maintaining a broad differential, even in the presence of a "classical presentation" of an initially suspected disease.

SCREENING FOR HIV IMMEDIATELY AFTER DIAGNOSING MILIARY TB Prasanna Marathe[1]; Vinod Sehgal[1]; Jeffrey L. Jackson[2, 1]. [1]Medical College of Wisconsin, Milwaukee, WI; [2]Zablocki VAMC, Milwaukee, WI. (Control ID #2700715)

LEARNING OBJECTIVE #1: Investigate HIV and HIV associated disease status in patients presenting with miliary TB

CASE: A 55- year- old Caucasian male with a past medical history of hepatitis C, abdominal aortic aneurysm, and sensorineural deafness presented to his primary care physician for 3 months of weight loss, productive cough, and night sweats and follow up of a perianal abscess. He was born and raised in the US and was homeless 15 years ago, but denied IV drug use, international travel, history of HIV, or infectious contacts. An abdominal CT to evaluate the perianal abscess revealed multiple necrotic celiac and para-aortic lymph nodes. A PPD test was positive and follow up chest X-ray demonstrated moderate reticular interstitial prominence. Chest CT showed peribronchial airspace opacities and scattered pulmonary nodules with mediastinal, hilar, supraclavicular and abdominal lymphadenopathy. A subsequent left supraclavicular lymph node biopsy revealed necrotizing granulomas with acid fast bacilli (AFB). Immediately afterwards, he was admitted to the hospital. Physical exam revealed palpable left supraclavicular lymph nodes. Labs revealed hyponatremia. 2 of 3 sputum cultures for AFB were positive and PCR revealed M. tuberculosis. Treatment for miliary TB was initiated with rifampin, isoniazid, pyrazinamide, and ethambutol. Despite negative history of HIV, HIV screening and confirmatory tests were positive, which triggered an exploration for HIV-associated infections. Additional labs revealed a CD4 count of 54 and elevated toxoplasma IgG. Pneumocystis pneumonia prophylaxis with azithromycin was initiated. Public health officials were alerted and patient was discharged in stable condition with an appropriate follow up plan to continue directly observed treatment for TB and to begin antiretroviral therapy.

IMPACT: More often, HIV status is already known prior to diagnosis of miliary TB. This case highlights the importance of evaluating HIV status early in a patient initially admitted for miliary TB. This also emphasizes the role of internal medicine physicians in identifying and responding to undiagnosed HIV.

DISCUSSION: Individuals with HIV are 20–30 times more likely to develop TB. Miliary TB makes up as few as 3.7% of all TB cases in the US but affects 10% of HIV infected persons. Thus, an investigation to identify underlying HIV infection in patients with miliary TB is warranted given the increased morbidity and mortality (25-30%) associated with an HIV-miliary TB coinfection. Given the association between HIV and miliary TB and patient's history of homelessness and hepatitis C, we had a reasonably high index of suspicion for HIV. Alarmingly, the patient had not been screened for HIV before. HIV test results prompted an investigation of HIV associated infections and influenced TB therapy as rifampicin was replaced with rifabutin as the latter has fewer drug-drug interactions. Early ART therapy has been shown to improve outcomes and was initiated after anti-TB therapy per WHO guidelines.

SECONDARY PLASMA CELL LEUKEMIA Jonila Murati; Sylvia V. Alarcon; Gabriela A. Ciofoaia. Berkshire Medical Center, Pittsfield, MA. (Control ID #2706418)

LEARNING OBJECTIVE #1: Multiple myeloma transforming to acute plasma cell leukemia.

LEARNING OBJECTIVE #2: Patient receiving chemotherapy are at high risk for opportunistic infections.

CASE: A 57 year-old female was diagnosed with an IgG kappa multiple myeloma with high grade histology and 80% plasma cell infiltration of bone

marrow. She was found to have multiple lytic bone lesions, renal insufficiency and hypercalcemia. She was started on bortezomib and dexamethasone, but not given lenalidomide in the setting of renal insufficiency. After completing five cycles of therapy, her follow up labs revealed a white count of 50.6k/μl, hemoglobin of 11.9g/dl and a platelet count of 72k/μl. Peripheral blood evaluation demonstrated 70% morphologic blasts with plasmablastic morphology. Flow cytometry revealed the cells to be CD 138 positive, CD 117 negative, TdT negative, CD 45 negative, CD 56 positive (dim), with a kappa light chain restriction. FISH analysis showed monosomy 13. She was treated with cyclophosphamide, etoposide, cisplatin and bortezomib with an initial favorable hematological response. She then relapsed prior to transplantation.The treatment regimen was changed to lenalidomide, carfilzomib and dexamethasone with prophylactic acyclovir and atovaquone. A month later she developed fever, lethargy, then went into cardiopulmonary arrest. Following resuscitation she was found to have pancytopenia, H1N1 pneumonia.She went into septic shock with multiorgan failure and became vegetative, unresponsive and died shortly afterwards.An autopsy examination revealed disseminated candidiasis with multifocal involvement of spleen, lungs and kidneys without evidence of residual plasma cell leukemia.

IMPACT: MM is a hemotologic disorder with a relative favorable prognoses but secondoray malignancies such as PCL can occur and leading to a poor prognosis. Opportunistic infections in patient on anticancer therapies can be fatal.

DISCUSSION: Plasma cell leukemia (PCL) is a rare and aggressive hematological malignancy defined by 20% circulating plasma cells in peripheral blood. It can originate de novo (primary PCL) or as a secondary transformation of multiple myeloma (secondary PCL).Secondary PCL accounts for 40% of all plasma cell leukemias, and 2-4% of multiple myeloma patients. The diagnosis is determined by the presence of 20% circulating monoclonal plasma cells. Osteolytic lesions are more common in secondary PCL. The presence of anemia and thrombocytopenia are a consequence of extensive involvement of the bone marrow by plasma cells (myelophthisic anemia) and usually indicate progression of disease. The prognosis of PCL is poor with a median survival of 7–11 months with primary PCL and 2–7 months with secondary PCL. Therapy includes proteoseome inhibitors, immunomodulatory drugs and bone marrow transplant. Patient receiving anticancer therapies have a higher risk of opportunistic infections like candidiasis. Empiric antifungal therapies in neutropenic patients who do not respond to broad spectrum antibiotics should be considered.

SECONDARY SCLEROSING CHOLANGITIS: A SEQUELA OF PANCREATITIS Lauren Liebling; Jonathan Robbins; Julien Chirouze. Oregon Health & Science University, Portland, OR. (Control ID #2705305)

LEARNING OBJECTIVE #1: Compare primary (PSC) to secondary (SSC) sclerosing cholangitis

LEARNING OBJECTIVE #2: Discuss the treatment and outcomes for patients with SSC

CASE: A 40 year-old man with a history of DM2, HNPCC, and pancreatitis presented with jaundice and RUQ pain. ERCP revealed a mass compressing the common bile duct which was subsequently stented. Biliary brushings and FNA were negative for malignancy. Labs: TBili 23.3 (4–8.7 mg/dL), Alk Phos 223 (52–128 U/L), WBC 24.3 (3.5–10.8 K/mm^3). He started Zosyn for cholangitis and was transferred for further workup. MRCP was used to evaluate the mass, presumably a pseudocyst secondary to pancreatitis. A cyst-gastrostomy drained the mass of bilious fluid. Follow-up MRCP revealed intrahepatic bile duct strictures. Workup for autoimmune and viral hepatitis and PSC was negative. SSC was the presumed diagnosis. Despite multiple ERCPs, stents, cyst-gastrostomy, necrosectomy, and PTC, the patient's intrahepatic bile ducts remained strictured and his labs worsened. Care was directed towards optimizing the patient's health for possible future liver transplant.

IMPACT: This case highlights the need to streamline a workup. It is unknown if the pseudocyst, cholangitis, or serial procedures contributed to the development of SCC. All procedures have a financial and physical cost to be considered when recommending interventions as part of a workup or treatment.

DISCUSSION: Few diseases cause intrahepatic bile duct stricturing. PSC presents with intermittent bile duct dilation and structuring giving a beaded appearance.[1] Up to 90% of PSC patients have UC.[1] PSC patients have cholestatic liver enzymes, positive P-ANCA, and sometimes increased IgG4, anti-smooth muscle Ab, anticardiolipin, or RF.[1] This patient had bile duct stricturing without the classic beaded appearance. He also lacked UC or positive auto-antibodies. SSC is diagnosed based on bile duct structuring without other features of PSC, plus an identifiable source of biliary pathology such as cholangitis, cholangiocarcinoma, pancreatitis, or surgical trauma.[1] SSC is rare (incidence significantly less than PSC, 1/100,000[3]). There is a lack of robust data on patient outcomes. Due to lack of medical treatment liver transplant is required for survival. In a retrospective study of 31 patients, those with SSC had a shorter survival without transplant compared to those with PSC (72 vs 89 months).[2] This may imply that SCC progresses more quickly than PSC, requires closer monitoring, and that patients with SSC may need liver transplant sooner in their clinical course.

SEROTONIN SYNDROME TRIGGERED BY BUPRENORPHINE COMBINED WITH ACUTE ALCOHOL INTOXICATION Margaret Omatsone; Lintu Ramachandran; Pye Oo; Anne Omatsone. Raritan Bay Medical Center, SAYREVILLE, NJ. (Control ID #2687630)

LEARNING OBJECTIVE #1: Recognize serotonin syndrome in patients on buprenorphine.

LEARNING OBJECTIVE #2: Distinguish the effects of alcohol on opoid dependent patients on buprenorphine maintenance therapy.

CASE: A 32 year old Caucasian female with a history of opoid dependence and diabetes was brought to the emergency department by EMS in a state of confusion and agitation. Her boyfriend who accompanied her reported that she drank half a bottle of vodka three hours prior to symptom onset and she was on prescribed suboxone 4mg which she takes regularly twice a day. At presentation, she was agitated, restless and uncooperative and was put on leather restraints. On examination, her vital signs were heart rate 131, blood pressure 154/77, respiration rate 30, oxygen saturation of 97% on room air and temperature 97.8. She appeared in distress, flushed and diaphoretic. Neurologic

exam revealed a Glasgow coma scale of 9, motor strength was 5/5 but there was hyperreflexia 3+ symmetrical in upper and lower extremities and ankle clonus present in the lower extremities. Chest was clear on auscultation and abdomen was unremarkable. Her agitation and restlessness persisted after use of benzodiazepine. She was subsequently intubated to protect the airway and admitted to intensive care. Urine toxicology was negative and serum alcohol was elevated, all other laboratory tests were normal and atypical alcohol levels were negative. She was then commenced on cyproheptadine on suspicion of possible serotonin syndrome. Her symptoms resolved and she was safely extubated after 12hours. She requested to be discharged home the next day.

IMPACT: Buprenorphine related deaths has been reported in patients on maintenance therapy, occurring when taken with other substances, especially benzodiazepines and alcohol, causing over sedation and respiratory depression. Buprenorphine may lead to moderate signs of serotonin syndrome as reported in a buprenorphine clinic where 43% of patients, mostly females, had signs of serotonin syndrome. The combination with alcohol led to a life-threatening presentation of serotonin syndrome in our patient.

DISCUSSION: Buprenorphine was FDA approved for the treatment of opioid dependence in 2002. It acts as a partial agonist at the μ-receptors in the CNS. Alcohol has been shown to interact with serotonergic synaptic transmission. Increased serotonin metabolites have been measured after a single drinking session suggesting increased serotonin release in the nervous system. We propose that the combination of the alcohol induced serotonin increase and buprenorphine therapy led to the serotonin syndrome in this patient. Her symptoms only improved after the administration of the cyproheptadine, a serotonin receptor antagonist. Physicians must be aware of such life-threatening situations that may occur when such patients are exposed to commonly abused substance like alcohol.

SEVERE DIFFUSE AXONAL POLYNEUROPATHY AND WEST NILE VIRUS INFECTION KAUL,MALVIKA MD, BUNYAN, ANN MD, LEE,KENNETH MD, SULLIVAN,LAUREN DO DEPARTMENT OF INTERNAL MEDICINE,MACNEAL HOSPITAL, BERWYN, IL

Malvika Kaul. MacNeal Hospital, Berwyn, IL. (Control ID #2694755)

LEARNING OBJECTIVE #1: West Nile (WN) is a mosquito-borne RNA Flavivirus causing meningitis,encephalitis, and very rarely diffuse axonal polyneuropathy(DAP) leading to acute flaccid paralysis. DAP is a rare presentation of WN neuroinvasive disease. Our case reports a patient with WN encephalopathy complicated with very severe and rapidly deteriorating DAP.

CASE: A 54-year old previously healthy man presented with fever, unresponsiveness, and acute respiratory failure. He was seen in the emergency department on the same day with viral prodromal symptoms for 5 days without neurological symptoms except for lightheadedness. Within 12 hours, he was readmitted with worsening symptoms requiring intubation. On day 2 of admission, he developed limb flaccidity in all extremities with diffuse areflexia on exam. Imaging of the brain was negative for any intracranial abnormalities. A lumbar puncture was obtained which showed elevated protein (98.6mg/dl), high normal glucose (71mg/dl), WBC (41 cells/UL), lymphocytes (73%), neutrophils (4%), and mononcytes (22%), indicating a viral etiology, and a viral panel was sent. WN IgM was positive in the serum and cerebrospinal fluid. An electroencephalogram was performed to evaluate his deteriorating mental status showing diffuse encephalopathy. The patient's course was complicated by sepsis secondary to pneumonia. His sepsis and encephalitis were treated with antibiotics and Acyclovir from the day of admission and de-escalated accordingly. Overtime,his mental status improved but no improvement in his limb movements. An electromyography (EMG) was performed which showed severe diffuse polyneuropathy with predominantly axonal features. Sensory nerve action potentials (SNAPs) were absent in the bilateral sural and ulnar nerves, and compound muscle action potentials (CMAPs) amplitudes were significantly decreased and in some cases absent in the bilateral peroneal, tibial,and ulnar nerves with some mild slowing. These findings primarily indicated axonal loss instead of demyelination with the latter being more common with WN virus. Due to his prolonged recovery, the patient was transferred to a long-term assisted care facility with physical therapy.

IMPACT: The prognosis of WN-associated DAP is unclear and only one controlled study has been completed for evaluation of specific therapies using Interferon and IV Immunoglobulin. Uncontrolled studies or case reports suggesting treatment efficacy should be cautiously interpreted,since clinical course and outcomes with WN virus neuroinvasive disease are highly variable.

DISCUSSION: Acute flaccid paralysis in WN infection is usually associated with poliomyelitis-like syndrome involving anterior horn cells. Whereas acute DAP, which is the absence or reduction of SNAPs and CMAPs on EMG occurring rapidly as in our case is an uncommon and severe presentation. As there is no specific treatment or vaccine currently approved in humans,standard treatment includes supportive care.

SEVERE HYPOALBUMINEMIA IN A PATIENT WITH HEREDITARY ACERULOPLASMINEMIA: NOT ALL THAT SWELLS IS HEART FAILURE OR CIRRHOSIS

Dhruv Mahtta; Kristopher P. Kline; Harry Powers; Hussam Hawamdeh. University of Florida, Gainesville, FL. (Control ID #2704044)

LEARNING OBJECTIVE #1: Recognize the importance of a thorough work up of peripheral edema, including consideration for uncommon etiologies

LEARNING OBJECTIVE #2: Recognize the clinical and biochemical features of patient presenting with protein losing enteropathy

CASE: A 64-year-old female with medical history significant for hereditary aceruloplasminemia, hypothyroidism, and peptic ulcer disease status-post Roux-en-Y gastric bypass 15 years prior presented with 2-week onset of worsening bilateral lower extremity edema. On hospital presentation, labs revealed a low total protein (4.7g/dl) and albumin (1.5g/dl), with otherwise normal liver function tests and coagulation tests. Regarding her history of hereditary aceruloplasminemia, she had received iron chelation therapy in past and stopped 4 years prior when ferritin levels remained normal. She since had a liver MRI and biopsy 2 years prior showing evidence of marked steatosis but no iron deposition or evidence of fibrosis. The patient was initially managed with diuresis. Repeat hepatic imaging including ultrasound and fibroscan along with preserved synthetic function and normal ferritin pointed against progression to fibrosis of the patient's hereditary aceruloplasminemia. NTproBNP was normal and transthoracic echocardiogram showed normal left ventricular systolic function with mild diastolic dysfunction. Normal urinalysis and protein-to-creatinine ratio (0.31mg/g) ruled out nephrotic syndrome. Given patient's severe hypoalbuminemia, albumin levels were trended for the past 5 years which showed a sudden decrease only over the past 6 months. Fecal alpha 1

anti-trypsin (A1AT) level was sent which returned grossly elevated, thereby confirming the diagnosis of protein losing enteropathy.

IMPACT: It is imperative to conduct a thorough evaluation of peripheral edema: including ruling out heart failure, nephrosis, cirrhosis, and malnutrition. Protein losing enteropathy is a less common cause of hypoalbuminemia usually caused by mucosal damage, increased interstitial pressure or lymphatic obstruction. However, the concept of bypass enteropathy, which consists of small intestinal bacterial overgrowth (SIBO) of the Y-limb, is an extremely rare cause in patients with gastric bypass.

DISCUSSION: Protein losing enteropathy is an uncommon cause of severe hypoalbuminemia characterized by excessive loss of serum protein via gastrointestinal tract leading to generalized edema. Reduction in all serum proteins is seen and diagnosis can be confirmed by an elevated fecal A1AT level. As part of bypass enteropathy in patients with gastric bypass, only two prior cases have been reported where SIBO of Y limb lead to hypoalbuminemia which was responsive to antibiotic therapy. This rare etiology of protein losing enteropathy was felt to be the reason of our patient's clinical presentation. This can be difficult to diagnose as in our patient, which had subjectively trivial symptoms of occasional diarrhea and abdominal pains, failing to even mention them until further questioning.

SEVERE HYPOKALEMIA, HYPERTENSION AND DIABETES INSIPIDUS IN THE POSTPARTUM PERIOD: A MOTLEY MEDLEY OR A SINGLE DIAGNOSIS? Gofran Tarabulsi[2]; Niharika Mehta[1]. [1]Brown University, Providence, RI; [2]Women and Infants hospital, Brown Alpert Medical School, Providence, RI. (Control ID #2700045)

LEARNING OBJECTIVE #1: Recognize that Primary Hyperaldosteronism can be masked during pregnancy and can be unmasked in the postpartum period.

LEARNING OBJECTIVE #2: Recognize severe hypokalemia manifestations.

CASE: A 22 year old African American presented 5 days postpartum with acute onset of severe abdominal pain, lower limb edema and generalized weakness. Her pregnancy and recent delivery had been uneventful. She was noted to be bradycardic and hypertensive (160/90 mmHg). Labs showed a critically low potassium at 1.9 mmol/L. Normal levels of Sodium (141 mmol/L), Creatinine (0.52mg/dl) Glucose (82 mg/dl) and bicarbonate (22 mmol/L) were noted. LFT showed elevated AST and ALT (148 IU/L and 137 U/L respectively) and elevated Ammonia (60 mcmol/L). Large volume diuresis in excess of 4 L was observed within the first few hours of admission despite no administration of IV fluids. Urine studies showed elevated urine protein: creatinine ratio at 1.0 and elevated urine potassium creatinine ratio (16%) suggesting renal potassium wasting. Plasma renin activity (PRA) < 0.6 ng/ml/hr and plasma aldosterone concentration (PAC) <0.4 ng/dl were suppressed. During hospitalization, the patient exhibited several manifestations of severe hypokalemia including sinus bradycardia, muscle weakness, rhabdomyolysis (CK level: 2,890 Intnl Units) and nephrogenic DI. After aggressive potassium replacement, magnesium infusion for seizure prevention and hydration to replace ongoing fluid loss, the patient was discharged home in stable condition with oral potassium and Nifedipine.

IMPACT: In Patients with preeclampsia and severe HTN, consider checking potassium levels as they may present with secondary hyperaldosteronism due to aquired Apparent Mineralocorticoid Excess (AME)

DISCUSSION: In this patient who presented postpartum with hypertension and proteinuria, preeclampsia was considered the primary diagnosis. However presence of severe hypokalemia led us to investigate for Primary hyperaldosteronism. The finding of a low PAC level did not support this. The syndrome of Apparent Mineralocorticoid Excess (AME) is a genetic disorder with similar presentation to primary hyperaldosteronism but with low levels of PRA and PAC. It results from a deficiency in the 11-beta-hydroxysteroid dehydrogenase enzyme (11HBSD2). The lack of this enzyme causes sodium retention, hypertension and hypokalemia, suppressing PRA, aldosterone levels. In patients with preeclampsia, there is reduced placental expression of 11HBSD2 which has a key role in protecting the fetus from circulating maternal glucocorticoids. We present this case of acquired AME resulting from preeclampsia.

SEVERE MALARIA: HOW TO PREDICT MORTALITY? Olena Slinchenkova[1]; Christina Coyle[2]. [1]Montefiore Medical center, Brooklyn, NY; [2]Albert Einstein College of Medicine, Bronx, NY. (Control ID #2706930)

LEARNING OBJECTIVE #1: recognize poor prognostication factors for patients with malaria

LEARNING OBJECTIVE #2: review definition of severe malaria

CASE: A 64-year-old man who arrived from Ghana on day of admission presented with fever and cough. He had intermittent fever associated with chills, cough, dyspnea, and severe malaise for 10 days. T = 102.9 F, HR 109bpm, BP 93/50mmHg, RR 18/min, Saturation 93%. He had rhonchi on chest exam. Hemoglobin 14 g/dL, platelets 25 k/uL, creatinine 1.5mg/dL, BUN 31mg/dL, bicarbonate was 19 mg/dl, total bilirubin 3mg/dL and lactate was elevated. Preliminary malaria smear was positive for parasites. Chest x-ray normal. No antimalarials were started on admission in the evening, but the next am the patient developed pulmonary edema and was in respiratory distress. The malaria smear revealed P. falciparum with 5% parasitemia which was corrected to 20% later. IV Quinine and doxycycline were begun and patient was soon changed to artesunate, but despite this the patient coded and expired.

IMPACT: Patients with *P. falciparum* may deteriorate rapidly; early recognition and aggressive treatment is warranted. A low bicarbonate, increased lactate, pulmonary edema and end organ damage (AKI) should suggest severe disease and prompt IV treatment while awaiting parasitemia. Hospitalists should be aware about management of malaria since we are frontline for management of these cases.

DISCUSSION: Malaria is a life-threatening disease, but if treated early and appropriately patients should do well. Approximately 1,500-2,000 cases of malaria are reported every year in the United States and the majority are immigrants going home to visit friends and family. Quantification of parasitemia, which is critical for guiding management, might be delayed. Therefore, recognition of severe disease is critical as these patients should be treated with parenteral antimalarial therapy. Severe malaria is defined as one or more of the following: encephalopathy, prostration, seizures, acidosis, hypoglycemia, severe malarial anemia, serum creatinine >3 mg/dL or BUN >20 mmol/L, bilirubin >2.9 mg/dL with a parasitemia of 2%, radiographically confirmed pulmonary edema or saturation <92% with RR >30/min, significant bleeding, hypotension, parasitemia >10%. This patient was hypotensive, saturation 93 and Creatinine of 1.5 mg/dL a high lactate and a parasitemia of 5% (corrected was 20%) should have prompted a monitored setting and IV therapy. It is critical to be aware about poor prognosticators in malaria. Early treatment in this patient may have saved his life and this case underscores that death due

to severe malaria can occur within hours of presentation and prompt assessment and initiation of antimalarial therapy is essential. Artesunate is Artemisinin Derivative. In the USA, Artesunate is not approved by the Food and Drug Administration but is available for use under an investigational protocol by enrollment with the Center for Disease Control and Prevention.

SEVERE NON-INSULIN MEDIATED HYPOGLYCEMIA AS A PRESENTING FEATURE OF BURKITT'S LYMPHOMA Alina Brener[1]; Irene Nunuk[1]; Joshua Kannankeril[1]; Laura Michaelis[2]; Gilbert Fareau[3]; Amit Taneja[3]. [1]MCW, Milwaukee, WI; [2]Medical College of Wisconsin, Milwaukee, WI; [3]MCW, Wauwatosa, WI. (Control ID #2700336)

LEARNING OBJECTIVE #1: Recognize rare presentation of lymphoma

LEARNING OBJECTIVE #2: Distinguish types of lactic acidosis

CASE: A 45-year-old male was admitted to an outside hospital for pancreatitis. Despite optimal treatment of the pancreatitis, patient had severe and persistent hypoglycemia (blood glucose in the 30's mg/dl) requiring continuous dextrose infusion. Transferred to tertiary hospital for extensive evaluation of hypoglycemia demonstrated appropriately low insulin and C peptide levels, normal adrenal glucocorticoid status, and intact kidney/liver function. Labs were notable for an elevated lactate level of 19.9 mmol/L (0.5–2.0 mmol/L). Evaluation for hypoxic/ischemic and infectious causes of lactic acidosis was unrevealing, while hypoglycemia persisted. Usual offending drugs that can cause hypoglycemia and elevated lactate were excluded. The patient's review of systems was positive for subjective fevers, night sweats, and a 13 pound weight loss that reportedly developed one month prior to hospital admission. He was also mildly bicytopenic. Further questioning revealed a pattern of high-risk sexual behavior and testing confirmed a new diagnosis of HIV infection. A bone marrow biopsy was performed which confirmed Burkitt's lymphoma. HAART therapy was initiated emergently, along with systemic chemotherapy (R-DA-EPOCH). Both the hypoglycemia and lactic acidosis completely resolved shortly after initiation of chemotherapy. Unfortunately, his hospital course was complicated by CNS involvement with lymphoma, acute renal injury and disseminated candidemia leading to multi-organ failure. Focus of care was transitioned to comfort care, and he expired in hospice.

IMPACT: This case illustrates the importance of detailed history taking and wide differential, allowing for sound decision making and lowering the risk of cognitive bias development.

DISCUSSION: The Warburg effect is a phenomenon in which cancer cells rely on energy production through high rates of glycolysis followed by production of lactate in the cytoplasm, rather than the usual aerobic metabolism of pyruvate via Krebs cycle and eventual mitochondrial oxidative phosphorylation. Profound consumption of glucose by tumor cells leading to hypoglycemia and lactic acidosis occurs in Warburg effect. In general, type A lactic acidosis is more common and is caused by tissue hypoxia from a variety of reasons. Type B lactic acidosis is less common and is seen with liver disease, thiamine deficiency, hematologic malignancies and certain drugs. In our case, persistent lactic acidosis without evidence of ischemia suggested Type B acidosis; and specifically, the combination of hypoglycemia and lactic acidosis pointed towards the Warburg effect. HIV-infected individuals have a 10-fold increased risk of non-Hodgkin lymphoma compared to general population; with Burkitt's lymphoma being one of the most common subtypes.

SEVERE RESPIRATORY DISTRESS NEARLY CONCEALED TYPICAL FINDINGS OF GRAVE'S DISEASE Urara Nakagawa[1]; Toshiaki Wakai[1]; Masaji Saijo[2]; yasushi tanabe[1]; Dongkyung Seo[1]. [1]Sapporo Tokushu-kai Hospital, Sapporo-shi, Japan; [2]Sapporo Tokushukai Hospital, Sapporo, Japan. (Control ID #2703008)

LEARNING OBJECTIVE #1: Typical findings of a certain disease tend to be overlooked especially in emergent situations.

LEARNING OBJECTIVE #2: Complete history and physical examinations are basic, simplest, yet essential procedures to prevent it, which should be repeatedly performed until proven otherwise.

CASE: A 45-year-old female with a history of mild intermittent asthma and smoking habit presented with dyspnea. She developed dyspnea 2 hours prior to admission accompanied by 1 week of mild upper respiratory symptoms. She had discontinued her follow-up with her primary care physician 3 months prior to admission, despite inhaled corticosteroid being recommended. She smoked 10 cigarettes a day. On arrival at the emergency department, she was respiratory distressed and lethargic. Her vital signs were significant for respiratory rate of 36/min, O2 saturation of 99% (on 15L/min of O2 with non-rebreather mask) and heart rate of 142 bpm with regular rhythm. Lungs sound revealed significant wheezing bilaterally on both expiration and inhalation with stridor. She was intubated immediately, and methylprednisolone and ceftriaxone for severe asthma exacerbation were initiated. Her respiratory status was improved, followed by successful extubation on hospital day 3. However, she was found to have sustained tachycardia despite absent shortness of breath, and repeated complete history and physical examinations revealed recent unintended weight loss and exophthalmos, which implied Graves' disease. Thyroid function tests on hospital day 4 revealed decreased TSH and significantly increased FT3 and FT4. Graves' disease was confirmed by elevated TSH receptor antibody. Methimazole was initiated, followed by normalization of thyroid function with improved tachycardia.

IMPACT: Weight loss, exophthalmos and tachycardia are classical findings of Graves' disease, which were overlooked in the initial encounter. Tachycardia was noted on arrival, however it was explained by alternative possible causes, which included shortness of breath or usage of beta stimulant inhaler. Alternatively explainable findings may prematurely close other differential diagnoses.

DISCUSSION: Although only 13% of patients with Graves' ophthalmopathy are diagnosed on physical examination, lid retraction (+LR: positive likelihood ratio = 33.2) and lid lag (+LR = 18.6) are the significant diagnostic findings. Presence of tachycardia slightly increases the probability of hyperthyroidism. (+LR of Pulse > 90 beats/min = 4.5) Furthermore, Wayne Diagnostic Index for Hyperthyroidism consists of history and physical findings. Complete history and physical examinations should not be omitted regardless of emergent situations, and are crucial for early and accurate diagnosis of hyperthyroidism.

SEVERE SYMPTOMATIC HYPOCALCEMIA IN A PATIENT WITH HYPERTRIGLYCERIDEMIA-INDUCED ACUTE PANCREATITIS Eva Clay[2]; Krysta Johnson-Martinez[1]. [1]Atlanta VA Medical Center, Decatur, GA; [2]Emory University, Atlanta, GA. (Control ID #2703305)

LEARNING OBJECTIVE #1: Recognize and treat severe symptomatic hypocalcemia in acute pancreatitis

LEARNING OBJECTIVE #2: Treat hypertriglyceridemia in acute pancreatitis

CASE: A 52 year old man presented with 1 day of emesis and severe epigastric pain radiating to the back. He had a history of alcohol abuse, gout, and hypertriglyceridemia. Physical exam revealed temperature 36.6, HR 78, BP 137/91, RR 20. Abdomen was mildly distended and tender to palpation in the epigastrium and both lower quadrants. Labs revealed WBC 12.7, AST 160, ALT 154, Ca 7.5, Na 128, K 3.7, albumin 3.7, phosphorus 3.5, lipase 577, triglyceride 820. This patient's serum triglyceride level had been as high as 2300 in the past. Apache II score was 6. On day 2 of hospitalization, serum calcium level dropped to 4.2 (ionized 0.62 mmol/L), and patient had hand cramps, muscle weakness, positive Chvostek sign, and newly prolonged QT interval. He was treated with IV calcium gluconate and started on cardiac monitoring. He was also treated with insulin and Gemfibrozil to decrease triglyceride levels. Labs improved, but the patient had a prolonged hospital course with multiple complications.

IMPACT: This case highlights one of the well known complications of acute pancreatitis. Caring for this patient shed light on the importance of monitoring for lab evidence and physical exam signs of hypocalcemia, even if these findings are not initially noted at time of presentation. It also brought attention to targeted treatment options both for hypocalcemia and for hypertriglyceridemia in the setting of acute pancreatitis, though no large clinical trials have been done to evaluate these.

DISCUSSION: Internists often take care of patients with acute pancreatitis. One of the well known predictors of poor outcomes in pancreatitis is hypocalcemia. Severe hypocalcemia can cause increased neuromuscular excitability, seizures, and cardiac dysrhythmias (Desai et al.). Hypocalcemia in pancreatitis rarely requires specific treatment beyond supportive measures with IV fluids and bowel rest. In some cases, however, hypocalcemia is so severe that patients are at risk for deadly complications. In such cases, treatment with IV calcium gluconate is recommended along with cardiac monitoring (Cooper et al.). In this patient's case, the presumed cause of pancreatitis was hypertriglyceridemia. Conservative treatment with IV fluids and bowel rest are usually sufficient for the treatment of hypertriglyceridemic pancreatitis, though isolated case studies recommend treatment with plasmapheresis, heparin, and insulin (Valdivieslo et al.). References: 1. Desai, TK, RW Carlson, MA Geheb. Prevalence and clinical implications of hypocalcemia in acutely ill patients in a medical intensive care setting. Am J Med. 1988;84(2):209–14. 2. Eur J Intern Med. 2014;25(8):689–94.

SEVERE VITAMIN B12 DEFICIENCY MASQUERADING AS A MORE DEVASTATING DIAGNOSIS Wilson Z. Mar[2]; Elizabeth S. John[1]; Sheetal Patel[1]; kristen wong[2]. [1]Rutgers Robert Wood Johnson, Montville, NJ; [2]Rutgers Robert Wood Johnson Medical School, Elmhurst, NY. (Control ID #2707619)

LEARNING OBJECTIVE #1: severe B12 deficiency can present with a hemolytic picture, and megaloblasts are often times mistaken for blasts.

CASE: We present a case of a 48 year old male withno significant past medical history who came into the emergency department with 2 weeks of scleral icterus, fatigue, and loss of balance, a 10 pound weight loss over the last month despite a regular diet, and a hemoglobin of 6.1 on admission. His vitals were within normal limits, and his physical exam was positive for sublingual jaundice, scleral icterus, and jaundice. Labs included WBC 3, Hb 6.1, platelets 94, MCV 106.5, AST 196, ALT 70, Total bilirubin 1.9, Direct bilirubin 0.2, LDH 7214, D-dimer 2971, fibrinogen 214, and fibrin split products >20. Haptoglobin was severely decreased at <8.1. The automated differential of the peripheral smear initially showed 3% blasts without any schistocytes. Upon hematology's reviews of the slide, they said the "blasts" were more likely hypersegmented neutrophils. Vitamin B12 levels were initially extremely low at <30pg/mL. Folate, homocysteine and methylmalanic acid levels were elevated at >20, 229.6, and 19.92, respectively. Iron studies showed an elevated ferritin but normal iron levels, at 698 and 97, respectively. Intrinsic factor and parietal cell antibodies were positive as well, consistent with pernicious anemia. Vitamin B12 subcutaneous injections were initiated for 7 days, followed by once weekly for 4 weeks, and then monthly injections long term. Over the first two days of treatment, the pancytopenia improved, the LDH improved from 7214 to 5604, fibrinogen and fibrin split products decreased, and the haptoglobin increased. The patient's constitutional symptoms ameliorated as well.

IMPACT: In this case, the patient's constitutional symptoms, the labs that looked largely inflammatory and hemolytic, and the misleading automated differential of the peripheral smear initially bought the patient a more devastating diagnosis than severe Vitamin B12 deficiency. A hemolytic anemia picture such as TTP was considered with the significantly elevated LDH, the elevated fibrinogen, the low haptoglobin, and subjective neurological finding of balance loss. The initial peripheral smear interpretation in the setting of the significantly elevated LDH and constitutional symptoms was concerning for leukemia as well.

DISCUSSION: It is important to recognize that severe B12 deficiency can present with a hemolytic picture, and megaloblasts are often times mistaken for blasts. Another unique aspect of this case was the finding of both pancytopenia and hemolysis in the same patient, which is extremely rare as per the literature. In megaloblastic anemia with severely elevated LDH, it is crucial to consider Vitamin B12 deficiency so as to avoid a large workup including bone marrow biopsies and plasmapheresis.

SHE'S NOT CRAZY: A CASE OF ANTI-NMDA RECEPTOR ENCEPHALITIS Hani Rashid[1]; Phuong T. Nguyen[2]; Raymond Munoz[1]. [1]Methodist Dallas Medical Center, Dallas, TX; [2]Medical City of Fort Worth, Fort Worth, TX. (Control ID #2700754)

LEARNING OBJECTIVE #1: Identify the signs and symptoms of anti-NMDA receptor encephalitis.

CASE: A 36-year-old female with no clear past medical history other than possible mood disorder presented after three days of decreased level of consciousness. Associated symptoms included body aches, fever, chills, nausea, vomiting, and headaches. The patient had been suffering from flu-like symptoms two weeks prior to presentation and was treated with antibiotics. The patient became progressively confused with accompanying visual hallucinations, memory deficits, and episodes of exuberance alternating with episodes of agitation. The patient's mother reported a family history of bipolar disorder, though the patient had never exhibited such symptoms in the past. Upon presentation, the patient's vital signs were stable other than elevated blood pressure. She appeared agitated with a labile mood. She did not have nuchal rigidity or meningeal signs. CBC, CMP, urine toxicology, and urinalysis were unremarkable. Lumbar puncture was performed. The CSF was clear and colorless with the following values: WBC 92/μL (99% lymphocytes and 0%

neutrophils), RBC 0/μL, glucose 49 mg/dL, and protein 61 mg/dL. The patient's CSF was negative for West Nile virus, herpes simplex virus, and enterovirus by PCRs, and cryptococcal antigen. However, the fluid was positive for NMDA receptor IgG. She was diagnosed with anti-NMDAR (N-methyl-D-aspartate receptor) encephalitis and was treated with IV methylprednisolone and plasmapheresis resulting in improvement of her mental status and functional capacity prior to discharge to a rehabilitation facility.

IMPACT: This case highlights the importance of identifying when psychiatric symptoms are manifestations of an organic disease process, rather than diagnoses in themselves. Patients that present with psychiatric symptoms are sometimes transitioned to the care of mental health professionals without thorough evaluation of underlying and potentially reversible causes. While infectious etiologies must be excluded in the encephalopathic patient, non-infectious encephalitis must also be considered.

DISCUSSION: Anti-NMDA receptor encephalitis is a potentially fatal but treatable form of non-infectious encephalitis. It is caused by autoantibodies targeted against the NR1 subunit on the NMDA receptors in the brain. Patients can present with viral-like symptoms, followed by psychiatric manifestations and finally neurologic decline. The affected patient population is typically composed of young females. Anti-NMDA receptor encephalitis is commonly associated with teratomas and therefore may also be considered a paraneoplastic syndrome. Diagnosis is made by identification of NMDA receptor antibodies in serum or CSF. Prompt initiation of immunotherapy (steroids and IVIG or plasma exchange) and tumor removal (if applicable) are the cornerstone of therapy. Patients require close monitoring and coordination between multiple specialties for favorable outcomes and prevention of long-term neurological sequelae.

SHEEP IN WOLF'S CLOTHING: THE GREAT MASQUERADER

Maxine Tang; Michael Layoun; Daniel Kahn. UCLA, Los Angeles, CA. (Control ID #2698783)

LEARNING OBJECTIVE #1: Recognize signs of Tuberculous Peritonitis

LEARNING OBJECTIVE #2: Outline the differential diagnosis of an elevated CA-125

CASE: The clinical presentation of tuberculous peritonitis is often nonspecific on initial presentation and may be mistaken for peritoneal carcinomatosis. While the diagnosis is under-recognized in non-endemic regions, early recognition can prevent significant morbidity. An 81-year-old Filipino female presented with a several month history of abdominal distension, early satiety, and night sweats. Computed tomography demonstrated abdominal ascites and a borderline gastro-hepatic lymph node. CA-125 was elevated at 889 U/mL. Paracentesis revealed lymphocytosis with negative cytology. A PET-CT showed diffuse omental nodularity concerning for carcinomatosis and multiple FDG-avid lymph nodes concerning for metastases. The patient underwent exploratory-laparotomy with total abdominal hysterectomy and bilateral salpingo-oophorectomy given the high concern for ovarian malignancy. During the operation, turbid ascites, widespread studding, and adhesions were observed. Pathology revealed necrotizing granulomatous inflammation with no evidence of malignancy. Acid fast staining of the omentum, ovaries, and cul-de-sac were positive for acid-fast bacilli. QuantiFERON TB Gold test was indeterminate. Rifabutin, isoniazid, ethambutol, and levofloxacin therapy was initiated per public health recommendations for empiric treatment of tuberculous (TB) peritonitis. At a follow-up appointment several weeks later, abdominal pain had resolved and CA-125 was down-trending to normal. Ascitic fluid culture eventually confirmed Mycobacterium Tuberculosis.

IMPACT: TB is still the great masquerader. Even in a high resource setting, TB can evade diagnosis. While CA-125 is traditionally used as a tumor marker, it is important to recognize the range of etiologies leading to elevated CA-125. This case reinforces that despite advanced diagnostics, an invasive procedure is frequently required to differentiate TB from malignancy.

DISCUSSION: This case illustrates how tuberculous peritonitis can closely mimic peritoneal carcinomatosis and often eludes diagnosis until surgical intervention has occurred. Tuberculous peritonitis has a similar presentation to intra-abdominal malignancies (such as ovarian cancer) with findings including new-onset ascites, pelvic masses, and elevated CA-125. Some findings that are more specific to TB are night sweats, fever, and abdominal pain. AFB staining is often negative; diagnosis frequently requires laparoscopy and peritoneal biopsy. CA-125 is associated with ovarian cancer as well as non-gynecologic malignancies, peritonitis, endometriosis, hepatitis, and pancreatitis. CA-125 is generally elevated in tuberculous peritonitis and may serve as a non-specific marker for response to TB treatment. Early recognition of TB is paramount as it is one of the few diffuse peritoneal processes that can be effectively cured.

SICKLY SWEET: CHALLENGES IN DIAGNOSING DYSGLYCEMIA IN A PATIENT WITH SICKLE CELL TRAIT (SCT)

Odeth Barrett-Campbell[1, 2]; Andrew A. Chang[1, 2]. [1]Health + Hospitals Kings County, New York, NY; [2]SUNY Downstate, Brooklyn, NY. (Control ID #2704677)

LEARNING OBJECTIVE #1: To recognize the challenges with use of HbA1c in dysglycemic patients with hemoglobinopathies and alternatives to A1c testing in these patients.

CASE: We present a 49 year old woman with SCT who presented for routine care. Review of systems was unremarkable. Family history revealed Diabetes Mellitus- mother and sister. She had normal vital signs and BMI of 25kg/m^2. Examination findings were normal. Laboratory studies including lipid panel, basic metabolic panel and complete blood count were normal save for HbA1c which read: variant hemoglobin, A1C = 25.5%. Oral glucose tolerance test (OGTT) revealed Impaired Glucose Tolerance (IGT). Diet and lifestyle changes were advised. Three months later, she remained asymptomatic and her weight was unchanged. Glycated Fructosamine was 290 umol/l (205–285). The continuation of diet and lifestyle changes and addition to low-dose Metformin, were discussed but she refused pharmacologic intervention at this time and opted for further monitoring.

IMPACT: In reviewing the case one may consider ruling out a hemoglobinopathy in dysglycemic patients when wide variations are seen in A1c values. The HbA1C trend can be used to identify patients at risk of Diabetes Mellitus but it is important to recognize the limitations in patients with hemoglobin variants due to increase in red cell turnover. The use of serum fructosamine in this case would not be appropriate for screening but for monitoring in a patient with Diabetes Mellitus.

DISCUSSION: Dysglycemia refers to a disorder in the metabolism and regulation of blood glucose and may be applied to pre-diabetic and diabetic individuals. Patients with IGT may be identified as pre-diabetics. Recognition of this intermediary group is important given the association with dyslipidemia, hypertension and obesity, all of which is used to identify metabolic syndrome.

Individuals with hemoglobin variants, such as SCT, may have falsely low or high levels of A1c due to increase in red cell turnover. Fasting glucose and OGTT are the most appropriate alternatives for screening in patients with hemoglobin variants. Glycated fructosamine and glycated albumin (GA) would be useful for monitoring in diabetic patients with hemoglobinopathies as values are not affected by disorders of hemoglobin metabolism or RBC survival. Both reflect short term control (2–3 weeks) and are affected by disorders of albumin metabolism. 1, 5-Anhydroglucitol is a newer test used as a measure of short term glycemic control but based on literature review it not extensively studied in hemoglobinopathies. Despite ongoing efforts to improve and standardize the measurements of HbA1C that would best apply to patients with hemoglobin variants it is still advisable not to use HbA1C in diabetics or prediabetics with sickle cell disease.

SILICONE INJECTIONS: RAISING MORE THAN JUST GLUTES.

Orlando Zepeda; Jennifer Weintraub; Lauren Peccoralo. Icahn School of Medicine at Mount Sinai, New York, NY. (Control ID #2703845)

LEARNING OBJECTIVE #1: Recognize silicone-mediated granulomatous disease as a potential cause etiology of hypercalcemia.

LEARNING OBJECTIVE #2: Manage silicone-mediated granulomatous disease.

CASE: A 37 year-old woman with no past medical history presented with 5 months of progressive fatigue, and recent onset nausea and vomiting. The patient was well appearing, afebrile, and normotensive. Benign abdomen without flank tenderness on exam though was notable for firm, non-tender, non-mobile indurations overlying her buttocks. Initial labs were notable for a creatinine of 3.77 and corrected calcium of 12. Renal ultrasound demonstrated severe bilateral hydronephrosis and hydroureter. CT abdomen-pelvis confirmed multiple bilateral distal ureteral stones, largest 1.7cm, in addition to multiple nodules within the soft tissue superficial to the gluteal muscles. The patient was started on intravenous hydration and calcitonin with placement of bilateral ureteral stents. Testing including SPEP/UPEP, intact parathyroid hormone and age-appropriate cancer screening were unremarkable. 25-OH vitamin D was low at 22.1 and 1,25-OH vitamin D was 78.6, the high end of the normal range. On further history, she reported having silicone gluteal injections 7 years prior in Colombia. Given the history and findings on imaging, her hypercalcemia was thought to be due to granulomatous reaction to silicone. Prednisone was started and plastic surgery was consulted for removal of gluteal granulomas. Her calcium and renal function improved over her hospitalization.

IMPACT: Silicone is gaining popularity for body augmentation as it is inexpensive and presumed non-immunogenic. However, there are increasing complications from use of unknown grades of silicone by unlicensed providers. While there are currently less than a dozen case reports of hypercalcemia related to silicone gluteal injections, silicone mediated granulomatous reactions should remain high on the differential for hypercalcemia in appropriate patients.

DISCUSSION: Hypercalcemia is a common finding with similar signs and symptoms regardless of etiology. Primary hyperparathyroidism and malignancy are responsible for up to 90% of cases. Often overlooked, granulomatous reactions, such as sarcoidosis and tuberculosis, can cause hypercalcemia due to hyperproduction of 1,25-OH vitamin D via activation of a mononuclear cell pathway independent of PTH. Clues to the diagnosis include an inappropriately elevated 1,25-OH vitamin D level and low 25-OH vitamin D suggestive of excessive conversion. In addition to fluids, hypercalcemia due to granulomatous reactions can be treated with steroids. In cases of silicone mediated granulomatous disease, removal of the insulting agent is key. While most often due to primary hyperparathyroidism or malignancy, this case highlights the importance of maintaining a broad differential for hypercalcemia and conducting a thorough history and physical to identify other potential causes.

SIRS BUT NO SEPSIS? SHORT BOWEL SYNDROME PRESENTING AS SIRS

Taylor Schmidt; Ami DeWaters; Oanh K. Nguyen. UT Southwestern Medical Center, Dallas, TX. (Control ID #2705786)

LEARNING OBJECTIVE #1: Recognize volume depletion in short bowel syndrome as an etiology of SIRS.

LEARNING OBJECTIVE #2: Recognize the need for medical therapy in the management of short bowel syndrome.

CASE: A 69 year old woman with an ostomy presented to the emergency department for nausea, vomiting, and unintentional weight loss of 100 lbs over 4 months. She had 2 episodes of non-bloody emesis the day of presentation, and her family reported she had general malaise. Review of systems was negative for fevers, abdominal pain, urinary symptoms, and increased ostomy output. She had a temperature of 36.4 C, pulse of 120 beats/minute, respiratory rate of 27, and blood pressure of 149/80 mmHg. On exam, she was cachectic, had dry mucous membranes, and a non-tender abdomen with a healthy, pink ostomy. Her sodium was 131 mmol/L, potassium 3.0 mmol/L, bicarbonate 11 mmol/L, creatinine 2.79 mg/dL, and lactate 5.6 mg/dL. White blood cell count (WBC) was 13,830 cells/ microliter. Urinalysis showed 5 WBCs/hpf. Computed tomography scan of her abdomen showed no etiology of infection. She was started on empiric antibiotics for presumed sepsis of urinary origin, given 3 liters of normal saline (NS), and admitted to the general medicine ward. Blood, urine, and stool cultures were negative. She had 4 liters/day of ostomy output. Outside records revealed she had a bowel resection with end-jejunostomy 4 months prior for obstruction. Thus, antibiotics were stopped and medical therapy for short bowel syndrome modified to include antimotility agents, stool bulking agents, and cholestyramine. Her stomal output eventually decreased to 1.7 L/ day, NS was stopped and she was discharged home.

IMPACT: This case changed our thinking by broadening our differential for SIRS, which now includes volume depletion related to short bowel syndrome. Our practice has changed to include medical therapy, as well as dietary changes, in treating short bowel syndrome.

DISCUSSION: SIRS criteria have been commonly used to identify potentially septic patients. While systemic infections commonly cause SIRS, other non-infectious etiologies can also cause it. Patients with short bowel syndrome, particularly those who have had ileal and colonic resections like our patient, are prone to fluid and electrolyte loss. This volume depletion can lead to SIRS, as in our case. Any differential of SIRS must include such non-infectious etiologies in order to avoid a delay in diagnosis. Dietary changes and medications can help prevent serious complications, like SIRS, of short bowel syndrome. Patients should avoid hypertonic foods to prevent osmotic loss of fluids into the bowel. A proton pump inhibitor can decrease gastric acid secretion. If stomal output continues to exceeds intake, antimotility drugs and bulk-forming laxatives can decrease intestinal motility and slow fluid loss. Overall, providers

must know the complications and treatment of short bowel syndrome to facilitate diagnosis and lead to appropriate management.

SKIN DARKENING AS AN ENLIGHTENING CLUE: AN 18 year OLD MALE WITH AUTOIMMUNE POLYGLANDULAR SYNDROME TYPE 2 Navya Nambudiri; Donald C. Eagerton. Grand Strand Medical Center, Myrtle Beach, SC. (Control ID #2706641)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of primary adrenal insufficiency.

LEARNING OBJECTIVE #2: Recognize the components of autoimmune polyglandular syndrome type II.

CASE: An 18 year old male with type 1 diabetes (since age 18 months), hypothyroidism (since age 4 years), and psoriasis presented with weight loss, several weeks of extreme fatigue, weight loss, and diffuse hyperpigmentation. He had recently been out in the sun; his mother reported the findings as tanned skin. His diabetes and hypothyroidism had been difficult to control in the past, including episodes of diabetic ketoacidosis. His medications were a continuous insulin pump and levothyroxine. There was no family history of autoimmune disease. On examination, he had low-normal blood pressure while supine. The patient was examined supine, as he lacked energy to sit up due to extreme fatigue. There was no thyromegaly. Neurological exam was within normal limits. His extremities showed diffuse hyperpigmentation and psoriatic plaques. Labs revealed hyponatremia (serum Na 129), hyperkalemia (serum K 5.6) and elevated TSH (30). A cortisol stimulation test showed baseline cortisol was 0.2 with markedly elevated plasma ACTH (1215). The +30 and +60 min cortisol levels were markedly low (0.2), reflecting failed response to stimulation. He was diagnosed with primary adrenal insufficiency and started on hydrocortisone with prompt improvement. With the triad of type 1 diabetes, hypothyroidism, and primary adrenal insufficiency, he was diagnosed with autoimmune polyglandular syndrome type II.

IMPACT: While initially tempting to attribute extreme fatigue to worsening hypothyroidism, a key learning point in such patients is including primary adrenal insufficiency in the differential diagnosis. His hyperpigmentation particularly helped broaden our thinking.

DISCUSSION: Several autoimmune polyglandular syndromes involving multiple endocrine organs exist. Autoimmune polyglanduar syndrome type II is most common, affecting the thyroid, pancreas, and adrenal gland. Other organ involvement may cause primary gonadal failure or primary hypopituitarism. Primary adrenal insufficiency most often arises from autoimmune destruction; other causes include infection, infarction, and adrenal metastases. Primary adrenal insufficiency may induce diffuse hyperpigmentation due ACTH upregulation and associated melanocyte stimulating hormone production. Other findings include weight loss, fatigue, hypotension, and gastrointestinal upset. Frequent, severe hypoglycemia is often seen. Lab findings can include low cortisol, high ACTH, high CRH, hyponatremia and hyperkalemia. Treating primary adrenal insufficiency includes stabilization of vital signs and electrolytes along with corticosteroid replacement. Physicians should have a high index of suspicion in individuals with underlying endocrinopathies presenting with diffuse skin darkening as an enlightening manifestation of primary adrenal insufficiency.

SLAM DUNK - PRESUMED BACTRIM INDUCED NEPHROPATHY Nina Fredericks; Aravdeep Jhand; Jeffrey Macaraeg; Gene Perschwitz; Vishisht Mehta; Venkata Andukuri. Creighton University, Omaha, NE. (Control ID #2705290)

LEARNING OBJECTIVE #1: Recognize the clinical features of Granulomatosis with Polyangiitis (GPA)

LEARNING OBJECTIVE #2: Identify hepatic involvement in GPA

CASE: A 62 y.o. obese caucasian female presented with 7 days of progressive generalized weakness, imbalance, and decreased urine output. She was thought to have nephropathy with acute kidney injury secondary to recent Bactrim use for possible cellulitis of a right pretibial ulcer. Review of systems was positive for chronic rhino-sinusitis and productive cough with occasional blood streaked sputum. Physical examination revealed a 4mm apthous ulcer under the tongue, decreased breath sounds in the base of the lungs bilaterally, 2+ pitting edema and a 2cm ulcerative lesion with surrounding petechiae on the right pretibial region. Laboratory results at admission included hemoglobin of 9.1 g/dL, white blood cell count of 23.1×10^3/uL, BUN of 65.7 mg/dL, serum creatinine of 4.75 mg/dL and ESR of > 140 mm/hr. Urinalysis revealed hematuria without casts and Fractional excretion of Urea (FeUrea) was 45% - consistent with intrinsic renal damage. Liver function tests were: AST 45 u/l ($N = 10$–40 u/l), ALT 17 ($N = 12$–78 u/l), Alkaline Phosphatase 339 (33–138 u/l), Total Bilirubin 1 mg/dl and Albumin 1.5 gm/dl. A CXR revealed diffuse bilateral interstitial infiltrates and empiric antibiotic therapy was initiated. Given multisystem involvement, rheumatologic work up was done. Serum ANA and hepatitis panel were negative, serum complement levels and abdominal US were normal. C-ANCA (>1:320) and PR-3 were positive, raising suspicion for Granulomatosis with Polyangiitis. Patient refused renal biopsy to confirm the diagnosis of GPA and therapy with IV pulse steroids and Rituximab was initiated. The patient's status declined on day 7 with worsening dyspnea, hemoptysis, and LFT's. A Chest CT showed bilateral ground glass opacification. Due to radiographic and clinical features, diffuse alveolar hemorrhage was suspected and therapeutic plasma exchange was initiated. Patient showed clinical improvement after three treatments and transitioned to oral steroids.

IMPACT: Gastrointestinal manifestations of vasculitis are relatively uncommon - particularly those affecting liver function. In this patient, the apparent decline in hepatic function, in the absence of hypotension, abnormality on liver ultrasound, or known hepatotoxic insult suggest hepatic involvement in the setting of GPA.

DISCUSSION: GPA is a small vessel vasculitis with pathognomic necrotizing granulomas. This case highlights various organ system involvement in GPA including pulmonary, renal, cutaneous, and upper respiratory tract. Hepatic involvement in GPA was previously thought to be rare. However, Willeke et al. recently reported LFT abnormalities may be seen in up to 50% of patients with ANCA associated vasculitis and, in the absence of other hepatic diseases, could be attributed to underlying vasculitis. It is key for clinicians to be aware of such derangements in the LFT's since they may indicate underlying active disease.

SLIDES OF RELIEF: KIKUCHI, NOT CANCER Adam Tepler[1, 2]; Danit Arad[2]. [1]Albert Einstein College of Medicine, BRONX, NY; [2]Montefiore Medical Center, Bronx, NY. (Control ID #2700595)

LEARNING OBJECTIVE #1: Outline the differential diagnosis of cervical lymphadenopathy with constitutional symptoms.

LEARNING OBJECTIVE #2: Recognize clinical features of Kikuchi disease.

CASE: A 30 year-old woman presented with 2 weeks of progressive, painful right neck swelling, fever, and throat and ear pain. She had no medical conditions and no significant surgical history. She reported no cough, dental pain, joint pain, easy bruising or bleeding, history of tuberculosis, history of autoimmune disease, sick contacts, cat exposure, history of HIV or any other STD and was sexually active only with her husband. Vitals were significant for fevers to 101.3F. She had a 3x4cm right submandibular lymph node with erythema, warmth, and tenderness. She appeared well, with clear oropharynx, no erythema, no exudates, good dentition, normal otoscope exam, no cardiac murmur, normal lung exam, no rash, and no other lymphadenopathy. Work-up for infection and autoimmune processes yielded negative results. Sonogram and computed tomography confirmed an enlarged lymph node without fluid collection. Fine needle aspiration contained no malignant cells. Pathology of an excisional biopsy reported necrotizing histiocytic lymphadenitis consistent with Kikuchi disease. The patient was discharged home and symptoms resolved within 12 weeks of admission.

IMPACT: This case highlights the importance of considering Kikuchi Disease, a self-limited, benign disease, in the presentation of cervical lymphadenopathy with constitutional symptoms, especially in women 30 or younger. Early biopsy is indicated to distinguish from lymphoma, which can present similarly.

DISCUSSION: Lymphadenopathy is often encountered as a manifestation of both grave and harmless conditions. Constitutional symptoms including fever or weight loss can indicate more serious disease. The differential diagnosis of painful cervical lymphadenopathy and fever is quite extensive, including cat scratch disease, infectious mononucleosis, toxoplasmosis, tuberculosis, and many other infections. Tests should be ordered accordingly. Autoimmune disease such as systemic lupus erythematous, and neoplastic diseases such as lymphoma may also cause a similar presentation, but are more difficult to rule out. Kikuchi disease is a rare cause of cervical lymphadenopathy with constitutional symptoms, described as histiocytic necrotizing lymphadenitis, usually affecting women under the age of 30. Constitutional symptoms vary and include fever, experienced by 35% of patients, as well as fatigue, joint pain, rash, weight loss, decreased appetite, sweating, and myalgia. Hepatomegaly, splenomegaly, other sites of lymphadenopathy, xerophthalmia, and aphthous ulcers may also be present. Lab values are largely non-specific, but can rule out other entities. In one review, leukopenia and elevated erythrocyte sedimentation rate were measured in 18 and 16% of patients, respectively. Histopathological analysis establishes diagnosis.

SMALL INTESTINAL METASTASIS OF UNDIFFERENTIATED CARCINOMA PRESENTING AS MELENA Kyle Glienke; Aiza Ashraf; Steven Palmer. St. Vincent Health, Indianapolis, IN. (Control ID #2707396)

LEARNING OBJECTIVE #1: Diagnose metastatic carcinoma as an unusual, yet serious cause of melena

CASE: A 54-year-old man presented to the emergency department due to neck and upper thoracic back pain. On review of systems, the patient also reported a three-month history of progressive dyspnea and melena. He had a 70 pack/year cigarette smoking history and had not seen a physician in many years. A chest x-ray revealed a left upper lobe nodular density and a CBC showed a hemoglobin of 2.8 g/dL, a CT scan of the chest, abdomen, and pelvis revealed a left medial pleural-based chest mass, hilar adenopathy, and additional masses in the liver, right adrenal gland, and the left 6th rib, concerning for metastatic disease. Several units of PRBCs were transfused, and the patient underwent an EGD to evaluate for causes of melena. Two one centimeter nodules and a larger mass-like structure were identified in the distal duodenum, with stigmata of recent bleeding. Biopsies were taken and hemostasis achieved. The patient's dyspnea improved with transfusion. An MRI of the brain and spinal cord showed 3 approximately 1.5cm diameter cerebral lesions as well as suspected metastatic disease at multiple vertebrae. Pathology of the duodenal masses revealed a poorly-differentiated carcinoma, which was confirmed on additional sampling of the left upper lung mass. Further staining was not able to confidently identify a source of origin, thus a diagnosis of carcinoma of unknown primary was established. After multiple discussions with medical and radiation oncology, the patient opted for palliative care alone and was discharged home without radiation or chemotherapy.

IMPACT: This case serves as an illustration that metastatic disease can have multiple presentations, often with relatively non-specific symptoms. Carcinoma of unknown primary accounts for 3-5% of all malignancies[1]. Diagnosis requires an exhaustive search for the primary source in a systematic manner with physical examination, imaging, and pathologic studies[2]. If not attributable to a likely source, these malignancies fall into an "unfavorable" category, which can make treatment decisions difficult for both patients and providers[3].

DISCUSSION: Metastatic disease can present with relatively non-specific signs and symptoms, and thus a high-degree of suspicion for serious causes of sometimes mundane patient presentations must be maintained. An exhaustive search both clinically and pathologically is required to diagnose and manage carcinoma of unknown primary. 1.Massard C, et al. Carcinomas of an unknown primary origin - diagnosis and treatment. *Nat. Rev. Clin. Oncol*. 2011;8:701–710. 2. Pavlidis N and Fizazi K. Carcinoma of unknown primary. *Critical Reviews in Oncology/Hematology*. 2009;69:271–278. 3. Amela EY, et al. Management of "unfavorable" carcinoma of unknown primary site: Synthesis of recent literature. *Critical Reviews in Oncology/Hematology*. 2012;84:213–223.

SMEAR CAMPAIGN: FALSE ATTRIBUTION OF PANCYTOPENIA TO TICK BITE Soraya Azzawi; Dr. Jessica T. Lee; Michael J. Peluso; Dr. Haiyan Ramirez Batlle; Aaron G. Richterman; Maria Yialamas. Brigham and Women's Hospital, Boston, MA. (Control ID #2704251)

LEARNING OBJECTIVE #1: Evaluate pancytopenia in the setting of Lyme disease

LEARNING OBJECTIVE #2: Manage Lyme disease in the neutropenic patient

CASE: AC is a 51-year-old woman with a past medical history of fibromyalgia who presented with a rash and pancytopenia following a tick bite she sustained while visiting Martha's Vineyard in the summer. AC endorsed months of malaise, easy bruising, and occasional night sweats. The day after she found a tick attached to her right arm, AC noticed a tender, erythematous, targetoid rash on her left calf. Subsequently, she experienced drenching night sweats and chills. AC presented to a local hospital; laboratory investigations revealed a white blood cell count of 0.7×10^3 cells/uL, hemoglobin of 9.6 gm/L and platelet count of 85×10^6 cells/uL, with a differential of 3% neutrophils, 89%

lymphocytes, 7% monocytes and 1% eosinophils. On admission day two, her leukopenia persisted (WBC 0.5 x10^3 cells/uL, absolute neutrophil count 10 cells/uL); this was attributed to tick-borne illness and she was transferred to our institution. Tick-borne disease panel returned with positive IgM for Lyme Disease and was negative for Babesia, Ehrlichia/Anaplasma, and Rickettsia. Peripheral smear demonstrated poikilocytosis, occasional tear-drop cells, thrombocytopenia, lymphocytosis (atypical appearance), no neutrophils, and possible blasts. Peripheral flow cytometry showed 7% myeloblasts. Bone marrow biopsy demonstrated 60% blasts. Ultimately, she was diagnosed with acute myelogenous leukemia. AC was treated with a 14-day course of doxycycline while receiving induction chemotherapy with a 7 + 3 regimen of cytarabine and daunorubicin.

IMPACT: Pancytopenia—while possible—is a rare manifestation of Lyme disease and should prompt evaluation for alternate processes, including co-infection with Ehrlichia/Anaplasma, which is associated with cytopenias, or hematologic malignancy. Peripheral blood smear is essential in this context as part of the diagnostic work up, and in this case suggested the possibility of malignancy.

DISCUSSION: To date, literature exploring how altered immunity shapes the course of Lyme infection is scant. One study by Furst et al. investigated potential differences in clinical characteristics and serological profile between patients with acquired immune deficiency and immunocompetent controls. Prevalence of IgG and IgM antibodies were similar between patient groups. Ultimately, the study concluded that immunosuppression did not significantly alter the manifestation or outcome of early Lyme disease, suggesting that similar antibiotic regimens can be used for both groups. Both the ideal antibiotic dose and duration have yet to be standardized across the field, likely due to a dearth of randomized trials. Using data from similarly indolent diseases like tuberculosis, some experts recommend prolonged courses. AC received a standard course; she had no advanced Lyme disease symptoms as she progressed through her treatment for her AML, including an allogenic bone marrow transplant.

SOLVING ONE PROBLEM TO CREATE ANOTHER: FROM WEIGHT LOSS TO WORSE Elizabeth P. Griffiths. UCSF, San Francisco, CA. (Control ID #2703289)

LEARNING OBJECTIVE #1: Review the differential diagnosis and work up of unintentional weight loss, with specific focus on the geriatric population

LEARNING OBJECTIVE #2: Distinguish frontotemporal dementia (FTD) from acute mania

CASE: A 74 year old man with a history of depression and chronic back pain presented with a four month history of 20 pound unintentional weight loss. Review of systems was negative except for one year of nausea, resulting in decreased food intake. He noted that his depression had worsened two months prior. His medications included Oxycontin, Ativan, Ritalin, and Wellbutrin. He was a highly functioning professional, lived with his wife, and drank 2 glasses of wine per night. His exam was unremarkable except for confirmation of weight loss. His initial work up including chemistries, CBC, TSH, ESR, PSA, FOBT, CXR, UA, and HIV was unrevealing. His Ritalin was stopped, and he quit drinking alcohol. He was referred for EGD and colonoscopy, which showed mild gastritis. He began to gain weight, coinciding with lifting of his depression. Two months later, his son reported significant personality changes in his father, including overspending, public urination, and threatening his wife, resulting in loss of employment and divorce. He had been seen by an outside psychiatrist and diagnosed with frontotemporal dementia (FTD). A referral was made to neurology clinic, where he was instead diagnosed with acute mania. He has subsequently improved on mood stabilizers.

IMPACT: As an internist, I tend to focus more on the importance of ruling out malignancy in cases of unintentional weight loss. This case reminded me that, especially in the geriatric population, psychiatric disease is more common. It should be addressed equally seriously and urgently, including probing regarding past episodes of mania in anyone with depression.

DISCUSSION: Unintentional weight loss is common in the geriatric population, with as many as 20% of adults over 65 meeting diagnostic criteria. Depression is the most common cause, followed by malignancy and dysphagia. Initial work up should include thorough history and physical, basic labs, CXR, and age appropriate cancer screening. Special attention should be paid to medication review, alcohol and substance use, diet, swallowing problems, dementia, depression, and social situation. While depression is a very common cause of weight loss, this patient's subsequent personality change is much less common. The primary diagnoses considered were FTD and acute mania. While his behavioral disinhibition and loss of empathy were consistent with FTD, he was instead diagnosed with acute mania based on the following features: abrupt onset, remote history of another manic episode, lack of FT atrophy, preservation of cognitive function, paranoid features, increased productiveness, insight into the inappropriateness of his behaviors, recent lifting of depression, grandiosity, and flight of ideas. Distinguishing between these causes is essential given the reversibility of mania with appropriate treatment.

SPINAL MASS DUE TO MYELOID HYPEREOSINOPHILC SYNDROME Kashiti Long. Emory University, Atlanta, GA. (Control ID #2706174)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of hypereosinophilic syndrome (HES).

LEARNING OBJECTIVE #2: Review the pathogenic variants of HES including the myeloid variant and how pathogenic variant guides treatment for HES.

CASE: 39 year old male presents with bilateral lower extremity weakness and difficulty walking. One month prior to admission, the patient developed numbness, hyerreflexia and loss of proprioception in bilateral lower extremities. He was found to have a circumferential epidural mass with lumbosacral central spinal stenosis.He underwent multilevel sacral laminectomy S1 to S3 with subtotal excision of the mass. Pathology of the mass showed inflammatory tissue and gram-positive cocci. He was treated with daptomycin for 10 days. Following this he developed bilateral lower extremity weakness, pain and progressive difficulty walking. MRI revealed T5 to T11 circumferential, epidural lesion. Patient underwent a biopsy of the epidural mass. Pathology of the mass and bone marrow biopsy revealed inflammatory tissue, fibrosis and eosinophilic infiltrate. Genetic analysis revealed evidence for CHIC2 deletion on chromosome 4 consistent with the clinical possibility of this being FLP1L1-PDGFR alfa fusion gene. The combination of eosinophilic infiltrates and detection of the FLP1L1-PDGFR alfa fusion gene suggested the diagnosis of a myeloid version of Hypereosinophilic syndrome (HES). He was treated with imatinib.

IMPACT: Our case is a rare case of hypereosinophilic syndromes manifesting as CNS mass. Albeit rare, recognizing HES is key as identification of disease variant guides treatment.

DISCUSSION: Hypereosinophilic syndromes (HES) is an uncommon, heterogeneous group of disorders characterized by persistent eosinophilia with evidence of eosinophil-induced organ damage. It occurs most frequently in young to middle-aged males. Varied clinical manifestations can occur with involvement of skin, heart, lungs, and nervous system in more than 50% of cases. The most common type of CNS involvement is cerebrovascular disease. It is thought that there are variants of HES based on the pathogenesis of the hypereosinophilia. A myeloid variant is thought to be arise from a chromosomal deletion on 4q12 leading to creation of the FIP1L1-PDGFRA fusion gene (F/P gene) in a myeloid cell line. This fusion gene encodes an aberrant tyrosine kinase that leads to unregulated growth of the cell. Presence of hypereosinophilia and end-organ damage with the exclusion of alternate causes of hypereosinophilia suggests the diagnosis of HES. Further cytogenetic testing to identify the variant is warranted. Therapeutic management depends on the severity of manifestations and pathogenic variants. For patients with the the F/P fusion gene, tyrosine kinase inhibitors are first line therapy. For patients without the F/P fusion gene, steroid therapy and mepolizumab, an anti-IL-5 antibody is indicated.

SPLENIC SEQUESTRATION CRISIS IN A PATIENT WITH SICKLE CELL-BETA THALASSEMIA TRAIT AND CONCOMITANT G6PD DEFICIENCY Agnes McAuliffe; Ayushi Chahuan. University of Connecticut, Manchester, CT. (Control ID #2706454)

LEARNING OBJECTIVE #1: Recognize splenic sequestration crisis in patients with a Sickle cell variant disorder

LEARNING OBJECTIVE #2: Identify timing of splenectomy in an acute splenic sequestration crisis

CASE: A 28 year old Kuwaiti male with self reported sickle cell disorder (HbSS) and G6PD deficiency was admitted with an acute pain crisis. Due to patient's complaint of abdominal pain, a CT abdomen was ordered which showed mild splenomegaly. Due to splenomegaly, sickle cell trait in father and beta thalassemia trait in mother, a variant disorder was suspected. Hemoglobin (Hb) electrophoresis was sent for confirmation. He was started on intravenous (IV) hydration, Dilaudid drip and folic acid. He declined hydroxyurea due to concern for azoospermia. His pain progressively worsened over the next three days, with development of severe left upper quadrant abdominal pain. Labs showed Hb and hematocrit (H/H) 5.8/18.1 and platelet count 58, decreased from a baseline H/H of 9/30 and normal platelet count. A repeat CT abdomen showed massive splenomegaly, increased from previous with extensive splenic infarcts. This was consistent with an acute splenic sequestration crisis. Hb electrophoresis revealed HbA 2%, HbA2 3.6%, HbS 76.2 and HbF 18.2%, consistent with a Sickle cell-Beta plus thalassemia syndrome. G6PD level was 0.2. His clinical status continued to worsen with persistent pain. Labs showed intravascular hemolysis with LDH 1000, haptoglobin <6, indirect hyperbilirubinemia and reticulocytosis. Multiple red cell transfusions were required. Surgical team was consulted for possible splenectomy. However there was concern for worsening hemolysis due to a surgical intervention and surgery was deferred. He was supported with conservative medical measures. Three weeks following initial presentation, after improvement in hemolytic indices, patient underwent open splenectomy.

IMPACT: We discuss the management of acute splenic sequestration crisis in a patients with sickle cell variant syndrome with concomitant G6PD deficiency, highlighting role and timing of splenectomy

DISCUSSION: Patients with sickle cell variant usually do not undergo autosplenectomy and are prone to adulthood splenic crises with a more severe course. Available data appears to favor splenectomy after the first splenic sequestration crisis; however no consensus exists on delayed versus early surgery. Our case was further confounded by the concomitant G6PD deficiency, which increased the risk of severe hemolysis and surgical risk. In HbSS patients, splenectomy does not affect morbidity or mortality. Surgeries, when performed, are based on expert consensus rather than evidence. This, however, might not be applicable to patients with sickle cell variants. Our experience suggests that cases with another concomitant hemolytic disorder might benefit from a delayed splenectomy while allowing for medical optimization with aggressive hydration, analgesia and transfusional support. It might be permissible to perform early splenectomy in solitary sickle cell variant syndromes.

SPONGIFORM CARDIOMYOPATHY: AN UNUSUAL MANIFESTATION OF SCLERODERMA Steven Song; Joselle Cook. SUNY Downstate Medical Center, Brooklyn, NY. (Control ID #2700532)

LEARNING OBJECTIVE #1: Recognize the emerging association between left ventricular non-compaction and autoimmune conditions such as scleroderma, leading to earlier diagnosis and appropriate treatment.

CASE: A 37-year-old woman presented with complaints of dyspnea on exertion and palpitations over one month. She had a 7-year history of scleroderma, on treatment with azathioprine and prednisone, and systolic heart failure, diagnosed 7 months earlier at an outside hospital. On admission, ECG demonstrated atrial flutter with a rapid ventricular rate of 154 bpm. The patient was started on a diltiazem drip for rate control. TEE established a LVEF of 30-35 and no thrombi. She underwent synchronized cardioversion with return to sinus rhythm. Post-procedure, the patient went into cardiac arrest; resuscitation was started with return of spontaneous circulation. She was intubated and started on vasopressors. Within 48 hours, vasopressors were weaned off and she was extubated. TTE revealed a LVEF of 5-10%. Cardiac catheterization demonstrated no occlusive coronary artery disease. Cardiac MRI revealed prominent LV trabeculations, with a ratio of non-compacted to compacted myocardium of 3:1, suggestive of left ventricular non-compaction (LVNC). The patient refused radiofrequency ablation and underwent cardiac transplant evaluation.

IMPACT: Cardiac involvement is an overlooked cause of morbidity and mortality in patients with systemic sclerosis. Conduction defects and myocardial fibrosis are more frequently reported cardiac manifestations. LVNC has been described in myopathic disorders and is gaining recognition in association with autoimmune conditions. This case aims to foster awareness of the association between LVNC and scleroderma. Early recognition, cardiac imaging, and management can improve outcome and patient care.

DISCUSSION: Left ventricular non-compaction (LVNC) is a rare genetic cardiomyopathy characterized by prominent abnormal trabeculations and deep recessions of the myocardium that communicate with the left ventricular cavity; attributed to an arrest of compaction during embryogenesis. Mitochondrial, musculoskeletal, and glycogen storage disorders are known associations. The prevalence is estimated between 0.01% to 0.27% of the general population. LVNC is diagnosed on echocardiogram with a ratio of non-compacted to compacted myocardium greater than 2; contrast ventriculography and MRI provide superior imaging. Cardiac involvement in scleroderma and the

presence of LVNC causing insidious heart failure may be overlooked in the assessment of these patients, possibly masked by dyspnea from pulmonary fibrosis. Early immunosuppressive therapy may halt the progression of devastating myocardial disease. If so, this population could benefit from early cardiac imaging and institution of treatment to prevent or delay onset of fulminant cardiac failure.

SPONTANEOUS BLEEDING: A DIAGNOSTIC NIGHTMARE AND RARE PRESENTATION OF LIGHT CHAIN AMYLOIDOSIS Anokhi Shah[1]; Anly Tsang[2]; Kimberly Woodward[2]; Jennifer Primeggia[2]. [1]George Washington University, Washington, DC; [2]Inova Fairfax Hospital, Falls Church, VA. (Control ID #2670924)

LEARNING OBJECTIVE #1: Recognize bleeding diathesis as a presentation of light chain amyloidosis and prevent delayed diagnosis.

CASE: A 69-year-old female with one month of weight loss and fatigue, presented to the hospital for severe flank pain. She had multiple hematomas, a retroperitoneal bleed, and acute kidney injury. She had no significant past medical history and denied trauma or abuse. A mid-abdominal mass, ascites, and elevated cancer antigen 125 raised concern for ovarian malignancy as the cause of her presentation, but the mass was later deemed to be a hematoma. She was readmitted one month later for declining renal function. Studies were significant for: serum and urine protein electrophoresis with elevated M spike, skeletal bone survey with focal lucencies, alkaline phosphatase of 1423, 91% hepatic, and mildly elevated liver transaminases. Plasma cell dyscrasia was suspected but liver and renal biopsies were deferred due to bleeding risk. Exploration of her bleeding diathesis with mixing studies suggested an inherent factor deficiency. Factor X activity was low at 22%. Bone marrow biopsy was eventually performed and confirmed amyloidosis. She was discharged with oncology follow-up but was readmitted with multi-organ failure and expired.

IMPACT: When evaluating adults with abnormal bleeding, light chain (AL) amyloidosis should be considered, as there may only be subtle clues to specific organ involvement even with advanced disease. These signs may be overlooked or confounded with other etiologies, as with this case. Even in suspected cases, the diagnosis is delayed by clinicians who refrain from biopsy of involved organs in those at risk of bleeding. Biopsy in less invasive, surrogate sites should be pursued for definitive diagnosis.

DISCUSSION: Amyloidosis is a broad label for the deposition of fibrils into extracellular tissue, and can affect single or multiple organ systems. AL amyloidosis is difficult to diagnose due to its variety of presentations, many of which can be nonspecific. Our patient's multi-organ abnormalities were attributed to other causes and were only suggestive but not definitive of amyloidosis. Concerns for bleeding delayed organ-specific biopsy. Bleeding is a known manifestation but rare (<5%) presenting sign of the disease. It can result from: vascular fragility from deposition of fibrils into vessels, platelet abnormalities, coagulopathy from hepatic dysfunction, or acquired clotting factor deficiency from fibrils binding to clotting factors. This patient had decreased factor X activity, the most common factor deficiency in AL amyloidosis, which occurs in up to 14% of patients. While surrogate site biopsy has lower sensitivity, fat pad and/or bone marrow biopsy has close to 90% sensitivity in AL amyloidosis, and should be done if tissue from involved organ cannot be obtained. Consideration of amyloid on initial presentation with abnormal bleeding and early biopsy of a surrogate site would have led to prompt diagnosis.

SPURIOUS HYPOKALEMIA AND HYPOPHOSPHATEMIA IN A CASE OF ACUTE MYELOID LEUKEMIA WITH HYPERLEUKOCYTOSIS. Tanureet Arora; Mukul Singal; Sowjanya Vuyyala. Rochester General Hospital, Rochester, NY. (Control ID #2706899)

LEARNING OBJECTIVE #1: Recognize electrolyte abnormalities associated with hyperleukocytosis in AML

LEARNING OBJECTIVE #2: Identify that directly analyzed blood sample or sample transported on ice can help prevent false electrolyte abnormalities in hyperleukocytosis.

CASE: We report a 56 year old woman admitted with nausea and vomiting followed by altered mental status. Her laboratory results were consistent with newly diagnosed AML with hyperleukocytosis. Her leukocyte count was 513,000/μL with 95% myeloid blasts and monocytic differentiation. Her serum uric acid was 24.7mg/dL, lactate dehydrogenase 4309 U/L and serum creatinine 3.2mg/dL. Interestingly, serum potassium was 3.3 mEq/L and phosphorus was 0.2 mg/dL. The repeat analysis of the blood specimen delivered on ice showed serum potassium level of 4.1 mEq/L and serum phosphorous level of 2.0mg/dL. Computed tomography of head was negative for intracranial hemorrhage. Her course was complicated by persistent blast crisis and spontaneous tumor lysis syndrome. Despite leukopheresis and hydroxyurea, her blast crisis persisted. She passed away after developing end organ failure with worsening metabolic acidosis.

IMPACT: Factitious electrolyte abnormalities in patients with AML having hyperleukocytosis should be recognized by physicians to avoid unnecessary diagnosis and treatment. Hypokalemia and Hypophosphatemia can occur due to transcellular shift of potassium and phosphorous respectively into the leukemic cells. It should not be confused with true hypokalemia which is more common in acute monocytic leukemia due to lysozymuria.

DISCUSSION: Hyperleukocytosis is defined as a total leukocyte count greater than 100,000/μL. Hyperleukocytosis is present in 10 to 20 percent of patients with newly diagnosed AML. In such patient, pseudohyperkalemia or exaggerated hyperkalemia is well known due to traumatic cell lysis during pneumatic tube transportation. On the other hand as in our case, falsely low levels potassium and phosphorous can occur in patients with white cell counts >100,000/μL which is mostly related to transcellular shift of the potassium and phosphorous respectively in leukemic cells. However, it should not be confused with true hypokalemia and hypophosphatemia which is known to be related to lysozymuria. It is the increased concentration of urinary lysozyme which is produced by primitive leukemic cells causing proximal tubular dysfunction and excretion of urinary potassium and phosphorus. As in our case factitious electrolyte abnormalities were avoided by sending the blood samples on ice or by testing them immediately after phlebotomy.

STANDING UP TO ORTHODEOXIA - THE CASE OF A POSITION-MEDIATED SHUNT Jafar Al-Mondhiry; Valerie Gausman; Verity Schaye. NYU School of Medicine, New York, NY. (Control ID #2673982)

LEARNING OBJECTIVE #1: Recognize the inciting factors of orthodeoxia with a patent foramen ovale.

CASE: An 82 year-old presented with acute onset hypoxia upon extubation after a laparoscopic gastrectomy. She had positional episodes of desaturation to

79% when sitting up, with other vitals signs normal and no dyspnea. Her oxygen saturation was 91% on 2L nasal cannula when supine. Her lungs were clear to auscultation bilaterally. PaO2 was 45 mmHg on room air and increased to only 74 mmHg with 100% O2. Initial transthoracic echocardiogram with bubble study demonstrated a patent foramen ovale (PFO) with normal right atrial and pulmonary artery pressures and function. She had a stable 4.1 cm ascending thoracic aortic aneurysm and multiple, stable hepatic cysts. She was diagnosed with Platypnea-Orthodeoxia Syndrome (POS) due to PFO and underwent successful percutaneous transfemoral closure of the defect. Upon discharge, she was saturating 97% on room air, regardless of position.

IMPACT: While PFOs can be seen in up to 29% of the general population, orthodeoxia is much more rare, with less than 200 cases described in the literature. With the elderly population increasing, the incidence of aortic aneurysms and other cardiovascular conditions distorting previously silent PFOs may increase as well, so it is important to maintain a high index of suspicion and perform the gold standard diagnostic test early: echocardiography with bubble study.

DISCUSSION: Orthodeoxia, or the arterial deoxygenation that accompanies the positional change from supine to erect, requires two conditions to coexist: an anatomical component (interatrial communication such as a patent foramen ovale [PFO] or atrial septal defect [ASD]) and a functional component that redirects shunted blood flow through the atrial septum. These functional defects can either preferentially direct blood flow through the anatomical defect or cause a transient increase in right atrial pressure, reversing the left-right gradient. The former can be caused by conditions that direct the jet of deoxygenated blood through the interatrial communication by repositioning the atrial septum, such as an ascending aortic aneurysm, intracardiac lipoma, hepatic cyst distorting the right atrium, or aortic valve replacement. Conditions which transiently increase right sided pressures include pulmonary embolism, pulmonary hypertension, pericardial effusion, pneumonectomy, chronic obstructive pulmonary disease and constrictive pericarditis. Measured right sided pressures are typically normal in POS. The pathophysiology in our patient is likely due to her thoracic aortic aneurysm, elongating in the erect position and stretching the interatrial septum and PFO. While a possibility, it is unlikely her hepatic cysts contributed to her presentation as they were small and there has only been one case report of a large liver cyst causing this presentation.

STERCORAL COLITIS - WHEN CONSTIPATION BECOMES DEADLY

Edmond Fomunung. UT Southwestern Medical School, Dallas, TX. (Control ID #2687906)

LEARNING OBJECTIVE #1: Recognize the implications of stercoral colitis

LEARNING OBJECTIVE #2: Evaluating the role of imaging in the evaluation of severe constipation

CASE: A 63-year-old woman presented with abdominal pain. She described the pain as constant, cramping in character and severe. She reported no bowel movement in 1 week. On exam, she was febrile and her abdomen was noted to be tender with a palpable mass in the left lower quadrant. Labs were significant for an elevated white blood cell count of 15.37. A CT abdomen/pelvis showed large amount of stool in the distal colon, in addition to mild diffuse wall thickening of the distal colon with pericolonic fat stranding consistent with stercoral colitis.

IMPACT: Constipation is a common complaint in the general population. There are myriad causes, including systemic, neurologic, psychiatric and structural etiologies. In the patient presenting with constipation, abdominal pain and the systemic inflammatory response syndrome, a CT scan should be strongly considered to exclude stercoral colitis, a localized ischemia of the colon caused by increased intraluminal pressure. If not treated promptly, focal ulceration can occur leading to peritonitis, sepsis and death.

DISCUSSION: Constipation is the most common digestive complaint in the general population. The evaluation of constipation should always begin with a very careful history, including review of any comorbid diseases and current medications. A physical examination is helpful in the evaluation for hemorrhoids, fissures or disorders of anal sphincter. Laboratory evaluation including a complete blood count, calcium, glucose and thyroid stimulating hormones can be helpful in the evaluation for contributory systemic disorders. Plain radiography can be used to ascertain stool burden, and for reassessment after interventional maneuvers. CT scans are not routinely recommended in the evaluation of constipation, but should be considered in patients presenting with constipation severe enough to lead to hospitalization and especially when accompanied by the systemic inflammatory response syndrome, as in our patient, as it could be indicative of more severe pathology like stercoral colitis. Stercoral colitis is an inflammatory colitis related to increased intraluminal pressure from impacted fecal material in the colon. If left untreated, it can lead to ulceration, the loss of bowel integrity from the pressure effects of insipissated feces. Because of associated diseases in the populations at risk, especially the elderly, perforation and hemorrhage are the principal complications and result in a mortality exceeding 50%. Stercoral perforation is a rare phenomenon with fewer than 90 cases reported in the literature to date, and is often a consequence of chronic constipation. Early recognition and aggressive treatment to relieve the fecal impaction is the cornerstone in the management of this potentially lethal complication of constipation.

STEROIDS AND RITONAVIR: A CASE OF DRUG-INDUCED CUSHING'S SYNDROME

Brian Lewis[2]; Vidthya Abraham[1]; David Feldstein[3]; Joan Addington-White[4]. [1]University of Wisconsin, Madison, WI; [2]University of Wisconsin, Middleton, WI; [3]University of Wisconsin School of Medicine and Public Health, Madison, WI; [4]University of Wisconsin-Madison, Madison, WI. (Control ID #2703681)

LEARNING OBJECTIVE #1: Recognize the significant drug interaction between glucocorticoid injections and ritonavir in HIV patients.

LEARNING OBJECTIVE #2: Distinguish between glucocorticoids based on their risk of interaction with ritonavir.

CASE: A 54-year-old male with a 23-year history of HIV, calcium pyrophosphate disease (CPPD) and COPD presented with 11 lbs weight gain, facial swelling, and new onset dyspnea. His HIV was well controlled on darunavir, etravirine, raltegravir and ritonavir (RTV) with a CD4 count of 448 and undetectable viral load. Prior to the presenting symptoms, he received bilateral knee injections of 120mg of intra-articular (IA) triamcinolone (TMC) for CPPD knee pain. His exam showed facial plethora, moon facies, hoarseness, lateral eyebrow loss and mild bilateral hand tremor. He had an enlarged pannus but did not display abdominal striae. His cortisol level was < 0.8 μg/dL and he was diagnosed with iatrogenic Cushing's syndrome. All corticosteroids were withheld and his symptoms resolved over the next five months. He was placed on anakinra and colchicine for his CPPD.

IMPACT: This case adds to the growing evidence in the literature that an interaction between ritonavir and IA glucocorticoid injections can cause Cushing's syndrome. The two drugs should not be used concurrently.

DISCUSSION: RTV strongly inhibits the cytochrome P450 CYP3A4 enzyme, which metabolizes glucocorticoid medications. Taken concurrently, RTV can prolong the half-life of glucocorticoid medications resulting in iatrogenic Cushing's syndrome. There are 16 other known cases reported in the literature describing ICS in HIV patients on ritonavir after receiving TMC injections. Most cases, including ours, took weeks to months for symptoms to fully resolve. However, not all glucocorticoids share the same level of risk of interacting with CYP3A4 inhibitors such as RTV. For instance, most topical glucocorticoids as well as inhaled/nasal beclomethasone have little to no interaction with ritonavir. On the other hand, inhaled/nasal fluticasone has one of the strongest interactions, making it important to avoid in this patient population. Other steroids such as budensonide, dexamethasone, prednisone and mometasome have intermediate interaction with ritonavir/CYP34A inhibitors and combination use should be monitored closely for any signs of Cushing's syndrome. This case illustrates the clinical implications of the strong interaction between RTV and glucocorticoid injections, and the importance of differentiating between glucocorticoids that have a higher interaction risk from those that do not. This is particularly important when patients on ritonavir present with comorbidities requiring glucocorticoid treatment.

STICKING TO A SUSPICION - A CASE OF HYPERVISCOSITY SYNDROME Meytal Shtayer; Michelle Tong; Patricia Dharapak. Mount Sinai Beth Israel, New York, NY. (Control ID #2706275)

LEARNING OBJECTIVE #1: Diagnose hyperviscosity syndrome

LEARNING OBJECTIVE #2: Recognize hyperviscosity as a possible presenting syndrome in patients with a monoclonal gammopathy

CASE: A 50 year old woman with hypertension and sciatica presented with a 2 month history of intermittent abdominal, leg and back pain, and a 14-lb weight loss. Her initial exam was unremarkable. Laboratory data was significant for elevated serum calcium to 11mg/dL and total protein to 11.4g/dL, a newly elevated Cr of 1.15mg/dL and new anemia with Hgb 7.2g/dL. CT imaging of the abdomen and pelvis and skeletal X rays showed multiple lytic lesions of the vertebral, iliac and femur bones. Additional lab work showed ESR >140, normal PTH, abnormal gamma globulin spikes on SPEP and UPEP, and markedly elevated free lambda M protein on UIFE and SIFE, with a serum IgM at 8950mg/dL. Bone marrow biopsy revealed almost complete replacement with lymphoid cells, plasmacytoid lymphocytes and plasma cells suggestive of a lymphoplasmacytic lymphoma, presumed Waldenstrom's macroglobulinemia (WM). Given the patient's marked serum IgM burden, somatic complaints, and new intermittent headache, hyperviscosity syndrome (HVS) was suspected. Pending the results of the serum viscosity, a fundoscopic exam was performed and showed cotton wool hemorrhages. The patient underwent urgent plasmapheresis, and her symptoms subsided. Days later, her serum viscosity finally resulted at 4.2CP (normal 1.4-1.8CP) and decreased to 1.6CP with continued plasmapheresis. Ultimately, FISH analysis of the bone marrow showed absence of the MYD88 mutation and t(11;14) with over 90% of cells positive for t(14;16), suggestive of an aggressive IgM myeloma rather than WM. Despite early initiation of chemotherapy, the patient had recurrent HVS, progressive pancytopenia and died within the year.

IMPACT: Our case highlights the potential pitfall of relying on lab values alone for diagnosing hyperviscosity syndrome. Therefore, it is important to keep a high index of suspicion in patients with a monoclonal gammopathy, especially when the disease burden is high and provide prompt treatment with plasmapheresis.

DISCUSSION: We describe a rare case of multiple myeloma with IgM paraprotein complicated by HVS. IgM myeloma comprises <1% of all multiple myeloma cases and is typically distinguished from WM by the presence of lytic bone lesions and specific cytogenetic abnormalities. Our case also highlights the importance of early recognition and treatment of HVS, which can be the presenting or complicating manifestation of several hematologic disorders. Symptoms are usually uncommon at serum viscosity levels below 4CP and can include skin and mucosal bleeding, blurred vision, headache, ataxia, and neuropathy. Severe HVS may cause confusion, stroke and coma. HVS is a medical emergency and requires immediate plasmapheresis to prevent further complications. However, serum viscosity is not uncommonly a 'send out' test and results can take days. A prompt fundoscopic exam may be life saving.

STILL HAVING FEVERS? AN UNCOMMON CAUSE OF FEVER OR UNKNOWN ORIGIN Alejandra Londono Jimenez[1]; Rishika Chugh[1]; Shereen Mahmood[1]; Lewis A. Eisen[2]. [1]Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY; [2]Montefiore Medical Center, Bronx, NY. (Control ID #2706521)

LEARNING OBJECTIVE #1: Recognize the clinical features of Still's disease

LEARNING OBJECTIVE #2: Identify potential life-threatening complications of Still's disease

CASE: A 29 year-old woman from Guatemala presented with three days of fever and chest pain. She also noted sore throat, arthralgias, and shortness of breath. She was febrile to 105°F with tachycardia and had a pink evanescent macular rash on both her knees and the base of her neck. Splenomegaly was noted. Laboratory abnormalities included leukocytosis, anemia, ALT of 1467 and AST of 2965 U/L. There were bilateral pleural effusions on chest x-ray. After three weeks, the patient continued to have double-quotidian fevers despite treatment with multiple antibiotics. Extensive infectious work up was negative. Further testing revealed a ferritin of 66000 ng/mL. Adult Still's disease was diagnosed based on the Yamaguchi major criteria of fever, arthralgias, maculopapular rash, granulocytosis, and the minor criteria of sore throat, abnormal liver tests, and splenomegaly. Treatment with intravenous methylprednisolone 1 gram per day was started with rapid resolution of fever and improvement in transaminases and respiratory status.

IMPACT: This case brings to light an uncommon cause for fever of unknown origin and emphasizes the importance of maintaining a high index of suspicion for Still's disease in a young, otherwise healthy patient with recurrent fevers.

DISCUSSION: Adult Still's disease (ASD) is a rare multisystem autoinflammatory disorder of unknown etiology. Diagnostic delays are common due to its non-specific clinical manifestations and lack of pathognomonic tests. The Yamaguchi criteria have the highest sensitivity (93.5%) for diagnosing ASD. However, infection and malignancy should be excluded. Elevated ferritin is not part of the diagnostic criteria and can be found in a variety of pathological conditions, such as infection, chronic liver and kidney diseases, storage diseases, malignancies and iron overload. *Fautrel et al*. developed updated criteria with increased specificity (98.5%) owing to the inclusion of glycosylated ferritin, which can aid in discriminating hyperferritinemia of ASD from other diseases. This test is not readily available at all health care facilities. Left untreated, ASD can be fatal. Up to 65% of the patients will have elevated

liver enzymes ranging from mild to fulminant liver failure requiring transplantation. The macrophage activation syndrome (MAS), a form of hemophagocytic lymphohistocytosis, occurs in about 12% of ASD patients. Additional complications include pleural and pericardial effusions seen in 25% to 60% of the patients, myocarditis (3%), transient pulmonary infiltrates and acute respiratory distress syndrome. In conclusion, it is important to recognize ASD as an etiology of fever of unknown origin. Diagnosis is frequently delayed. Left untreated, ASD can be fatal due to multisystem involvement.

STILL'S A MYSTERY: A DIAGNOSIS OF EXCLUSION Allison Guttmann; Jason Ng; Ramon Jacobs. New York University School of Medicine, New York, NY. (Control ID #2679885)

LEARNING OBJECTIVE #1: Review existing and future therapeutic options for Adult Onset Still's Disease

CASE: A 45-year-old Hispanic female presented with four weeks of high-grade fever and polyarthralgias, and one week of sore throat and night sweats. She visited an urgent care center and laboratory evaluation revealed white blood cell count 4.6K/uL with 48% bands and lactate dehydrogenase 953 U/L. Serum and urine protein electrophoresis revealed no monoclonal bands, and flow cytometry immunophenotypes were normal. Five days prior to presentation, she developed a pruritic rash on her arms and chest. Her condition failed to improve leading to her hospitalization. Her physical exam revealed a non-blanching erythematous maculopapular rash on her extremities, and pain with range of motion in her knees, ankles, elbows and wrists. Laboratory testing showed hemoglobin 11.2g/dL, erythrocyte sedimentation rate 67mm/hr, c-reactive protein 217mg/L and ferritin 4972ng/mL. Respiratory viral panel, quantiferon gold assay, HIV, parvovirus B19 IgM, CMV/EBV, antinuclear antibody and rheumatoid factor were unremarkable. Peripheral blood smears were negative for Plasmodium, Babesia, Trypanosoma and Microfilaria, as were serologies for Anaplasma, Ehrlichiosis, and Lyme. Whole body computed tomography scan was unrevealing. Skin biopsy showed neutrophilic urticarial dermatosis, and bone marrow aspirate revealed hypercellularity with trilineage hematopoiesis without evidence of lymphoma or leukemia. Given these findings, she was diagnosed with Adult Onset Still's Disease and initiated on corticosteroids. Immunotherapy was considered, however she experienced symptom improvement.

IMPACT: This case allowed us to explore the broad differential diagnosis for fever of unknown origin, forcing us to consider and ultimately exclude a range of pathologies - infectious, malignant, and rheumatologic - before arriving at this diagnosis of exclusion.

DISCUSSION: Adult Onset Still's Disease (AOSD) is rare, with an estimated prevalence of 0.16-1 per 100,000 persons. Lacking a definitive diagnostic test, it is characterized by clinical and laboratory findings including fevers, arthralgias, rash and elevated ferritin. Corticosteroids have been the mainstay of treatment, with 76-95% of patients achieving symptom improvement and resolution of laboratory abnormalities. However, given complications of chronic steroid use, focus has shifted toward interventions on the cytokine cascade, including tumor necrosis factor-α (TNF- α), interleukin (IL)-1 and 6, thought to be a driver in AOSD. Research has shown that while serum TNF-α is increased in AOSD, TNF-α inhibitors offer little clinical benefit, thus shifting focus toward the interleukin response. In one study, the IL-1 receptor antagonist Anakinra resulted in defervescence and resolution of leukocytosis in 79% of subjects, compared to a 36% response with other biologics. IL-6 has also been studied as a treatment target, with Toclizumab showing improvement in arthritic symptoms.

STOP, HYPOTHENAR HAMMERTIME Minnsun Park[2]; Danielle King[1]; Stephen Morris[3]. [1]SLVHCS, New Orleans, LA; [2]Tulane University School of Medicine, New Orleans, LA; [3]Tulane University, New Orleans, LA. (Control ID #2705261)

LEARNING OBJECTIVE #1: Consider hypothenar hammer syndrome as a cause of distal ischemia

LEARNING OBJECTIVE #2: Understand the common angiographic findings in hypothenar hammer syndrome.

CASE: A 69-year-old man presented with acute onset numbness and blue and white discoloration of the fourth digit on his left hand. He has no medical history, including Raynaud's disease, autoimmune, clotting, or other vascular disorders. Family history is significant for a sister with systemic lupus erythematous. He is a carpenter by trade and left hand dominant. He takes no medications. At time of presentation, his pulse rate was 56, blood pressure 103/73, SatO2 96% on room air. Physical exam was significant for pallor of left fourth digit with blue discoloration of the distal phalanx. No tenderness, motor or sensory deficits were noted, with good strong left radial pulse. No rash noted on exam. Laboratory values were unremarkable. Arterial ultrasound of left upper extremity came back positive for Allen test. Given these findings, a left upper extremity angiography was performed, which showed distal occlusion of ulnar artery. The patient's hand re-vascularized without need for intervention. Aspirin 325mg daily was prescribed, and referral to occupational therapy was ordered.

IMPACT: Rapid recognition of distal limb ischemia allows for timely treatment to prevent catastrophic consequences. A detailed history including occupational history may delineate the cause of vascular compromise.

DISCUSSION: Ischemia of the digits of the hand can be caused by numerous factors: Raynaud's phenomenon, autoimmune processes, vasculitis, and cardio-embolic events. A less common cause of upper extremity digital ischemia is hypothenar hammer syndrome. Hypothenar hammer syndrome is an overuse syndrome that is caused by repetitive trauma to the palmar portion of the ulnar artery. This palmar portion crosses the surface of the hypothenar muscles for about 2 cm before penetrating the palmar aponeurosis, making it susceptible to injury. Patients who work with hammers, chain saws, and other power tools that generate vibrations may experience this trauma. Hypothenar hammer syndrome can also manifest in athletes who have repetitive trauma to the palm, such as in karate, baseball, golf, and tennis. If hypothenar hammer syndrome is suspected, angiography is the gold standard for establishing the diagnosis. Common findings on angiography include: 1) tortuous ulnar artery with "corkscrew" appearance, 2) presence of an aneurysm, 3) occlusion of the ulnar artery segment overlying the hook of the hamate, 4) occluded digital arteries in an ulnar artery distribution, and 5) demonstration of intraluminal emboli at sites of digital obstruction. This case is an example of how a few focused questions about a patient's history such as occupation and hand dominance can quickly lead an internist to an accurate diagnosis, even one as rare as hypothenar hammer syndrome.

STRIKING EOSINOPHILIA

Cameron Long[1]; Jaime Palomino[2]; Brandon J. Mauldin[2]. [1]Tulane Medical Center, New Orleans, LA; [2]tulane university, New Orleans, LA. (Control ID #2705483)

LEARNING OBJECTIVE #1: Create a differential for pulmonary opacities with eosinophilia

LEARNING OBJECTIVE #2: Distinguish between Hypereosinophilic syndrome and Chronic eosinophilic pneumonia

CASE: A 68-year old white man, with hypertension and psoriasis (on topical medications) presents with 1 month of fatigue, weight loss, fevers and a dry cough. Since a URI one month ago, he continues to have intermittent episodes of shortness of breath at rest that is not associated with position changes. He denies pleurisy or night sweats. He has no history of asthma, recent foreign travel or incarceration. He is afebrile, pulse of 94, blood pressure of 156/87, respiratory rate of 20, and has an oxygen saturation of 99% on room Air. He has coarse crackles bilaterally. He has no lymphadenopathy or hepatosplenomegaly. His cardiac exam is normal. Labs are notable for a WBC of 16.2 with 35% neutrophils, 7% lymphocytes, 4% monocytes, and 54% eosinophils. He has normal hemoglobin and an elevated ESR and CRP. IGE level is normal. Additional laboratory studies are negative: C-ANCA, P-ANCA, rheumatoid factor, Anti-DS DNA, smith antibody, HIV, Aspergillus antibody, and Beta-(1,3)-D-Glucan. Diffuse nodules and patchy opacities are seen bilaterally on high resolution CT. Bronchoalvelolar lavage reveals no eosinophils, no malignancy and no fungi. A transbronchial biopsy shows interstitial and alveolar eosinophilic infiltration, patchy eosinophilic involvement in blood vessels, and patchy fibrosis. He was started on oral steroids and his symptoms rapidly resolve within 2 weeks.

IMPACT: Clinical history and bronchoalveolar lavage with transbronchial biopsy are essential in sorting out the correct diagnosis in patients with peripheral eosinophilia and pulmonary infiltrates.

DISCUSSION: A unique differential of diseases is associated with peripheral eosinophilia and pulmonary infiltrates. The list includes parasitic and fungal infections, drug reactions, hyper-eosinophilic syndrome (HES), vasculitides, and acute and chronic eosinophilic pneumonias (CEP). CEP requires four weeks of symptoms, pulmonary infiltrates, and peripheral eosinophilia. It is thought to due to TH2 cell and chemoattractant mediated aggregation of eosinophils in the lung, which leads to eosinophil degranulation and tissue injury. A BAL with >40% of cells being eosinophils is diagnostic for CEP. Without eosinophils in the BAL, alternative diseases were explored to evaluate the massive peripheral eosinophilia. HES is a hyper production of eosinophils in the blood (>1500 eosinophils/uL) with end organ involvement. Secondary causes such as parasitic and fungal infection, asthma, neoplasm, Addison's, and viral infections must be excluded. With no blasts on peripheral smear, no anemia or no thrombocytopenia, this patient fits lymphocyte-derived eosinophilia HES. The mainstay of treatment for the majority of non-infectious eosinophilic lung disease including non-myeloid HES and CEP is corticosteroids for symptom improvement.

STROKE IN THE PRESENCE OF A CLOTTING FACTOR DEFICIENCY Joshua M. Rodriguez; Mary Sehl. Ronald Reagan University of California Los Angeles Medical Center, Los Angeles, CA. (Control ID #2704470)

LEARNING OBJECTIVE #1: Recognize the proposed role of factor XII (FXII) in the blood coagulation cascade and its implications in drug development

CASE: A 64 year old man with no past medical history presented with transient temporal vision loss in his right eye. The patient underwent a brain MRI which revealed a small infarct in the left occipital region with a diffusion-perfusion mismatch. On labs, the patient was noted to have an aPTT > 180 s despite not being on any anticoagulation. His surgical history was notable for a hernia repair with no bleeding complications. He had no family history of bleeding diathesis but had an older brother with a FXII deficiency diagnosed in the setting of a cardiac thrombus, and an older sister diagnosed with a recent TIA. Further cardiac work-up including EKG and transcranial doppler were unremarkable. TTE showed no evidence of left atrial enlargement or thrombus. Hematologic work-up revealed a FXII activity of <6%, with a negative anti-phospholipid antibody panel, and an aPTT mixing study showing no detection of an immediate or late acting inhibitor. He was started on daily aspirin and atorvastatin upon discharge with outpatient hematology follow-up.

IMPACT: Upon review of this case, there are some considerations which merit further investigation. First, is thrombosis clinically relevant in FXII deficient patients? Secondly, what is the rational treatment choice for anticoagulation in this patient population? Should certain anticoagulants be avoided? Lastly, given the recent interests in targeting the FXII pathway, a discussion in managing thrombotic risks in this population would be timely and relevant for patients who may be eventually exposed.

DISCUSSION: FXII is a zymogen that is involved in the plasma contact system and acts as a procoagulant, working through the kallikrein-kinin system. FXII deficiency, an autosomal recessive condition, is characterized by a marked prolongation in the aPTT. FXII deficiency does not increase bleeding risk, but is rather linked to possible thrombotic risks in both the arterial and venous systems. In a recent report describing thrombotic events in FXII deficient patients, cases of thrombosis involved both the arterial and venous systems equally, with MI and DVT being the most prevalent respectively. The proposed mechanism for this effect is thought to be related to reduced fibrinolytic activity. Despite increasing evidence of this association, the role of FXII in coagulation remains controversial as controlled clinical studies have shown the opposite. Additionally, epidemiological studies showed a positive association between FXII/FXIIa levels with arterial thrombosis and inflammation. As a result, several classes of FXIIa inhibitors have been developed with most of these inhibitors displaying both anti-inflammatory and thrombo-protective effects. Importantly, treatment with these agents did not impair hemostatic function or increase the risk of bleeding.

STRONGYLOIDER THAN THE AVERAGE SUSPICION: AN INTRIGUING CASE OF PULMONARY STRONGYLOIDIASIS Asad H. Khan[2]; Eesha Khan[1]; Puncho Gurung[1]. [1]Baystate Medical Center, Springfield, MA; [2]Baystate Medical Centre, Broad Brook, CT. (Control ID #2707563)

LEARNING OBJECTIVE #1: Recognize that pulmonary Strongyloidiasis can occur in young, healthy individuals

LEARNING OBJECTIVE #2: Highlight the importance of travel history in helping to make an earlier diagnosis of pulmonary Strongyloidiasis

CASE: A 45-year-old healthy male presented with complaints of a dry cough and acid reflux symptoms and was treated with omeprazole with transient relief. However, a few months later he had a persistent cough and intermittent wheezing and was placed on an albuterol inhaler. The patient had a history of chewing tobacco and occasional cigarette smoking and worked in maintenance at a hospital. Physical exam at that time was consistent with expiratory wheezes. Initial testing revealed a normal chest x-ray (CXR) and pulmonary function tests.

He underwent a barium swallow that showed some esophageal dysmotility and an upper endoscopy that revealed esophagitis. The patient's cough persisted and became productive. Allergy testing done was grossly negative. He was placed on a course of oral prednisone that helped his symptoms transiently. The cough, however, continued and a repeat CXR showed complete left lower lobe collapse and a CT chest revealed a left hilar mass with extension into the left lower lobe of the bronchial tree. Bronchoscopy revealed the entire left lower bronchial tree to be filled with a lesion which was not originating from the bronchial wall and was removed piecemeal. Followup bronchoscopy a month later showed two more similar endobronchial lesions which revealed necrotic debris with eosinophils and Charcot Leiden crystals on analysis. On further questioning, the patient revealed that he was in Mississippi a few weeks prior to developing symptoms. Subsequent testing done was positive for serum IgE, Strongyloides antibody and a marked eosinophilia. The patient was placed on oral Ivermectin and has been stable to date.

IMPACT: This case underscores how systematic and timely investigation can lead to an eventual diagnosis while highlighting the importance of a thorough basic history. It also supports the few case reports in the literature where symptomatic pulmonary Strongyloidiasis has occurred in healthy, immunocompetent individuals.

DISCUSSION: Strongyloides stercoralis is an intestinal parasitic nematode commonly found in certain parts of southeastern United States. Pulmonary symptoms from Strongyloidiasis can be mild, consisting only of cough and bronchospasm, and the importance of a through travel history is crucial. The potential for severe pulmonary disease or 'hyperinfection' syndrome is great in the immunocompromised and has a very high mortality rate, with rare occurrence in immunocompetent hosts. Infection with strongyloides is lifelong and reactivation with suppression of cell-mediated immunity can occur decades after initial exposure and hence systemic corticosteroids should be avoided in such patients where it is not absolutely needed.

SUBACUTE BACTERIAL ENDOCARDITIS IMITATING VASCULITIS: LESSONS FROM AN ATYPICAL CASE

Alexander Teng; Amar Kohli. UPMC, Pittsburgh, PA. (Control ID #2706852)

LEARNING OBJECTIVE #1: Recognize Subacute Bacterial Endocarditis (SBE) as a potential rheumatologic disease mimicker.

LEARNING OBJECTIVE #2: Identify how patient handoffs may cause delay in care and management.

CASE: A 53 year old male with a history of HTN presents with subjective fevers and general malaise. Three months prior, he presented to an outside hospital with a petechial rash and general malaise. Expansive work up found pancytopenia, AKI, and hypocomplementemia but was otherwise negative. A renal biopsy was non-diagnostic: early type I MPGN vs. lupus. He was diagnosed with presumed seronegative SLE and started on prednisone and mycophenolate with improvement in renal function. Two weeks prior to arrival, he reported recrudescence of symptoms and again presented to the outside hospital. Ultimately, he was transferred for a "lupus flare". On arrival, he was afebrile and hemodynamically stable. Physical exam was notable for a transient right lower sternal border 2/6 diastolic blowing murmur (not documented before), and purpura over both legs. Initial labs revealed: AKI (Cr 2.0), pancytopenia, ESR 83, C3 16, C4 < 10, PR3 2.8, and negative ANA. He was started on stress-dose steroids and four sets of blood cultures were obtained (none prior). By hospital day 5, blood cultures were positive in 4/4 bottles (2 sets), with subsequent Streptococcus Sanguinis speciation. A TEE demonstrated bicuspid aortic valve with vegetations, leaflet perforations, and severe regurgitation. A final diagnosis of subacute endocarditis with primarily immunologic manifestations (immune complex GN, purpura, etc.) was made. The patient was treated with ceftriaxone for 6 weeks followed by valve replacement.

IMPACT: With rheumatologic features but an infectious etiology, this case highlights how bias can delay diagnosis, particularly in atypical presentations. It exhibits the need to reevaluate suppositions when initial management fails.

DISCUSSION: This case offers two teaching points. First, it shows how chronic infections can mimic rheumatologic conditions. As per Mahr et al. (2014), 1 in 5 patients with SBE are ANCA positive. It is thought that infection can cause polyclonal B-cell activation and autoantibodies production. This vignette adds to case series of SBE mimicking vasculitis, and the need to exclude infection. Second, this case represents a "perfect storm" in which cognitive biases can impair the physician from pivoting to the right diagnosis. With a handoff framing the case as a "lupus flare", there may have been an over-reliance on prior workup by specialists (expert bias), focus on predominantly rheumatologic exam signs (anchoring bias), and avoidance of tests for alternate hypothesis (congruence bias) until objective results necessitated study (e.g. TEE delay until blood culture result). The confluence of these and other factors resulted in delay of care and undue harm from almost 3 months of immunosuppressive therapy for an infectious condition.

SUBACUTE INFLAMMATORY DEMYELINATING POLYNEUROPATHY MIMICKING TOXIC NEUROPATHY

Hadi Zein; Disha Shah; Jing Guo. New York Presbyterian Queens, Flushing, NY. (Control ID #2706606)

LEARNING OBJECTIVE #1: Recognize subacute inflammatory peripheral neuropathy and distinguish it from other polyneuropathies

CASE: A 68-year-old male presented with progressive distal weakness and sensory loss. Medical history was significant for esophageal cancer for which he underwent chemotherapy with paclitaxel and carboplatin. The last dose was 2 months prior to the onset of symptoms. His distal weakness progressed over 4 weeks. He was unable to feed himself, shave or comb his hair because of the weak grip he was exhibiting. Subsequently, he also developed an unsteady gait. Physical exam indicated symmetrical distal bilateral upper and lower extremity weakness with sparring of the proximal muscles. He was areflexic and showed decreased muscle tone and gait ataxia. All of these findings were consistent with a type of peripheral neuropathy. A lumbar puncture was performed and the cerebrospinal fluid (CSF) studies were unremarkable. Magnetic resonance imaging (MRI) of the brain showed mild white matter changes. Multiple autoantibodies were tested to rule out paraneoplastic syndromes, all of which were negative. Nerve conduction studies on the left arm and left leg showed severe sensorimotor polyneuropathy, with diffuse severely demyelinating features in all nerve segments. A needle electromyogram showed active and chronic denervation in the distal arm and leg segments. Finally, a left sural nerve biopsy was done and showed mild and patchy axonal loss with no evidence of vasculitis or amyloidosis. Given the onset and progression of symptoms, the diagnosis of subacute inflammatory demyelinating peripheral neuropathy (SIDP) was made. The patient was initiated on intravenous immunoglobulins (IVIG). Two weeks after the initial treatment, his gait and his sensation in the extremities improved

IMPACT: SIDP may simulate toxic neuropathy in cancer patients. Electrodiagnostic studies are required in patients with a subacute onset of sensorimotor symptoms to exclude treatable neuropathies. Severe axonal involvement, mixed with demyelinating features calls for additional workup including a nerve biopsy.

DISCUSSION: There are no strict diagnostic criteria for SIDP. However, establishing the correct diagnosis is imperative as it can guide treatment and subsequently, help lead to resolution of symptoms. Given the proximity of the chemotherapy and the onset of symptoms, our patient's presentation can mimic chemotherapy-induced peripheral neuropathy (CIPN). Paclitaxel and platinum-based chemotherapy have been widely reported to be associated with CIPN. However, our patient did not exhibit symptoms during the treatment and showed delayed onset of symptoms. He also experienced extensive motor involvement, which CIPN usually spares. Through our case, we were able to establish the diagnosis of SIDP by ruling out other causes of polyneuropathy, which provided significant clinical improvement for our patient

SUBSTANCE ABUSE AND IMPLICIT BIAS - INCUBATING FATAL INFECTIONS Sisir Akkineni; Hardik Patel; Ravi George. University of Miami, Ft Lauderdale, FL. (Control ID #2702879)

LEARNING OBJECTIVE #1: Recognize implicit bias as an entity in the practice of medicine

LEARNING OBJECTIVE #2: Identifying a complex presentation of substance abuse

CASE: A 32-year-old man with known history of IV drug abuse presented to the ER delirious, complaining of "pain all over" and seeking "dilaudid". He endorsed chills and "pain starting at the head and going down legs like lightning". He appeared agitated and anxious. Physical Exam was significant for tachycardia. Labs showed 11,400 WBCs, urine toxicology positive for opioids and cocaine. He was admitted to the observation unit with presumed diagnosis of substance abuse and opioid withdrawal. Pain management was consulted to assist with managing opioid withdrawal with buprenorphine and naloxone. On hospital day 2, he was febrile. Blood cultures obtained at the time were positive for MRSA. Infective endocarditis was suspected. Subsequently, trans-esophageal echo confirmed tricuspid vegetation. Throughout hospitalization, he continued to complain of "pain all over". On hospital day 3, he reported bilateral lower extremity weakness. An urgent whole spine MRI showed C5-C6 discitis with osteomyelitis and epidural abscess associated with cord compression. This was surgically drained and anterior cervical instrumentation was placed for stabilization. Hospital course was also complicated by sudden onset lower GI bleed. Colonoscopy revealed an arterial bleed in a segment of ischemic colitis. This was attributed to septic emboli and managed with endoscopic clipping. Our patient completed a prolonged course of IV antibiotics and eventually made a full recovery.

IMPACT: This case allowed us to identify a situation where implicit bias could hinder health care delivery to a vulnerable population. Literature review did not yield sufficient research directed towards physician implicit bias towards IV drug abusers and its impact on outcomes when diagnosed with fatal infections.

DISCUSSION: Explicit bias is a reflection of a physician's attitudes toward management of disease recognized on a conscious level. On the contrary, implicit bias refers to the subtle cognitive processing and subconscious stereotypes which affect understanding, actions and decisions on patient management. It is important to understand situations under which implicit bias influences patient management which in turn affects outcomes. An IV drug user complaining of vague pain and seeking opioids by name in the absence of objective clinical findings can trigger implicit bias in physicians. As in the case of this patient, our implicit bias was that he was presenting himself to the ER for secondary gain - seeking more opioids. Effort should be made to obtain unbiased review of systems and thorough physical examination with a low threshold for further evaluation. Infectious complications from intravenous drug use vary from local soft tissue infections to bacteremia, including septic embolization to distant sites. These complications are fatal if they are not recognized early and treated appropriately.

SUCCESSFUL TREATMENT OF SEVERE IMMUNE THROMBOCYTOPENIA AS AN EXTRAHEPATIC MANIFESTATION OF HEPATITIS C Bryan Doherty[1]; Akwaugo Uzoegwu[1]; Dipali R. Sahoo[1]; Andrew Mangano[1]; Emily Touloukian[2]; Vinod E. Nambudiri[1]. [1]Grand Strand Medical Center, Myrtle Beach, SC; [2]Coastal Cancer, Myrtle Beach, SC. (Control ID #2702895)

LEARNING OBJECTIVE #1: Describe a case of secondary immune thrombocytopenia as an extrahepatic manifestation of HCV

LEARNING OBJECTIVE #2: Review the treatment of secondary immune thrombocytopenia

CASE: A 60-year-old female presented to the emergency department endorsing progressive melena, multiple episodes of hemoptysis, epistaxis, and multiple ecchymoses. The diffuse ecchymoses began 2 months prior to admission. The melena had progressed over one week, with hemoptysis starting the morning of presentation along with left-sided abdominal colicky pain. Notable history included longstanding untreated hepatitis C virus (HCV). On presentation, vital signs were within normal limits. Physical exam was notable for cervical lymphadenopathy, a 1 cm hematoma on the right lateral aspect of the tongue, right and left lower quadrant abdominal tenderness and guarding, diffuse ecchymoses, and a petechial rash. Lab values were significant for normal transaminases and coagulation values, normal albumin, anemia, and profound thrombocytopenia (platelets 1,000/uL). HCV viral load was 899,164. Abdominal CT showed no evidence of splenomegaly or hepatosteatosis. The patient was started on methylprednisolone 125 mg IV every 8 hours. After her platelets failed to respond to steroid treatment, intravenous immunoglobulin (IVIG) was initiated. Given persistent thrombocytopenia on IVIG therapy, she was started on rituximab, after which her platelets showed improvement and stabilization. She also received 1 dose of romiplostim. The patient was discharged on 60 mg of prednisone tapered over six-months and was initiated on treatment for hepatitis C. She had no further episodes of bleeding and resolution of thrombocytopenia.

IMPACT: The association between HCV causing immune thrombocytopenia (ITP) as an extrahepatic manifestation has been well documented in patients with evidence of chronic liver disease, but case reports of ITP caused by chronic HCV infection without liver disease are limited. This case adds to the literature an example of ITP as an extrahepatic manifestation of HCV in a patient with normal liver function tests.

DISCUSSION: HCV has been proposed to trigger secondary ITP resulting from the body's production of antibodies against viral antigens that cross-react with normal platelet antigens through a form of molecular mimicry. Thrombocytopenia is a common presenting finding in patients with undiagnosed HCV infection,

though the extent is typically not as profound as frank ITP. The initiation of treatment in patients with ITP is guided by platelet count. Patients with platelet counts below 30,000 or bleeding symptoms should receive either IVIG or glucocorticoids. Patients with platelet counts below 20,000 and those refractory to first line therapy should receive rituximab or be considered for splenectomy. In many cases of secondary ITP, treatment of the underlying condition may improve the platelet count.

SUGGESTIONS FOR IMPROVING CARE OF A PATIENT WHO HAS LEFT AGAINST MEDICAL ADVICE MORE THAN 20 TIMES IN THE PAST YEAR. Dylan Sherry. Beth Israel Deaconess Medical Center, Brookline, MA. (Control ID #2706059)

LEARNING OBJECTIVE #1: When working with patients who frequently leave AMA, communication between providers beyond electronic communication is necessary.

LEARNING OBJECTIVE #2: Contingency plans and standard approaches are important to ensure a consistent message across providers.

CASE: A 72 year old man with cirrhosis due to alcohol use complicated by ascites, hepatic encephalopathy and variceal bleed also with bladder/prostate cancer s/p cystectomy and multiple UTIs with multiple previous instances of leaving AMA presents with alcohol intoxication and hematochezia. He was concerned about his bleeding, yet had a stable hemoglobin/hematocrit on admission with stable vital signs. On the day of admission, he informed his treatment team that he would be leaving against medical advice. He was able to state that he risked worsening bleeding, infection or death in this setting and was deemed to have capacity to leave. In the past 6 months, the patient has left AMA either from the ED or medical floor approximately 20 times. Admissions are frequently for bleeding or infection. Once he has felt well enough, he will often decide to leave against medical advice. In almost all of these instances, he had capacity to make this decision. His reasons for leaving were variable– needing to care for his pet, wanting to see his family, or needing to go to work. There was little communication documented between the multitude of providers who have cared for this patient.

IMPACT: This case has encouraged me to consider compensity to leave AMA as a medical problem in and of itself. The etiology should be understood and communication between providers can provide context and prognosis. Finally, attempts should be made to prevent the morbidity and mortality associated with leaving AMA.

DISCUSSION: Understanding why a patient leaves AMA is paramount to attempting to stem the morbidity and mortality of the patient as well as the increased resource utilization of the hospital. Lack of a primary care physician, substance abuse, male sex, and history of leaving against medical advice have been associated with leaving against medical advice. In an ideal world, one would understand his reason for leaving against medical advice, connect him quickly to a primary care physician, and communicate to all providers a plan for his care going forward. It is not clearly documented in many of the discharge summaries why the patient wanted to leave AMA even though his capacity to do so was clearly indicated. In this case, an e-mail, phone, or face to face conversation between providers who have cared for him may have helped to put pieces together which might not be clear in documentation. Finally, a plan for when it is appropriate for him to be admitted and contingencies for leaving against medical advice should be made clear to all healthcare providers caring for this patient. Helping to provide better care to patients who routinely leave AMA is a difficult iterative process which requires increased communication and contingency planning.

SUPERIOR OPHTHALMIC VEIN THROMBOSIS: A RARE CASE OF OPHTHALMIC EMERGENCY LU CHEN; Garen Polatoglu; PARAG MEHTA; GENNADIY GRUTMAN. NEW YORK PRESBYTERIAN - BROOKLYN METHODIST HOSPITAL, BROOKLYN, NY. (Control ID #2706373)

LEARNING OBJECTIVE #1: Diagnosis and Initial Management of Superior Ophthalmic Vein Thrombosis

CASE: A 44 year-old man with uncontrolled Diabetes Mellitus Type II presented overnight to the Emergency Department for worsening right facial swelling and orbital pain that started ten days prior to arrival. He developed myalgias, arthralgias, fever, and malaise. He reported pain with ocular motion, but denied changes in visual acuity or color perception. Of note, the patient was employed as a construction worker and admitted to frequent wiping of his face with gloved hands. He reported non-compliance with diabetic medications. On ocular exam, chemosis, ptosis and conjunctival injection were noted in the right eye. Extraocular movements were limited by pain and swelling. Visual acuity and pupillary light reflex were bilaterally intact. Periorbital swelling, tenderness and erythema extended to the right maxilla. Phlebitis was appreciable along bilateral frontal sinuses and extended inferiorly to the nasal ridge. Laboratory studies were remarkable for leukocytosis of 14,600 per microliter with neutrophil predominance and glycohemoglobin 11.1%. Initial ophthalmology evaluation suggested Herpes Zoster induced orbital cellulitis. Patient was started on acyclovir and admitted to the medical ward. Maxillofacial Computed Tomography (CT) without intravenous (IV) contrast demonstrated inconclusive findings. He was aggressively managed for sepsis as his cellulitis appeared to worsen. Maxillofacial CT was repeated with IV contrast and demonstrated proptosis of the right eye, thrombosis of the right superior ophthalmic vein and possible cavernous sinus thrombosis. Anticoagulation with unfractionated heparin was initiated and patient was transferred to the Intensive Care Unit in a tertiary care center.

IMPACT: Superior Ophthalmic Vein Thrombosis (SOVT) is a rare condition faced by internists. It is important to suspect the condition in the setting of orbital cellulitis to reduce delay in care and prevent fatal complications. Internists should be vigilant in seeking early imaging studies and ophthalmology consultation for patients with orbital involvement or visual impairment.

DISCUSSION: SOVT is a rare but serious clinical condition that requires immediate intervention. Etiologies most commonly include Infection, followed by trauma, neoplasm, inflammation and hypercoagulable states. Orbital findings with or without optical nerve compression are commonly seen in patients with SOVT. Early recognition of SOVT is crucial for preventing complications such as cavernous sinus thrombosis and permanent blindness. Immediate imaging with CT with IV contrast, emergent ophthalmology consultation, early antibiotic treatment if indicated, and anticoagulation are important steps to optimize patient outcome.

SWEATING OVER A SECOND PARANEOPLASTIC SYNDROME Elise Coulson[1]; Nicholas J. Kiefer[2]; Jason Moran[1]. [1]Beth Israel Deaconess Medical Center, Boston, MA; [2]Beth Isreal Deaconess Medical Center, Brookline, MA. (Control ID #2701449)

LEARNING OBJECTIVE #1: Diagnose the paraneoplastic disease known as Morvan's Syndrome

LEARNING OBJECTIVE #2: Recognize neuropsychiatric symptoms as a potential manifestation of a paraneoplastic syndrome

CASE: A 68 year-old male with a past medical history notable for autoimmune autonomic ganglionopathy (AAG) and thymoma presented with hyperhidrosis. His initial symptoms of AAG were anhidrosis, miosis, and urinary retention. At that time, he was treated successfully with steroids and mycophenolate, but three years later he presented for fatigue and weight loss with work-up revealing a malignant thymoma. He was treated initially with chemotherapy, radiation, and subsequently resection. Five weeks after resection, he re-presented with a chief complaint of new hyperhidrosis, entirely distinct from his prior anhidrosis. He was also found to have severe insomnia, profound anxiety, weight loss, and muscle fasciculations on exam. An EMG was performed which showed diffuse myokymia (fine fascicular contractions), and a serum paraneoplastic panel showed positive antibodies to the Neuronal V-G K+ Channel confirming Morvan's Syndrome (MoS). PET/CT imaging revealed no evidence of recurrent thymoma. After treatment with plasmapheresis and high-dose steroids, his mental status, sleep, muscle fasciculations, and caloric intake all improved, though his hyperhidrosis persisted.

IMPACT: This case illustrates that patients can develop new paraneoplastic syndromes despite being in remission from their cancer. Additionally, multiple distinct paraneoplastic syndromes can develop in a single patient. Lastly, neuropsychiatric symptoms including anxiety and insomnia can rarely be manifestations of a paraneoplastic syndrome.

DISCUSSION: MoS is a rare disorder which is often paraneoplastic in nature and characterized by peripheral nerve hyper-excitability, limbic encephalopathy (LE), and autonomic dysfunction. Autoantibodies to two target antigens associated with the Neuronal V-G K+ Channel, LGI1 and Caspr2, have been implicated in the pathophysiology of both the peripheral and central manifestations. The LE is often manifested as sleep disturbances, cognitive dysfunction, and mood disturbances, while the autonomic dysfunction can manifest as hyperhidrosis and orthostasis. Prior case studies have reported multiple paraneoplastic syndromes in one individual, but they have been in the setting of recurrent disease. To our knowledge there is only one other case in which MoS occurred after resection of thymoma. Typically, discovery of a paraneoplastic syndrome alerts physicians to the presence of the tumor, and treatment would be expected to resolve the syndrome. This case demonstrates that cancer treatment and remission do not always track with paraneoplastic disease. Physicians should consider paraneoplastic syndromes in patients with cancer who present with new neuropsychiatric symptoms. Surveillance is important for recurrence of tumor, but providers should also be vigilant for paraneoplastic syndromes regardless of treatment or remission status.

SYNCHRONOUS PRIMARY GASTRIC DIFFUSE LARGE B CELL LYMPHOMA AND ADENOCARCINOMA: CASE REPORT Punita Grover; Rakesh Gaur; Ayman Qasrawi. UMKC, Kansas City, MO. (Control ID #2706354)

LEARNING OBJECTIVE #1: Recognize the occurrence of concomitant double primary gastric malignancies and the associated treatment challenges.

CASE: 75-year-old Caucasian male with a history of hypertension, hyperlipidemia and type 2 diabetes presented to the emergency department with ST elevation myocardial infarction. Emergent coronary angiography revealed severe three vessel disease. Echocardiogram showed reduced left ventricular systolic function, ejection fraction (EF) of 38%. Routine laboratory investigations revealed acute normocytic anemia, concerning for an occult gastrointestinal bleed in the setting of dual antiplatelet therapy. Esophago-gastro-duodenoscopy (EGD) showed two separate 3-cm ulcers; one in the stomach body and antrum and the other in the cardia and fundus. Histopathology of the gastric body ulcer showed an invasive moderately differentiated adenocarcinoma, negative for H. pylori and HER2/neu. Histopathology of the cardia/fundus ulcer revealed a dense atypical large lymphoid infiltrate, immunophenotypic profile consistent with diffuse large B-cell lymphoma (DLBCL), activated B-cell type. Positron-emission tomography revealed foci of increased floro-deoxyglucose uptake in the gastric cardia and posterior body of the stomach. Bone marrow biopsy showed no infiltrating lymphoma cells and computed tomography of abdomen was negative for metastatic disease. The diagnosis of early stage gastric adenocarcinoma and diffuse large B cell lymphoma, stage IE (Ann Arbor Staging System) was thus confirmed. Following a multidisciplinary review, it was decided to proceed with revascularization prior to initiating treatment for the gastric malignancies. He was at a high risk for consideration of a partial or total gastrectomy owing to his recent cardiac co-morbidities. It was elected to start chemo-immunotherapy, followed by an EGD after three cycles to determine response, and subsequent consolidative radiation. He underwent successful CABG, with improvement in cardiomyopathy. He has received three cycles of RCHOP (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisone) till date.

IMPACT: Treatment of synchronous malignancies has traditionally been according to the stage of adenocarcinoma, with surgical resection being first line therapy followed by chemotherapy.[4] Our approach was different in being primarily non-surgical and based on the presence of lymphoma. Additionally, our case was complicated by coronary artery disease and ischemic cardiomyopathy. Revascularization prior to chemotherapy allowed the cardiac function to recover to allow the use of anthracyclines.

DISCUSSION: Coexistence of primary gastric DLBCL and adenocarcinoma is a rare entity. However, it is important to recognize the presence of concurrent primary malignancies, especially given the vastly different treatment strategies. Pre-operative imaging and biopsy of all suspicious lesions should be carried out. Clear guidelines for management of have not yet been defined and treatment must be individualized.

SYSTEMIC CANDIDA PARAPSILOSIS PRESENTING AS CRITICAL LIMB ISCHEMIA Christina Kitsos; William C. Lorson; Simi Vincent. University of Tennessee Medical Center, Knoxville, TN. (Control ID #2704948)

LEARNING OBJECTIVE #1: Diagnosing *Candida Parapsilosis* endocarditis

LEARNING OBJECTIVE #2: Recognizing the risk factors associated with *C. parapsilosis* fungemia

CASE: A 36 year-old male with a history of IV drug abuse was transferred to a tertiary care center from an outside hospital for an emergent embolectomy due to critical limb ischemia. At the outside facility he reported sudden onset of pain, numbness, and paralysis. He endorsed recent intermittent fevers, chills, and tea colored urine. Ultrasound confirmed an acute embolic occlusion of the right superficial femoral artery. Cultures from the embolectomy grew *Candida parapsilosis* (*C. parapsilosis*). IV micafungin was started. A transesophageal echocardiogram was completed which demonstrated a "bicuspid aortic

valve… A large vegetation involving the aortic valve with severe aortic insufficiency." With these findings, he underwent an aortic valve replacement. Workup for his acute renal failure revealed an infectious embolic etiology, which was confirmed by biopsy. After stabilization, he was discharged with a total of 6 weeks of IV micafungin therapy. Unlike most *C. parapsilosis* infections, this patient had no prior history of hospitalizations, parenteral nutrition, or valvular surgery.

IMPACT: Tennessee has some of the highest reported incidence of illicit drug abuse. This case illustrates how with certain behaviors, IV drug abuse, fungemia is becoming more prevalent. Therefore, in order to save lives, it is imperative to recognize that fungal endocarditis can present with embolic complications.

DISCUSSION: The incidence of fungal endocarditis only accounts for 1.3-6% of all cases of endocarditis. Candida is found to be the cause in 53-68% of all fungal endocarditis cases, but only about 10-15% of those are caused by *C. Parapsilosis*. Candidemia itself carries a high mortality rate and reviews show that candida endocarditis can carry a mortality rate up to 72%. Risk factors include an immunosuppressed state, congenital heart defects, prosthetic heart valves, and IV drug abuse. Twenty five percent of infective endocarditis cases occur on a bicuspid aortic valves, and 10%-30% of bicuspid aortic valves develop endocarditis. Ventral septal defects are thought to cause up to a 20-fold increased risk of endocarditis compared to the general population. IV drug abuse also increases the risk of *C. parapsilosis* infection, with 20% of those infected with *C. parapsilosis* being users of IV drugs. Surgery and valve replacement is the first line treatment for candida endocarditis. For medical treatment, amphotericin-B based preparations, specifically lipid-based preparations, are thought to be most effective. Newer antifungals such as Echinocandins (micafungin) can also be used in place of amphotericin. *C. Parasilosis* is a rare form of endocarditis. If not treated quickly, death is inevitable.

TAFRO: A NEW SYNDROME Rie Ozawa[2]; Akira Ryu[2]; Sandra Y. Moody[1]; Mitsuya Katayama[2]. [1]Kameda Medica Center & UCSF/SFVAMC, Kamogawa City, Japan; [2]Kameda Medical Center, Kamogawa, Japan. (Control ID #2702230)

LEARNING OBJECTIVE #1: Diagnose TAFRO syndrome when the patient has thrombocytopenia, anemia, fibrosis of the bone marrow, renal failure and organomegaly

CASE: A 52-year-old healthy man presented to our hospital with dyspnea and fatigue. He was well until 3 weeks prior, when he noticed mild fatigue and bilateral lower leg edema. He reported a weight gain of 7–10 kg over one month. Workup at a nearby clinic revealed anasarca, acute renal failure and proteinuria. His protein-creatinine ratio was 3.2. He was transferred to our hospital for a kidney biopsy. On physical examination, a 2 × 2 cm left anterior cervical lymph node was noted. He had a distended, but nontender abdomen. There was significant pitting edema of both legs. Laboratory testing revealed a BUN of 82 mg/dL, creatinine 3.2 mg/dL, hemoglobin 9.8 g/dL, platelet count of 66,000, and CRP 18 mg/dL. He underwent computed tomography (CT), which showed multiple small cervical lymph nodes, bilateral pleural effusions, splenomegaly, and ascites. Hemodialysis for uremia was started; he eventually became anuric and dialysis-dependent. Thrombocytopenia and coagulopathy precluded a kidney biopsy; bone marrow biopsy showed a hypocellular marrow. Positron emission tomography showed high uptake in multiple neck lymph nodes bilaterally. Biopsy of the cervical lymph nodes revealed reactive lymphoid hyperplasia. On hospital day 15, his mental status worsened while on dialysis. Large bilateral occipital lobe infarcts were found on brain MRI. He was transferred to the intensive care unit and intubated for airway protection. Pulse steroids and tocilizumab were started for a presumed diagnosis of TAFRO syndrome. On day 17, he had an episode of apnea and was found to be without brain stem reflexes. Head CT showed significant brain edema, and comfort care was initiated. The patient died on day 20, and an autopsy was performed.

IMPACT: When a patient is seen with significant inflammation, thrombocytopenia, and renal failure with minimal signs of infection, malignancy or collagen vascular disease, then TAFRO syndrome should be considered.

DISCUSSION: TAFRO syndrome is a subtype of Castleman's disease; new diagnostic criteria were published in 2016. Over the course of this patient's illness, it became clear that he suffered from this newly established disease. Given the presence of significant inflammation, this syndrome is very difficult to diagnose early, as it is a diagnosis of exclusion, after infections, malignancies and collagen vascular diseases are ruled out. Unfortunately, the patient died; autopsy confirmed the diagnosis. We will share our experience of this rare and newly established disease and the findings of the autopsy.

TAKOTSUBO CARDIOMYOPATHY IN A PATIENT WITH BIPOLAR DISORDER AND AMPHETAMINE OVERDOSE Firas Alzaiem[2]; Yvette DiMarco[3]; Jenyfeer Blanco[3]; Joseph Escobar[3]; Darran M. Khublall[3]; Damian Casadesus[1]. [1]Capital Health Regional Medical Center, Trenton, PA; [2]Ross University School of Medicine, Miramar, FL; [3]American University of the Carribean, Coral Gables, FL. (Control ID #2702868)

LEARNING OBJECTIVE #1: Recognize signs and features of stress induced cardiomyopathy

LEARNING OBJECTIVE #2: Assess social and psychiatric history of patients with chest pain

CASE: A 35-year-old Hispanic female presented to the emergency department (ED) with agitation. She has past medical history of Bipolar disorder and polysubstance abuse and was previously admitted to Crisis Psychiatric ED due to an unidentified drug use secondary to a recent emotional event. Patient also reported dyspnea, pain and paraesthesias in upper extremities, dizziness, and lightheadedness. On physical exam vitals were within normal limits. She was very agitated and confused and did not follow commands or answer questions properly. Cardiopulmonary evaluation was normal and with no abdominal organomegaly. She was treated with two doses of Haloperidol 5mg and Diphenhydramine 50mg, and three doses of Lorazepam 2mg IV within the first 24hours of admission. On the day after admission, the agitation improved, but reported dyspnea with exertion and palpitations. Cardiopulmonary and abdominal exams were normal. Her initial laboratory evaluation revealed: EKG with normal sinus rhythm, Troponin T was 0.28ng/mL, Pro-BNP 3,888pg/mL, and a Urine Analysis positive for amphetamines. Chest radiography exhibited pulmonary edema and cardiomegaly. An echocardiogram showed concentric left ventricular hypertrophy with mildly reduced systolic function, balloon dilation of the left ventricle, apico-lateral hypokinesis. A CT angiogram demonstrated no signs of atherosclerotic lesions of the coronary arteries. Considering the patient's young age, the absence of coronary artery disease risk factors, no significant coronary artery calcification and echocardiogram results, the diagnosis of stress induced cardiomyopathy was established. The patient was discharged home on a trial of metoprolol 12.5mg twice daily and outpatient echocardiogram to follow up in 2 months.

IMPACT: This case reinforced the significance of obtaining a comprehensive history and better understanding the patient's situation in order to properly assess their overall condition. Investing more time investigating the patient's mental status and history leads to a better and more accurate diagnosis.
DISCUSSION: Takotsubo Cardiomyopathy is a transient systolic dysfunction of the apical and midsegments of the left ventricle usually associated with acute emotional stress. Amphetamine stimulating types associated cardiomyopathies describe a novel condition commonly found in young males that present with severe dilated cardiomyopathy. We present a female case with bipolar disorder that used amphetamines due to recent emotional events, who presented with agitation and confusion. Takotsubo cardiomyopathy has been associated with acute psychiatric episodes, stressful events, amphetamines and benzodiazepines use, in which all were present in this patient. This case demonstrates the fundamental significance of obtaining a complete social and psychiatric history when investigating rare etiologies of chest pain.

TAMPONADE MYSTERY - HEART DROWNED BY ANGIOSARCOMA Roshanak Habibi[1]; Alvaro Joaquin Altamirano Ufion[2]; Negar Faramarzi[1]. [1]Presence Saint Francis Hospital, Evanston, IL; [2]Advocate Illinois Masonic Medical center, Chicago, IL. (Control ID #2706370)

LEARNING OBJECTIVE #1: Diagnose a unique cause of cardiogenic shock in a patient with tamponade symptoms.
CASE: 59-year-old male referred by cardiologist to our hospital complaining of worsening shortness of breath, weight gain of 6 pounds, leg swelling and low blood pressures(BP) down to 80/60 mmhg for a few weeks. Medical history was significant for Hypertension, Coronary Artery Disease, and a recent tamponade diagnosed 4 months prior to this hospitalization. A large serosanguinous pericardial effusion was drained at that time with inconclusive fluid analysis. His medications included Amlodipine, Lisinopril and Atorvastatin. Positive findings on exam were a BP of 85/60 mmhg, mild respiratory distress on room air, increased jugular vein pressure, muffled heart sounds and pitting edema of the shins. Echocardiogram showed a moderate sized posterior pericardial effusion with borderline signs of tamponade. The echo also revealed a fibrinous material and stranding suggestive of adhesions in the collection. Ejection fraction was 59%. Attempt to drain the pericardial effusion with subxiphoid pericardial window was terminated due to fusion of pericardium to the anterior surface of right ventricle. Partial pericardiectomy was then attempted with frozen section, which revealed a neoplastic process. Because of these findings, a subtotal pericardiectomy was performed. Repeat echocardiogram showed no further effusion. Final pathology report revealed epithelioid angiosarcoma of the pericardium. Chest computed tomography scan showed nodular opacifications within both lungs with concern for metastasis. His condition stabilized with Lasix and Oxygen. He was then referred to Loyola University for a second opinion regarding his angiosarcoma management.
IMPACT: We described a case of pericardial angiosarcoma in which initially diagnosis was a challenge due to rarity of the pathology. Reporting this case is another example in literature showing how to recognize the rare pattern of such tumors at presentation.
DISCUSSION: Primary malignancies of the heart are so rare that most of the available data come from case reports or large single center based studies, with the overall incidence of 0.02% in the United States. Pericardial angiosarcoma can be seen at almost any age with peak incidence in middle aged men. The majority are asymptomatic until they become large enough to cause symptoms. Pericardial angiosarcoma may arise from the epicardial surface of the heart and penetrate the pericardial space. Signs of right sided heart failure and pericardial effusion are common, which can lead to tamponade. By the time of diagnosis, most patients have metastases, most commonly to the lung. Histologically, angiosarcomas consist of endothelial cells & spindle cells lining, not well-defined anastomotic vascular spaces, causing sheet like pericardial thickening. 90% of patients die within 9 to 12 months of diagnosis without resection. The optimal treatment remains to be discovered.

TARGETING LYME DISEASE WITHOUT A BULLSEYE Jonathan Wolfe[2]; Amar Kohli[1]. [1]UPMC, Mars, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA. (Control ID #2705670)

LEARNING OBJECTIVE #1: Diagnose Lyme disease in the absence of erythema migrans.
LEARNING OBJECTIVE #2: Detail the appropriate timing of serologic testing utilized in confirming Lyme disease.
CASE: A 45-year-old woman with no past medical history presented to outpatient clinic with fever, chills, and myalgias. She had been in her usual state of health until five days prior to presentation when she awoke with fever to 101°, chills, diaphoresis, and crampy pain in her shoulders and neck. Her symptoms waxed and waned, but generally persisted prompting a clinic visit for evaluation. Extensive review of systems was negative including cough, rhinorrhea, sore throat, gastrointestinal symptoms, joint pain, or rash. She denied any sick contacts or recent travel. She was an avid gardener at her home in Pennsylvania, and spent a lot of time outdoors. However, she denied a known tick bite. On physical exam, she was diaphoretic with a temperature of 99.4°. Her exam was otherwise unremarkable. Laboratory testing revealed mild leukopenia and thrombocytopenia, normal ESR, elevated CRP, and mildly elevated transaminases. Subsequent ELISA screening test for Lyme was positive. The diagnosis of Lyme disease was confirmed when Western Blot was positive for IgM. She was treated with doxycycline and recovered.
IMPACT: Lyme disease is classically taught as presenting with erythema migrans. While this is true in the majority of cases, a substantial minority of patients present without any rash. Clinicians practicing in Lyme endemic areas must have a high index of suspicion to diagnose Lyme in these cases.
DISCUSSION: Early localized Lyme disease typically presents with non-specific symptoms that may mimic a viral illness. Symptoms are accompanied by a pathognomonic, "bullseye" rash termed erythema migrans in approximately 80% of cases. Patients presenting with erythema migrans should be treated for Lyme disease and do not require confirmatory serologic testing. For patients presenting without a rash, the diagnosis is more challenging. Our patient presented to clinic with nonspecific symptoms. Notably, she denied respiratory and gastrointestinal symptoms, which are not associated with Lyme disease and should prompt an evaluation for an alternative diagnosis. Her physical exam was largely unremarkable, including the absence of a rash. Labs revealed mild transaminitis, leukopenia, and thrombocytopenia, findings which are commonly seen in tick-borne illnesses but also in various viral infections. For patients presenting without a rash, serologic testing may be helpful. However, serologies may be negative for up to several weeks before becoming positive. Serologic testing for Lyme IgM does not become positive for 1 to 2 weeks until after symptoms develop. Lyme IgG appears 1 to 6 weeks after symptoms develop. In our patient, her

IgM serologies were fortunately positive after approximately 10 days, which established the diagnosis.

TAVR AND HEYDE: THE ROLE OF TRANS-CATHETER AORTIC VALVE REPLACEMENT IN AORTIC STENOSIS ASSOCIATED GASTROINTESTINAL BLEEDING Natalie Achamallah; Alexander Hardwick. Santa Barbara Cottage Hospital, Santa Barbara, CA. (Control ID #2692667)

LEARNING OBJECTIVE #1: Illustrate the potential of TAVR in treatment of Heyde's syndrome related bleeding

CASE: A 73-year-old woman with history of diabetes, hypertension, atrial fibrilation and bio-prosthetic aortic valve replacement was evaluated for acute anemia secondary to GI bleed. She had been admitted eight times in the preceding five years for acute anemia requiring transfusion. She complained of progressive exertional dyspnea and angina. Echocardiogram showed aortic valve area of 0.75cm^2 with max velocity 4.5m/s, consistent with bioprosthetic aortic valve stenosis. She subsequently underwent redo sternotomy with redo bio-prosthetic valve replacement. Recovery was complicated by persistent atrial fibrillation requiring cardioversion and amiodarone and she was discharged home one week post-operatively on oral anticoagulation (OAC). In the intervening months she has had no episodes of acute GI blood loss despite OAC for atrial fibrillation. An 84-year-old woman admitted for GI bleed was referred for echocardiogram because of an ejection systolic murmur noted on exam. Medical history included endometrial cancer, hypertension, and diabetes, as well as seven hospitalizations for acute anemia secondary to GI bleed over the preceding four years. Recurrent endoscopy and colonoscopy revealed AVMs requiring cauterization. Echocardiogram demonstrated severe AS with valve area 0.94cm^2 and jet velocity 4.2m/s. She was considered a high risk surgical candidate and instead underwent trans-catheter aortic valve replacement (TAVR) without complication. She has had no further episodes of acute gastrointestinal bleeding despite taking standard dual anti platelet therapy (DAPT) after TAVR.

IMPACT: The first of these cases demonstrates complications after surgical replacement in a patient with multiple co-morbid conditions. The second represents a good outcome following TAVR in a patient with similar co-morbidities who would not have been a candidate for surgery. For both patients, recurrent GI bleeding ceased after aortic valve replacement. The success of the latter illustrates the potential of TAVR in treatment of Heyde's syndrome related bleeding.

DISCUSSION: The association between calcific aortic stenosis (AS) and gastrointestinal bleeding - Heyde's syndrome - has been a controversial one since its proposition in 1958. The source of AS related GI bleeding has been postulated as submucosal angiodysplasia, with related von Willebrand factor (vWF) activation and acquired deficiency secondary to shear forces through the stenotic valve. Although the exact mecahnism remains unelucidated, several studies have demonstrated a temporal association between valve replacement and resolution of GI bleeding. This has been directly demonstrated through measurement of vWF multimer levels pre- and post- valve replacement. With the advent of trans-catheter aortic valve repair (TAVR) a less invasive option now exists for patients with Heyde's syndrome who would otherwise not be surgical candidates.

TB OR NOT TB? THE DRAMA UNFOLDS WITH MACROPHAGE ACTIVATION SYNDROME (MAS) Andrea Beck[3]; Jimmy Mullally[2]; Etsemaye P. Agonafer[2]; Andrew Trifan[1]. [1]University of Pittsburgh, Pittsburgh, PA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA; [3]University of Pittsburgh School of Medicine, Pittsburgh, PA. (Control ID #2672534)

LEARNING OBJECTIVE #1: Recognize the limitations of TB screening prior to initiation of TNF-α inhibitors

LEARNING OBJECTIVE #2: Diagnose MAS in immunosuppressed patients

CASE: A 44-year-old Indian immigrant male with Crohn's Disease presented with a 12-day history of persistent fevers to 103 F without associated cough, shortness of breath, nausea, vomiting, joint pain, myalgias, or rash. He endorsed baseline abdominal pain with defecation and drainage from a previously diagnosed perianal abscess. His medications included budesonide, mesalamine and adalimumab, begun 6 months prior to presentation. On admission, he was febrile to 105 F, tachycardic, and intermittently hypoxic with an otherwise unremarkable exam. His fevers persisted after abscess debridement and treatment with meropenem. CT abdomen then revealed nodules and effusions at both lung bases, raising concern for TB despite a negative PPD prior to initiation of adalimumab. QuantiFERON-TB Gold (QFT-Gold) was indeterminate, but he was empirically treated with RIPE therapy after lung biopsy confirmed caseating and non-caseating granulomatous inflammation. The patient's fever resolved on TB therapy, but labs showed pancytopenia, transaminitis, hypertriglyceridemia, ferritin > 9000, and elevated CRP. Bone marrow biopsy revealed hemophagocytes and rare mycobacteria, and he was diagnosed with concurrent MAS and miliary TB. In addition to RIPE therapy, the patient received 5 days of anakinra during which his labs normalized. Shortly thereafter, he was discharged home.

IMPACT: MAS is a rare, life-threatening condition necessitating prompt recognition and treatment. MAS has not been well-studied in the context of IBD, and there are only a handful of cases published involving MAS, IBD, and TB concurrently. This case provides an example of a successful outcome, which will be useful in determining the appropriate course of treatment for similar patients in the future.

DISCUSSION: This complex case raises several clinical considerations. First, a negative PPD cannot definitively rule out latent TB in patients starting immunosuppressive therapy. For IBD patients on TNF-α inhibitors, TB reactivation still occurs despite compliance with recommended screening. In miliary TB, anergy is as common as 68%. QFT-Gold is a comparable alternative to PPD for latent TB screening, but is not useful for diagnosis of active infection. An indeterminate result is common in immunosuppressed patients. Second, prompt recognition and treatment of MAS was likely critical for this man's survival based on reported mortality rates of 30%. A high index of suspicion is necessary to diagnose MAS since it typically presents in the context of underlying autoimmune disease and acute infection. The immune system is inappropriately over-stimulated in MAS, eventually leading to cytokine storm and multiple organ failure. Hyperferritinemia in an immunosuppressed patient should raise concern for MAS, particularly when accompanied by pancytopenia, hypertriglyceridemia, and hypofibrinogenemia.

THAT TROPONIN IS HIGH, OH MY! Rachel N. Clark. Tulane University, New Orleans, LA. (Control ID #2705348)

LEARNING OBJECTIVE #1: Recognize acute myopericarditis as a cause of acute chest pain.

LEARNING OBJECTIVE #2: Formulate a differential diagnosis for an elevated troponin in the setting of chest pain.

CASE: A 47-year-old woman with SLE and hypertension, presented with an acute onset of sharp, substernal, non-radiating chest pain associated with dyspnea and fatigue. She denied any pain with position changes, paroxysmal nocturnal dyspnea, or orthopnea. Due to fear of a heart attack, she presented to the emergency room for evaluation. Upon physical exam, she was in moderate distress. She continued to complain of pain despite three doses of nitroglycerin. She was afebrile, with a heart rate of 110 and blood pressure of 167/98. The pain was unable to be reproduced with palpation. Cardiovascular exam was significant for a mild friction rub and tachycardia. Pulmonary auscultation was normal. Electrocardiogram was remarkable for sinus tachycardia with no changes suggestive of ischemia. CT angiography was negative for pulmonary embolism. She had a hemoglobin of 10.8, a platelet count of 108, and a normal white count, electrolytes, and liver function. Troponin was elevated to 3.9 and C-reactive protein elevated to 10.5. Transthoracic echocardiogram was normal. Cardiac catheterization was negative for evidence of coronary artery disease. Her chest pain continued to worsen; cardiac MRI exhibited findings suggestive of myopericarditis. Following diagnosis, she was treated with aspirin and colchicine. At her 6-week follow up, her symptoms resolved.

IMPACT: Along with acute coronary syndrome, an internist should consider diagnoses such as myocarditis and pericarditis when evaluating a patient with an elevated troponin. Correct diagnosis can avoid unnecessary invasive procedures and allow initiation of an appropriate treatment plan to minimize long-term morbidity.

DISCUSSION: Acute myopericarditis is primarily a pericarditic syndrome - an acute pericarditis with associated myocardial inflammation. In developed countries, the most common etiology of myopericarditis includes viruses, but other causes include connective tissue diseases. The above etiologies introduce inflammation through direct cytotoxic cellular damage. For diagnosis of myopericarditis, a definitive diagnosis of acute pericarditis is needed and includes at least 2 of the following: typical chest pain, pericardial friction rub, ST segment elevation, and new or worsening pericardial effusion. Once pericarditis has been established, the patient must have cardiac enzyme elevation or cardiac MRI consistent with myocarditis. In order to definitively confirm myopericarditis, histopathologic evidence by endomyocardial biopsy is considered. Prognosis is generally good when treated appropriately to decrease the risk of recurrence. NSAIDs are typically the mainstay of treatment for acute pericarditis. Our patient was treated according to the CORP trial, which included colchicine treatment for recurrent pericarditis.

THE 3 MAGIC WORDS - TELL ME MORE?

Pratyusha Bollimunta[2]; Venu M. Ganipisetti[1]; Sreelakshmi Panginikkod[2]; Sowjanya Naha[2]. [1]Miami Valley Hospital, Evanston, IL; [2]Presence Saint Francis Hospital, Evanston, IL. (Control ID #2706965)

LEARNING OBJECTIVE #1: Recognize importance of assessing dietary habits of patients.

LEARNING OBJECTIVE #2: Recognize Pica and associated perceptions of social stigma

CASE: A 24-year-old female was evaluated for progressively worsening shortness of breath and fatigue for several months along with severe anemia. She had prior extensive workup by her Gynecologist and was diagnosed with iron deficiency anemia presumed to be because of menorrhagia. She was following with her Gynecologist for almost over a year and receiving treatment for menorrhagia, which improved with treatment. However, her anemia was persistent despite being prescribed for iron supplements. Her hemoglobin levels 1 year ago, was 10.5 g/dl, 6 months ago, was 9.2 g/dl and at presentation 6.4 g/dl. Iron indices showed low Ferritin level 14 ng/ml and iron saturation of 7%. Stool occult blood and other anemia workup was negative. After several min into a discussion about her lifestyle and dietary habits, patient confessed that she initially tried to take iron pills, but was not able to be compliant as they made her stomach feel weird and added- " I have been eating toilet tissue paper for some time and I crave for it. I feel very embarrassed about it and did not tell anyone so far". At the time of encounter, she reported that she was consuming about 1–4 rolls per day. A diagnosis of Xylophagia/Pica was made and given her noncompliance with oral iron she was started on parenteral iron. On 6 month follow up, patient reported improvement in fatigue and her craving had resolved.

IMPACT: Xylophagia/Pica are perceived as stigmatizing conditions by patients and the strongest diagnostic tool is effective communication and education. Unless treated the condition can lead to life-threatening emergencies.

DISCUSSION: Pica is defined as craving and ingestion of nonfood or inedible substances. Xylophagia is a type of pica associated with eating paper and its related products. Iron deficiency anemia, zinc deficiency, schizophrenia, obsessive compulsive disorders can all lead to Pica. However, pica itself can lead to iron deficiency anemia. Diagnosis of Pica can be challenging as the only diagnostic tool is strong interpersonal communication with patients and achieving their trust, for them to open up and discuss these issues. Most of the patients as aware that these eating habits are unusual and are embarrassed about them. Untreated pica can cause complications such as intestinal obstruction, gastric perforation, heavy metal toxicity, etc. Correcting the nutritional deficiencies treats the condition, unless a psychiatric condition is involved and such patients should be referred to psychiatrist.

THE ANCA BIAS: IT'S NOT ALWAYS AUTOIMMUNE

Elizabeth Park[2]; Jonathan Cheah[1]; Lee S. Shearer[3]. [1]Hospital for Special Surgery, New York, NY; [2]New York Presbyterian Hospital, New York, NY; [3]Weill Cornell Medical College, New York, NY. (Control ID #2678825)

LEARNING OBJECTIVE #1: Distinguish Cocaine-Induced Elevation of Anti-Neutrophil Cytoplasmic Antibodies [ANCA] from ANCA-Associated Vasculitis [AAV]

CASE: 62 year old man with Diabetes and newly diagnosed Hepatitis C was admitted to the hospital after an episode of passing black clots from the nose and mouth, as well as melena. He complained of chronic subjective weight loss, fatigue as well as oro-palatal pain. His physical exam was notable for a sizable defect of the upper palate and sunken depressions on the nasal bridge. No joint swelling, tenderness nor skin rash were noted and the neurological exam was unremarkable. Initial studies were notable for a rise in Creatinine from a baseline of 1 to 1.89, urinalysis negative for protein or active sediment, and an active Hepatitis C viral load. Given the upper airway bleeding with palatal and nasal defects as well as new renal insufficiency, suspicion was raised for Granulomatosis with Polyangiitis [GPA]. This was further validated when positive ANA [1:80 speckled] as well as a very high titer cytoplasmic ANCA [cANCA] against proteinase 3 [PR3] at 564 and positive perinuclear

ANCA [pANCA] against myeloperoxidase [MPO] were noted. However, his urine toxicology was positive for Cocaine and upon further inquiry, patient endorsed decades of Cocaine use. He also reported chronic Aspirin and Naproxen use. Biopsy of the nasal turbinates was negative for vasculitis. Overall, given the negative biopsy, lack of active urine sediment, and bleeding better explained by medication use, his clinical presentation was thought to be more consistent with a Cocaine Induced Midline Destructive Lesion [CIMDL] rather than GPA.

IMPACT: Despite apparent clinical features and very high titers of cANCA PR3 which may anchor one's thinking towards AAVs such as GPA, the generalist should be aware of common mimics including cocaine.

DISCUSSION: ANCAs can be divided into two distinct fluorescence patterns, cANCA from antibodies against PR3, and pANCA against MPO. ANCAs, while primarily raised by vasculitides, can be raised by medications including Cocaine, Hydralazine and Sulfasalazine, and infections like Hepatitis C and subacute bacterial endocarditis. While cANCA PR3 is frequently found to be positive in both AAV and CIMDL, current research reports discrete differences between the epitopes recognized by PR3 antibodies as well as differences in functionality, including hydrolytic activity of key peptides, suggestive of a different pathophysiology. Beyond biopsy and urine toxicology testing, the presence of a second pANCA subtype human neutrophil elastase [HNE] can be utilized to differentiate CIMDL from GPA. One cohort study demonstrated that 84% of CIMDL patients tested positive for HNE ANCA, while *none* were detected in patients with GPA. The mechanism by which cocaine induced lesions actually trigger ANCA production has yet to be fully elucidated, but barrier dysfunction from both cocaine and chronic nasal colonization of S. aureus has been suggested as one possibility.

THE CALM AFTER THE STORM Effie Tsomos[3]; Neetha Reddy[2]; Vafa Tabatabaie[1]. [1]Montefiore Medical Center, New York, NY; [2]Montefiore Medical Center, Bronx, NY; [3]Montefiore Medical Center, Bayside, NY. (Control ID #2703225)

LEARNING OBJECTIVE #1: Recognize the clinical features of thyroid storm

LEARNING OBJECTIVE #2: Identify the potential benefits of plasmapheresis in resistant thyroid storm

CASE: A 28 year old woman presented with one week of progressively worsening paranoia and auditory hallucinations as well as abdominal pain, vomiting, and increased stool frequency. The patient had a heart rate of 150 beats per minute, pressured speech, and was actively hallucinating. She had a smooth, diffusely enlarged thyroid gland and a bilateral hand tremor. Labs revealed a thyroid-stimulating hormone <0.005 U/mL, free thyroxine >7 ng/dL, and anti-thyroid peroxidase antibody 660 IU/mL. Thyroid US revealed an enlarged, heterogeneous thyroid gland with increased blood flow. The patient was treated accordingly with methimazole, potassium iodide, and propranolol. After 10 days of therapy, the patient continued to hallucinate and her free thyroxine remained elevated at 13 ng/dL. Given that she did not improve on conventional therapy, plasmapheresis was initiated resulting in rapid normalization of thyroid hormone levels after two sessions of plasmapheresis. She subsequently underwent a total thyroidectomy and her thyroid function tests normalized.

IMPACT: Thyroid storm is a life-threatening and rare condition caused by untreated hyperthyroidism. This case demonstrates the need to consider plasmapheresis as a stabilizing measure when patients in thyroid storm do not respond to conventional therapy.

DISCUSSION: Individuals with thyroid storm synthesize and release an excess of thyroid hormone and experience an exaggeration of the usual symptoms of hyperthyroidism such as fever, abdominal pain, nausea, vomiting, diarrhea, and tremors. More serious manifestations of this disease include cardiac failure, arrhythmia, psychosis and hyperthermia. Conventional management of thyroid storm is multimodal. It includes concurrent treatment with methimazole to stop the synthesis of new thyroid hormone followed by potassium iodide to prevent the release of pre-formed thyroid hormone from the thyroid gland, and beta blockers to control hyperadrenergic symptoms. In the rare circumstance that antithyroid drugs do not result in clinical improvement or lowering of thyroid hormone levels, plasmapheresis can be used as a stabilizing measure for thyroid storm, helping reduce thyroid hormone levels while patients await definitive treatment with thyroidectomy. Plasmapheresis works by removing thyroxine-bound globulins in the circulation and replacing this with unbound globulins found in fresh frozen plasma which can subsequently bind free thyroid hormones. It is also thought to assist with removal of factors that exacerbate thyroid crisis such as catecholamines and cytokines. Thus, in patients presenting with thyroid storm, combining the use of antithyroid drugs and plasmapheresis is an effective modality for improvement of clinical symptoms and should be considered in cases of thyroid storm resistant to conventional therapy.

THE CASCADE EFFECT Kimberly R. Cavaliere. Montefiore Medical Center, New York, NY. (Control ID #2700840)

LEARNING OBJECTIVE #1: Recognize the clinical features concerning for cascade stomach.

LEARNING OBJECTIVE #2: Diagnose cascade stomach.

CASE: A 48-year-old man with a history of gallstone pancreatitis and peptic ulcer disease presented to the hospital with abdominal pain, nausea, and emesis for three days. The abdominal pain started 30 min after a meal and persisted, prompting his presentation to the hospital. The pain was a 10/10 burning sensation in the epigastric region, radiating to his back. The patient noted that he had bouts of this abdominal pain for years and despite an extensive work-up, no etiology had been found. Work-up was significant for normal lipase and liver tests, and an abdominal CT scan negative for pancreatitis. The patient was treated with morphine, fluids, viscous lidocaine, anti-emetics and proton pump inhibitors with minimal improvement. An EGD was done which was unremarkable. An upper GI series was then performed to look for structural abnormalities, revealing the presence of a cascade stomach. The patient was first treated with endoscopic botox injections without improvement. He subsequently underwent laproscopic partial gastrectomy without complication. Four days after the surgery the patient's pain was controlled, he was able to tolerate a pureed diet, and he was discharged home.

IMPACT: This case demonstrates the importance of upper gastrointestinal series when evaluating symptomatic patients for structural abnormalities of the gastrointestinal tract, even in the presence of a normal endoscopic evaluation.

DISCUSSION: Cascade stomach is an anatomic anomaly of the gastrointestinal tract in which the stomach is separated into two parts. This separation is caused by the top portion of the fundus folding over the lower portion of the stomach. This anomaly can only be diagnosed by barium studies and often

yields a normal endoscopic evaluation, much like was seen in our patient. On barium exam the swallowed contrast will pool in the first portion of the stomach until it fills to the level of the fundus fold, at which point it flows over, or "cascades" into the lower portion of the stomach. Endoscopic examination is often unrevealing as the endoscope inflation frequently straightens out the problematic stomach fold. Additionally only subtle luminal abnormalities are present, which are often not appreciated. There are many factors that can predispose one to cascade stomach including but not limited to, congenital malformations, external compression, peptic ulcer disease, displacement of the splenic flexure or spleen, and abnormal mobility of the fundus. Symptoms of cascade stomach most frequently occur in the postprandial setting such as gastroesophageal reflux, fullness, and abdominal pain, all of which our patient experienced. Treatment options are limited but are focused on straightening the upper portion of the stomach and include behavioral modifications, such as laying down after eating, and surgical options, such as gastropexy, or surgical resection.

THE CASE OF THE DISAPPEARING CHEST PAIN: MULTIPLE EPISODES OF SUBCLINICAL PERICARDITIS IN A YOUNG ADULT WOMAN WITH SUBSEQUENTLY DIAGNOSED UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE Imikomobong Ibia[1]; Heidi Guzman[1]; Micaela F. Bayard[1]; Joseph Truglio[2]. [1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]Icahn School of Medicine at Mount Sinai, Maplewood, NJ. (Control ID #2706074)

LEARNING OBJECTIVE #1: Develop a differential diagnosis for a young woman with CTD and multiple episodes of severe, self-limiting chest pain

CASE: A 31-year-old female with a history of mild-persistent asthma and recently diagnosed Undifferentiated Connective Tissue Disorder (UCTD) with Hashimoto's thyroiditis came to our clinic with chest pain of five days duration. She described the pain as left-sided, tender, and pleuritic in nature. After days of self-treating with naproxen without improvement, she came in for evaluation. She denied any abdominal symptoms, diarrhea, dysuria, recent travel or sick contacts. Interestingly, she described the pain as similar to episodes she had experienced over the past few years. The previous episodes were almost always identical: days of left-sided, pleuritic chest pain that did not improve with NSAIDs, followed by an emergency room visit without a clear diagnosis, and eventual self-resolution of the pain weeks later. On physical exam, blood pressure was 120/81, heart rate was 95, respiratory rate was in the low 20's, and she was febrile to 39.5C. Upon pulmonary examination, her lungs were clear to auscultation bilaterally, without evidence of rales or decreased breath sounds to suggest a large effusion. She had normal heart sounds and had no signs of lower extremity edema. She was sent to the emergency room to get a chest computed tomography angiography (CTA) to rule out a pulmonary embolism, and considering her history of UCTD, a bedside ultrasound was ordered to rule out a pericardial effusion. Her comprehensive metabolic panel, CBC, CXR, CTA, EKG, and urine were normal. Her CRP was elevated at 68 mg/L, and a bedside ultrasound showed a small pericardial effusion. Rheumatology was consulted given her history of UCTD. It was recommended to start low dose oral prednisone for five days. She was discharged with a diagnosis of pericarditis on prednisone and ibuprofen with follow-up at her primary care doctor and rheumatology. With an additional short course of steroids, her pericarditis slowly resolved over the next few weeks. She was subsequently restarted on her hydroxychloroquine and levothyroxine as previously prescribed.

IMPACT: From our literature review, there are few reported cases of CTD presenting as multiple episodes of subclinical pericarditis. Nonetheless given this case, one must be cognizant that this initial presentation is possible, albeit unusual, and hence CTD should be included in one's differential. In addition, this case emphasizes that patients' CTD may have an early onset of highly active disease. Thus, one should fully evaluate the history of related symptoms and use this to guide treatment.

DISCUSSION: This case stresses that although more common causes of chest pain must be ruled out first (including valvular heart disease, anxiety/depression, musculoskeletal pain, esophageal reflux, pulmonary embolism, pneumonia, pneumothorax, myocardial infarction), a full differential diagnosis for patients with possible CTD includes pericarditis.

THE CASE OF THE MISTAKEN ETIOLOGY: GASTROPARESIS AS A RESULT OF EHLERS DANLOS SYNDROME Bernard Partiula. Northwell Health Lenox Hill Hospital, Brooklyn, NY. (Control ID #2704986)

LEARNING OBJECTIVE #1: Recognize the association between congenital syndromes such as Ehlers Danlos Syndrome and their clinical manifestations.

CASE: A 44 year old female with Ehlers Danlos syndrome (diagnosed 5 years ago after experiencing an unexplained myocardial infarction with 100% patent coronaries) presented with 3 days of nausea and vomiting occurring after meals and intermittent watery, nonbloody, and self resolving diarrhea. The patient denied any sick contacts, travel, or consumption of undercooked or unpasteurized food. A CT abdomen showed mild enterocolitis; the patient was treated and discharged with ciprofloxacin and metronidazole for suspected infectious colitis. She returned to the hospital 2 weeks later with the same symptoms and again discharged on antibiotics. She claimed that despite completing the full course, her nausea and vomiting did not improve. She went to see her outpatient gastroenterologist who performed an EGD and colonoscopy, both of which were normal. She returned to the hospital once more and underwent a gastric emptying study to rule out a functional cause of her nausea and vomiting. The results of the study were abnormal; her gastric emptying times were delayed. Four hours post initiation of the test, she had over 50% food content in her stomach, consistent with gastroparesis (greater than 10%). It was deemed that her gastroparesis was due to Ehlers Danlos, therefore her antibiotics were stopped. She was referred back to her gastroenterologist who started her on a pro-motility drug with good response.

IMPACT: This case shows the importance of not anchoring onto a single, more commonly seen diagnosis (e.g. gastroenteritis), seeing the patient as a whole and considering all differentials, given the medical history and history of present illness. It also makes physicians aware of the broad scope of multiorgan complications of Ehlers Danlos syndrome.

DISCUSSION: Connective tissue is present throughout the body, and in the digestive tract it is essential to the passive mechanical movements needed to complete digestion. Any abnormalities in the tissue are likely to alter the tract's movements, which could contribute to the range of symptoms EDS patients experience. These symptoms include delayed gastric emptying/dysmotility as seen in our patient, heartburn, bloating, and constipation. Our patient presented with recurrent gastrointestinal symptoms in the setting of EDS, was misdiagnosed with an infectious etiology and treated multiple times in the same vein. This case, as emphasized earlier, demonstrates the clear association

between congenital syndromes such as Ehlers Danlos and common clinical conditions such as gastroparesis. It also stresses the importance of a thorough history, complete physical examination, and broad differential diagnosis. This is imperative for preventing misdiagnosis, avoiding any further unnecessary diagnostic tests or treatments, and initiating appropriate therapy in a timely manner.

THE CAT'S OUT OF THE BAG: A RARE PRESENTATION OF INVASIVE PASTEURELLA MULTOCIDA INFECTION Yasmin Marcantonio; Shira Sachs; Prathit Kulkarni; Kevin Ting; Jennifer Lee; Daniel Mendoza. Baylor College of Medicine, Houston, TX. (Control ID #2704275)

LEARNING OBJECTIVE #1: Review risk factors for *P. multocida* infection.
LEARNING OBJECTIVE #2: Recognize complications of invasive *P. multocida* infection.
CASE: A 67-year-old man with uncontrolled Type 2 diabetes mellitus (A1C 12.6), peripheral neuropathy, chronic foot wounds, and prior left below-the-knee and right fifth digit ray amputations presented with three days of right lower extremity erythema, pain, and swelling. The patient also noted new, severe pain in the left lumbar paraspinal muscles over this time period. The day prior to presentation, he developed subjective fever and chills. He reported exposure to a pet cat at home. On exam, he was afebrile with a blood pressure of 85/55 mmHg, heart rate of 120 beats per minute, with a saturation of 97% while breathing ambient air. The right lower extremity was warm to touch with pitting edema and erythema extending from the ankle to the knee; there was full range of motion in the ankle and knee joints. The patient also had pain to palpation of the left paraspinal muscles in the L1-L5 region; there were no overlying skin changes. Laboratory findings were notable for a white blood cell count of 5200 cells/microliter with 96% neutrophils and a lactic acid of 3.7 mmol/L. The patient's hypotension and tachycardia improved with intravenous fluid resuscitation. He was started on empiric vancomycin and ceftriaxone. Blood cultures from admission grew pan-sensitive *P. multocida* in two aerobic bottles and two anaerobic bottles. Contrast-enhanced magnetic resonance imaging of the lumbar spine revealed osteomyelitis of the L4-L5 pedicles with associated myositis of the L1-L5 paraspinal region. The patient improved clinically with ceftriaxone. He was transitioned to oral amoxicillin to complete at least a six-week course of antibiotics as an outpatient.
IMPACT: *P. multocida* cellulitis complicated by distant osteomyelitis and myositis has not previously been described in the literature. Fifty-four cases of *P. multocida* osteomyelitis have been reported; bone infection most commonly results from direct inoculation of the periosteum at the time of a bite or from extension of cellulitis. There are only six reported cases of vertebral osteomyelitis, five of which were attributed to hematogenous spread. There are no reported cases of *P. multocida* myositis.
DISCUSSION: Cellulitis due to *P. multocida* should be considered in patients with exposure to domestic cats or dogs. Resulting bacteremia can occur, particularly in very young, elderly, or immunocompromised patients. Our patient's risk factors for *P. multocida* cellulitis and bacteremia were exposure to a cat and poorly controlled diabetes. In the presence of bacteremia, the patient's musculoskeletal complaints were highly concerning for a focus of metastatic infection. Practitioners should consider *P. multocida* infection in the appropriate clinical context, and must maintain a high index of suspicion for invasive disease.

THE CAVITARY CONUNDRUM Deepak Ravindranathan; Dustin Staloch; Mayur D. Mody; Henry K. Walker. Emory University School of Medicine, Atlanta, GA. (Control ID #2690604)

LEARNING OBJECTIVE #1: Form a differential for cavitary lesions
LEARNING OBJECTIVE #2: Recognize that sarcoidosis can present as pulmonary cavitary lesions
CASE: A 38-year-old black female with prior tobacco abuse presented with four-month history of productive cough, dyspnea, pleuritic chest pain, documented fevers, and a 25-pound weight loss. She was thrice previously treated with antibiotics for presumed pneumonia without improvement. She denied rashes or joint pain. She also denied any exposure to animals, sick contacts, international travel, or history of tuberculosis or incarceration. At presentation, she was afebrile, normotensive, and in no respiratory distress. She was non-toxic appearing. Her lungs were clear to auscultation throughout, clubbing was absent, and no tender nodules were identified. Initial testing showed no leukocytosis and was negative for HIV. Chest radiograph revealed a cavitary lesion in the left upper lobe of the lung. Computed tomography (CT) scan of the chest, abdomen, and pelvis confirmed a 2.6 × 2.4 cm cavitary lesion within the superior portion of the left upper lobe and noted multiple areas of hypoenhancement in the spleen as well as heterogeneous perfusion of the liver with well-defined areas of hyperperfusion. Three sputum samples stained negative for acid-fast bacilli. Her angiotensin-converting-enzyme inhibitor levels were elevated at 83 U/L (normal 9–67) and biopsy showed peribronchial granulomatous inflammation with foci of necrosis with no evidence of malignancy. With no acid fast bacilli or fungal organisms noted on stains, she was diagnosed with sarcoidosis and started prednisone 1 mg/kg daily, reporting drastic symptomatic improvement upon follow-up.
IMPACT: We diagnosed sarcoidosis in an immunocompetent individual with a cavitary lesion. While greater than 90% of sarcoidosis cases have pulmonary involvement, cavitary lesions are rare and seen in 0.6-8.3% of cases per chest radiograph or <5% on CT per literature review. This case reminds clinicians to consider non-infectious, non-malignant etiologies for cavitary lesions and reaffirms presence of sarcoidosis in the differential.
DISCUSSION: Respiratory symptoms encountered by internists typically involve radiographic workup. Cavitary lung lesions can pose a diagnostic challenge. The differential can be dichotomized as either infectious or noninfectious in nature. Infectious etiologies include pneumonia, abscess, tuberculosis, or fungal infections. Noninfectious etiologies include embolism, malignancy, or rheumatological diseases. If infectious workup is unrevealing or antibiotics do not bring clinical improvement, clinicians should consider advanced imaging. While the cavity's location, wall thickness, and relationship to the airway aid in narrowing the differential, biopsy is frequently indicated. Transbronchial biopsy by bronchoscopy has a diagnostic yield of >85% when multiple segments are sampled. It remains unclear why cavitary lesions appear in sarcoidosis, and the natural history of these lesions are largely unknown.

THE COMPLICATED MILLENNIAL
Dorothy Knutsen; Uwe Blecker; Margot Anderson. Tulane University, New Orleans, LA. (Control ID #2705284)

LEARNING OBJECTIVE #1: Gain familiarity with HIV screening guidelines for young adults

LEARNING OBJECTIVE #2: Understand the treatment recommendations for Salmonellosis in immunocompromised patients

CASE: An 18 year-old gentleman was transferred from an outside facility for management of an acute kidney injury with a creatinine of 6, following several days of vomiting and abdominal pain. He had no known medical problems. He had been recently treated for a prolonged psychotic episode secondary to synthetic marijuana use. He was prescribed daily haloperidol, valproic acid, and benztropine. With new fevers and an elevated creatine kinase, NMS was considered but patient had been non-adherent with his medications. His drug screen was negative and he denied current use of synthetic marijuana or bath salts. As his creatinine improved, his lipase and transaminases began to increase, without an increase in abdominal pain or tenderness. The abdominal ultrasound was unremarkable. Gastroenterology was concerned with a possible obstruction as the lipase remained >3000; an MRCP was negative. A screening HIV antibody test was performed during admission and was positive, which was then confirmed with secondary testing. He had a high viral load at time of diagnosis with a low CD4+ cell count (13). Further history was obtained confirmed unprotected sexual intercourse with 5 heterosexual partners in his lifetime. A day later, the outside facility called to report that the patient's blood cultures grew Gram negative rods. The cultures speciated to a nontyphoidal Salmonella, serotype hadar. He was treated with ciprofloxacin for 4 weeks and instructed to follow-up with an Infectious Disease provider in his hometown.

IMPACT: General internists may be the primary evaluators of young adults. Given the variability in presentation from acute to chronic HIV infection, HIV should be included in the differential of any atypical or confusing disease presentation.

DISCUSSION: Adolescents represented one out of every five new HIV diagnoses in 2014 in the United States, with many more unaware of their HIV-positive status. This age group presents specific challenges for HIV prevention with low rates of testing, insufficient sex education, limited condom use, and increased substance use. The USPSTF, CDC, and AAP recommend routine HIV screening in adolescents. These screening tests are especially important in certain states such as Louisiana with one of the highest rates of HIV diagnoses in the country. Salmonellosis is known to cause severe GI infections in immunocompromised patients, as it had in this patient. These patients with dysfunctional immune systems are more prone to the endovascular dissemination of Salmonella, resulting in far more serious complications. An extended course of antibiotics, ideally a fluoroquinolone, for 4–6 weeks in patients with HIV/AIDS is recommended to promote clearance of the organism.

THE CONFUSING NATURE OF ICD INFECTIONS Lindsay McCullough[1]; Sweny Gulati[3]; Kevin A. Johnson[1]; Margaret C. Lo[2]. [1]University of Florida, Gainesville, FL; [2]University of Florida College of Medicine, Gainesville, FL; [3]University of Florida, Lady Lake, FL. (Control ID #2706056)

LEARNING OBJECTIVE #1: Identify risk factors and atypical presentations of cardiac implantable electronic device (CIED) infections

LEARNING OBJECTIVE #2: Evaluate and manage CIED endocarditis in the setting of severe cardiomyopathy

CASE: A 71 years-old male presented with confusion, dyspnea, weakness, leg edema, and myalgias. He had no fevers, cough, hematuria, dysuria, diarrhea, or rashes. History included systolic CHF s/p recent ICD, CKD, diabetes, fibromyalgia on opioids, recent DVT on xarelto, and steroid-dependent COPD. Exam revealed normal vital signs, fluctuating mentation, and signs of volume overload. ICD site had no erythema or fluctuance. Labs noted normal WBC, anemia, elevated creatinine, elevated NT-proBNP, and mild troponinemia. Urine and blood cultures were sent. CXR showed pulmonary edema but no pneumonia. CT head revealed chronic ischemic demyelination. TTE showed reduced EF of 20% with dilation of all heart chambers but no valvular or lead vegetations. Encephalopathy was attributed to morphine overdose and decompensated systolic heart failure. Patient's mentation deteriorated despite appropriate therapy. Both sets of blood cultures later grew Serratia marcecens. Cefepime was promptly started and his encephalopathy improved. CT abdomen/pelvis found no GI or GU source of infection. With Infectious Disease consultation, nidus of Serratia bacteremia was attributed to recent ICD placement. A TEE was postponed due to patient's tenuous clinical state.

IMPACT: This case demonstrates the diagnostic dilemma in the evaluation of encephalopathy. Bacteremia from cardiac implantable electronic device (CIED) infections often present atypically in chronically-ill patients. Many have nonspecific symptoms with no signs of systemic toxicity. Patient-specific risk factors for CIED infections include renal dysfunction, diabetes, heart failure, long-term steroid use, presence of >2 pacing leads, and anticoagulation - all seen in our patient. Procedural risk factors include fever within 24 hours of implantation, preprocedural temporary pacing, early re-intervention, lack of periprocedural antimicrobial prophylaxis, and volume of device implantations. Staphylococcal species contribute to 60-80% of CIED infections. About 9% are from gram-negative bacilli, such as the Serratia bacteremia in our case.

DISCUSSION: Immediate blood cultures and generator-pocket cultures must be obtained in patients with risk factors for CIED infections given the vague, atypical presentations. Those with positive blood cultures, recent antibiotic use, or suspected CIED endocarditis should undergo TEE to evaluate for vegetations. TEE results dictate treatment course. Treatment includes complete removal of all hardware and antibiotic therapy for at least 72 hours or two weeks for lead or valvular vegetations, respectively. Device can be re-implanted upon subsequent negative cultures. Long-term suppressive antibiotic therapy is used for patients who are not candidates for device removal, as true for our patient.

THE COST OF SOBRIETY: DISULFIRAM-INDUCED ACUTE LIVER FAILURE Allison P. Rogers[1]; Stacey Watkins[1]; Starr Steinhilber[1, 2]. [1]University of Alabama at Birmingham, Birmingham, AL; [2]Birmingham VA Medical Center of Alabama, Birmingham, AL. (Control ID #2706017)

LEARNING OBJECTIVE #1: Recognize drug-induced hepatotoxicity as a leading cause of acute liver failure (ALF).

LEARNING OBJECTIVE #2: Identify hepatotoxicity as an uncommon but serious adverse reaction to disulfiram in cirrhotic patients.

CASE: A 72-year-old man with compensated alcoholic cirrhosis presented with 2 days of fatigue and fever without chills, shortness of breath, chest pain, or abdominal pain. His last drink was the evening prior to presentation. He had no acetaminophen use but disulfiram 500mg daily started 10 days prior as an alcohol cessation tool. Initial vital signs included temperature 101.8° F, pulse 95 bpm, and blood pressure 175/80 mmHg. His white blood cell count was $8.0x10^3/mm^3$ with peripheral eosinophilia (20%), aspart aminotransferase

(AST) 42 u/L, alanine transaminase (ALT) 35 u/L, and total bilirubin (tbili) 1.5 mg/dL. Infection was suspected and he was started on broad-spectrum antibiotics while home medications including disulfiram were continued. Antibiotics were discontinued after blood and urine cultures were negative and chest radiograph unremarkable. Fevers persisted, the patient became progressively confused, and disulfiram was discontinued on day 5. His liver enzymes peaked on day 10 with AST 2089 u/L, ALT 1024 u/L, tbili 7.0 mg/dL, and international normalized ratio (INR) 2.3. Comprehensive evaluation for ALF ruled out acetaminophen, hepatitis, autoimmune diseases, and hemochromatosis as possible causes. An abdominal ultrasound showed cirrhosis and patent vessels. It was determined that he had ALF from disulfiram.

IMPACT: Drug-induced ALF accounts for up to 52% of ALF cases in the United States alone, and disulfiram is a rare cause. It is important to understand that alcoholics may have undiagnosed cirrhosis putting them at higher risk for drug-induced ALF such that certain medications should be used with great caution.

DISCUSSION: Disulfiram is a well-established medication for treating outpatient alcohol dependence. In altering the metabolism of alcohol, disulfiram induces adverse reactions including palpitations, nausea/vomiting, blurred vision, and diaphoresis with a goal of motivating the patient to decrease and/or avoid alcohol use. ALF secondary to disulfiram has been documented in case reports with a dose dependent relationship; age and underlying cirrhosis may be risk factors for hepatotoxicity. While no studies exist focusing solely on disulfiram-mediated ALF in patients with pre-existing liver disease, some studies have suggested that chronic liver disease is a risk factor for poor outcomes in drug-induced ALF, as exemplified in our patient. The exact mechanism of liver injury from disulfiram is unclear Case reports support a hypersensitivity-mediated component to this drug-mediated liver toxicity, with common signs and symptoms of rash, fever and/or peripheral eosinophilia. If disulfiram causes jaundice, mortality is thought to be as high as 15–20%.

THE CULTURE CONUNDRUM: A CASE OF CHEST PAIN IN A DRUG USER WITH DEFIBRILLATOR IMPLANTATION Lu Wang[2]; James R. Wong[1]; Xolani Mdluli[1]. [1]Eisenhower Medical Center, Rancho Mirage, CA; [2]Eisenhower Medical Center, Palm desert, CA. (Control ID #2688215)

LEARNING OBJECTIVE #1: Recognize infective endocarditis in patients with atypical presentations of chest pain and pulmonary embolism.

LEARNING OBJECTIVE #2: Manage culture negative right sided endocarditis associated with implantable cardioverter defibrillator lead infection and drug abuse

CASE: A 45 year-old male with a history of intravenous drug use (IVDU), dilated cardiomyopathy and status post implantable cardioverter defibrillator (ICD) placement presented with substernal chest pain for 8 hours. He also reports cough and night sweats for 2 weeks. Physical examination was notable for fever of 100.5°F. He had a 1/6 systolic murmur at right lower sternal border. The ICD generator site was nonerythematous. Initial labs showed leukocytosis of 25.4 k/uL, negative serial troponins, and a drug screen positive for methamphetamine. ECGs and chest X-ray was unremarkable. CT angiogram demonstrated a small thrombus in the left upper lobe. Questioning the diagnosis of pulmonary embolism (PE), a transesophageal echocardiogram was performed and demonstrated vegetations on both the tricuspid valve and ICD lead in the right atrium. Empiric treatment for right-sided infective endocarditis (IE) and septic emboli with vancomycin, gentamicin and rifampin was initiated. The patient demonstrated excellent clinical improvement. His ICD was removed and he wore a wearable defibrillator since then. Initial and serial blood cultures remained negative. For culture-negative IE, antibiotics were changed to vancomycin and cefepime for 6 weeks. A subcutaneous ICD was placed later.

IMPACT: Endocarditis and pulmonary embolism caused by septic emboli should be considered in patients with chest pain, fever, leukocytosis, history of IVDU and ICD placement.

DISCUSSION: The incidence of culture-negative IE is 2–7% of patients with IE when utmost care is taken to obtain blood cultures prior to antibiotic treatment. Risk factors include valvular disease, and presence of cardiac device. PE occurs in 11–40% of the device infection cases. The etiology of our case may include ICD lead infection, IVDU or both. Initial empiric treatment should include coverage of Staphylococcus, Streptococcus and Enterococcus. Vancomycin and gentamicin are the standard approach. Use of rifampin as adjunct therapy for Staphylococcus is recommended in the presence of prosthetic materials, because rifampin penetrates biofilms effectively. If blood cultures remain negative and ICD lead is removed, gentamicin and rifampin are not necessary. Since then, vancomycin and cefepime are used to cover Staphylococcus, Streptococci and aerobic gram-negative bacilli. The duration of antibiotics for complicated IE is 4–6 weeks, while for uncomplicated IE, it is 2 weeks. Our patient had endocarditis complicated by septic emboli and was treated for 6 weeks. Explantation of the ICD is required. Re-implantation could happen 14 days after first negative blood cultures following lead removal if vegetations are present on both valve and lead, 3 days if vegetation is present on lead only.

THE DILEMMA OF MANAGING RUPTURED PANCREATIC PSEUDOCYST WITH COMMUNICATION TO THE GASTRO-INTESTINAL TRACT Mitali Agarwal[2]; Vikas Khullar[1]. [1]University of Florida, Gainesville, FL; [2]University of Florida, Apopka, FL. (Control ID #2705850)

LEARNING OBJECTIVE #1: Define pancreatic pseudocysts and how it is formed.

LEARNING OBJECTIVE #2: Define the main modalities for treatment of pancreatic pseudocysts with an empahsis on endoscopic management.

CASE: This is the case of a 64-year-old female with history of cirrhosis, chronic pancreatitis, and pancreatic pseudocyst (PPC) who was transferred from an outside hospital (OSH) for management of increasing size of PPC. The patient had presented to the OSH with symptoms of nausea, vomiting, decreased oral intake, constipation, and abdominal distention. CT abdomen at the OSH showed increased size of PPC from 45 mm to 88 mm in 6 months, resulting in gastric outlet and common bile duct obstruction. At our hospital, an EUS was attempted, which revealed necrotic PPC with connection into the duodenum. Further evaluation revealed bloody clots and fluid filled debris within the necrotic cavity and duodenum. No further drainage was attempted; it was felt that the pseudocyst would self-resolve by draining into the duodenum. Follow up CT showed decreased PPC size. The patient's symptoms improved.

IMPACT: Due to the paucity of cases in the literature, there is no clear guidelines on the management of a ruptured pancreatic pseudocyst (PPC) that have formed a connection with the gastrointestinal tract. Our case report demonstrates that PPCs that have eroded into the gastrointestinal cavity can be managed conservatively without invasive procedures. Our patient's

pseudocyst self-resolved by draining into the duodenum as evidenced by follow up CT and symptomatic improvement.

DISCUSSION: Pancreatic pseudocyst (PPC) formation is not an uncommon phenomenon following pancreatic insult; however, rupture and fistulous communication between the PPC and the gastrointestinal tract is rare. PPCs are pockets made of granulation and fibrous tissue, mainly containing pancreatic enzymes. They are located within the pancreas or in the adjacent pancreatic space. The optimal management of PPCs that have ruptured or formed a fistula is not clearly defined in literature. PPCs that have not ruptured can be treated via three main mechanisms: percutaneous drainage, surgical intervention, or endoscopic transpapillary or transmural drainage. Endoscopic drainage is the preferred method of treatment because it carries lower risk of complication, with similar rates of success as surgery. However, the feasibility of endoscopic drainage is highly dependent on the location of the pseudocyst. Spontaneous rupture of PPCs can occur through lytic enzymes and compression ischemia into the stomach, duodenum, biliary tract, renal collection system, colon and bronchial tree. Our case report demonstates that when erosion of the pseudocyst occurs near the gastrointestinal tract and a fistula is formed, the fistula can lead to resolution of the pseudocyst. The pseudocyst can self-resolve as it drains into the abdominal cavity.

THE GREAT IMITATOR OF BACK PAIN AND NUMBNESS Jessica Valente; Daniel Kwon; Jeffrey A. Tice. University of California - San Francisco, San Francisco, CA. (Control ID #2706902)

LEARNING OBJECTIVE #1: Recognize the clinical findings and time course of neurosyphilis, in particular tabes dorsalis

LEARNING OBJECTIVE #2: Acknowledge the discordance between clinical findings and cerebrospinal fluid (CSF) fluid studies in diagnosing neurosyphilis

CASE: A 39 year old man with prior occupational back injury and remote methamphetamine use presented to Urgent Care with 2 weeks of back pain and right arm numbness. The numbness was intermittent and associated with stabbing pains in the right upper body that radiated to his epigastrium. He denied headaches or changes in his vision, speech, and gait. He was married, with no new sexual partners. Exam was remarkable for mild tachycardia, decreased sensation to light touch, vibration, and pinprick along entire right upper trunk and right arm, 4/5 right biceps and triceps strength, 3+ patellar reflex in left leg, and palmar erythema of both hands. Pupil exam was unremarkable. Chemistries, complete blood count, thyroid studies, vitamin B12, and HIV were unremarkable. Treponema antibody screen was positive, with Rapid Plasma Reagin (RPR) titer of 1:64. Spinal and head imaging revealed chronic C5-C6 degenerative changes but was otherwise normal. He was sent to the Emergency Department, where lumbar puncture demonstrated normal cell count and glucose, mildly elevated protein count at 59, and negative bacterial cultures and VDRL testing. Given his concerning overall clinical picture, he was treated for neurosyphilis with a 14 day course of intravenous penicillin G. His surveillance RPR titer 3 months later was 1:4, and the lacinating pains had resolved.

IMPACT: Our case highlights the high index of suspicion required for diagnosis of neurosyphilis, and the importance of treatment despite negative CSF VDRL in patients whose clinical features suggest neurosyphilis.

DISCUSSION: The clinical exam and history are key components in accurately distinguishing the stages of syphilis. Primary and secondary syphilis typically present with characteristic skin findings, while tertiary syphilis manifests with symptomatic cardiac and neurological disease. Neurosyphilis can occur at any stage; meningitis and cranial neuropathies more commonly occur in early neurosyphilis (within weeks to years of infection) while paresis, dementia, and tabes dorsalis appear in late neurosyphilis (decades after infection). Distinctive features of tabes dorsalis include posterior column involvement, lancinating pain, Argyll Robertson pupils, arreflexia, and gastric crises with recurrent attacks of epigastric pain. The diagnosis of neurosyphilis can be supported by CSF analysis, with mild lymphocytosis, elevated protein levels, and positive CSF-VDRL. However, literature review suggests negative CSF-VDRL findings in up to 1/3 of patients with tabes dorsalis. It is not uncommon to even have normal CSF results; thus, the diagnosis of tabes dorsalis remains largely clinical. In patients with negative CSF findings, serum RPR titers and symptom resolution can be monitored for treatment response.

THE GREAT UNKNOWN: BUG VERSUS DRUG CAUSING MULTI-ORGAN DYSFUNCTION Freba Farhat[1]; Christopher Iriarte[2]; Julia Schwartz[2]; Charles Mitchell[2]. [1]The George Washington University Hospital, Gainesville, VA; [2]The George Washington University Hospital, Washington, DC. (Control ID #2705352)

LEARNING OBJECTIVE #1: Recognize the need for a broad differential when there may be an opportunity for significant morbidity and mortality.

CASE: A 49-year-old male presented to clinic with a three day history of malaise and rash. His symptoms began as a pruritic rash and tongue irritation. A review of his medications revealed a recent prescription for terbinafine. Physical exam was noteworthy for discrete white papules on the tongue and erythematous papules coalescing into plaques in a morbilliform distribution over the back, chest, abdomen, bilateral upper and lower extremities. Targetoid lesions with dusky centers were present on the dorsal aspect of the hands. Management included punch biopsy, routine labs and initiation of high dose steroids. Within two days of his visit, patient presented to the emergency room with shortness of breath and chest pain. He was found to have a CBC with elevated eosinophils of 740, troponin 10.2, CRP 21 and ESR 21. Based on physical exam, radiographic imaging and EKG there were no signs of heart failure or myocardial infarction. He was admitted to the cardiology service for treatment of presumed myocarditis. Histopathology highlighted spongiotic and superficial perivascular dermatitis with eosinophils and extravasated erythrocytes. Serum testing confirmed high titers of coxsackie B1-6 antibodies.

IMPACT: This case helps to highlight the importance of identifying non-specific rashes when both infectious and drug reactions may be the culprit for multi-organ failure.

DISCUSSION: The challenge of diagnosing any illness based on history and physical exam is one that dermatologists tackle daily. While initial management may not differ, disease complications may go unrecognized if the underlying etiology is misdiagnosed. The initial differential diagnosis included acute drug reaction, viral exanthema, Steven Johnson's syndrome, DRESS syndrome, Leukocytoclastic vasculitis or Erythema multiforme. Initially, the medical team believed it was a drug reaction secondary to terbinafine. The second round of diagnostic investigation led to a diagnosis of DRESS syndrome without using the RegiSCAR Score. The case highlights the importance of a broad differential, appropriate utilization of diagnostic testing and validated scoring criteria to guide treatment and anticipate complications that may cause significant morbidity and mortality.

THE HIDDEN CULPRIT FOR THE ACUTE ANEMIA IN SICKLE CELL DISEASE Arpan Patel[1]; Dipen Khanapara[2]; Yelena Averbukh[1]. [1]Montefiore Medical Center, Bronx, NY; [2]montefiore medical center, Bronx, NY. (Control ID #2707493)

LEARNING OBJECTIVE #1: Recognize the increased risk of colchicine side effects in patients with sickle cell disease

LEARNING OBJECTIVE #2: Understand the basic pharmacology of colchicine toxicity in sickle cell disease

CASE: A 69-year-old man was admitted for altered mental status (AMS). His past medical history was significant for sickle cell disease (SCD), chronic kidney disease (CKD) stage 3, and recent gout flare treated with colchicine. His hemoglobin was found to be 2.9 mg/dl. He underwent workup for worsening of anemia from baseline hemoglobin 6–7 g/dl. No acute source of bleeding was identified in extensive gastrointestinal workup. Laboratory tests revealed normal platelet and white blood cells (WBCs) count, low absolute reticulocyte count (0.8%), negative IgM parvovirus antibody, and normal lactate dehydrogenase (LDH). He received multiple transfusions, following which he maintained his hemoglobin at 8g/dl. The likely source of the acute worsening of hemoglobin was attributed to colchicine-induced erythroblastopenia, and he was discharged and kept under close follow-up. One month after discharge, his hemoglobin was back to baseline (7g/dl).

IMPACT: Colchicine should be used with great caution in patients with sickle cell disease

DISCUSSION: Hyperuricemia is a common feature of sickle cell disease occurring between 31 to 40% (percentage). Increased nucleic acid production, accelerated hemolysis and impaired renal function contribute for such high prevalence of hyperuricemia in sickle cell disease. Management of Hyperuricemia and gout in sickle cell disease patients is limited by a high prevalence of (between 40 to 50) chronic kidney disease. Thus colchicine is more favorable and preferred for managing acute gout compared to NSAIDs. Colchicine should be used with caution in sickle cell disease due to increased risk of side effects for the reasons explained below. Colchicine acts predominantly on actively dividing cells by inhibiting cell division, most commonly affecting the intestinal tract and bone marrow, causing diarrhea and myelosuppression respectively. Red blood cells lineage is more active in sickle cell patients as a mean lifespan of red blood cells in SCD is only 20 days due to chronic hemolysis and ineffective erythropoiesis. Thus having rapidly dividing red blood cell lineage, they are more prone to suppression and causing acute anemia due to erythroblastopenia. Secondly, colchicine side effects are dose dependent and its clearance is decreased in setting of chronic kidney disease in sickle cell patients making them more susceptible to side effects of colchicine.

THE IMPORTANCE OF AUTOMATED EXTERNAL DEFIBRILLATOR IN AMBULATORY CARE FACILITIES Sidra Khalid; Jyothirmai Seepana; Praful Maroo. Fariview Hospital - Cleveland Clinic, Cleveland, OH. (Control ID #2706758)

LEARNING OBJECTIVE #1: − to recognize the importance of time to defibrillation in a cardiac arrest patient

CASE: A 60-year-old female presented for an urgent outpatient appointment with her cardiologist when she became unresponsive in the office. She did not have a pulse, respirations or heart sounds. CPR was initiated and an automated external defibrillator (AED) was obtained. The initial rhythm was ventricular fibrillation. The patient was shocked and return of spontaneous circulation was achieved. Subsequently, the patient became alert and provided a history of left sided chest pain for 3 days. Her vital signs were BP of 170/102 mmHg, pulse 73/min, RR 17/min and afebrile. Her physical examination was unremarkable. EKG showed acute anterior wall MI. She was taken to the hospital and underwent emergency cardiac catheterization, which revealed a total occlusion of the proximal LAD, which was successfully stented. She was admitted to the cardiac care unit and optimal medical management was provided with aspirin, atorvastatin, prasugrel, metoprolol, and lisinopril. She was later discharged home in a stable condition.

IMPACT: This case highlights the importance of an AED in the outpatient setting. The goal of early defibrillation by first responders in an ambulatory setting is less than 3 min. Therefore, having a functional AED is important to prevent morbidity and mortality in a physician's office.

DISCUSSION: AHA in 2015 released that the incidence of out of hospital cardiac arrest is 326, 200. In which the average survival rate is 10.6% with a good neurological function in 8.3%. To achieve better outcomes early defibrillation within 5 min is key. The most frequent initial rhythm is ventricular fibrillation in a cardiac arrest, with defibrillation as its most effective treatment. Each minute that the defibrillation is delayed the probability of successful defibrillation is decreased. Thus, with delayed defibrillation, the ventricular fibrillation coverts to pulseless electrical activity. Survival rates in a ventricular fibrillation cardiac arrest decrease 7 to 10% for every minute the defibrillation is delayed. If the time from the collapse to defibrillation is approx. 6–10 min, many adults retain their neurological function. Hence, the goal is to have AED in accessible places, especially in ambulatory care facilities where trained personnel can recognize cardiac arrest and treat ventricular fibrillation for better survival outcomes in patients.

THE IMPORTANCE OF EARLY DIAGNOSIS AND TREATMENT TO PREVENT PERMANENT VISUAL IMPAIRMENT IN GIANT CELL ARTERITIS Manpreet Parmar; Gargi Patel; Michael Smerina. Rutgers Robert Wood Johnson, Piscataway, NJ. (Control ID #2707267)

LEARNING OBJECTIVE #1: Recognize giant cell arteritis (GCA) with bilateral symptoms early in presentation to direct appropriate treatment

CASE: Patient is an 83-year-old female with a past medical history of hypertension, hyperlipidemia, and anemia who presented with neck pain and jaw claudication. Three days prior to admission, the patient began experiencing sudden onset of cervical neck pain and jaw pain, which progressed to a constant throbbing bitemporal headache. She had similar headaches daily for about a month. One day prior to admission, the patient experienced sudden onset of bilateral cloudy vision while playing the piano. She was unable to read the sheet of music and could only visualize the gross shape of large objects. Given the persistent waxing and waning visual impairment, the patient went to her optometrist the following day, who advised her to go to the emergency room. Vitals signs on admission were stable. Pupils were equally round and 2 mm, but minimally reactive to light and accommodation. Extraocular movements were intact. Visual acuity was impaired, and patient was only able to make out shadows. Patient had bilateral temporal artery tenderness. Laboratory data was significant for elevated ESR (over 140) and CRP (10.2). Patient's signs and symptoms were concerning for temporal arteritis and thus patient

was immediately started on pulse dose steroids and aspirin 325 mg daily. Within about nine hours since admission, she was completely blind bilaterally. MRA of the head showed unusual appearance with prominent venous structure surrounding both optic nerves. Pathology from bilateral temporal artery biopsies showed changes consistent with giant cell arteritis.

IMPACT: This rare and unfortunate case of bilateral temporal arteritis highlights the importance of early diagnosis of GCA. If suspected, patient should immediately be started on pulse dose steroids and treatment should not be delayed for any further imaging.

DISCUSSION: Giant cell arteritis is a large and medium artery vasculitis, which mostly commonly presents in the elderly, leading to visual loss if left untreated. Our patient was experiencing bilateral temporal and frontal headaches for three months prior to admission. Unfortunately, she attributed symptoms to stress related headache. Due to delay in presentation, she had permanent vision loss. It is important to recognize that GCA can present with bilateral symptoms, which could be mistaken as a tension headache until visual symptoms begin. The chance of visual reversibility and recovery largely depends on the length of time that the optic nerve and retina suffer from acute ischemia. In a large retrospective study published in 2002, only 4% of eyes had visual improvement in visual acuity and central visual field, and only when steroid therapy had been started within three to four day of vision loss. Thus, given that the brief, yet critical, interval in which the inflammatory process can be influenced by pharmacotherapy, GCA should remain high on the differential.

THE INSIDIOUS MAC Elizabeth Hayes[1]; Joseph Conigliaro[1, 2]. [1]Hofstra Northwell School of Medicine, Hempstead, NY; [2]Northwell Health, Manhasset, NY. (Control ID #2707545)

LEARNING OBJECTIVE #1: Describe a typical presentation of a *Mycobacterium avium complex* (MAC) infection

LEARNING OBJECTIVE #2: Describe the population where MAC infections should be considered

CASE: 84 yo male presented with dyspnea but no chills, fever, night sweats, chest pain or cough. Past history of lung cancer treated with chemo and lobectomy 20 years ago and no recurrence, 30 pack year smoking history (quit 30 years ago) and significant asbestos exposure. Physical exam with clear breath sounds, O2 Saturation 96%, no cyanosis or clubbing. He had no weight loss and was afebrile. Three months prior he was treated for pneumonia. CT revealed prior right lower lobectomy, COPD and scattered patchy opacity in the right upper and lower lobes and clustered nodularity in the left upper lobe and lingula. CT 3 months later showed resolution of right lower lobe consolidations but new opacities in central bronchi. A new right lower lobe nodule and left upper lobe nodule with "tree in bud" appearance consistent with bronchiectasis were noted. Two months later exam revealed crackles at left base. PFTs showed moderate to severe COPD with loss of alveolar units. CT showed "tree in bud" opacities and new small nodular and patchy opacities in right lower lung. He then presented with cough, purulent sputum, fatigue and unchanged exam. Given chronicity and appearance on CT scan, sputum for MAC infection was sent and was positive with negative blood cultures.

IMPACT: *MAC* infections are becoming more prevalent in immunocompetent patients and are currently more common in the US than TB and increasing in prevalence. MAC infections should be considered in patients with known impaired respiratory defense due to primary or secondary causes and presenting with chronic cough, dyspnea, or fatigue.

DISCUSSION: Risk factors for MAC are divided into primary and secondary causes. Primary includes HIV, inadequate cytokine production or receptors and treatment with TNF-α antagonists or corticosteroids. Secondary causes include functional weakness, lung tissue alternation, chest skeletal malformation, ciliary disorders, airway obstruction and pathologic changes of lung parenchyma seen in patients with asbestos exposure, smokers, COPD, and CF. These factors alter defense mechanisms including alveolar macrophages allowing mycobacteria to colonize. Our patient had secondary risk factors including smoking and change in lung architecture. This case illustrates the insidious onset with nonspecific symptoms such as chronic cough, increased sputum, dyspnea, low grade fever, malaise and weight loss. Due to his vague symptoms, appropriate diagnostic workup with serial CT scans elicited the radiologic pattern suggesting an MAC infection. There are a broad range of radiologic patterns associated with MAC including bronchiectasis, nodular and cavitary lesions, and consolidation with fibrocavitary and nodular bronchiectic forms. Our patient demonstrated a consistent a bronchiectic pattern and multiple small nodules, some at the area of the previous lobectomy.

THE INTERNIST AND THE UTERUS: HOW ARE GENERAL INTERNISTS FAILING REPRODUCTIVE AGE WOMEN? Meghan C. Geary[2]; Mindy Sobota[1]. [1]Brown, Providence, RI; [2]Brown University, Providence, RI. (Control ID #2706489)

LEARNING OBJECTIVE #1: To describe the role of internists in counseling women on pregnancy options

LEARNING OBJECTIVE #2: To examine social determinants of inequality in access to abortion service

CASE: 21-year-old woman with a history of asthma, injection drug use and hepatitis C was admitted with an asthma exacerbation. Last menstrual period was 2 months prior to admission. Ultrasound confirmed an intrauterine pregnancy with gestational age of 63 days. Hearing confirmation of her pregnancy, she stated "I need a Mirena!" Options counseling was provided, including parenting, adoption and abortion. She was certain she did not want to parent or adopt. We discussed aspiration versus medication abortion. She wanted a medication abortion and we referred her to a local clinic that could see her expeditiously as medication abortion is available up to 70 days gestation(Henderson, Hwang et al. 2005, Zane, Creanga et al. 2015). She was dismayed to learn that we could not provide her medication abortion within our hospital and that it would cost $550 despite her Medicaid insurance. In 1976 the Hyde Amendment banned the use of federal funds for abortions with rare exception. Rhode Island is one of 33 states that has not opted to use state funds to cover the banned federal share of abortion services. Our patient was fortunate to receive her medication abortion near her house at a reduced cost due to funding from the National Network of Abortion Funds. Unfortunately she was lost to follow up and never came to clinic for control of her asthma, addiction disorder or placement of her requested Mirena IUD.

IMPACT: 45% of all pregnancies in the US are unintended(Finer and Zolna 2016). As abortion clinics' continue to close(Gerdts, Fuentes et al. 2016) and the political landscape shifts, internists can play a critical role in meeting the fundamental needs of reproductive-age women including counseling and provision of contraception and medication abortion.

DISCUSSION: Internists can play a crucial role in reproductive health care. Patients express a strong desire to receive contraceptive and abortion services

from their PCP,(Godfrey, Rubin et al. 2010, Page, Stumbar et al. 2012, Wu, Godfrey et al. 2015, Summit, Casey et al. 2016) yet internists rarely meet this need(Jacobson, Garbers et al. 2016). Although the ABIM considers family planning a core competency, only 25% of 146 general internal medicine faculty and residents at one academic institution routinely provide contraceptive counseling(Dirksen, Shulman et al. 2014). Internists perform more poorly in contraceptive counseling than do family medicine or gynecology colleagues(Sridhar, Forbes et al. 2015). Referring patients such as ours to specialists for routine reproductive health care risks lack of access and fragmenting patients' care. Almost half of internal medicine residents surveyed at 11 sites were willing to provide medication abortion(Schwarz, Luetkemeyer et al. 2005), but training is lacking. General internal medicine residency is the ideal time to implement such training.

THE LONG CONN: SPONTANEOUS CORONARY ARTERY DISSECTION AS A PRESENTING SIGN Sara Jane Cromer. New York Presbyterian Hospital - Columbia University Medical Center, New York, NY. (Control ID #2672666)

LEARNING OBJECTIVE #1: Consider spontaneous coronary artery dissection (SCAD) on the differential diagnosis for acute chest pain

LEARNING OBJECTIVE #2: Screen patients with diagnosed SCAD for comorbid conditions

CASE: A 57 year-old woman with resistant hypertension, transient ischemic attack 13 years prior, hospitalization for hypokalemia 3 years prior, and distant cocaine and heroin use on methadone therapy presented to the emergency department (ED) for substernal chest pressure. Blood pressure was elevated to 180s/120s. EKG revealed ST elevations in II, III, aVF, and V2-4, and troponin I was elevated to 6.32 ng/mL (normal range 0.01-0.03 ng/mL). Cardiac catheterization revealed spontaneous coronary artery dissection (SCAD) of the distal left anterior descending (LAD) artery with Thrombolysis in Myocardial Infarction (TIMI) flow 3 throughout. She was managed medically, with her course complicated by persistent hypokalemia despite initiation of lisinopril. She presented again to the ED 15 months later with acute "pushing" substernal chest pain. Blood pressures were 200s/100s. She reported that she had recently been discharged from an outside hospital for an episode of syncope then cardiac arrest with course complicated by hypokalemia treated with amiloride. EKG revealed stable T wave flattening in V4-6, and troponin I was elevated to 6.54 ng/mL. Cardiac catheterization revealed dissection of the mid-LAD with TIMI flow 3 and intramural hematoma seen by optical coherence tomography (OCT). She was again managed medically with resolution of symptoms. Given recurrent SCAD, workup was initiated for associated conditions and revealed normal renal artery dopplers but severely elevated aldosterone-renin ratio at 257.5 ng/dL per ng/(mL-h) (normal value < 35 ng/dL per ng/(mL-h)) suggesting primary hyperaldosteronism.

IMPACT: Spontaneous coronary artery dissection (SCAD) is a rare but often under-recognized cause of chest pain and myocardial ischemia which occurs more frequently in young women. 10-year recurrence of SCAD approaches 30%, so investigation of predisposing conditions should be pursued in all patients presenting with unprovoked dissection. Pregnancy or post-partem state and oral contraceptive use in women, severe hypertension, and vascular and connective tissue diseases such as Marfan syndrome, Ehlers-Danlos, and fibromuscular dysplasia (FMD) have been implicated as major contributors to SCAD. In our patient, recurrent hypokalemia and resistant hypertension led to workup for FMD and renal artery stenosis which instead revealed a primary hyperaldosteronism which likely contributed to her profound hypertension and recurrent SCAD.

DISCUSSION: Finally, although SCAD is diagnosed primarily by cardiac catheterization, especially with the increasing prevalence of intravascular imaging such as OCT, intervention is often limited due to inability to pass the point of dissection and an increased risk of complications. Some studies now suggest that medical management is the preferred treatment method for SCAD and its complications.

THE LONG ROAD HOME Meaghan S. Roche. Boston University Medical Center, Boston, MA. (Control ID #2705939)

LEARNING OBJECTIVE #1: Review the diagnosis and treatment of hepatorenal syndrome type 1 (HRS-1)

LEARNING OBJECTIVE #2: Explore the use of interdisciplinary resources to aid in patient-centered care at the end of life

CASE: A 57-year-old gentleman with a history of cirrhosis complicated by recurrent spontaneous bacterial peritonitis (SBP), alcohol use disorder in sustained remission, and bipolar disorder presented with diffuse abdominal pain of one week's duration. He denied nausea, vomiting, or diarrhea, though he noted mild dyspnea that he attributed to increased abdominal girth. His history was notable for cirrhosis due to alcohol use and severe persistent mental illness. He was prescribed furosemide, spironolactone, nadolol, lactulose, and Bactrim, but he endorsed intermittent adherence. The patient had a diagnosis of narcissistic personality disorder in addition to bipolar disorder and had been estranged from family and friends for many years. He lived in housing provided by a non-profit mental health services organization, and his outpatient case manager was his only contact. Paracentesis confirmed the diagnosis of SBP, and the patient was treated with antibiotics and albumin. By hospital day 5, his BUN and creatinine were rising, and he developed persistent oliguria. Urine sediment was bland, and the diagnosis of HRS-1 was made after two days of holding diuretics and giving an albumin challenge. The patient was deemed not to be a liver transplant candidate by gastroenterology due to lack of social support. He was treated for HRS-1 with albumin, octreotide, and midodrine for five days, but his clinical condition deteriorated. At that time, the patient opted to pursue comfort measures, and he repeatedly expressed a desire to return home to be with his cat. Inpatient hospice was felt to be a safer alternative, but the patient adamantly refused. In conjunction with inpatient case management and social work as well as the patient's own case manager, special arrangements were made to discharge home with hospice and visiting nurse services that provided several hours of direct care per day. He passed peacefully at home four days after discharge.

IMPACT: This case has emboldened me to reach out to interdisciplinary team members to strategize creative solutions for patients with challenging social dynamics, especially at the end of life. Additionally, the patient himself reminded me daily of the iterative nature of discussing terminal diagnoses and hospice.

DISCUSSION: This is a classic case of HRS-1, as SBP is the most common risk factor. Furthermore, medical management is often ineffective, and the only definitive treatment is liver transplantation. The case also illustrates the need for coordinated case management in approaching patients with limited social

supports. This patient had no family to help with his care at home, but with input from various team members, we were ultimately able to meet his wishes.

THE MYSTERIOUS MEDIASTINAL MASS

Zunirah Ahmed[3]; Nida N. Ahmed[1]; Syed M. Hasan[2]; Jewell Halanych[1]. [1]UAB, Montgomery, AL; [2]UAB MONTGOMERY, Montgomery, AL; [3]UAB Montgomery, Montgomery, AL. (Control ID #2706786)

LEARNING OBJECTIVE #1: Recognize atypical presentation of renal cell carcinoma.

LEARNING OBJECTIVE #2: Distinguish renal cell carcinoma as a differential diagnosis for anterior mediastinal mass

CASE: A 46-year-old male with past medical history significant for hypertension, multiple urinary tract infections and quadriplegia secondary to gunshot wound presented with palpitations, hiccups and unintentional weight loss. Physical exam was remarkable for tachycardia with irregularly irregular rhythm. Laboratory data was significant for hemoglobin of 9.7gm/dl, TSH <0.01IU/ml, T3> 20 pg/ml. Initial EKG demonstrated atrial fibrillation with rapid ventricular response. Chest x-ray was notable for right paratracheal mass. CT chest showed thyroid gland enlargement and right anterior mediastinal mass measuring 8.2 × 6.0 × 4.9cm. Thyroid ultrasound showed enlarged heterogeneous thyroid gland with increased vascularity. Patient was treated for new onset atrial fibrillation associated with hyperthyroidism. CT abdomen done for unexplained weight loss, revealed hypo-densities in bilateral kidneys. Biopsy of mediastinal mass showed renal cell carcinoma and the patient was referred to oncology for further management.

IMPACT: Certain neoplasms are commonly found in the anterior mediastinum. This case is a reminder to expand the differential of mediastinal masses beyond the expected neoplasms.

DISCUSSION: Mediastinal masses can be divided into three categories depending on their location: anterior, middle and posterior, with anterior mediastinal masses being the most common. These typically include neoplasms of thymus or thyroid, germ cell tumors (notably teratoma), lymphoma or hemangioma. Renal cell carcinoma (RCC) presents with a wide array of symptoms with most common presentation of flank pain, abdominal mass, hematuria and weight loss. Around 16% of RCC patients have advanced disease with metastasis at the time of presentation. Common sites of metastasis include lung, lymph node, liver, bone, and brain. Chest cavity involvement of renal cell carcinoma usually manifests as pulmonary parenchymal disease with or without hilar lymphadenopathy. Renal cell carcinoma manifesting as an anterior mediastinal mass is rare with only two reported cases. One third of patients with renal cell carcinoma do not have the typical triad of presentation. Incidental findings of renal cell carcinoma are now being increasingly reported. This case illustrates an unusual presentation of renal cell carcinoma. It highlights the need to broaden the differential diagnosis of anterior mediastinal masses and merit renal cell carcinoma as one of the differentials.

THE OCCASIONAL UNFORTUNATE COST OF COST-EFFECTIVE MEDICINE

Amanda Bisset[2]; Naomi Karlen[1]. [1]Southeast Louisiana Veterans Health Care System, New Orleans, LA; [2]Tulane University, New Orleans, LA. (Control ID #2705961)

LEARNING OBJECTIVE #1: Explore the risks and benefits of cost-conscious care.

LEARNING OBJECTIVE #2: Discuss the recommendations for diagnosis and treatment of GERD

CASE: A 75-year-old man presented to primary care with 6 months of severe epigastric pain. He described heartburn and pain concerning for gastrointestinal reflux disease (GERD). His prior history included mild pancytopenia, followed by outpatient hematology. Age and risk factor appropriate cancer screening and HIV testing were negative. He denied any alarm symptoms such as dysphagia, weight loss, or bleeding. He was started on a proton-pump inhibitor for empiric treatment. His reflux persisted despite multiple therapies. He was referred for an esophagogastroduodenoscopy (EGD). EGD showed mild gastritis with no malignancy. He was referred to hematology/oncology for urgent bone marrow biopsy. Prior to the biopsy, he was admitted to the hospital for uncontrolled abdominal pain. An abdominal CT showed an adrenal mass measuring 8.5 × 8.6 × 4.3 cm mass with extension into the liver and right kidney. A chest X-ray showed consolidation of the right upper and lower lobes, secondary to a right infrahilar mass. The patient was placed in hospice care due to unresectable presumed adrenocortial carcinoma and died six months after re-presenting to primary care.

IMPACT: Internists are asked to balance not only the benefit and harm of screening tests and diagnostic testing but also the cost of these evaluations. This case demonstrates the role of the internist in high-value, cost-conscious care.

DISCUSSION: To curb the rising tide of health care expenditure, internists have been challenged to maintain high-quality care while reducing health care costs. Suggested principles for providing this care include the following: avoid performing a diagnostic test that does not change management, consider the pre-test probability of a disease, and consider the cost of testing as including the test itself and the downstream costs. Often when pre-test probability is low, the likelihood of a false positive test result is higher than the likelihood of a true positive result. When evaluating reflux, typical symptoms such as heartburn and regurgitation are considered suggestive of GERD. Internists attempt trial of proton-pump inhibitors for eight weeks to control symptoms and support the diagnosis of GERD. In patients diagnosed with GERD, roughly two thirds of patients have normal results on upper endoscopy. As a result, professional societies advocate for empiric treatment of symptoms before further laboratory or radiologic testing. The guidelines recommended for the diagnosis and management of GERD follow the principles of providing high-value, cost-conscious care with the desire to decrease the cost of testing and avoid false-positive results. However, at times, following the principles of cost-conscious care may lead to a delay in testing and diagnosis. Internists must maintain balanced decision-making when approaching each patient and his/her care.

THE PERIL OF AN INITIAL MISDIAGNOSIS

Marc Heincelman. Medical University of South Carolina, Charleston, SC. (Control ID #2703775)

LEARNING OBJECTIVE #1: Define the characteristics that distinguish orbital cellulitis from preseptal cellulitis

LEARNING OBJECTIVE #2: Recognize potential complications of orbital cellulitis including cavernous sinus thrombosis

CASE: A 24 year-old previously healthy man presented with a complicated orbital cellulitis. Symptoms started a few days prior with a pimple on the inside

of his left nostril in which he tried to pop unsuccessfully. The pimple expanded to a fluid collection within the left nostril with surrounding erythema and swelling of the dorsum of his left nose with extension to the left eyelid. Facial swelling was associated with pain and difficulty with eye movements. He presented to an urgent care and was prescribed oral antibiotics for presumed preseptal cellulitis. Over the next day, the patient began having left-sided headaches, decreased visual acuity, and worsening difficulty with extraocular movements. CT revealed an infectious process of the face with intraorbital extension and a cavernous sinus thrombosis. He was referred to our tertiary care center. Temperature was 38.6C. There was bilateral periorbital edema, erythema, and chemosis. The left pupil was 5mm and nonreactive to light. Opthalmoplegia was noted. White blood cell count was 22k/cumm. Blood cultures returned positive for MRSA. MRI Brain confirmed orbital cellulitis with globe distortion, cavernous sinus thrombosis, cerebritis, and a new small left temporal empyema. MRI Angiogram revealed extensive thrombophlebitis of several intracranial arteries and veins. Despite antibiotics, he developed a ruptured brain aneurysm and died.

IMPACT: Our case illustrates an incredibly severe presentation of orbital cellulitis that was initially misdiagnosed as preseptal cellulitis. Pain with eye movements, opthalmoplegia, and a rhinosinus origin of infection should prompt internists to favor the diagnosis of orbital cellulitis over preseptal cellulitis and warrant immediate intravenous antibiotics and inpatient admission.

DISCUSSION: Facial cellulitis is a common disease seen by both internists and hospitalists. When the eyelid is involved, it is imperative to differentiate between preseptal and orbital cellulitis. Preseptal cellulitis is an infection of the anterior portion of the eyelid that spares the orbit and other ocular structures. It is generally a mild infection that does not lead to serious complications and can be managed with oral antibiotics. In contrast, orbital cellulitis is an infection of the orbit including the fat and extraocular muscles. The most common originating source of infection is the paranasal sinuses. Although eyelid swelling and ocular pain occur with both conditions, orbital cellulitis is differentiated from preseptal cellulitis by pain with eye movements, opthalmoplegia, and proptosis. Complications of orbital cellulitis include orbital abscess, cavernous sinus thrombosis, and intracranial extension. Cavernous sinus thrombosis merits consideration with symptoms of unilateral headaches, vision changes, and eye tearing.

THE PITFALLS OF SUPPLEMENT USE Tina Shah; Frederick Yick; Hatef Massoumi; Darlene LeFrancois. Montefiore Medical Center, Bronx, NY. (Control ID #2706726)

LEARNING OBJECTIVE #1: Recognize the importance of taking a thorough medication history including supplement and over the counter medication use.

CASE: A 30 year-old woman presented to her PCP's office with several week history of fatigue, nausea, and vomiting. She also reported two week history of dark urine and yellow-hued skin. Patient denied alcohol use, excessive acetaminophen use and intravenous drug use. Physical exam was remarkable for a lethargic woman with severely jaundiced skin and RUQ tenderness. She was afebrile and her mental status was intact. Initial labs showed AST and ALT greater than 1000, INR of 3, total bilirubin of 16.1, direct bilirubin of 14 and albumin of 3.1. Her labs were consistent with acute liver failure requiring emergent liver transplantation. All viral and autoimmune tests were negative including HAV, HBV, HCV, HIV, EBV, CMV, HSV, smooth muscle AB, mitochrondrial AB and liver-kidney AB. On further targeted history, patient revealed that she had been taking a weight loss supplement for the past six months, which was made of herbal ingredients including black cohosh.

IMPACT: This case highlights the importance of a thorough medication history as patients often ingest substances that may negatively affect their health. Patients may not divulge information about natural or herbal product use unless prompted, as they feel the substances are harmless.

DISCUSSION: Many case reports in the literature report black cohosh as a cause for hepatoxicity. However an analysis done by Teschke et al. of 69 such cases showed only one case with possible causal relationship. Regardless, the NIH has listed black cohosh as a hepatotoxin. Other natural or herbal products the internist should be cognizant of include kava, green tea extracts, usnic acid, among many others. Many of these products have been implicated as hepatotoxic through case reports, but data is scarce. The perceptions of safety surrounding "herbal" or "natural" products remain an issue that internists must face. Public perception of these alternative therapies being harmless continues to be pervasive. It is imperative that internists remain vigilant and elicit a thorough medication history during patient encounters, as patients may not consider these products as part of their medication list. It is important to recognize that many of these products may not have a proper safety profile and can be toxic and life threatening, as highlighted in our case of acute fulminant liver failure.

THE ROOT OF THE MATTER: A CASE OF PAP SMEAR AVOIDANCE Adaugo Amobi[1, 2]; Katherine Johnston[1]. [1]Massachusetts General Hospital, Brookline, MA; [2]Harvard Medical School, Boston, MA. (Control ID #2680197)

LEARNING OBJECTIVE #1: Recognize signs a patient with a history of intimate partner violence (IPV) may exhibit during pap smear examinations.

LEARNING OBJECTIVE #2: List steps for conducting trauma-informed cervical cancer screening.

CASE: Ms. M is a 37 yo F with h/o of hypertension presenting for her annual physical and to establish care. Her last pap smear was over 7 years ago and she says she hates pap smears. She has no history of abnormal pap smears. Review of systems is otherwise negative. Social history is significant for a former abusive relationship. Ms. M is not sexually active. She has no family history of cancer. As she is assuming the dorsal lithotomy position she becomes pale, diaphoretic and tremulous.

IMPACT: This case taught me to always directly ask about trauma as a cause of patient difficulty with pap smears.

DISCUSSION: A history of intimate partner violence (IPV) should be considered as a cause of patient difficulty with pap smears. Nearly 1 in 5 women in the US have been raped and 43% of women have experienced sexual violence other than rape, for example, sexual coercion, throughout their lifetime. Women with a history of IPV may display signs of tremulousness, diaphoresis, tachypnea, tearfulness, and sometimes dissociation (non-response to verbal stimuli) during pap smear testing. A history of IPV of any type, physical, sexual and emotional, is associated with increased risk of cervical dysplasia (OR 2.6). Victims of sexual abuse have a particularly elevated risk of cervical cancer due to increased exposure to high-risk HPV strains. These patients may be 4.5 times more likely to test positive for high risk HPV strains compared with women without a sexual

abuse history. Increased avoidance of pap smears in patients with trauma history also results in detection of cervical dysplasia at later, invasive stages. It is important to inquire about patients' past experiences with pelvic exams and directly ask about trauma as one possible cause of difficulty with undergoing pap smears. This conversation should occur prior to examination while patients are fully clothed. Trauma-informed clinical practice includes validating patients' anxiety about the test. Women should then be reassured that steps can be taken to alleviate fears and discomfort. Patients can be encouraged to bring a companion for support and be assured that they can stop the exam at any time. Patients can reposition themselves more comfortably and self-insert the speculum. Anxiolytic medication can be used during office testing. An alternative to office-based pap smears is vaginal self-collection swabs to detect high-risk strains of HPV. This method, when used as primary screening to detect CIN2 or worse, has a sensitivity of 76 and specificity of 86% compared to 91 and 88% respectively with clinician-obtained liquid based cytology. Exams under anesthesia can be offered if prior attempts at pap smears are unsuccessful. All healthcare providers should be proficient in trauma-informed cervical cancer screening.

THIRD TIME IS A CHARM: MISSED ENDOCARDITIS IN AN INTRAVENOUS DRUG USER Jacob Hupp; Michael Chandler. Summa Health System, Ravenna, OH. (Control ID #2694603)

LEARNING OBJECTIVE #1: Evaluation of intravenous drug users
LEARNING OBJECTIVE #2: The evolving definition of Sepsis

CASE: The patient is a 33 year old woman who presents to the third different emergency room in three weeks with similar symptoms. The patient complains of dyspnea, weakness, and abdominal pain for the past six weeks. During her previous two emergency department visits, laboratory evaluation including CBC, CMP, and UA was unremarkable except for documentation of anemia. She was found to have a fever, patchy bilateral pneumonia, and a urine toxicology positive for heroin. On her third presentation, she had all prior findings, but was hemodynamically unstable and had acute kidney injury. A CTA showed multiple large pulmonary emboli. Surgical pulmonary artery embolectomy retrieved multiple large septic emboli. Echocardiogram showed a 1.3x2.1cm tricuspid vegetation as well as a perivalvular abscess and associated atrial-septal defect. Further evaluation revealed septic emboli to the left kidney, liver, spleen, brain, and multiple medium and large joints. Blood cultures grew MSSA. She developed complete heart block, requiring a permanent pacer. After a 56 day hospital stay, multiple abdominal, cardiac, and orthopedic procedures, and IV antibiotics, she was eventually discharged to a long-term acute care facility.

IMPACT: This case offers a rare presentation and complication of a common disease. As IV drug use continues to rise in the US, devastating complications such as this are likely to become more prevalent. Increased vigilance by primary care providers will be vital moving forward.

DISCUSSION: There has been a steady increase in the amount of illicit drug users over the last decade, costing the American healthcare system over 11 billion dollars annually. There is a large gap between prevalence and available treatment programs and facilities. It is estimated that, of the patients that would benefit from treatment in a specialty facility, only 11% were able to receive it. It is crucial to maintain hypervigilance. HIV, hepatitis, STDs, tuberculosis, acute psychosis, endocarditis/bacteremia, and drug overdose are all ailments that the CDC has identified as directly tied to drug use. Sepsis is the leading cause of death from infection and accounts for over 20 billion dollars in hospital costs in 2011. The Society of Critical Care Medicine published new recommendations for the diagnosis of sepsis in *JAMA*. The new guidelines aim to quickly identify the patients at highest risk of sepsis. The Sequential Organ Failure Assessment (qSOFA) is a diagnostic tool that can be done at bedside by healthcare staff. It consists of three questions: Is there an alteration in mental status? Is the systolic blood pressure ≤100mmHg? And is the respiratory rate >22? Two or more of these being present increases the risk of a prolonged hospital stay or death during admission.

THREE CASES OF AORTITIS FINALLY DIAGNOSED BY PET/CT

Taiju Miyagami[4]; Yuichi Takahashi[1]; Reiko Sakama[3]; Hiromizu Takahashi[5]; Yuki Uehara[3]; Toshio Naito[2]. [1]Juntendo Hospital, Tokyo, Japan; [2]Juntendo University, Tokyo, Japan; [3]Juntendo University School of Medicine, Tokyo, Japan; [4]Juntendo University of school, Bunkyo-ku, Japan; [5]Juntendo university, Tokyo, Japan. (Control ID #2707374)

LEARNING OBJECTIVE #1: When we consider aortitis, PET/CT is useful for diagnosis.

CASE: Case 1: A 17-year-old woman was admitted to our department due to persistent fever for 2 months and bilateral femoral pain for 1 month. On admission, her temperature was 38.0 degrees Celsius. In physical examination, she had an induration at inside of bilateral thighs and weakness at bilateral lower limbs. Ultrasound examination and MRI revealed thick wall of bilateral femoral vein, but biopsied vessel had neither inflammation nor thrombi formation. Case 2: A 80-year-old woman with a history of cerebral infarction was admitted to our hospital due to high fever for 2 months. Two months before admission, she started to have mild fever, visual field constrictions and diplopia. Her visual field constriction and diplopia improved without any treatment, but her fever persisted, so she was admitted to our hospital. On admission, her temperature was 37.3 degrees Celsius. In physical examination, abdominal bruit was audible, but temporal artery was not tender and no induration was found. Case 3: A 71-year-old woman with a history of left breast cancer was admitted to our hospital due to high fever, loss of appetite and sore throat. 2 months before visiting, she had high fever, loss of appetite and sore throat. She visited previous hospital, and antimicrobials were prescribed. But her fever persisted, so she was admitted to our hospital. On admission, her temperature was 37.9 degrees Celsius. Abdominal bruit was audible in physical examination, but temporal artery was not tender and no induration was found. Every case showed no typical abnormal findings as aortitis which made it difficult to diagnose immediately. Enhanced CT could not be performed for Case 1 because of asthma. Enhanced CT of Case 2 and 3 revealed thickening of the arterial wall but the finding was difficult to be distinguished from atherosclerosis. PET/CT with 18F-FDG showed high maximum standardized uptake value (SUVmax) at aorta and major branch arteries in all three cases, so Case 1 was diagnosed as Takayasu's arteritis, and Case 2 and 3 were as giant cell arteritis. Predonisolone was administered, then their symptom was resolved quickly.

IMPACT: Patients with persistent fever and non-specific abnormalities, aortitis should be a differential diagnosis. SUVmax of PET/CT was useful to distinguish arteries with inflammation from atherosclerosis.

DISCUSSION: Primary aortitis showed variety of symptoms and findings, which could cause difficulty for diagnosis. We could diagnose three cases of fever of unknown origin as aortitis using PET/CT. SUVmax of PET/CT with

18F-FDG was useful to detect arteritis with inflammation. Disadvantage of PET/CT is that intracranial legions cannot be detected, but 15% of giant cell arteritis is not accompanied by temporal arteritis, as Case 2 and 3. Therefore, PET/CT can be a useful diagnostic tool of aortitis when biopsy of arteries seems impossible or low yield.

THROMBOSIS AND THROMBOCYTOPENIA: AN UNUSUAL DIAGNOSIS AND A THERAPEUTIC DILEMMA Muhammad Hammad; Sowjanya Naha; Marianna Sargsyan; Kushal Naha. Presence Saint Francis Hospital, Evanston, IL. (Control ID #2703208)

LEARNING OBJECTIVE #1: Recognize the characteristic clinical presentation of PNH

LEARNING OBJECTIVE #2: Initiate appropriate therapy for thrombosis in patients with PNH

CASE: We report a 38 year old Caucasian male who presented with chest pain, shortness of breath and right leg pain and swelling after a trivial injury. At presentation he was noted to be pale and tachycardic. Examination of his right calf demonstrated swelling and tenderness. Cardiac and respiratory examination was unremarkable. Preliminary blood work showed marked pancytopenia. Thoracic CT angiography was negative for pulmonary embolism. Venous sonography of his right leg confirmed presence of deep vein thrombosis. Further laboratory evaluation was consistent with hemolysis. Flowcytometry for CD 59 showed deficient clones confirming the diagnosis of paroxysmal nocturnal hemoglobinuria (PNH). Bone marrow study subsequently ruled out coexisting aplastic anemia and/or myelodysplasia. An IVC filter was placed because of high risk of bleeding with anticoagulation. The patient, thereafter, reported recurrence of his respiratory symptoms and repeat CT angiography showed an acute pulmonary embolism involving the distal right main pulmonary artery extending into the segmental branches. He is now on follow up with Hematology and is expected to shortly commence therapy with eculizumab.

IMPACT: How did this case change my practice? Venous thromboembolism (VTE) is commonly encountered in everyday clinical practice. Evaluation for underlying thrombophilia often has no immediate impact on medical management. PNH is unique inasmuch that specific therapy exists in the form of eculizumab that has been shown to reduce the risk of recurrent thrombosis. This case therefore underscores the importance of screening patients with unprovoked VTE for underlying PNH.

DISCUSSION: PNH is a rare acquired hematopoietic stem cell disorder characterized by the unique combination of pancytopenia and thrombophilia. Primary presentation with thrombosis is rare in PNH and seen in only 5% of cases, although over 40% of patients ultimately develop this complication. Thrombosis is typically venous and often occurs in unusual locations such as hepatic, portal, mesenteric and cerebral veins. Individuals with PNH granulocyte clones that make up more than 60 percent of white blood cells are at highest risk; these clones constituted over 80 percent of our patient's leukocytes. Pancytopenia is typically modest; however it can be severe if PNH overlaps or co-exist with aplastic anemia and rarely myelodysplastic syndrome. These conditions, therefore should be ruled out especially in setting of severe pancytopenia, as was done in this case. This patient also demonstrates the therapeutic challenge posed by simultaneous presence of thrombocytopenia and thrombosis. While insertion of an IVC filter is helpful, only eculizumab has been shown to reliably lower the risk of thrombosis in patients with PNH.

THYROTOXIC HYPOKALEMIC PARALYSIS: A LIFE-THREATENING PRESENTATION OF THYROTOXICOSIS Iris Huang. Mount Sinai, New York, NY. (Control ID #2706403)

LEARNING OBJECTIVE #1: Recognize the clinical features of thyrotoxic hypokalemic paralysis (THP)

LEARNING OBJECTIVE #2: Manage and prevent THP

CASE: 21 year-old Hispanic male with past medical history of hyperthyroidism of unknown etiology presented with one day of severe diffuse weakness accompanied by profuse vomiting and diarrhea. He had worsening diarrhea, palpitations, night sweats and insomnia for six months. He drank four beers at a party two days prior to presentation and took thyroid medications intermittently. Significant physical exam findings included an ill appearance, tachycardia to 110 bpm, 2/5 upper and lower extremity strength and enlarged non-tender thyroid gland. He did not have fever, hypotension or exophthalmos. Admission labs included leukocytosis with 92% neutrophils, potassium 1.9 mEq/L, troponin 0.48 ng/mL and creatinine kinase myocardial band 8.2 ng/mL. Electrocardiogram showed sinus tachycardia, diffuse ST depressions and QTc interval of 600. Upon transfer to the Cardiac Monitoring Unit, he was started on methimazole and propranolol with aggressive intravenous potassium and magnesium supplementation. Thyroid hormone levels resulted the following morning: TSH 0.01 mIU/mL, T4 22.8 μg/dL and T3 317 ng/dL. After resolution of his weakness and tachycardia in 24 hours, he was discharged home with endocrinology follow-up, extensive counseling and bedside medication delivery.

IMPACT: THP is a life-threatening presentation of thyrotoxicosis and can be diagnosed clinically based on presenting signs, symptoms and basic labs before TSH and T4 levels result. Key features include diffuse weakness, tachycardia, signs and symptoms of thyrotoxicosis and hypokalemia. These features should be recognized early so that prompt triage to a Cardiac Monitoring Unit and management with thionamides, beta blockers and potassium supplementation are initiated.

DISCUSSION: THP is caused by excess thyroid hormone, adrenergic activity and potassium influx into skeletal muscle. The incidence of THP is approximately 0.2% in non-Asian populations with over 95% of cases occurring in men. Clinical features of THP include diffuse weakness greater in lower extremities, tachycardia and signs and symptoms of thyrotoxicosis. Although rare, cases of respiratory muscle weakness requiring mechanical ventilation and life-threatening arrhythmias have been reported. Management of THP involves decreasing thyroid hormone synthesis with thionamides. Beta-blockade with propranolol decreases adrenergic activity and potassium entry into cells. Potassium and magnesium levels are aggressively supplemented and frequently monitored to avoid rebound hyperkalemia. Cardiac monitoring is recommended given the risk of arrhythmias. Common triggers of THP include strenuous physical activity, increased alcohol and carbohydrate intake and medication non-adherence. Therefore, educating hyperthyroid patients about the signs and symptoms of thyrotoxicosis, dietary and lifestyle modifications and the importance of medication adherence can prevent recurrent THP.

THYROTOXIC PERIODIC PARALYSIS: AN ALARMING DISEASE WITH AN INEXPENSIVE DIAGNOSIS AND SIMPLE CURE Pauras Memon. Washington University in St. Louis, St. Louis, MO. (Control ID #2706289)

LEARNING OBJECTIVE #1: Recognize TPP in a patient presenting with sudden unexplained weakness

CASE: A 37 year-old African American male with no significant past medical history presented to the ED with one day of progressive paralysis in his extremities. He endorsed progressive generalized weakness and loss of muscle mass over the preceding few months so began a strenuous exercise regimen in the week prior to presentation. A few days later, he noticed worsening proximal muscle weakness more prominent in his lower extremities to the point that he was unable to lift his legs out of bed and hence presented to the hospital. On review of systems he endorsed palpitations, heat intolerance, diarrhea, and a 20-pound unintentional weight loss over the same time period. He denied any focal neurologic deficits, fevers, recent upper respiratory illness, chest pain, or history of strokes or seizures. Notable social history revealed that he had just started working at a pizza shop and his carbohydrate intake had increased for this reason. He denied any alcohol use, smoking, or illicit drug use, family history was non-contributory, and he did not take any medications. In the ED his vital signs were stable and physical exam was otherwise unremarkable except for 0/5 strength in all extremities and a goiter without nodules. No focal neurologic deficits were appreciated. Labs were notable for a potassium level of 2.1 mmol/L and TSH of <0.01 mcIUnits/ml, free T4 3.38 ng/dl, and FT3 12.20 pg/ml. ECG was concerning for U waves in leads V4-V6. His overall picture was concerning for thyrotoxic periodic paralysis (TPP). He was immediately given IV potassium chloride and his paralysis completely resolved within hours. His hyperthyroidism was treated with methimazole and propranolol and he underwent radioactive iodine ablation shortly thereafter.

IMPACT: Prior to encountering this patient, TPP was not something I routinely considered. This case changed my thinking when approaching young patients with paralysis. In addition to conditions such as Guillan-Barre syndrome, transverse myelitis, myasthenic crisis, and botulism, TPP will also be high on my differential diagnosis.

DISCUSSION: This patient presented with a classic case of TPP as he fit the male demographic, was experiencing symptoms of hyperthyroidism, recently started exercising, and increased his carbohydrate intake - the latter two have been known to trigger TPP. Sudden paralysis in a young adult can be an alarming presentation which often prompts an extensive and expensive diagnostic workup. Although TPP is a relatively rare condition (occurring in 0.1–0.2% of individuals with hyperthyroidism, 2% in Asians), diagnosis is cost-effective and treatment with non-selective beta-blockade, potassium repletion, and correction of hyperthyroidism can completely reverse symptoms. Hence, TPP should always be a consideration in such patients in the appropriate clinical context.

TITLE: A LEGION OF CK: LEGIONELLA PNEUMONIA PRESENTING AS RHABDOMYOLYSIS-INDUCED ACUTE RENAL FAILURE

Jason Unger; Tanner Slayden; Chin Hee Kim. Walter Reed National Military Medical Center, Bethesda, MD. (Control ID #2707184)

LEARNING OBJECTIVE #1: Recognize the rare extrapulmonary manifestations of Legionella pneumophila.

LEARNING OBJECTIVE #2: Recognize the limitation of the Legionella urinary antigen test in the setting of international travel.

CASE: A previously healthy 51-year-old woman presented with seven days of fatigue, muscle weakness, hemoptysis, diarrhea, and oliguria after returning from vacation to Abu Dhabi and Dubai two days prior to presentation. She had no mylagia or sick contacts. She spent most of her time in five-star hotels, except for one planned excursion to ride camels in the desert. She only drank bottled water, but utilized air conditioning heavily. On admission, she was febrile, tachycardic, hypoxic, and had coarse crackles over the right basilar lung field. Labs were significant for leukocytosis with a left shift, hyponatremia, elevated creatinine, transaminitis, hyperbilirubinemia, and a CK of 130,000U/L. Urine studies were significant for a FENA of 0.8 and muddy brown casts consistent with acute tubular necrosis from rhabdomyolysis. Chest imaging showed a right lower lobe infiltrate. Broad-spectrum antibiotics were administered for severe sepsis from pneumonia. Despite aggressive IV hydration, kidney function continued to worsen, and she remained oliguric. Dialysis was initiated. With concomitant hyponatremia and diarrhea, suspicion for legionella remained high despite a negative urine legionella antigen. Legionella serum titer ended up being positive at 1:528 (>1:128 cut off for diagnosis). With legionella pneumonia diagnosed, antibiotics were deescalated to a fluoroquinolone. She had clinical improvement with resolution of serum legionella antibody titer. Her kidney function also improved, and dialysis wasn't required at discharge.

IMPACT: This patient presented with an atypical presentation of legionella pneumonia complicated by rhabdomyolysis-induced acute renal failure. The severity of her disease with no significant immunosuppressive risk factors and negative urine legionella antigen test show the importance of having a high degree of suspicion for L. pneumophilia in cases of new pneumonia with extrapulmonary manifestations.

DISCUSSION: Only 43 publications between 1980 and 2016 (mainly case reports) discuss the link between L. pneumophilia and rhabdomyolysis. This may be secondary to direct infection of the organism into muscle or through release of endotoxin. Other infections, such as Staph aureus, Strep pyogenes, and viral etiologies, are associated with rhabdomyolysis. We also show the limitation of the legionella urine antigen. For serogroup 1, the urinary antigen is highly sensitive and specific; but for non-serogroup 1 (more likely in setting of international travel), sensitivity and specificity are unknown. Patients with pneumonia, diarrhea, and electrolyte abnormalities should have L. pneumonia high on the differential even with a negative urine antigen. A serum legionella antibody is a useful confirmatory test, and a CK should be ordered if there is renal involvement.

TO CLOSE OR NOT TO CLOSE A PATENT FORAMEN OVALE: THAT IS THE QUESTION

Waleed Al-Darzi[1]; Maxim Zlatopolsky[2]; Alaa Abu Sayf[1]; Rana L. Awdish[1]. [1]Henry Ford Hospital, Detroit, MI; [2]American University of the Caribbean, Coral Gables, FL. (Control ID #2687668)

LEARNING OBJECTIVE #1: Recognizing that cardiac shunting often occur in setting of severe pulmonary hypertension (PH) and serves to relieve the severe increase in the right sided pressures.

LEARNING OBJECTIVE #2: Recognizing one of the contraindications to patent foramen ovale (PFO) closure.

CASE: A 65-year old female presented to Heart Failure clinic after a follow up transthoracic echocardiography (TTE). She complained of dyspnea, bilateral lower extremity edema, and right 4th digit pain. On physical exam, patient was noted to have darkening of her right 4th digits. She had hypoxia with higher oxygen requirement than baseline. Past medical history is significant for Interstitial Lung Disease (ILD), Pulmonary Hypertension (PH) groups (2 and

3), coronary artery disease with three prior stents, and chronic diastolic dysfunction. Her TTE showed EF of 50%, pulmonary artery systolic pressure of 60 mmHg, and large (greater than 20 bubbles) PFO, that is new, with predominantly right to left shunting across the atrial septum. Patient was hospitalized due to concern for paradoxical emboli and for her hypoxia. Right heart catheterization (RHC) was done that showed mean Pulmonary arterial pressure of 45 mmHg, wedge pressure of 8 mmHg, cardiac index of 2.13 L/min/m2, pulmonary vascular resistance of 840 dynes.sec.cm-5 (10.5 Wood units), and systemic vascular resistance (SVR) of 797.84 dynes.sec.cm-5 at rest. CT angiography was done that showed acute pulmonary embolus (PE) to segmental branches of right lower lobe and demonstrated stable ILD. An upper extremity arterial study demonstrated reduced perfusion to the right 4th digit attributable to a possible embolic event. High intensity heparin was initiated. Risks and Benefits of PFO closure were discussed at a multi-disciplinary meeting. Given that patient's PVR > 2/3 of SVR in the RHC, PFO closure was deferred. The patient was ultimately discharged on warfarin.

IMPACT: Careful decision making in PFO closure should be pursued for PH patients, even in presence of a known indication for closure. One of the contraindications to PFO closure is the irreversible pulmonary hypertension (PVR >2/3 SVR or pulmonary artery pressure > 2/3 systemic arterial pressure). It is important to recognize that closure of PFO in those situations could precipitate decompensation of right ventricular (RV) function and sudden drop in cardiac output which could be fatal.

DISCUSSION: While PFO closure may be pursued in cases of paradoxical emboli, a risk/benefit analysis, especially looking at PH, is necessary. In this case, acute PE is the likely cause of acute rise in the right sided cardiac pressures. Eventually, the acute PFO provided a necessary outflow tract for right sided pressure overload.

TOO HEALTHY FOR HOSPICE: WHEN THE RIGHT CARETAKER CHANGES A PATIENT'S PROGNOSIS Jessica Tanenbaum[2]; Hadas Reich[1]. [1]NYU, NEW YORK, NY; [2]NYU, New York, NY. (Control ID #2704431)

LEARNING OBJECTIVE #1: Appreciate caregivers' influence on prognosis in patients with life-limiting disease

CASE: A 93-year-old bedbound woman with dementia was referred from medicine clinic to a resident-led home visit program. The patient appeared to be near the end of life. She had a Functional Assessment Scale (FAST) score of 7D (that is, she would be unable to sit without assistance), as well as cachexia, evidence of recent weight loss, and pressure ulcers. The patient's family and home health aide (HHA) agreed to hospice enrollment and a referral was placed. Follow-up several months later revealed that the hospice agency had deemed the patient too well for their services. We made a second home visit and observed that the patient was no longer cachectic, was free of pressure ulcers, and was more interactive. While her dementia remained life-limiting, we agreed that she was no longer hospice-eligible. Discussion with the patient's HHA of over 30 years revealed that our initial evaluation had occurred soon after the aide's month-long vacation. She had returned to find her patient in severe decline. We are not sure if the patient's appetite lapsed without her regular companion, if substitute caregivers showed inadequate persistence with spoon feeding, or if other factors accounted for the patient's previous grave condition. However, subsequent visits reinforce our impression that our patient is sustained by her deep connection with her regular caregiver.

IMPACT: Hospice evaluations do not account for non-patient factors such as caregiver quality. However, for patients with dementia, key hospice criteria such as change in body weight and presence of pressure ulcers may relate as much to caregiving quality as to the patient's disease. Accurate prognostication should take into account the quality of available home care.

DISCUSSION: While evidence suggests that disabled elderly patients with home attendants fare better than those without (Albert et al. 2005), the precise health advantage conferred by superior caretakers is not easily measured. However, during home visits to disabled elders, we have observed caregivers' potential impact on patient health. For example, some home attendants are eager for a doctor's home visit; they have been waiting to show us their observations about skin breakdown or lists of needed medical supplies. Others appear passive or disconnected. Homebound elders with dementia are highly vulnerable to caregiver neglect (Boye and Yan 2016). But apart from cases of frank neglect or abuse, the relationship between patient and home attendant may still be of prognostic value. Here, we observed that the remarkable bond between a long-time attendant and an elderly frail patient allowed the patient to "graduate" from hospice eligibility. Although doctors may focus on patients' internal pathophysiology, it is intuitive that the quality of daily care a patient receives can also profoundly influence outcomes, often to a greater degree than our own medical interventions.

TRICK OF THE TRAIT Jay J. Chudow[1]; Jeremy Fertel[1]; Tulay Aksoy[2]. [1]Montefiore, Bronx, NY; [2]Montefiore Medical Center, Bronx, NY. (Control ID #2703826)

LEARNING OBJECTIVE #1: Distinguish hemoglobin electrophoresis patterns; including Sickle-Beta plus thalassemia (S/β^+-thal)

LEARNING OBJECTIVE #2: Diagnose acute splenic sequestration crisis (ASSC) in a minor hemoglobinopathy

CASE: A 61 year-old Antiguan woman with reported sickle cell trait presented with several days of lethargy, multiple pre-syncopal episodes and one hour of generalized weakness following a recent three-day trip to Puerto Rico. She was afebrile, tachycardic, and lethargic but responsive to voice without other neurologic deficit. Initial hemoglobin was 12 and leukocytosis to 18K. Later, she experienced worsening mental status and abdominal tenderness. The spleen was 14cm with acute splenic infarct by ultrasound and CT. Hemoglobin decreased to 7, platelets dropped to 80K. Hemoglobin electrophoresis revealed 21% HbA and 62.7% HbS consistent with S/β^+-thal, confirmed by genetic analysis. Her mental status improved to baseline following exchange transfusion to HbS <30%.

IMPACT: This is a rare presentation of ASSC in a patient with a minor hemoglobinopathy. It highlights the need for recognition of different patterns of hemoglobin electrophoresis before making the assumption of sickle cell trait as in this patient's reported past medical history.

DISCUSSION: There are several known mutations to the HBB gene which encodes the hemoglobin beta chain; including sickle cell and beta thalassemia mutations. Approximately three million people carry at least one sickle cell gene in the United States underscoring the need familiarity with related conditions. There are typical patterns on hemoglobin electrophoresis in various disease states. In the normal state >95% HbA and no HbS is produced. Sickle cell trait, with one mutation, produces 50% HbA and 40% HbS. Sickle cell disease, with no normal HBB gene, produces no HbA and >85% HbS. Sickle beta thalassemia occurs when both mutations are inherited. There are two main

variants: S/β^0-thal produces no HbA and near 80% HbS whereas S/β$^+$-thal produces near 20% HbA and 60% HbS. S/β^0-thal is clinically similar to HbSS disease. S/β$^+$-thal has a milder clinical course and retained splenic function. ASSC is a sudden, massive pooling then destruction of red blood cells in an enlarging spleen with marrow activity. It is commonly encountered in children with HbSS disease before eventual splenic autoinfarct and rare in those with minor hemoglobinopathies such as S/β$^+$-thal. Triggers for ASSC are the same as a vaso-occlusive crisis. This patient denied high altitude travel and infectious work up was negative. The cause of this episode is unclear though air travel is possible, a reported trigger in case reports. Further research is necessary to fully understand the pathophysiology of this crisis in a patient with S/β$^+$-thal at a late stage in life.

TUBE TROUBLES: AN UNCOMMON CAUSE OF NEUTROPENIA

John P. Haydek[1]; Karen M. Xu[1, 2]; Emily S. Poppens[1]; Jennifer Wilkinson[1]; Fuad El Rassi[1]; Stacie Schmidt[1]. [1]Emory University School of Medicine, Atlanta, GA; [2]Winship Cancer Institute, Emory University School of Medicine, Atlanta, GA. (Control ID #2700619)

LEARNING OBJECTIVE #1: Recognize copper deficiency as a cause of neutropenia that should be considered in cases without identified etiology.

LEARNING OBJECTIVE #2: Develop a low threshold for assessing copper deficiency in patients receiving tube feeds chronically.

CASE: A 47-year-old man with profound cognitive impairment and epilepsy secondary to infantile meningoencephalitis was admitted from his long-term care facility for neutropenic fever and diarrhea. He was quadriplegic, with permanent gastrostomy tube and Foley catheters in place. His admission exam was pertinent for normal temperature, chronic contractures in the arms and legs. His gastrostomy tube and Foley catheter sites appeared normal, without signs of infection. There was no lymphadenopathy or organomegaly. Initial laboratory investigation identified a white blood cell count of 2,600 cells per microliter with an absolute neutrophil count of 260 cells per microliter, hemoglobin of 12.3 grams per deciliter, and platelet count of 342,000 cells per microliter. Bone marrow biopsy was performed which showed a mild myeloid hypoplasia with megaloblastic and megaloblastoid features. Cytogenetic evaluation, flow cytometry and myelodysplastic syndrome fluorescence in situ hybridization panel was normal. A serum copper level resulted at 2 micrograms per deciliter. Daily intravenous copper chloride was started. Within two days, the patient's absolute neutrophil count returned to 5,300 cells per microliter. The patient's diarrhea resolved without intervention during the hospital stay. He was subsequently discharged to his long-term care facility with oral copper supplementation.

IMPACT: This case highlights the importance of considering copper deficiency in cases of neutropenia without identified cause. In particular, institutionalized patients and those undergoing chronic enteral feeding are at high risk for developing nutritional deficiencies.

DISCUSSION: Internists commonly encounter neutropenia. Although vitamin- and mineral-associated neutropenias are less common compared to other etiologies, they should always be included in the differential diagnosis. Copper deficiency is clinically characterized by fragile hair, skin depigmentation, muscle weakness, neurological and hematological abnormalities. It frequently results from malabsorptive diseases, including cystic fibrosis, inflammatory bowel disease or malabsorption following bariatric surgery. In the case of our cognitively impaired, quadriplegic patient, his only manifestation of copper deficiency was neutropenia. Patients chronically bed-bound due to underlying neurological diseases and on permanent tube feeding are at high risk of developing copper deficiency. There is currently no consensus about the most appropriate dose, duration, route and form of copper supplementation. In this case, our patient responded quickly to daily 2.5 mg intravenous copper chloride, a dose and formulation reported in other case reports. His copper level returned to normal range after 2 days' supplementation.

TYPE B LACTIC ACIDOSIS IN A PATIENT WITH METASTATIC SQUAMOUS CELL LUNG CANCER

Nivedita Arora[2]; Laurette P. Femnou Mbuntum[2]; Arjun Gupta[2]; Sujata Bhushan[1]. [1]Dallas VA Medical Center, Dallas,, TX; [2]University of Texas Southwestern Medical Center, Dallas, TX. (Control ID #2685106)

LEARNING OBJECTIVE #1: Recognise Type B lactic acidosis as a cause of anion gap metabolic acidosis in patients with aggressive solid tumors and liver metastasis

LEARNING OBJECTIVE #2: Distinguish between type A and type B lactic acidosis

CASE: A 63-year-old man with poorly differentiated squamous cell carcinoma of the right lung presented with worsening shortness of breath. He denied fevers, sick contacts, travel, or focal symptoms. Medications included hydrocodone, ranitidine and senna. He was afebrile, hemodynamically stable, well perfused with oxygen saturation 97% on room air. Decreased breath sounds over the right upper lung field and non-tender hepatomegaly were noted. Laboratory testing showed unremarkable blood counts and renal function, bicarbonate 20 mmol/L (ref 22–30), anion gap 21 mmol/L (ref 8–16), AST 174 U/L (ref 15–41), ALT 90 U/L (ref 5–58), Alkaline phosphatase 931 U/L (ref 40–129) and lactate 7.6 mmol/L (ref 0.5–2.2). CT scan revealed interval enlargement of the lung mass with innumerable metastatic lesions in the liver and hepatomegaly. He had no symptomatic, laboratory or imaging evidence of infection. He was hemodynamically stable, euvolemic and was not taking any medications that could contribute to lactic acidosis. A repeat lactate was 9.2 mmol/L. His elevated lactate was presumed secondary to extensive tumor burden and liver dysfunction. He declined further testing/treatment and was transitioned to hospice care.

IMPACT: This case describes lactic acidosis in a patient with a solid tumor and liver dysfunction secondary to metastasis. Though type B lactic acidosis is known to occur in haematological as well as solid malignancies, it remains a diagnosis of exclusion and it is necessary to rule out sepsis, tissue hypoperfusion or drug effects (alcohol, salicylates, reverse transcriptase inhibitors) as potential causes of the elevated lactate.

DISCUSSION: Lactic acidosis can occur in the presence (type A) or absence (type B) of tissue hypoperfusion. It has high sensitivity but poor specificity for tissue hypoperfusion. Type B lactic acidosis can be seen with cancer, renal or liver disease, drug or toxin ingestion or congenital enzyme deficiency. Cancer-associated type B lactic acidosis has rarely been described with solid tumors. This is postulated to be a result of the Warburg phenomenon of altered energy metabolism in cancer cells, whereby they preferentially undergo aerobic glycolysis, leading to production of lactate from pyruvate, instead of the more energy efficient oxidative phosphorylation. Liver dysfunction secondary to metastasis with resultant decreased clearance of circulating lactate by the liver (Cori Cycle) likely also played a role in lactic acidosis in this patient. The etiology of malignancy associated hyperlactatemia is thus likely multifactorial.

Hyperlactatemia has been shown to be a negative prognostic marker in cancer patients. This case highlights an unusual cause of lactic acidosis in a patient presenting with progression and metastasis of lung cancer with high tumor burden.

ULCERATIVE SKIN LESIONS IN A PATIENT WITH A PERIPHERAL T-CELL LYMPHOMA Sean E. Scott[1, 2]; Mary Maiberger[3]; Ribka Ayana[1]. [1]Washington DC VA Medical Center, Washington DC, DC; [2]Edward Hébert School of Medicine, Bethesda, MD; [3]Washington DC VAMC, Washington DC, DC. (Control ID #2705956)

LEARNING OBJECTIVE #1: Recognize the variable clinical presentations of pyoderma gangrenosum (PG)

LEARNING OBJECTIVE #2: Articulate the differential diagnosis of cutaneous lesions in patients with hematologic malignancies

CASE: A 62 year-old man developed a painful, indurated ulcer on his mid upper back.Three weeks prior, he was admitted with melena and found to have a bleeding, ulcerated gastric mass on esophagogastroduodenoscopy, with biopsy revealing a peripheral T cell lymphoma.Two days after a bedside incision and drainage was performed on the back lesion, it transformed into a five centimeter draining, erythematous, edematous plaque with central ulceration and overhanging borders.Within the next week, he developed several new lesions including a two by two centimeter eroded, draining, purulent plaque at the site of a previous intravenous line on the right forearm and a two by three centimeter vegetative, exophytic, tender nodule with crusting on the right temporal scalp.The patient did not have any fevers. A punch biopsy of the right forearm lesion revealed a heavy infiltrate of neutrophils in the dermis with GMS, PAS, and Gram stains negative for microorganisms. The patient was diagnosed with pyoderma gangrenosum and started on high-dose prednisone. Two days after starting prednisone his lesions dramatically decreased in size, erythema, and induration and continued to improve over the following weeks with a slow prednisone taper.

IMPACT: Pyoderma gangrenosum occurs in association with various systemic disorders including hematologic malignancies approximately 50% of the time. Rarely is peripheral T-cell lymphoma associated with PG, as in our patient.This case represents one of the few reported cases in literature.

DISCUSSION: Pyoderma gangrenosum is an uncommon neutrophilic dermatosis.Patients often present with a small papule or pustule. It rapidly progresses to an erythematous, exquisitely tender plaque, pustule, or nodule, which may ulcerate.PG can also appear atypically as bullous, pustular, or vegetative lesions.Diagnosis is based on clinical and histopathologic findings and exclusion of other causes.Skin biopsy and tissue culture are important for ruling out other conditions.Pathergy, the appearance or worsening of skin lesion at the site of minor trauma, occurs in 25-50% of patients and is a contraindication for surgical management of the ulcers.The differential diagnosis for patients with hematologic malignancies who develop ulcerative cutaneous lesions should include: infection by bacteria, deep fungi, or atypical mycobacterium; malignancy, such as leukemia cutis; neutrophilic dermatoses, such as PG and Sweet's syndrome; inflammatory conditions, such as vasculitis; and paraneoplastic disorders.PG should be considered when evaluating ulcers, especially in patients with rapidly progressive lesions and systemic diseases known to be associated with PG.Incision and drainage or surgery of these lesions can lead to pathergy, resulting in significant pain, morbidity, and scarring.

UNCHARTED COURSE: MAPPING THE PATH OF FAMILIAL MEDITERRANEAN FEVER (FMF) IN JAPAN Ryuichi Sada[2]; Mitsuya Katayama[2]; Sandra Y. Moody[1, 2]. [1]Kameda Medica Center & UCSF/SFVAMC, Kamogawa City, Japan; [2]Kameda Medical Center, Kamogawa, Japan. (Control ID #2707430)

LEARNING OBJECTIVE #1: Recognize that familial Mediterranean fever (FMF) occurs among people of Japanese descent.

LEARNING OBJECTIVE #2: Recognize that asking a simple question such as "Have you had similar symptoms in the past several years?" may help the patient recall relevant symptoms.

CASE: A healthy 24-year-old Japanese man presented with a six-week history of fever, headache, and fatigue. He was well until a low-grade fever and difficulty walking developed six weeks before admission. He had no relevant past medical or family history. Because his symptoms did not resolve after his primary care doctor prescribed levofloxacin and acetaminophen four weeks before admission, he was admitted for evaluation. On physical examination, his vital signs were stable except for a temperature of 37.5° C. He had no meningeal signs, skin rashes, or joint swelling. Laboratory data were completely normal, including two sets of blood cultures, thyroid and adrenal function tests, anti-HIV antibody, rheumatoid factor, antinuclear antibody, cerebrospinal fluid and whole body computed tomography. His fever and headache resolved spontaneously, and he was discharged to home two weeks later. However, general fatigue persisted, interfering with his ability to work. Four months after the previous admission, a low-grade fever recurred for eight days. He was asked a simple question, "Have you had similar symptoms in the past several years?" He informed us that he had experienced similar symptoms two to three times per year in the last two years. Based on this history, we suspected FMF and performed genetic screening and found MEFV exon 2 mutations. We diagnosed an atypical phenotype of FMF (atypical FMF) and treated him with oral colchicine. His fever resolved, but the fatigue persisted. Etanercept was added to his treatment regimen and his symptoms resolved completely which led him to return to work.

IMPACT: This case highlights the importance of taking an accurate medical history regarding recurrent fever. A simple question can help diagnose periodic fever syndrome. Atypical FMF tends to present with low-grade fever, a longer duration of symptoms, and a lower frequency of febrile attacks.

DISCUSSION: Patients with FMF are reported to be predominantly from the Mediterranean region, however, FMF can occur among people of Japanese descent. One case series mentioned that over one-third of patients with FMF in Japan have an atypical clinical course. Atypical FMF is usually difficult to diagnose quickly because the clinical features of atypical FMF differ from the typical phenotype of FMF, and because patients with atypical FMF might not be aware that a single disease may be the cause of several episodes of fever. The first step in the diagnosis of periodic fever syndrome is taking an accurate medical history concerning recurrent fevers. Genetic screening is essential for the diagnosis of FMF, and MEFV mutations in other than exon 10 are related to atypical FMF.

UNCONVENTIONAL BUT PATIENT CENTERED APPROACH TO MARKEDLY ELEVATED HEMOGLOBIN A1C Rebecca Kapolka. Indiana University, Indianapolis, IN. (Control ID #2707576)

LEARNING OBJECTIVE #1: Recognize the importance of a patient centered approach to clinical decision making and adapting guidelines and how this can improve outcomes.

CASE: A 50 year old Hispanic female presented to establish care after moving from Mexico. A live interpreter was utilized during the visit. She had known type 2 diabetes mellitus and hypertension but was not currently on any treatment and did not know the results of her recent blood sugars or hemoglobin A1C (HbA1C). She reported symptoms of increased fatigue, polyuria and polydipsia. Her exam was significant for a blood pressure of 152/92, BMI of 36, trace lower extremity edema and stasis dermatitis of the anterior shins bilaterally. Monofilament testing was normal bilaterally. Pertinent labs included an HbA1C of 12.9, random blood glucose of 317, urine ketones of 50, urine glucose of 1000, and microalbuminuria of 100. Given the patient's markedly elevated HbA1C, I initially proposed starting metformin and basal insulin. The patient was visibly upset by these recommendations and began to cry. With the assistance of the interpreter I was able to better understand that her fear of insulin resulted from the recent passing of her mother who was also on insulin for diabetes management. Although I explained the benefits of insulin, she was still very upset. I acknowledged her fears and we came up with a plan to trial only oral medications and lifestyle changes for the next 3 months. She thanked me for giving her the chance to improve.She was started on metformin 1000mg twice daily, glipizide 5mg daily, and lisinopril 10mg daily in addition to lifestyle modifications. She was provided with a glucometer and supplies. When she returned to clinic three months later, she reported blood sugars of 70–165. She reported excellent compliance with her medications, decreased consumption of carbohydrates including rice and tortillas, and increased physical activity by walking around her neighborhood. Her repeat HbA1C was 6.3 and random blood glucose was 159. She was continued on her oral regimen. A subsequent follow up visit three months later again confirmed her excellent compliance and glycemic control with an HbA1C of 6.5 and random blood glucose of 131.

IMPACT: This case highlights the difficulties that language barriers contribute to the patient-physician relationship and how taking the time to better understand their beliefs and valuing their opinions regarding treatment can lead to better outcomes.

DISCUSSION: This case demonstrates the importance of addressing patient values and incorporating their preferences into their management plan. The 2016 American Diabetes Association guidelines recommend a patient centered approach to diabetes management. However, they also recommend starting a much more aggressive glycemic control regimen including insulin for patients with HbA1C greater than 10. This case demonstrates a situation of when to adapt guideline recommendations based on the patient's values and preferences.

UNILATERAL ADRENAL HYPERPLASIA: AN UNUSUAL PRESENTATION OF PRIMARY ALDOSTERONISM AND HYPERTENSIVE EMERGENCY Steven Song; Joselle Cook. SUNY Downstate Medical Center, Brooklyn, NY. (Control ID #2700528)

LEARNING OBJECTIVE #1: Recognize unilateral adrenal hyperplasia, a rare subset of primary aldosteronism, as a cause of long-standing refractory hypertension.

CASE: A 54-year-old African American woman presented with complaints of headache, blurred vision, and progressive bilateral leg swelling for the past week. This was her 4th visit to the hospital in 4 months with similar complaints. Medical history was significant for 10 years of refractory hypertension, many no-show visits, consequent chronic kidney disease stage 4, on a 5 drug anti-hypertensive regimen. Admission blood pressure (BP) was 248/164 mmHg. Physical exam was significant for bilateral papilledema and lower extremity edema. Labs demonstrated acute deterioration in her renal function with creatinine 6.8 mg/dL (increased from baseline 3.3 mg/dL) and hypokalemia (3.0 mEq/L). She was admitted to the ICU for management of hypertensive emergency, with initiation of nitroglycerin drip and improved BP. Once stabilized and normokalemic, workup demonstrated elevated plasma aldosterone, suppressed plasma renin activity, and an aldosterone-to-renin ratio of 48.8 ng/dl per ng/(ml*h). Workup for pheochromocytoma was negative. Renal artery ultrasound revealed no stenosis. CT abdomen reported thickening of the left adrenal gland with features suggestive of hyperplasia. The patient was transitioned to oral anti-hypertensive agents with resolution of her clinical symptoms. She was scheduled for adrenal vein sampling and possible laparoscopic left adrenalectomy.

IMPACT: This case of long-standing uncontrolled hypertension and eventual discovery of unilateral adrenal hyperplasia (UAH) on admission emphasizes that secondary causes of long-standing refractory hypertension not be overlooked. The differential of UAH and similar pathologies should be considered in these patients. Early recognition would direct management more conclusively and prevent irreversible end-organ damage.

DISCUSSION: Primary aldosteronism (PA) is a principal disorder of the zona glomerulosa that is characterized by hypertension, hypokalemia, increased plasma aldosterone, and suppressed plasma renin activity. Actual prevalence of PA is reported in 5 to 15% of the hypertensive population. The eponymous Conn's syndrome, which described aldosterone-producing adenomas (APA), is the most common subtype, implicated in 50-70% of cases of PA; bilateral adrenal hyperplasia accounts for 30%. Unilateral adrenal hyperplasia (UAH) however, is a rare cause of PA accounting for less than 1% of cases. Though hyperplastic on imaging, histopathology of UAH has demonstrated adenomatous changes, and is managed as an adenoma. Early recognition is crucial to prevent permanent long-term sequelae, as management is distinctly different for adenomas versus bilateral hyperplasia. Laparoscopic adrenalectomy is indicated for both APA and UAH, resulting in normalization of BP and resolution of hypokalemia in as few as 2 years post-procedure. Bilateral adrenal hyperplasia is managed medically.

UNMASKING THE TRUE CULPRIT: IMPARTIAL TREATMENT LEADING TO DEFINITIVE DIAGNOSIS Justine Phifer[1]; Linda Wang[2]; Yelena Averbukh[2]. [1]Montefiore Medical Center, Bronx, NY; [2]Montefiore Medical Center, New York, NY. (Control ID #2704348)

LEARNING OBJECTIVE #1: Identify bilateral tubo-ovarian abscesses as an uncommon presentation of disseminated tuberculosis

LEARNING OBJECTIVE #2: Understand the pathophysiology of TB associated immune reconstitution disease

CASE: A 28-year-old HIV-negative woman from West Africa presented with an enlarging left neck mass of three weeks and twenty-pounds of unintentional weight loss for four months. The mass was 3x4cm, firm, non-tender, and a fine needle aspirate was non-diagnostic. A CT of the neck revealed a conglomerate of necrotic lymph nodes and a MRI of the brain revealed multiple intra-parenchymal,

ring-enhancing supra and infratentorial lesions with surrounding edema and mass effect. Xpert® MTB/RIF PCR of a core biopsy of the mass confirmed Mycobacterium tuberculosis (MTB) and RIPE therapy was initiated. Three months prior, the patient presented with abdominal pain and fevers of five months, and was found to have bilateral tubo-ovarian abscesses (TOA). A Quantiferon® test was positive, but an aspirate of the abscess was negative for MTB and other bacteria. She was treated with a two-week course of doxycycline and levofloxacin, which led to an improvement in her symptoms before she re-presented with the neck mass three months later.

IMPACT: Internists in the U.S. see increasing numbers of patients from TB endemic areas, necessitating recognition of various TB presentations. Frequent prescription of fluoroquinolones also requires knowledge of partially treated TB and immune reconstitution disease (IRD).

DISCUSSION: Disseminated TB increases in frequency with immunodeficiency, but may also present in patients with intact immune systems. Genitourinary TB is an uncommon presentation of TB and is even less common in immunocompetent persons. IRD occurs when previously subclinical or partially treated opportunistic infections worsen as a result of host inflammatory response activation. It can occur when an immunocompromised person achieves restoration of immune function, and is most commonly reported in HIV positive individuals receiving anti-retroviral therapy. In this setting, mycobacterial infections are most commonly implicated. However, IRD can occur in young, HIV seronegative patients, such as this patient. In persons with active TB, there may be an alteration in the balance of immunosuppressive and pro-inflammatory mechanisms and amplified cell-mediated immune responses that can lead to paradoxical reactions early in anti-TB treatment. In this case, the patient underwent partial treatment for TB while being treated for TOA and subsequently developed worsening TB lymphadenitis.The lymph nodes are the most common site of TB IRD and lymphadenitis can be observed in up to 25% of HIV uninfected patients. After initiation of anti-TB therapy, patients may develop paradoxical worsening of their symptoms before resolution. Physicians should be aware of uncommon presentations of disseminated TB, including genitourinary TB, and that they may affect immunocompetent patients who are younger in age and from TB endemic regions.

UNMASKING THE TRUTH ABOUT MASKED MACROCYTOSIS: REVEALING FOLATE AND VITAMIN B12 DEFICIENCIES IN A PATIENT WITH BETA THALASSEMIA TRAIT Elissa Szalkiewicz. Montefiore Medical Center, NYC, NY. (Control ID #2706227)

LEARNING OBJECTIVE #1: Recognize masked macrocytosis in patients with co-existing beta thalassemia trait and folate and vitamin B12 deficiencies

CASE: A 38 year old man presented with 2 months of worsening weakness and exertional dyspnea. He denied signs of bleeding. For the past two years he had been eating only one small meal at night. His past medical history was significant for beta thalassemia trait, Gilbert's disease, and bipolar disease. Denied alcohol use. On physical exam, he had conjunctival pallor and a flow murmur. Labs revealed CBC: WBC 5.9 k/ul, RBC 1.04 mL/uL (L), Hgb 3.0 g/dL (L), Hct 9.0% (L), MCV 86.5 fL, RDW 21.6% (H), and Plts 170 k/uL. Additional labs: reticulocyte index 0.3 (L), LDH 1971 U/L (H), haptoglobin <8 mg/dL (L) and serum folate <2 ng/mL (L), vitamin B12 192 pg/mL (L), homocysteine 35.4 umol/L (H), and methylmalonic acid 150 nmol/L. Intrinsic factor antibody was positive. Peripheral blood smear showed: anisocytosis, poikilocytosis, and hypersegmented neutrophils. It was concluded that the patient had severe vitamin B12 and folate deficiencies in the setting of pernicious anemia and dietary insufficiency with megaloblastic anemia, ineffective erythropoiesis and hemolysis. He was transfused three units of packed red blood cells and administered parenteral cobalamin and enteral folate with clinical improvement, increased reticulocytosis and stability of his hemoglobin.

IMPACT: This case changed my thinking about macrocytosis associated with vitamin B12 and folate deficiencies and made me realize that the macrocytosis could be masked.

DISCUSSION: Vitamin B12 and folate deficiencies are typically investigated for as the cause of anemia when patients present with labs consistent with macrocytic anemia; however, the macrocytic expression of megaloblastic anemia can be masked in the setting of co-existing disorders such as iron deficiency and thalassemia. Evidence of these disorders can be revealed in the RDW, reticulocyte index, and peripheral blood smear. Vitamin B12 and folate deficiencies should be in the differential diagnosis in patients with known thalassemia and worsening non-macrocytic anemia. Patients with beta thalassemia trait typically have mild anemia that is microcytic with a normal RDW. When RDW is elevated in these patients, it is suggestive of a coexisting hemolytic, hemorrhagic or maturation disorder. These disorders can be distinguished from each other by the reticulocyte index, which is high (>2.0) in hemolytic and hemorrhagic disorders and low (<2.0) in maturation disorders such as vitamin B12 and folate deficiencies. The peripheral blood smear could have evidence of anisocytosis, poikilocytosis, and hypersegmented neutrophils which are not masked by coexisting beta thalassemia trait and are common in vitamin B12 deficiency. It is important to remember not to rule out Vitamin B12 and folate deficiencies in the absence of macrocytic anemia because the macrocytosis can be masked as in patients with co-existing beta thalassemia trait.

UNUSUAL CASE OF JAUNDICE Valentine O. Millien[2]; Ryle W. Przybylowicz[1]; Janis L. Sethness[1]; Lee Lu[1]. [1]Baylor College of Medicine, Houston, TX; [2]Baylor College of medicine, Houston, TX. (Control ID #2707317)

LEARNING OBJECTIVE #1: Review spontaneous tumor lysis syndrome

LEARNING OBJECTIVE #2: Recognize that spontaneous tumor lysis syndrome (TLS) could be the initial manifestation of small cell lung cancer.

CASE: A 63-year-old male with HTN, COPD, and chronic HCV infection presented with progressively worsening abdominal distention, jaundice, and scleral icterus. Physical exam was significant for jaundice and mildly distended abdomen with fluid wave. His laboratory studies revealed ALT 71, AST 116, alkaline phosphatase 324, total bilirubin 11.2, direct bilirubin 7.4, total protein 6.1, albumin 1.9, LDH 457, Bun 72 and Cr 7.75 (baseline Cr 0.8). In addition, other significant laboratory derangement included uric acid 18.5, phosphorus 7.6, corrected calcium 10.2, and potassium 5.1; these results were consistent with tumor lysis syndrome based on Cairo-Bishop criteria. He was immediately treated with rasburicase and intravenous fluid repletion. An abdominal ultrasound showed multiple masses in the liver with cirrhotic changes, but the alpha fetoprotein was normal at 2.33 ng/mL. Biopsy of liver masses revealed small cell carcinoma consistent with lung primary given history of heavy smoking. The patient subsequently underwent whole body PET-CT which showed left upper lobe lung mass with metastases to ribs and skull. He was diagnosed with spontaneous TLS caused by small cell primary lung cancer.

Given overt liver failure, persistent renal impairment despite treatment, and the extent of his metastases, the patient elected to be discharged home on hospice.
IMPACT: Spontaneous tumor lysis is a rare oncologic emergency classically seen in hematologic malignancies. This patient presented with spontaneous TLS as the initial manifestation of small cell lung cancer. Physicians must have low threshold for suspicion of this rare entity, in the proper clinical context, to initiate prompt lifesaving treatment.
DISCUSSION: Tumor lysis syndrome after initiation of cancer treatment is an oncologic emergency. Spontaneous TLS which occurs in absence of treatment is a rare form of TLS seen in about 1% of hematologic malignancies and in even rarer instances, in solid organ malignancies. In review of literature, there have been only two cases of spontaneous TLS reported in small cell lung cancer. The mechanism is not well known and is often seen in high tumor burden and high proliferation rate. Therefore, high index of suspicion and low threshold for treatment should be maintained in patients who present with high risk for lung cancer and laboratory findings suggestive of spontaneous tumor lysis syndrome in order to promptly diagnose and treat this lethal disease process.

UPPER GASTROINTESTINAL (GI) BLEED AS A MANIFESTATION OF POORLY DIFFERENTIATED METASTATIC SQUAMOUS CELL CARCINOMA (SCC)OF THE LUNG Richa Bhardwaj[1]; Gaurav Bhardwaj[2]; Raffi Karagozian[2]. [1]University of Connecticut, Hartford, CT; [2]Saint Francis Hospital, Hartford, CT. (Control ID #2704006)

LEARNING OBJECTIVE #1: Recognize upper GI bleeding as a potential complication of metastatic primary lung cancer.
LEARNING OBJECTIVE #2: Distinguish and manage upper GI bleeding secondary to metastatic lung cancer
CASE: 39-year-old female presented to the ED with complaints of dizziness and black tarry stools for 1 day. The patient had a history of smoking (23 pack years) and was diagnosed with stage IV, SCC of the lung (T2N3M1) about 6 weeks ago. She was started on a chemotherapy regimen with paclitaxel and carboplatin. Initial workup revealed a hemoglobin and hematocrit of 7.9 gm/dL and 23.7 and a platelet count of 14,000/u L.Initial EGD assessment revealed blood clots in the stomach with poor visualization of the fundus. No source was identified.A second look EGD demonstrated a large(6cm × 6cm), ulcerated, friable, mass in the gastric fundus that was biopsied.Final pathology of the mass revealed poorly-differentiated carcinoma consistent with her preexisting non-keratinizing SCC of the lung that showed immunoreactivity for Pan-Keratin, p40, p63, and p16. Given the advanced disease of the patient, she was started on Nivolumab and localized radiation therapy (RT). However she continued to have progression of disease with a significant decline in her performance status. Patient subsequently passed away due to widely metastatic cancer.
IMPACT: This case highlighted the importance of considering gastric metastasis as a potential cause for upper GI bleeding in patients with primary lung cancer. Also it is imperative to establish metastaic lesions as the cause of bleeding as the management strategies in these scenarios may include chmotherapy and RT in addition to the other endoscopic modalities.
DISCUSSION: Primary lung cancer frequently metastasizes to the contralateral lung (49.8%), liver (36.9%), adrenal gland (30.8%), and bones (29.4%), while metastasis to digestive system are rare (0.2% - 5.0%).Although most gastric metastases are asymptomatic, when overlooked or misdiagnosed, fatal complications such as severe bleeding and perforation can occur.Histologic types of lung cancer involved in gastrointestinal metastasis are not well known and according to studies these lesions have most commonly been reported as adenocarcinomas (27%). These metastatic foci mostly present as asymtomatic submucosal lesions.If symptomatic,the major symptoms include upper abdominal pain,anemia,melena or hematemesis.Management strategies include approaches such as chemotherapy, RT and surgery.For patients with advanced disease, RT may be used to manage GI bleeding in patients who are unable to undergo surgery or endoscopy. Studies have reported a significant improvement in hemoglobin levels with RT,along with an increase in mean survival. To conclude,in patients with lung cancer presenting with a GI bleed, evaluation for possible GI metastasis must be considered for appropriate management. Palliative RT can impact quality of life and prognosis in these patients but additional studies are required to further establish its role.

UREA-INDUCED OSMOTIC DIURESIS AS AN UNSUSPECTED CAUSE OF HYPERNATREMIA IN HYPERCATABOLIC STATE
Guramrinder S. Thind; Karthik Kailasam; Richard Roach. Western Michigan University School of Medicine, Kalamazoo, MI. (Control ID #2701321)

LEARNING OBJECTIVE #1: Identify the presence of hypercatabolic state in a patient with sympathetic hyperactivity due to anoxic brain injury.
LEARNING OBJECTIVE #2: Diagnose and manage urea-induced osmotic diuresis and differentiate it from diabetes insipidus.
CASE: A 57-year old male with a history of type-2 diabetes was admitted to the intensive care unit (ICU) after he had a cardiac arrest. In the field, patient received several rounds of epinephrine and defibrillation, and spontaneous circulation returned after 25 min. Patient was intubated for airway protection. He was found to be unresponsive on arrival and hypothermia protocol was initiated. Upon conclusion of therapeutic hypothermia, patient started developing high-grade fever, tachycardia, and hypertension. Sympathetic hyperactivity due to anoxic brain injury was suspected. At the same time, his serum sodium and urine output started trending up. On day 4, his serum sodium was 158 Meq/L and urine output was 6 L/day. Further workup showed: serum osmolality: 346 mosm/kg, urine osmolality: 771 mosm/kg, urine sodium: <20 Meq/L, and urine urea nitrogen: 810 mg/dl. The high urine osmolality ruled out diabetes insipidus. BUN at this time was 38 mg/dL. Urea-induced osmotic diuresis was suspected as the cause of patient's polyuria. Patient's protein intake at that time was not high enough to cause this degree of urea production. Hence, body protein wasting due to a hypercatabolic state was suspected. Sympathetic hyperactivity and underlying insulin resistance likely contributed to the hypercatabolic state. Intravenous D5W and free water flushes via OG tube were administered. The dysautonomia resolved after a few days, and his serum sodium and urine output returned to normal.
IMPACT: This case identifies urea-induced osmotic diuresis as an important cause of polyuria and hypernatremia in critically ill patients. Temporary hypercatabolic carbolic state in ICU patients can be caused by various causes including sympathetic hyperactivity due to anoxic brain injury. While working up these patients, both urine osmolality and urine urea nitrogen should be checked. Replacement of free water via intravenous (D5W infusion) or oral route is the only effective treatment strategy.
DISCUSSION: Urea is the end product of protein catabolism and a known cause of osmotic diuresis. Both high protein intake and increased proteolysis can increase urea production. Hypercatabolic states are common in ICU

patients. Underlying insulin resistance and a surge of counterregulatory hormones (e.g. cortisol in stress response, catecholamines in sympathetic hyperactivity) facilitate whole-body proteolysis. Increased urea production in these cases may cause osmotic diuresis, which eventually leads to hypernatremia. Sympathetic hyperactivity commonly seen after anoxic brain injury is an important cause of hypercatabolic state. Notably, central diabetes insipidus is also possible with anoxic brain injury can cause hypernatremia and poluria; urine osmolality level of >600 mosm/kg effectively rules it out.

UTILITY OF CARDIAC MAGNETIC RESONANCE IMAGING IN PATIENTS WITH HYPERTROPHIC CARDIOMYOPATHY

Kristin Mangalindan; Edward Hulten; Kevin Woods; John Lichtenberger; Paul G. Peterson; Maureen Hood; Vincent Ho. Walter Reed National Military Medical Center, Bethesda, MD. (Control ID #2704377)

LEARNING OBJECTIVE #1: Recognize utility of dobutamine stress cardiac magnetic resonance (CMR) imaging in patients with hypertrophic cardiomyopathy (HCM)

CASE: A 53 year old man with history of HCM and dynamic outflow obstruction status post septal myectomy presents with declining exercise tolerance and chest pressure with rest and exertion. He was on ranolazine with some relief but reported symptoms worse than his pre-operative state. Medical history notable for HCM on verapamil and coronary artery disease on aspirin and atorvastatin. He had a septal myectomy in 2013 with normal post-operative gradient. Family history remarkable for father with myocardial infarction at 56. On exam, 2/6 holosystolic murmur was heard across the precordium and increased to 3/6 with Valsalva, more notable than prior exams. With concern for worsening HCM, repeat stress echocardiogram was performed, showing moderate mitral regurgitation (MR) and sub-chordal systolic anterior motion (SAM) of the anterior mitral leaflet at rest. However, image quality was limited due to muscular chest and fibrosis from prior sternotomy. With suspicion for underestimation of disease, dobutamine stress CMR was performed to better assess anatomy during simulated exercise physiology. It revealed a 23% decline in aortic flow at stress indicating left ventricular outflow tract (LVOT) obstruction, increased MR at stress, elongation of anterior mitral leaflet, and inappropriate blood pressure response to stress (40mmHg SBP decrease, resulting in termination of exam), all of which were not elucidated with echo. Patient was referred to a specialized HCM center for concurrent myectomy and mitral valve Alfieri stitch. Genetic testing for his aggressive disease revealed MYBPC3 gene positivity. He is asymptomatic at 16 month follow-up.

IMPACT: The diagnosis of HCM is commonly focused on LV hypertrophy while MV abnormalities receive less emphasis. Echocardiograms are routinely used to evaluate HCM, but have limitations in patients with large body habitus or prior CT surgeries and can underestimate MV pathology. These patients are rarely referred for dobutamine stress CMR, which can evaluate fibrosis, ischemia, outflow obstruction, and MR volume, providing invaluable information regarding prognosis, management, and eventual surgery.

DISCUSSION: Dobutamine stress CMR is underutilized in evaluation of HCM. In our patient, increased LV intracavity pressure from LVOT combined with SAM resulted in severe MR underestimated by echo. An eccentric, posteriorly directed MR jet hit the atrial wall and lost kinetic energy, decreasing the echo Doppler velocity (Coanda effect) and miscalculating MR severity. On CMR, aortic flow decreased with stress, consistent with eject-obstruct-leak physiology that was prevalent in our patient with an elongated mitral leaflet, but only elucidated clearly on CMR. With careful patient selection and monitoring, dobutamine stress CMR has been proven to be a safe and accurate assessment for diagnosis, prognosis, and procedural planning.

UTILITY OF PET SCANS IN BIOPSY NEGATIVE LUNG MASSES

Andrew Kelly; Bryden Considine. University of Connecticut, Hartford, CT. (Control ID #2706156)

LEARNING OBJECTIVE #1: Outline the utility of PET (positron emmision tomography) imaging in biopsy negative lung masses in identifying and treating malignanies.

CASE: A 29 year-old male with history of asthma presented to the hospital for progressive dyspnea and neck swelling. Two years prior workup for a cough revealed a large right lung mass whose biopsy pathology revealed mixed small T and B lymphocytes, but was non-diagnostic. He was lost to follow up. On return to the emergency department he had right-sided neck pain and swelling, orthopnea and paroxysmal nocturnal dyspnea but no dyspnea on exertion, no pedal edema, no chest pain or palpitations. His vitals included: T 97.2 °F, HR 107, BP 120/82, RR 20. On exam he had a thick neck with bilateral cervical adenopathy but no JVD or change in color of the head and neck. He had bulky right sided supraclavicular adenopathy. He had decreased breath sounds over the right upper lung fields with dullness to percussion. He did not have any wheezes, stridor or rales. He had tachycardia but no murmurs, gallops or rubs. His abdominal exam was benign. He had no pedal edema, axillary or inguinal lymphadenopathy. Work-up with a chest X ray and CT scan of the chest and neck which revealed an interval enlargement of the right upper lobe lung mass 11.7 cm × 12.5 cm transaxially × 14.5 cm craniocaudally, near complete occlusion of the right upper bronchus and the mass also encircled the lower trachea. He additionally had evidence of superior vena cava syndrome. He was discharged for outpatient follow up to schedule a PET scan which guided a biopsy that was able to established the diagnosis of large B cell non-Hodgkin's lymphoma. He was started on R-EPOCH and after 6 cycles, his latest PET scan shows interval shrinking of the tumor size, now 6.9 cm × 5.2 cm × 5.1 cm with mild FDG activity.

IMPACT: This case exemplifies the utility in additional imaging where otherwise repeat biopsies would result in added testing with its inherent risks including hemorrhage and pneumothorax and prolong time to diagnosis.

DISCUSSION: It is not uncommon to have non-diagnostic results on bronchoscopy or IR guided biopsy of lung masses due to a variety of reasons including inadequate sampling of the actual mass lesion. Additionally with large, fast growing tumors, the risk of sampling areas of necrotic tissue increases as the mass outgrows its blood supply making pathology non-diagnostic. This case highlights the utility in obtaining PET imaging to further guide repeat biopsies. A PET scan will readily show areas of metabolically active tissue and help with staging disease which also guides the definitive chemotherapeutic regimens. Without considering PET imaging, repeat biopsies by IR or endoscopy can continue to yield non-diagnostic results and ultimately delay patient care. Repeat non-diagnostic biopsies would also unnecessarily put the patient at increased risk of hemorrhage, pneumothorax.

VENTRICULAR ARRHYTHMIA IN A PATIENT WITH MYOTONIC DYSTROPHY

Yuichi Murayama[2, 2]; Ivor Cammack[1]; Hiroyuki Sato[2]; Kentaro Hayashi[2]; Yuichiro Mori[2]; Haruki Sasaki[2]; Satoshi Yuda[2]; Mitsugu

Hirokami[2]. [1]Keijinkai, Yoichi, Japan; [2]Teine Keijinkai Hospital, Sapporo, Japan. (Control ID #2703045)

LEARNING OBJECTIVE #1: Recognize the increased risk of arrhythmia in patients with this condition, and the limitations of echocardiogram in patient assessment.

LEARNING OBJECTIVE #2: Assess use of implantable cardioverter defibrillators (ICD) in patients with myotonic dystrophy.

CASE: A 45 year-old Japanese woman collapsed while gambling. Bystander CPR was performed immediately, and she was transported to hospital via ambulance. On arrival at the hospital, she was in sinus bradycardia, but remained unconscious and was intubated. Her vital signs were stable and there were no other abnormal physical findings. Her long-term medical conditions are type 1 myotonic dystrophy (DM1), type 2 diabetes mellitus and dyslipidemia. Her regular medications are teneligliptin, glimepiride and rosuvastatin. She is an ex-smoker, with no pertinent family history. Her initial blood results showed a raised white blood cell count of 11430/μL, and slightly deranged liver function (ALP 416 IU/L, γ-GTP 112 U/L). Her venous blood gas showed pH of 7.14 with lactic acidosis. Her EKG showed sinus bradycardia on arrival but she then had an episode of ventricular fibrillation. She underwent electrical defibrillation, and reverted to atrial fibrillation with bradycardia. Her EKG showed atrioventricular block and a prolonged QT interval and electrophysiological testing confirmed HV interval prolongation(110msec) but showed noinducible sustained ventricular tachycardia. An echocardiogram reported normal left ventricular structure and function. Coronary arteriography was normal, and an acetylcholine provocation test was negative. A sub-endocardial myocardial biopsy showed fibrosed interstitial tissue and replacement of connective tissue by fat. These findings are consistent with DM1. She made a good recovery and was extubated. A joint decision was made to implant an ICD prior to discharge.

IMPACT: Although DM1 is known to cause left ventricular hypertrophy, dilatation, and systolic dysfunction, in our case the patient had a normal echocardiogram. This was an unexpected finding. Her EKG and myocardial biopsy however revealed the underlying conduction system pathology which led to her potentially fatal arrhythmia. This highlights the limitations of echocardiography in assessing the cardiac conduction system.

DISCUSSION: DM1 is the most common muscular dystrophy among adults. This hereditary condition is known to cause ventricular arrhythmia and sudden death. This case highlighted the importance of screening for arrhythmia risk in DM1 patients, and showed the limitations of echocardiography in this case. Fortunately, this patient had a good outcome despite her out-of-hospital cardiac arrest. Chromosomal testing can confirm diagnosis of DM1 and can also predict disease severity. We also discuss the use and benefit of ICDs in this group of patients, and compare to previous case reports.

VITAMIN C-INDUCED RENAL FAILURE: A CAUTIONARY TALE IN ALTERNATIVE MEDICINE Michael D. Richter1; Stuart A. Ostby[2]; Ognjen Gajic[3]. [1]Mayo Clinic, Rochester, Rochester, MN; [2]Mayo Clinic School of Medicine, Rochester, MN; [3]Mayo Clinic, Rochester, MN. (Control ID #2706136)

LEARNING OBJECTIVE #1: Identify the potential harm of non-prescription ascorbic acid supplementation.

LEARNING OBJECTIVE #2: Recognize the importance of historical data in cases of acute renal failure.

CASE: A 69-year-old man with history of type II diabetes mellitus, obesity, and nephrolithiasis presented with three days of generalized weakness. During this period he also suffered from intermittent shortness of breath, loose stools, and decreased urine output. Ten days prior to his presentation, a chiropractor recommended he take a "Vitamin C Flush" to help with chronic constipation. This consisted of roughly 6 grams of over-the-counter ascorbic acid daily for one week. He had a history of calcium oxalate stones though no known diabetic nephropathy or other renal disease. Initial laboratories revealed a creatinine of 11.8 (from baseline of 1.1 two months prior), potassium of 9.0, and pH of 7.1. Electrocardiogram demonstrated wide complex QRS and peaked T waves prompting immediate treatment with calcium chloride, bicarbonate, insulin, and dextrose. Upon admission to the ICU, he received repeat doses of medical therapy and underwent urgent hemodialysis for hyperkalemia. Further laboratory work-up revealed oxalate crystals in his urine and a blood oxalate level of 22.8 μmol/L (normal limit <1.8). ESR, C-reactive protein, peripheral smear, creatine kinase, haptoglobin, antinuclear antibodies, HIV antibodies, and a hepatitis B and C panel were all normal. Renal biopsy demonstrated oxalate nephropathy with interstitial inflammation indicative of acute interstitial nephritis. The patient was treated with a three week course of prednisone and continued on hemodialysis. Six weeks after discharge his creatinine was down to 4.9 and he was producing roughly 1–2 liters of urine daily, though continued to require three-times-weekly hemodialysis.

IMPACT: This case illustrates the potential serious consequences of supplement misuse and addresses the misconception that ascorbic acid is a universally benign water-soluble vitamin. Patients are increasingly seeking alternative therapies and clinicians should routinely ask about these practices, particularly in patients with underlying kidney disease, altered metabolism, or advanced age.

DISCUSSION: Oxalate nephropathy is most commonly seen with ethylene glycol ingestion, though several studies have identified ascorbic acid as a causative agent. It is most common in patients with existing renal disease or fat malabsorption syndromes such as gastric bypass, celiac disease, and Crohn's disease. Biopsy is required for definitive diagnosis though urine crystals and blood oxalate levels can be suggestive. Temporary hemodialysis may be adequate in some cases though chronic renal failure has been described.

VOMITING AND WEIGHT LOSS IN A YOUNG WOMAN WITH TUBEROUS SCLEROSIS COMPLEX (TSC) Joo-Hye C. Park[1]; Mariecel Pilapil[2]. [1]Hofstra Northwell School of Medicine, Hempstead, NY; [2]Hofstra Northwell School of Medicine, New Hyde Park, NY. (Control ID #2699379)

LEARNING OBJECTIVE #1: Discuss how common primary care complaints such as vomiting and weight loss may have unique etiologies in patients with TSC.

LEARNING OBJECTIVE #2: Review the common clinical features of TSC and the need for periodic surveillance.

CASE: SB is a 23 year old female with TSC who presented with vomiting, anorexia, and weight loss. She had non-bloody non-bilious vomiting every 2–3 days for 4 weeks, decreased appetite, and unintentional weight loss of 30 lbs over 6 months. Her medical history included TSC diagnosed at 5 months old after presenting with infantile spasms, developmental delay, renal angiomyolipomas, cardiac rhabdomyoma, and retinal hamartoma. Her psychiatric history included depression, anxiety, psychosis with a prior episode of

anorexia and weight loss, and obsessive compulsive disorder with restricted dietary intake. Her father died at age 30 from a pancreatic neuroendocrine tumor (pNET). CBC and CMP were normal. A CT scan showed a mass at the pancreatic head measuring 4.5 × 6.1 × 4.4 cm. An endoscopic ultrasound with fine needle aspiration suggested a neuroendocrine neoplasm. An octreotide scan confirmed a somatostatin receptor-bearing lesion, confirming the diagnosis of pNET. SB underwent a Whipple procedure, and surgical pathology demonstrated a well-differentiated pNET, grade 2, T2N0, with negative surgical margins. At 2 months post-op, SB had no vomiting, improved appetite, and gained 20 lbs. MRI at 5 months post-op showed no evidence of metastatic or recurrent disease.

IMPACT: Evaluation of new symptoms in patients with genetic syndromes such as TSC requires expansion of the differential diagnosis. Common complaints such as vomiting and weight loss in a young female pose a diagnostic pitfall, particularly in a patient with psychiatric disease. While neuroendocrine tumors are rare in the general population, our case highlights the importance of familiarizing oneself with features of a multisystemic disease such as TSC.

DISCUSSION: TSC is an autosomal dominant neurocutaneous disorder characterized by hamartomas in multiple organs. It affects 1 in 14,000, and the most commonly affected tissues include: brain, kidney, lung, skin, teeth, heart, and eye. Patients often also have cognitive deficits, autism, and behavioral problems. GI involvement usually presents in the form of asymptomatic colorectal polyps, but it is rare in TSC. GI symptoms such as vomiting and weight loss, therefore, may often be attributed to psychiatric causes even by physicians familiar with the clinical features of TSC. PNETs are rare, representing 1–2% of all pancreatic tumors, with an annual incidence of 2.2 per 1,000,000. Associations between TSC and pNET via the mTOR oncogenic pathway have been reported, with pNETs developing in approximately 1.5% of TSC patients, far greater than in the general population. PNET also develops at an earlier age in patients with TSC than without. Our case highlights the need for a broad differential in workups of patients with complex disorders in a primary care setting.

WAS IT HIDING IN PLAIN SIGHT? Tehseen Haider; shahistha hameed; Mahsa Kanzali; Maneesha Bangar. montefiore medical center, Bronx, NY. (Control ID #2706143)

LEARNING OBJECTIVE #1: Identify the psychosocial factors associated with patients, hindering the provision of complete history.

LEARNING OBJECTIVE #2: Recognize the importance of performing complete physical examination on first encounter with patients.

CASE: A 41 year old African American male from North Carolina (NC) with history of microcytic anemia presented with dizziness and blood in stools. He also reported one episode of syncope and 10 lbs unintentional weight loss over 1 month. He had conjunctival pallor, posterior cervical lymphadenopathy, mild epigastric discomfort, and a normal rectal exam. Genitourinary exam was not performed. Laboratory workup was significant for hemoglobin (Hb) of 4.3 g/dL, hematocrit (Hct) 15.1%, mean corpuscular volume (MCV) of 73.6 fL, iron studies consistent with iron deficiency anemia. One year back he had extensive work up for microcytic anemia in NC including bone marrow biopsy which revealed hypercellular marrow, no tumor infiltrates and negative chromosomal analysis. He received 4 units of packed red blood cells with appropriate response. He underwent colonoscopy which was normal. While, he was sedated on table for colonoscopy, a large, fungating and ulcerated penile mass with oozing blood was discovered. He revealed that he had been hiding this mass from doctors and nurses for over a year as he was scared. Biopsy of the mass showed Invasive squamous cell carcinoma. He underwent radical penectomy, bilateral orchiopexy, and perineal urethrostomy.

IMPACT: The importance of detailed physical examination including the rectal and genital exam cannot be stressed enough. Physical examination still holds the key to diagnosis and diminished focus on it may lead to medical errors and delayed diagnosis which may be harmful to the patient.

DISCUSSION: Recently there have been many publications reporting a decline in physical examination skills. This has caused many detrimental diagnostic and therapeutic consequences which could have been prevented easily. The major cause of error is simply that physical examination is not performed. Physical examination is a low cost procedure which requires skill. Consequences of an inadequate physical examination are missed, delayed or incorrect diagnosis, unnecessary exposure to radiation or contrast or invasive diagnostic tests, unnecessary or delayed treatment. It is recommended that physicians should seek full exposure of the patient when necessary. Physicians should also be taught to identify psychosocial factors which may hinder in obtaining the required information from the patient. Sometimes patients are not comfortable disclosing information especially if it relates to genitourinary complaints, in which case appropriate setup should be provided and patient reassured.

WASHED AWAY: AN UNUSUAL CASE OF ACUTE RENAL FAILURE AND PROFOUND ELECTROLYTE DISTURBANCES Matthew Labriola; Maria K. Abril; David Y. Ming. Duke University Medical Center, Durham, NC. (Control ID #2703811)

LEARNING OBJECTIVE #1: Recognize the clinical features of diuretic poisoning

LEARNING OBJECTIVE #2: Manage the ethical dilemma of Munchausen by proxy

CASE: A 61 year-old woman presented with 3 months of nausea and generalized weakness. She denied diarrhea, persistent vomiting, or chest pain. She was afebrile, non-tachycardic, with blood pressure 76/51 mmHg. She was obtunded with dry mucous membranes and cool extremities. Laboratory studies revealed hypokalemia (1.8 mmol/L), hypomagnesemia (1.0 mg/dL), and acute renal failure (BUN 218 mg/dL, Cr 13.2 mg/dL) with an anion gap metabolic acidosis (anion gap 44). She developed torsades des pointes requiring emergent dialysis. Her clinical status improved, and she was discharged home in stable condition. Her husband, a physician, exhibited behaviors that raised concern for the patient's safety. For example, he initially refused central line placement and dialysis. He disclosed that he lavaged ciprofloxacin into the patient's bladder to treat urinary tract infections. In light of these behaviors and the pattern of electrolyte derangements, diuretic poisoning was suspected. A urine diuretic screen sent on admission returned negative. Due to recurrent hypokalemia noted at a follow-up visit, a urine diuretic screen was repeated and returned positive. A diagnosis of Munchausen by proxy was made. An adult protective services (APS) report is pending.

IMPACT: This case prompted consideration of diuretic abuse as a possible cause of acute renal failure with profound electrolyte depletion in the setting of inappropriate spousal behavior when common etiologies have been ruled out. These cases can be difficult to detect given challenges in obtaining historical details and potential for false negative diuretic screens. It is important to speak with the patient and family members separately when adult abuse is suspected.

DISCUSSION: This case of acute renal failure was due to diuretic poisoning by the patient's spouse. If a patient presents with acute renal failure with hypotension, hypokalemia, and hypomagnesemia, causes of volume loss must be suspected, including persistent vomiting, diarrhea, or urinary losses. Diuretic use (intentional or unintentional) must be considered when more common causes have been ruled out, especially in the setting of unusual spousal behavior. A high level of suspicion is required as it is difficult to obtain accurate historical details and there is potential for false negative diuretic screens. The urine diuretic panel is 75–95% sensitive, but if negative and high clinical suspicion exists, the test should be repeated. This case highlights the ethical dilemma of treating a patient suffering from Munchausen by proxy. It is particularly challenging to confront medical professionals as they are knowledgeable regarding objective data and can offer alternative medical explanations to disguise the etiology of the patient's condition. In such scenarios, it is important to confront the patient and spouse separately, and an APS report should be filed.

WERNICKE'S ENCEPHALOPATHY: ANOTHER GREAT MIMICKING SYNDROME

Darran M. Khublall[1]; Jenyfeer Blanco[1]; Joseph Escobar[1]; Yvette DiMarco[1]; Firas Alzaiem[3]; Damian Casadesus[2]. [1]American University of the Caribbean, Miami, FL; [2]Capital Health Regional Medical Center, Trenton, PA; [3]Ross University School of Medicine, Miramar, FL. (Control ID #2702872)

LEARNING OBJECTIVE #1: Recognize the clinical features of Wernicke's encephalopathy in a patient with an atypical presentation.

LEARNING OBJECTIVE #2: Assess all pertinent differential diagnoses while further investigating the most likely problem.
