## LITPOMS

Binding  
Stoichiometry  
Binding Sites  
Site-Specific  
Binding Affinity

**Abstract.** We report a novel method named LITPOMS (ligand titration, fast photochemical oxidation of proteins and mass spectrometry) to characterize protein-ligand binding stoichiometry, binding sites, and site-specific binding constants. The system used to test the method is melittin-calmodulin, in which the peptide melittin binds to calcium-bound calmodulin. Global-level measurements reveal the binding stoichiometry of 1:1 whereas peptide-level data coupled with

fitting reveal the binding sites and the site-specific binding affinity. Moreover, we extended the analysis to the residue level and identified six critical binding residues. The results show that melittin binds to the N-terminal, central linker, and C-terminal regions of holo-calmodulin with an affinity of 4.6 nM, in agreement with results of previous studies. LITPOMS, for the first time, brings high residue-level resolution to affinity measurements, providing simultaneously qualitative and quantitative understanding of protein-ligand binding. The approach can be expanded to other binding systems without tagging the protein to give high spatial resolution.

**Keywords:** LITPOMS, Fast photochemical oxidation of proteins (FPOP), Ligand titration, Binding affinity, Melittin Calmodulin, Site-specific binding

## Introduction

Protein-ligand interactions are the basis for numerous biological processes for which quantitative understanding is vital [1, 2]. To quantify binding, investigators have used circular dichroism [2], fluorescence and fluorescence polarization [3, 4], nuclear magnetic resonance [5], surface plasma resonance [6, 7], and isothermal titration calorimetry [8]. The macroscopic binding affinity, however, does not permit complete understanding of a protein-ligand system. The requirements for specific fluorescence labeling [3, 4], special sample preparation [5, 6], and large sample amounts [5] also limit these approaches.

Among the mass spectrometry (MS)-based approaches for quantitative protein-ligand interactions, one class, termed direct methods, utilize the spectrometer to measure concentrations at equilibrium [9–12]. Despite their convenience, there is always a question of whether the measured gas-phase concentrations represent those in solution. To avoid this, indirect methods using hydrogen/deuterium exchange (HDX) can also be used. Stability of unpurified proteins from rates of HDX (SUPREX) [13] yields a protein-ligand binding affinity by measuring the stability of proteins as bound and unbound.

Another method, protein-ligand interactions by MS, titration and HDX (PLIMSTEX) [14, 15], gives binding affinity in a titration-based experiment [16–19]. Titrating the protein at high-concentration (e.g., 100 times  $K_d$ ) yields binding stoichiometry, whereas titration at  $\sim K_d$  gives the binding affinity without any modifications (e.g., tagging by a fluorophore) [14, 15]. Indirect methods also characterize binding-induced conformational changes at a regional level represented by peptides from digestion [20–22]; an example is apolipoprotein

E3 and a small-molecule drug candidate where location and affinity were determined [19]. HDX is reversible and occurs at sec-to-min timescale [22], which may be competitive with off-rates of protein-ligand equilibrium, giving convergence in HDX for bound and unbound at long times. Further, D<sub>2</sub>O dilution decreases protein concentration, making tight binding challenging. Back exchange and D scrambling during fragmentation challenge the extension beyond the peptide level.

Fast photochemical oxidation of proteins (FPOP) labels proteins with hydroxyl radicals generated by hydrogen peroxide photolysis [23–29]. Hydroxyl radicals irreversibly label solvent-accessible areas [23, 24] in sub-milliseconds, faster than changes in protein conformation [24, 26, 27]. This ensures that FPOP labeling will not distort or compete with the binding equilibrium. Because the labeling is irreversible, experiments can be executed off-line, where concentrations are no longer determined by the MS detection limit. Moreover, there are no back exchange and scrambling, facilitating detection at the amino-acid level [26, 28, 29].

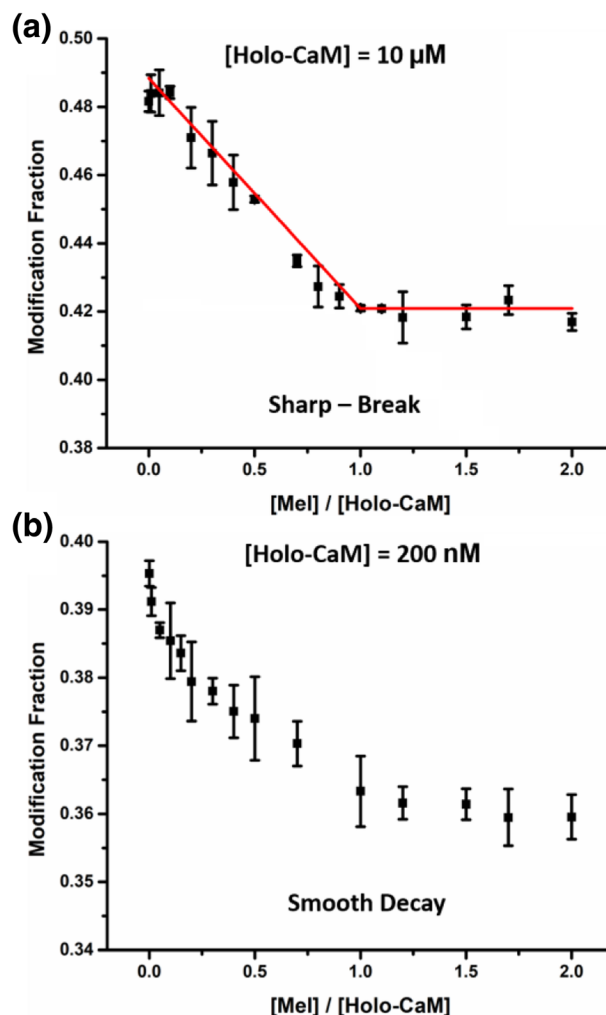

Here, we report a novel FPOP-based ligand titration method, protein-ligand interaction by Ligand Titration, Fast Photochemical Oxidation of Proteins and Mass Spectrometry (LITPOMS). This new approach allows measurement of binding stoichiometry and site-specific binding constants for any protein-ligand system that experience a change in solvent-accessible area upon binding. Such measurements also access the equilibrium composition indirectly and, importantly, provide the affinity in the liquid phase. LITPOMS overcomes disadvantages of PLIMSTEX, as stated above, providing another significant strategy to assess binding stoichiometries, affinities, and dynamics.

## Results and Discussion

To demonstrate LITPOMS, we chose calmodulin-melittin as a model. Melittin (Mel) binds to calcium-bound calmodulin (holo-CaM) at a ratio of 1:1 with a  $K_d$  of 3 nM [30–33]. Crosslinking suggests that melittin binds at the N-terminus, C-terminus, and the central linker region of the holo-CaM [31, 32]. In the current study, we equilibrated holo-CaM with melittin overnight in Tris buffer (pH = 7.4). A series of aliquots were prepared at [Mel]:[Holo-CaM] of 0–3 to fulfill the titration process. Hydrogen peroxide and *L*-histidine were added followed by a pulsed 248 nm laser irradiation to footprint the complex. The sample was introduced by a syringe pump into a capillary tubing with a transparent window. *L*-histidine works as a hydroxyl radical scavenger to control the lifetime of the radicals. The footprinted sample was collected at the end of the capillary in a solution of *L*-methionine and catalase to quench any residual oxidants. Global-level responses were by direct measurement of the intact complex with a Bruker MaXis 4G Q-TOF mass spectrometer. For peptide-level responses, the complex was digested with trypsin/Lys-C mix [29] and the peptides were characterized with a Thermo Scientific Q Executive Plus Orbitrap instrument. Two series of samples with different holo-CaM concentrations (i.e., 10  $\mu$ M and 200 nM) were prepared for global- and peptide-level studies. Detailed descriptions of the experimental setup and data processing are in supporting information.

Given that the shape of the titration curve is sensitive to protein concentration, experiments were carried out at the two protein concentrations (Figure 1). A more compact conformation forms as holo-CaM binds with melittin, leading to a lower overall solvent accessibility and a decrease in the macroscopic modification fraction. At [holo-CaM] = 10  $\mu$ M, 3000-fold  $> K_d$  of the system, a sharp-break curve is obtained (Figure 1a) with a break at [Mel]/[Holo-CaM] of 1.0, indicating the binding stoichiometry is 1:1. For a low-concentration titration ([holo-CaM] = 200 nM), the fraction modified decays smoothly as [Mel] is increased (Figure 1b). This promising tendency encouraged us to digest the protein and obtain spatial resolution for binding and affinity.

Taking advantage of the irreversible labeling of the protein through FPOP, we combined titration with FPOP-based bottom-up proteomics to report the modification change as a function of ligand concentration. To model the titration process and obtain the binding affinity, we carried out peptide-level experiments at a protein concentration of 200 nM, enabling a plot of

**Figure 1.** Modification fraction measured at global level as a function of melittin concentration with initial protein concentration of (a) 10  $\mu$ M and (b) 200 nM. Error bars are standard deviations from two independent runs whereas the data points are the average of the two runs

**Figure 2.** Modification fraction as a function of melittin:holo-calmodulin for selected peptides. Red solid lines in (a) and (d) represents the fitting result with the algorithm described previously [14, 15]. Error bars are standard deviations from two independent runs whereas the data points represent the average of two runs. Response curves for the remaining peptides can be found in SI

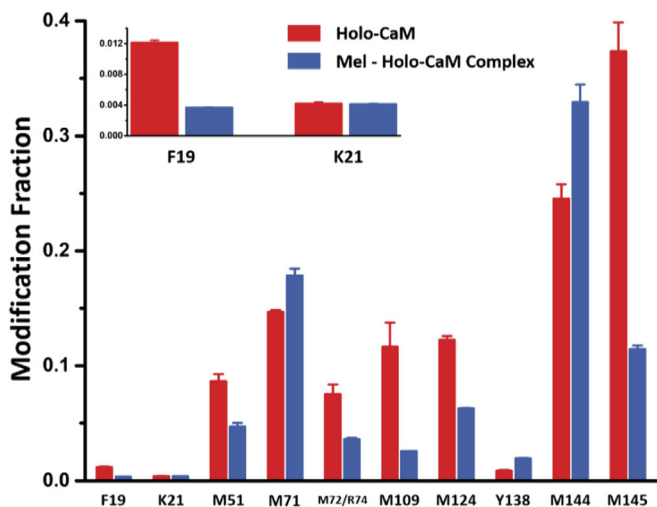

modification fraction as a function of ligand concentration for each individual peptide (Figure 2 and Figure S5 in SI). Note that sequence coverage for calmodulin is 99%. Two different behaviors can be distinguished (Figure 2 and Figure S5 in SI), namely, increased protection for binding regions and no change in protection for non-binding regions. Fractional modifications for peptides 1–13, 31–37, 38–74, 76–90 and 91–106 remain relatively stable as the titration proceeds, indicating that the conformations for these regions remain unchanged upon binding. Thus, these regions are unlikely binding sites and serve as controls.

On the contrary, regions 14–30, 107–126, and 127–148 experience increased protection as reported by decreases in fractional modification as the titration proceeds. The increase of protection becomes constant at the later titration stages (i.e., when  $[\text{Mel}]/[\text{Holo-CaM}] \geq 2$ ), indicating complete formation of the complex. These regions are likely to contain residues that are involved in binding. Moreover, the decrease in modification, whether caused by a conformation change or direct binding, provides quantitative information of the binding interaction ( $K_d$ ). Because melittin binds with holo-CaM at 1:1 (Figure 1a), the three curves were modeled together to afford a single binding affinity (modeling algorithm described previously [14, 15]). In brief, both holo-CaM and the melittin/holo-CaM complex have distinct modification fractions. A search utilizes both of the fractions and the overall equilibrium binding  $K_d$  to find the best fit of the experimental data in the plot. Because all the data were measured at equilibrium, modeling is simplified, allowing extraction of a dissociation constant of 4.6 nM ( $R^2 > 99\%$ ), in good

agreement with a reported affinity of 3 nM [30]. Although each sample was measured in duplicate, statistical certainty of the data increases through curve fitting and resampling. A total of 128 resampling trials were executed based on a previously developed strategy [15], and the estimated standard deviation is 2.7 nM.

Accepting that FPOP footprints in sub-msec, faster than binding-induced conformational changes [24, 26, 27], we propose FPOP “snapshots” the real-time equilibrium composition. These features provide a solid foundation for making LITPOMS reliable and informative. The irreversible modifications preserve structural information upon sample workup and MS/MS fragmentation, allowing extension to the residue level [26, 28, 29] (Figure 3) at the three binding regions. For the full protein, 10 amino-acid residues can be successfully resolved (Figure 3). Among them, K21 does not show any significant change upon binding, indicating it is not involved. Residues F19, M109, M124, and M145 show decreases in modification fraction upon binding, indicating that these residues likely bind with melittin, thus experiencing decreases in solvent accessibility owing to spatial hindrance from the melittin ligand. Residues Y138 and M144, however, become more exposed upon binding, suggesting a binding-induced conformational change rather than direct binding.

Another promising observation involves the two adjacent residues M144 and M145, where M144 becomes exposed whereas M145 becomes protected upon binding. The observations not only provide deeper understanding of melittin/holo-calmodulin binding but also demonstrate the promising spatial resolution for LITPOMS.

**Figure 3.** Modification fraction as a function of melittin:holo-calmodulin for selected amino-acid residues. Red bars show modification fraction for holo-calmodulin itself whereas blue bars represent melittin-bound holo-calmodulin where  $[Mel]/[Holo-CaM] = 3$ . Residue F19 and K21 data are enlarged in top left. Error bars are standard deviations from two independent runs, and data points are the average of the two runs

Out of the previously identified binding regions, three different residues M51, M71, and M72/R74 were successfully identified. Note that the spectral quality is currently not sufficient to distinguish M72 and R74, and the result is reported as M72/R74. M71 becomes more exposed through binding-induced conformational changes given that the modification fraction increases upon binding. Further, M51 and M72/R74 are both involved in binding owing to a decrease in modification fraction. Given that peptide 38–74 does not exhibit a noticeable change upon binding (Figure 2b), this once again reveals that LITPOMS brings more detailed understanding than does PLIMSTEX.

In summary, not only the N-terminal (peptide 14–30) and C-terminal region (peptide 107–126 and peptide 127–148), but also central linker regions (residue M51, M72/R74) of holo-CaM are involved in binding with melittin. We identified six critical binding residues and three conformational change residues and determined a  $K_d = 4.6$  nM. These findings agree with those in a previous crosslinking study [32]. The coupling of FPOP with titration and MS permits characterization of protein-ligand binding stoichiometry, binding sites (peptide and amino-acid levels), and site-specific binding constants, even for a tight binding system like melittin:holo-CaM.

In conclusion, the high-concentration mode for determining stoichiometry and the low-concentration mode for locating binding sites and determining site-specific affinities make LITPOMS promising for characterizing protein-ligand binding for high picomole quantities of protein. Moreover, the irreversible labeling allows rigorous post-labeling digestion without erasing any labeling information (e.g., from back exchange). LITPOMS is also readily compatible with various buffers, pH, salts, lipid-based media (e.g., nano and pico disks), and binding affinities (ranging from nM to  $\mu$ M), making it generally

applicable even to membrane proteins. The approach should not be affected by high off-rates for weaker binding systems as for HDX, but that remains to be established. Importantly, residue-level analysis becomes possible owing to the irreversible labeling that will be maintained for MS/MS, and more complete residue locations will be enabled by complementary footprinters (e.g.,  $CF_3^+$  [34], carbenes [35]). Although we demonstrated the applicability to tight binding (nmolar) of 1:1 binding system, we plan to extend the method to other, more complex binding systems with stoichiometries greater than 1:1.
